We are now ready to define the edges in the graph  $G$  sampled by  $\mu$ . First we check if  $|J| \geq 4 \cdot \delta^{-\frac{1}{q-1}} n^{\frac{q-2}{q-1}}$ . If this is the case then  $\mu$  outputs the empty graph (by Eq.2 this happens with probability at most  $1/4$ ). Otherwise for each  $i \in [n]$  we check to see if  $J$  contains the distinguished  $(q-1)$ -subset from one of the  $q$ -subsets of  $M_i$ . If there is at least one such  $q$ -subset, we pick one of them uniformly at random. Suppose the  $q$ -subset we chose is  $\{j_1, \dots, j_q\}$  and that the distinguished elements are the first  $q-1$ . Then we add the directed edge  $j_q \rightarrow i$  to the graph  $G$ . By the above discussion, we know that, restricted to the intersection of all sets indexed by  $J$  the set  $S_{j_q}$  is contained in  $S_i$  (hence the directed edge representing set inclusion).

► **Claim 31.**  *$\mu$  is  $(1/4, 1/\delta)$ -spread.*

**Proof.** By Claim 30, and since the probability that  $|J|$  is too large is at most  $1/4$  we see that any fixed  $i \in [n]$  will get an incoming edge in  $G$  with probability at least  $\alpha = 1/4$ . For any fixed  $i, j \in [n]$ , since the distribution of the special  $q$ -subset which is contributing an edge to  $i$  is uniform in  $M_i$  (conditioned on  $J$  containing a  $q$ -subset from  $M_i$ ), we can conclude that  $(j, i) \in E(G)$  with probability at most  $1/(\delta n) = \beta/n$ . This proves the claim. ◀

Now, applying Lemma 26, we get that, after  $t = O(\log_2 n)$  steps, the graph process  $G_t^\mu$  will contain at most  $O(1/\delta)$  sources with positive probability. Let  $J_1, \dots, J_t$  be the sets chosen in the different steps of the process and, w.l.o.g, remove any of them that were too big (i.e., when the graph sampled by  $\mu$  was empty). Hence, all of the sets satisfy  $|J_i| \leq 4 \cdot \delta^{-\frac{1}{q-1}} n^{\frac{q-2}{q-1}}$ . Now, let  $S$  be the intersection of all sets  $S_j$  such that  $j$  belongs to at least one of the sets  $J_i$ .

Then, restricted to  $S$ , each of the sets  $S_i$  contains one of the sources in the graph  $G_t^\mu$ . Hence, if we add to our intersection a representative from each of the sources, we will get a set that is contained in all the sets  $S_j$ . The total number of sets we end up intersecting is bounded by

$$O(1/\delta) + \sum_{i=1}^t |J_i| = O\left(\delta^{-\frac{1}{q-1}} \cdot n^{\frac{q-2}{q-1}} \log_2 n\right).$$

This completes the proof of the theorem.  $\blacktriangleleft$

#### 4 Constructing $q$ -LCSs with high rank

In this section we prove the lower bound part of Theorem 10 (the lower bound for the 2-query case follows from the Hadamard code construction). We will in fact generate this spanoid at random by picking, for each  $i \in [n]$ , a random  $q$ -matching  $M_i$  on  $[n]$  and, for each  $q$ -subset  $T \in M_i$  add the rule  $T \models i$ . The resulting spanoid will thus have, by design, the structure of a  $q$ -LCS. The reason why this spanoid should have high rank (with high probability) relies on the following observation. Suppose  $A \subset [n]$  is a set that spans  $[n]$ . This means that there is a sequence of derivations  $T_i \models i$  with each  $q$ -subset  $T_i$  in the matching  $M_i$  that eventually generates all of  $[n]$ . We can limit ourselves to the first  $C \cdot |A|$  such derivations for some large  $C$ . These derivations generate a set  $A'$  of size  $(C+1)|A|$  (including the original  $A$  and the  $C|A|$  newly derived elements). Now, the set  $A'$  must contain all of the  $q$ -subsets  $T_i$  for  $C|A|$  values of  $i$ . However, the union of randomly chosen  $C|A|$   $q$ -subsets will generally have size much larger than  $(C+1)|A|$  (closer to  $q \cdot C|A|$ ).

**► Theorem 32** (Existence of high rank  $q$ -LCSs). *For any integer  $q \geq 3$  and all sufficiently large  $n$  the following holds. Consider the following distribution generating a spanoid  $\mathcal{S}$  on base set  $[n]$ . For each  $i \in [n]$  pick a  $q$ -matching  $M_i$  of size  $\lfloor n/2q \rfloor$  uniformly at random and add the rule  $T \models i$  for all  $T \in M_i$ . Then, with probability approaching one,  $\text{rank}(\mathcal{S})$  is larger than  $r = cn^{\frac{q-1}{q-2}} / \log_2(n)$ , where  $0 < c < 1$  is an absolute constant.*

**Proof.** Let  $m = r \cdot \log_2(n) = cn^{\frac{q-1}{q-2}}$ . If the rank of  $\mathcal{S}$  is at most  $r$  then there exists a set  $A \subset [n]$  of size  $r$  that spans (using the rules obtained from the  $n$  random matchings  $M_1, \dots, M_n$ ) the entire base set  $[n]$ . We will upper bound the probability that such a set exists by bounding the smaller event given by the existence of a set of  $m$  rules that can be applied one after another starting with the original set  $A$ . That is, let  $\mathcal{E}$  denote the event that there exists a set  $A$  of size  $r$  on which one can sequentially apply  $m$  rules of the form  $T_{j_i} \models j_i$  with each  $T_{j_i}$  belonging to the matching  $M_{j_i}$  and for  $m$  different values  $j_1, \dots, j_m \in [n]$  arriving at the final set  $\hat{A} = A \cup \{j_1, \dots, j_m\}$ . If  $A$  spans  $[n]$  then clearly the event  $\mathcal{E}$  must hold and so, it is enough to show that  $\mathcal{E}$  happens with probability approaching zero.

We will present the event  $\mathcal{E}$  as the union of (possibly overlapping) smaller events and then use the union bound, bounding the probability that each one occurs and multiplying by the number of bad events. Given a set  $A \subset [n]$  of size  $r$ , a tuple of  $m$  indices  $\hat{J} = \{j_1, j_2, \dots, j_m\}$  and a family of  $q$ -subsets  $\hat{T} = \{T_{j_1}, \dots, T_{j_m}\}$  with  $T_{j_i} \in M_{j_i}$  denote by  $\mathcal{E}(A, \hat{J}, \hat{T})$  the event in which the set  $A$  spans the set  $\hat{A} = A \cup \hat{J}$  using the rules  $T_{j_i} \models j_i$  applied in order with  $i$  going from 1 to  $m$ . For every fixing of  $A, \hat{J}, \hat{T}$  we can bound

$$\Pr[\mathcal{E}(A, \hat{J}, \hat{T})] \leq \prod_{i=1}^m \Pr[T_{j_i} \subset \hat{A}].$$

W.l.o.g suppose we sample the random matchings iteratively, picking a new  $q$ -subset at random among the available elements not covered by any previously chosen  $q$ -subsets in the current matching. Since the number of  $q$ -subsets in each matching is  $\lfloor n/2q \rfloor$  we have, at each step, at least  $n/2$  available elements to chose from and so

$$\Pr[T_{j_i} \subset \hat{A}] \leq \frac{\binom{m+r}{q}}{\binom{n/2}{q}} \leq \left(\frac{4m}{n}\right)^q.$$

Taking the product over all  $m$   $q$ -subsets in  $\hat{T}$  we get

$$\Pr[\mathcal{E}(A, \hat{J}, \hat{T})] \leq \left(\frac{4m}{n}\right)^{qm}.$$

To complete the proof we bound the number of tuples  $(A, \hat{J}, \hat{T})$  as above by

$$\binom{n}{r} \cdot \binom{n}{m} \cdot \lfloor n/2q \rfloor^m \leq n^r \cdot (en/m)^m \cdot n^m \leq \left(\frac{6n^2}{m}\right)^m,$$

where the last inequality used the fact that  $r/m \leq 1/\log_2(n)$ . Putting these bounds together we get that

$$\Pr[\mathcal{E}] \leq \left(\frac{4m}{n}\right)^{qm} \left(\frac{6n^2}{m}\right)^m = \left(\frac{6 \cdot 4^q \cdot m^{q-1}}{n^{q-2}}\right)^m$$

which is exponentially decreasing in  $m$  for the given choice of  $m = c \cdot n^{(q-2)/(q-1)}$  and for  $c$  a sufficiently small constant.  $\blacktriangleleft$

One could ask for a more explicit construction of an LCS with rank equal to (or even close to) that stated above. We are not able to give such a construction but can relate this problem to a longstanding open problem in explicit construction of expander graphs. A bipartite (balanced) expander of degree  $q$ , is a bipartite graph with  $n$  left vertices  $L$  and  $n$  right vertices  $R$  such that the degree of each vertex is  $q$  and such that sets  $A \subset L$  of size ‘not too large’ have many neighbors in  $R$ . More specifically, one typically asks that sets with  $|A| \leq n/2$  have at least  $(1 + \epsilon)|A|$  right neighbors for some constant  $\epsilon > 0$ . It is quite easy to see that a random graph of this form will be a good expander with high probability and, by now, there are also many explicit constructions [17]. One can also consider *unbalanced* bipartite expanders in which  $|L| \gg |R|$ . Take, for example, the setting in which  $|L| = n^2$ ,  $|R| = n$  and when the degree of every vertex in  $L$  is some constant  $q$ . A simple probabilistic argument shows that sufficiently small sets in  $L$ , namely sets of size  $|A| \leq n^{\alpha_q}$  with  $\alpha_q < 1$  a constant depending on  $q$  and approaching 1 as  $q$  grows, have many neighbors in  $R$  (say, at least  $2|A|$ ). However, no explicit constructions of such graphs are known (for any constant  $q$  and any  $\alpha_q > 0$ ). The property we needed in our random construction of LCSs can be thought of as an ‘easier’ variant of the expander construction problem. Given  $q$ -matchings  $M_1, \dots, M_n$  each of size  $\delta n$  consider the bipartite graph with  $L = [n] \times [\delta n]$  and  $R = [n]$ . We identify each vertex  $(i, j) \in L$  with the  $j$ ’th  $q$ -subset  $T_{ij}$  of  $M_i$  and connect it to the  $q$  neighbors in  $R$  given by that  $q$ -subset. For our proof to work we need the property that there is no small set containing many  $q$ -subsets from different matchings. This corresponds to asking for the above graph to be an expander for a restricted family of sets, namely to sets that have at most one vertex  $(i, j)$  for a given  $i$  (with each subgraph  $(i, *)$  defining a matching).

## 5 Conclusion and open problems

Our work introduces the abstract notion of a spanoid in the hope that further study of its properties will lead to progress on LCCs and perhaps in other areas. We list below some concrete directions for future work.

1. We showed that there exist spanoids, called  $q$ -LCSs, which “look like”  $q$ -LCCs and whose rank matches the best known upper bounds. Can we bypass this ‘barrier’ by using additional properties of LCCs? We have at least two examples where this was possible. One is the result of [21] for LCCs over constant size alphabet and the other is the work in [11] for linear 3-LCCs over the real numbers. The bounds of [21] crucially depend on the alphabet having small size and the bounds in [11] exploit properties of real numbers.
2. Understanding the possible gap between functional rank and formal rank of a spanoid is a very interesting question. We proved that there can be a polynomial gap. The next challenge is to find a spanoid on  $n$  elements whose f-rank is  $n^{o(1)}$  and rank is  $n^{\Omega(1)}$ . Naturally,  $q$ -LCSs for constant  $q \geq 3$  are plausible candidates for this. If there are no such spanoids, then it would imply the existence of  $q$ -LCCs of length  $n$  and  $n^{\Omega_q(1)}$  dimension!<sup>1</sup>
3. Suppose we start with a functional representation with large alphabet, can we do alphabet reduction without losing too many codewords?
4. We have seen that one way to go past the rank barrier is to use  $\text{LP}^{\text{entropy}}$ . Can we improve the existing upper bounds on the dimension of  $q$ -LCCs by upper bounding  $\text{LP}^{\text{entropy}}$  of  $q$ -LCSs? Can we use LP duality and construct good feasible solutions to the dual of  $\text{LP}^{\text{entropy}}$  to prove good upper bounds on  $\text{LP}^{\text{entropy}}$ ?
5. What are other connections of spanoids to existing theory of set systems, matroids, algebraic equations and other problems described in the introduction?

## Abstract

Algorithmic fairness, and in particular the fairness of scoring and classification algorithms, has become a topic of increasing social concern and has recently witnessed an explosion of research in theoretical computer science, machine learning, statistics, the social sciences, and law. Much of the literature considers the case of a single classifier (or scoring function) used once, in isolation. In this work, we initiate the study of the fairness properties of systems composed of algorithms that are fair in isolation; that is, we study *fairness under composition*. We identify pitfalls of naïve composition and give general constructions for fair composition, demonstrating both that classifiers that are fair in isolation do not necessarily compose into fair systems and also that seemingly unfair components may be carefully combined to construct fair systems. We focus primarily on the individual fairness setting proposed in [Dwork, Hardt, Pitassi, Reingold, Zemel, 2011], but also extend our results to a large class of group fairness definitions popular in the recent literature, exhibiting several cases in which group fairness definitions give misleading signals under composition.

## 1 Introduction

As automated decision-making extends its reach ever more deeply into our lives, there is increasing concern that such decisions be fair. The rigorous theoretical study of fairness in algorithmic classification was initiated by Dwork *et al* in [4] and subsequent works investigating alternative definitions, fair representations, and impossibility results have proliferated in the machine learning, economics and theoretical computer science literatures.<sup>3</sup> The notions of fairness broadly divide into *individual fairness*, requiring that individuals who are similar with respect to a given classification task (as measured by a task-specific

---

<sup>1</sup> This work was supported in part by Microsoft Research and the Sloan Foundation.

<sup>2</sup> This work was supported in part by the Smith Family Fellowship and Microsoft Research.

<sup>3</sup> See also [20] [9] and [10], which predate [4] and are motivated by similar concerns.

similarity metric) have similar probability distributions on classification outcomes; and *group fairness*, which requires that different demographic groups experience the same treatment in some average sense.

In a bit more detail, a *classification task* is the problem of mapping *individuals* to *outcomes*; for example, a decision task may map individuals to outcomes in  $\{0, 1\}$ . A classifier is a possibly randomized algorithm solving a classification task. In this work we initiate the study of *fairness under composition*: what are the fairness properties of systems built from classifiers that are fair in isolation? Under what circumstances can we ensure fairness, and how can we do so? A running example in this work is online advertising. If a set of advertisers, say, one for tech jobs and one for a grocery delivery service, compete for the attention of users, say one for tech jobs and one for a grocery delivery service, and each chooses fairly whether to bid (or not), is it the case that the advertising system, including budget handling and tie-breaking, will also be fair?

We identify and examine several types of composition and draw conclusions about auditing systems for fairness, constructing fair systems, and definitions of fairness for systems. In the remainder of this section we summarize our results and discuss related work. A full version of this paper, containing complete proofs of all our results, is available on ArXiv.

### Task-Competitive Compositions

We first consider the problem of two or more tasks competing for individuals, motivated by the online advertising setting described above. We prove that two advertisers for different tasks, each behaving fairly (when considered independently), will not necessarily produce fair outcomes when they compete. Intuitively (and as empirically observed by [17]), the attention of individuals similarly qualified for a job may effectively have different costs due to these individuals' respective desirability for other advertising tasks, like household goods purchases. That is, individuals claimed by the household goods advertiser will not see the jobs ad, regardless of their job qualification. These results are not specific to an auction setting and are robust to choice of “tie-breaking” functions that select among multiple competing tasks (advertisers). Nonetheless, we give a simple mechanism, `RandomizeThenClassify`, that solves the fair task-competitive classification problem using classifiers for the competing tasks, each of which is fair in isolation, in a black-box fashion and without modification. In the Appendix (Lemma 15) we give a second technique for modifying the fair classifier of the lower bidder (loser of the tie-breaking function) in order to achieve fairness.

### Functional Compositions

Is the “OR” of two fair classifiers also fair? More generally, when can we build fair classifiers by computing on values that were fairly obtained? Here we must understand what is the salient outcome of the computation. For example, when reasoning about whether the college admissions system is fair, the salient outcome may be whether a student is accepted to at least one college, and not whether the student is accepted to a specific college<sup>4</sup>. Even if each college uses a fair classifier, the question is whether the “OR” of the colleges' decisions is fair. Furthermore, an acceptance to college may not be meaningful without sufficient accompanying financial aid. Thus in practice, we must reason about the OR of ANDs of acceptance and financial aid across many colleges. We show that although in general there

---

<sup>4</sup> In this simple example, we assume that all colleges are equally desirable, but it is not difficult to extend the logic to different sets of comparable colleges.

are no guarantees on the fairness of functional compositions of fair components, there are some cases where fairness in ORs can be satisfied. Such reasoning can be used in many applications where long-term and short-term measures of fairness must be balanced. In the case of feedback loops, where prior positive outcomes can improve the chances of future positive outcomes, functional composition provides a valuable tool for determining at which point(s) fairness must be maintained and determining whether the existing set of decision procedures will adhere to these requirements.

### Dependent Compositions

There are many settings in which each individual's classifications are dependent on the classifications of others. For example, if a company is interviewing a set of job candidates in a particular order, accepting a candidate near the beginning of the list precludes any subsequent candidates from even being considered. Thus, even if each candidate actually considered is considered fairly in isolation, dependence between candidates can result in highly unfair outcomes. For example, individuals who are socially connected to the company through friends or family are likely to hear about job openings first and thus be considered for a position before candidates without connections. We show that selecting a cohort of people – online or offline – requires care to prevent dependencies from undermining an independently fair selection mechanism. We address this in the offline case with two randomized constructions, `PermuteThenClassify` and `WeightedSampling`. These algorithms can be applied in the online case, even under adversarial ordering, provided the size of the universe of individuals is known; when this is not known there is no solution.

### Nuances of group-based definitions

Many fairness definitions in the literature seek to provide fairness guarantees based on group-level statistical properties. For example, “Equal Opportunity” [6] requires that, conditioned on qualification, the probability of a positive outcome is independent of protected attributes such as race or gender. Group Fairness definitions have practical appeal in that they are possible to measure and enforce empirically without reference to a task-specific similarity metric.<sup>5</sup> We extend our results to group fairness definitions and we also show that these definitions do not always yield consistent signals under composition. In particular, we show that the intersectional subgroup concerns (which motivate [11, 7]) are exacerbated by composition. For example, an employer who uses group fairness definitions to ensure parity with respect to race and gender may fail to identify that “parents” of particular race and gender combinations are not treated fairly. Task-competitive composition exacerbates this problem, as the employers may be prohibited from even collecting parental status information, but their hiring processes may be composed with other systems which legitimately differentiate based on parental status.

Finally, we also show how naïve strategies to mitigate these issues in composition may result in learning a nominally fair solution that is clearly discriminating against a socially meaningful subgroup not officially called out as “protected,” from which we conclude that understanding the behavior of fairness definitions under composition is critical for choosing which definition is meaningful in a given setting.

---

<sup>5</sup> However, defining and measuring qualification may require care.

## Implications of Our Results

Our composition results have several practical implications. First, testing individual components without understanding of the whole system will be insufficient to safely draw either positive or negative conclusions about the fairness of the system. Second, composition properties are an important point of evaluation for any definitions of fairness or fairness requirements imposed by law or otherwise. Failing to take composition into account when specifying a group-based fairness definition may result in a meaningless signal under composition, or worse may lead to ingraining poor outcomes for certain subgroups while still nominally satisfying fairness requirements. Third, understanding of the salient outcomes on which to measure and enforce fairness is critical to building meaningfully fair systems. Finally, we conclude that there is significant potential for improvement in the mechanisms proposed for fair composition and many settings in which new mechanisms could be proposed.

### 1.1 Related Work

Fairness retained under post-processing in the single-task one-shot setting is central in [22, 19, 4]. The definition of individual fairness we build upon in this work was introduced by Dwork *et al.* in [4]. Learning with oracle access to the fairness metric is considered by [5, 13]. A number of group-based fairness definitions have been proposed, and Ritov *et al.* provide a combined discussion of the parity-based definitions in [21]. In particular, their work includes discussion of Hardt *et al.*'s Equality of Opportunity and Equal Odds definitions and Kilbertus *et al.*'s Counterfactual Fairness [6, 12]. Kleinberg *et al.* and Chouldechova independently described several impossibility results related to simultaneously satisfying multiple group fairness conditions in single classification settings [14],[2].

Two concurrent lines of work aiming to bridge the gap between individual and group consider ensuring fairness properties for large numbers of large groups and their (sufficiently large) intersections [11, 7]. While these works consider the one-shot, single-task setting, we will see that group intersection properties are of particular importance under composition. Two subsequent works in this general vein explore approximating individual fairness with the help of an oracle that knows the task-specific metric [13, 5]. Two works also consider how feedback loops can influence fair classification, and how interventions can help [8, 18].

Several empirical or observational studies document the effects of multiple task composition. For example, Lambrecht and Tucker study how intended gender-neutral advertising can result in uneven delivery due to high demand for the attention of certain demographics [17]. Datta *et al.* also document differences in advertising based on gender, although they are agnostic as to whether the cause is due to multiple task composition or discriminatory behavior on the part of the advertisers or platform [3]. Whether it is truly “fair” that, say, home goods advertisers bid more highly for the attention of women than for the attention of men, may be debatable, although there are clearly instances in which differential targeting is justified, such as when advertising maternity clothes. This *actuarial fairness* is the industry practice, so we pose a number of examples in this framework and analyze the implications of composition.

## 2 Preliminary Definitions and Assumptions

### 2.1 General Terminology

We refer to classifiers as being “fair in isolation” or “independently fair” to indicate that with no composition, the classifier satisfies a particular fairness definition. In such cases expectation and probability are taken over the randomness of the classification procedure

and, for group fairness, selection of elements from the universe. We denote the universe of individuals relevant for a task as  $U$ , and we generally use  $u, v, w \in U$  to refer to universe elements. We generally consider binary classifiers in this work, and use  $p_w$  to denote the probability of assigning the positive outcome (or simply 1) to the element  $w$  for a particular classifier. We generally write  $C : U \times \{0, 1\}^* \rightarrow \{0, 1\}$ , where  $\{0, 1\}^*$  represents the random bits of the classifier. This allows us to comfortably express the probability of positive classification  $\mathbb{E}_r[C(u)]$  as well as the output of the classifier under particular randomness  $C(u, r)$ . In this notation,  $p_u = \mathbb{E}_r[C(u)]$ . When considering the distribution on outputs of a classifier  $C$ , we use  $\tilde{C} : U \rightarrow \Delta(\{0, 1\})$ . When two or more classifiers or tasks are compared, we either use a subscript  $i$  to indicate the  $i^{\text{th}}$  classifier or task, or a prime ( $'$ ) to indicate the second classifier or task. For example  $\{C, C'\}$ ,  $\{C_i | i \in [k]\}$ ,  $\{T, T'\}$ ,  $\{T_i | i \in [k]\}$ .

## 2.2 Individual Fairness

Throughout this work, our primary focus is on *individual fairness*, proposed by Dwork *et al* in [4]. As noted above, a *classification task* is the problem of mapping *individuals* in a universe to *outcomes*.

► **Definition 1** (Individual Fairness [4]). Let  $d : \Delta(O) \times \Delta(O) \rightarrow [0, 1]$  denote the total variation distance on distributions over  $O$ <sup>6</sup>. Given a universe of individuals  $U$ , and a task-specific metric  $\mathcal{D}$  for a classification task  $T$  with outcome set  $O$ , a randomized classifier  $C : U \times \{0, 1\}^* \rightarrow O$ , such that  $\tilde{C} : U \rightarrow \Delta(O)$ , is *individually fair* if and only if for all  $u, v \in U$ ,  $\mathcal{D}(u, v) \geq d(\tilde{C}(u), \tilde{C}(v))$ .

Note that when  $|O| = 2$  we have  $d(\tilde{C}(u), \tilde{C}(v)) = |\mathbb{E}_r[C(u)] - \mathbb{E}_r[C(v)]| = |p_u - p_v|$ . In several proofs we will rely on the fact that it is possible to construct individually fair classifiers with particular distance properties (see Lemma 16 and corollaries in the Appendix).

## 2.3 Group Fairness

In principle, all our individual fairness results extend to group fairness definitions; however, there are a number of technicalities and issues unique to group fairness definitions, which we discuss in Section 6. Group fairness is often framed in terms of *protected attributes*  $\mathcal{A}$ , such as sex, race, or socio-economic status, while allowing for differing treatment based on a set of *qualifications*  $\mathcal{Z}$ , such as, in the case of advertising, the willingness to buy an item. Conditional Parity, a general framework proposed in [21] for discussing these definitions, conveniently captures many of the popular group fairness definitions popular in the literature including Equal Odds and Equal Opportunity [6], and Counterfactual Fairness [16].

► **Definition 2** (Conditional Parity [21]). A random variable  $\mathbf{x}$  satisfies parity with respect to  $\mathbf{a}$  conditioned on  $\mathbf{z} = z$  if the distribution of  $\mathbf{x} \mid (\mathbf{a}, \{\mathbf{z} = z\})$  is constant in  $\mathbf{a}$ :  $\Pr[\mathbf{x} = x \mid (\mathbf{a} = a, \mathbf{z} = z)] = \Pr[\mathbf{x} = x \mid (\mathbf{a} = a', \mathbf{z} = z)]$  for any  $a, a' \in \mathcal{A}$ . Similarly,  $\mathbf{x}$  satisfies parity with respect to  $\mathbf{a}$  conditioned on  $\mathbf{z}$  (without specifying a value of  $\mathbf{z}$ ) if it satisfies parity with respect to  $\mathbf{a}$  conditioned on  $\mathbf{z} = z$  for all  $z \in \mathcal{Z}$ . All probabilities are over the randomness of the prediction procedure and the selection of elements from the universe.

<sup>6</sup> [4] also considered other notions of distributional distance.

### 3 Multiple-Task Composition

First, we consider the problem of composition of classifiers for multiple tasks where the outcome for more than one task is decided. Multiple Task Fairness, defined next, requires fairness to be enforced independently and simultaneously for each task.

► **Definition 3** (Multiple Task Fairness). For a set  $\mathcal{T}$  of  $k$  tasks with metrics  $\mathcal{D}_1, \dots, \mathcal{D}_k$ , a (possibly randomized) system  $\mathcal{S} : U \times r \rightarrow \{0, 1\}^k$ , which assigns outputs for task  $i$  in the  $i^{\text{th}}$  coordinate of the output, satisfies multiple task fairness if for all  $i \in [k]$  and all  $u, v \in U$   $\mathcal{D}_i(u, v) \geq |\mathbb{E}[\mathcal{S}_i(u)] - \mathbb{E}[\mathcal{S}_i(v)]|$  where  $\mathbb{E}[\mathcal{S}_i(u)]$  is the expected outcome for the  $i^{\text{th}}$  task in the system  $\mathcal{S}$  and where the expectation is over the randomness of the system and all its components.

#### 3.1 Task-Competitive Composition

We now pose the relevant problem for multiple task fairness: competitive composition.

► **Definition 4** (Single Slot Composition Problem). A (possibly randomized) system  $\mathcal{S}$  is said to be a solution to the single slot composition problem for a set of  $k$  tasks  $\mathcal{T}$  with metrics  $\mathcal{D}_1, \dots, \mathcal{D}_k$ , if  $\forall u \in U$ ,  $\mathcal{S}$  assigns outputs for each task  $\{x_{u,1}, \dots, x_{u,k}\} \in \{0, 1\}^k$  such that  $\sum_{i \in [k]} x_{u,i} \leq 1$ , and  $\forall i \in [k]$ , and  $\forall u, v \in U$ ,  $\mathcal{D}_i(u, v) \geq |\mathbb{E}[x_{u,i}] - \mathbb{E}[x_{v,i}]|$ .

The single slot composition problem captures the scenario in which an advertising platform may have a single slot to show an ad but need not show any ad. Imagine that this advertising system only has two types of ads: those for jobs and those for household goods. If a person is qualified for jobs and eager and able to purchase household goods, the system must pick at most one of the ads to show. In this scenario, it may be unlikely that the advertising system would choose to show no ads, but the problem specification does not require that any positive outcome is chosen.

To solve the single-slot composition problem we must build a system which chooses at most one of the possible tasks so that fairness is preserved simultaneously for each task, across all elements in the universe. Clearly if classifiers for each task may *independently* and fairly assign outputs without interference, the system as a whole satisfies multiple task fairness. However, most systems will require trade-offs between tasks. Consider a naïve solution to the single-slot problem for ads: each advertiser chooses to bid on each person with some probability, and if both advertisers bid for the same person, the advertiser with the higher bid gets to show her ad. Formally, we define a tie-breaking function and Task-Competitive Composition:

► **Definition 5** (Tie-breaking Function). A (possibly randomized) *tie-breaking function*  $\mathbb{B} : U \times \{0, 1\}^* \times \{0, 1\}^k \rightarrow [k] \cup \{0\}$  takes as input an individual  $w \in U$  and a  $k$ -bit string  $x_w$  and outputs the index of a “1” in  $x_w$  if such an index exists and 0 otherwise.

For notational convenience, in the case of two tasks  $T$  and  $T'$ , we use  $\mathbb{B}_w(T)$  to refer to the probability that  $\mathbb{B}$  chooses task  $T$  for element  $w$  if both  $T$  and  $T'$  return positive classifications, and analogously define  $\mathbb{B}_w(T')$ .

► **Definition 6** (Task-Competitive Composition). Consider a set  $\mathcal{T}$  of  $k$  tasks, and a tie-breaking function as defined above. Given a set  $\mathcal{C}$  of classifiers for the set of tasks, define  $y_w = \{y_{w,1}, \dots, y_{w,k}\}$  where  $y_{w,i} = C_i(w)$ . The task-competitive composition of the set  $\mathcal{C}$  is defined as  $y_w^* = \mathbb{B}(w, y_w)$  for all  $w \in U$ .

Definition 6 yields a system  $S$  defined by  $S(w) = 0^k$  if  $y_w = 0^k$  and  $S(w) = e_{\mathbb{B}(w, y_w)}$  (the  $\mathbb{B}(w, y_w)$  basis vector of dimension  $k$ ) if  $y_w \neq 0^k$ . We evaluate its fairness by examining the Lipschitz requirements  $|\Pr[y_u^* = i] - \Pr[y_v^* = i]| \leq \mathcal{D}_i(u, v)$  for all  $u, v \in U$  and  $i \in [k]$ .

Task-competitive composition can reflect many scenarios other than advertising, which are discussed in greater detail in the full paper. Note that the tie-breaking function need not encode the same logic for all individuals and may be randomized. We start by introducing Lemma 7, which handles the simple case for a strict tie-breaking function for all individuals, and extend to all tie-breaking functions in Theorem 8.

► **Lemma 7.** *For any two tasks  $T$  and  $T'$  such that the metrics for each task ( $\mathcal{D}$  and  $\mathcal{D}'$  respectively) are not identical and are non-trivial<sup>7</sup> on a universe  $U$ , and if there is a strict preference for  $T$ , that is  $\mathbb{B}_w(T) = 1 \forall w \in U$ , then there exists a pair of classifiers  $\mathcal{C} = \{C, C'\}$  which are individually fair in isolation but when combined with task-competitive composition violate multiple task fairness.*

**Proof.** We construct a pair of classifiers  $\mathcal{C} = \{C, C'\}$  which are individually fair in isolation for the tasks  $T$  and  $T'$ , but do not satisfy multiple task fairness when combined with task-competitive composition with a strict preference for  $T$  for all  $w \in U$ . Task-competitive composition ensures that at most one task can be classified positively for each element, so our strategy is to construct  $C$  and  $C'$  such that the distance between a pair of individuals is stretched for the ‘second’ task.

By non-triviality of  $\mathcal{D}$ , there exist  $u, v$  such that  $\mathcal{D}(u, v) \neq 0$ . Fix such a pair  $u, v$  and let  $p_u$  denote the probability that  $C$  assigns 1 to  $u$ , and analogously  $p_v, p'_u, p'_v$ . We use these values as placeholders, and show how to set them to prove the lemma.

Because of the strict preference for  $T$ , the probabilities that  $u$  and  $v$  are assigned 1 for the task  $T'$  are

$$\Pr[\mathcal{S}(u)_{T'} = 1] = (1 - p_u)p'_u$$

$$\Pr[\mathcal{S}(v)_{T'} = 1] = (1 - p_v)p'_v$$

The difference between them is

$$\begin{aligned} \Pr[\mathcal{S}(u)_{T'} = 1] - \Pr[\mathcal{S}(v)_{T'} = 1] &= (1 - p_u)p'_u - (1 - p_v)p'_v \\ &= p'_u - p_u p'_u - p'_v + p_v p'_v \\ &= p'_u - p'_v + p_v p'_v - p_u p'_u \end{aligned}$$

Notice that if  $\mathcal{D}'(u, v) = 0$ , which implies that  $p'_u = p'_v$ , and  $p_u \neq p_v$ , then this quantity is non-zero, giving the desired contradiction for all fair  $C'$  and any  $C$  that assigns  $p_u \neq p_v$ , which can be constructed per Corollary 18.

However, if  $\mathcal{D}'(u, v) \neq 0$ , take  $C'$  such that  $|p'_u - p'_v| = \mathcal{D}'(u, v)$  and denote the distance  $|p'_u - p'_v| = m'$ , and without loss of generality, assume that  $p'_u > p'_v$  and  $p_u < p_v$ ,

$$\Pr[\mathcal{S}(u)_{T'} = 1] - \Pr[\mathcal{S}(v)_{T'} = 1] = m' + p_v p'_v - p_u p'_u$$

Then to violate fairness for  $T'$ , it suffices to show that  $p_v p'_v > p_u p'_u$ . Write  $p_v = \alpha p_u$  where  $\alpha > 1$ ,

$$\alpha p_u p'_v > p_u p'_u$$

<sup>7</sup> A metric  $\mathcal{D}$  is said to be *non-trivial* if there exists at least one pair,  $u, v \in U$  such that  $\mathcal{D}(u, v) \notin \{0, 1\}$ .

$$\alpha p'_v > p'_u$$

Thus it is sufficient to show that we can choose  $p_u, p_v$  such that  $\alpha > \frac{p'_u}{p'_v}$ . Constrained only by the requirements that  $p_u < p_v$  and  $|p_u - p_v| \leq \mathcal{D}(u, v)$ , we may choose  $p_u, p_v$  to obtain an arbitrarily large  $\alpha = \frac{p_v}{p_u}$  by Corollary 19. Thus there exist a pair of fair classifiers  $C, C'$  which when combined with strictly ordered task-competitive composition violate multiple task fairness. ◀

► **Theorem 8.** *For any two tasks  $T$  and  $T'$  with nontrivial metrics  $\mathcal{D}$  and  $\mathcal{D}'$  respectively, there exists a set  $\mathcal{C}$  of classifiers which are individually fair in isolation but when combined with task-competitive composition violate multiple task fairness for any tie-breaking function.*

**Proof.** Consider a pair of classifiers  $C, C'$  for the two tasks. Let  $p_u$  denote the probability that  $C$  assigns 1 to  $u$ , and analogously let  $p_v, p'_u, p'_v$  denote this quantity for the other classifier and element combinations. As noted before, for convenience of notation, write  $\mathbb{B}_u(T)$  to indicate the preference for each (element, outcome) pair, that is the probability that given the choice between  $T$  or the alternative outcome  $T'$ ,  $T$  is chosen. Note that in this system, for each element  $\mathbb{B}_u(T) + \mathbb{B}_u(T') = 1$ .

Note that if  $\mathbb{B}_w(T) = 1 \forall w \in U$  or  $\mathbb{B}_w(T') = 1 \forall w \in U$ , the setting is exactly as described in Lemma 7. Thus we need only argue for the two following cases:

1. Case  $\mathbb{B}_u(T) = \mathbb{B}_v(T) \neq 1$ . We can write an expression for the probability that each element is assigned to task  $T$ :

$$\Pr[\mathcal{S}(u)_T = 1] = p_u(1 - p'_u) + p_u p'_u \mathbb{B}_u(T)$$

$$\Pr[\mathcal{S}(v)_T = 1] = p_v(1 - p'_v) + p_v p'_v \mathbb{B}_v(T)$$

So the difference in probabilities is

$$\begin{aligned} \Pr[\mathcal{S}(u)_T = 1] - \Pr[\mathcal{S}(v)_T = 1] &= p_u(1 - p'_u) + p_u p'_u \mathbb{B}_u(T) - p_v(1 - p'_v) - p_v p'_v \mathbb{B}_v(T) \\ &= p_u - p_v + p_v p'_v - p_u p'_u + p_u p'_u \mathbb{B}_u(T) - p_v p'_v \mathbb{B}_v(T) \\ &= p_u - p_v + (p_v p'_v - p_u p'_u)(1 - \mathbb{B}_u(T)) \end{aligned}$$

By our assumption that  $\mathbb{B}_u(T) \neq 1$ , we proceed analogously to the proof of Lemma 7 choosing  $C'$  such that  $p_v p'_v > p_u p'_u$  and choosing  $C$  to ensure that  $p_u - p_v = \mathcal{D}(u, v)$  to achieve unfairness for  $T$ .

2. Case  $\mathbb{B}_u(T) \neq \mathbb{B}_v(T)$ . Assume without loss of generality that  $\mathbb{B}_u(T) \neq 1$ . Recall the difference in probability of assignment of 1 for the first task in terms of  $\mathbb{B}$ :

$$= p_u - p_v + p_v p'_v (1 - \mathbb{B}_v(T)) - p_u p'_u (1 - \mathbb{B}_u(T))$$

Choose  $C$  such that  $p_u - p_v = \mathcal{D}(u, v)$  (or if there is no such individually fair  $C$ , choose the individually fair  $C$  which maximizes the distance between  $u$  and  $v$ ). So it suffices to show that we can select  $C'$  such that  $p_v p'_v (1 - \mathbb{B}_v(T)) - p_u p'_u (1 - \mathbb{B}_u(T)) > 0$ . As before, write  $p_u = \alpha p_v$  where  $\alpha > 1$ . We require:

$$p_v p'_v (1 - \mathbb{B}_v(T)) > \alpha p_v p'_u (1 - \mathbb{B}_u(T))$$

$$p'_v (1 - \mathbb{B}_v(T)) > \alpha p'_u (1 - \mathbb{B}_u(T))$$

Writing  $\beta = (1 - \mathbb{B}_v(T))/(1 - \mathbb{B}_u(T))$  (recall that  $\mathbb{B}_u(T) \neq 1$  so there is no division by zero), we require

$$p'_v \beta > \alpha p'_u$$

$$\beta/\alpha > p'_u/p'_v$$

Constrained only by  $|p'_u - p'_v| \leq \mathcal{D}'(u, v)$ , we can choose  $p'_u, p'_v$  to be any arbitrary positive ratio per Corollary 19, thus we can select a satisfactory  $C'$  to exceed the allowed distance.

Thus we have shown that for the cases where the tie-breaking functions are identical for  $u$  and  $v$  and when the tie-breaking functions are different, there always exists a pair of classifiers  $C, C'$  which are fair in isolation, but when combined in task-competitive composition do not satisfy multiple task fairness which completes the proof. ◀

The intuition for unfairness in such a strictly ordered composition is that each task inflicts its preferences on subsequent tasks, and this intuition extends to more complicated tie-breaking functions and individuals with positive distances in both tasks. Our intuition suggests that the situation in Theorem 8 is not contrived and occurs often in practice, and moreover that small relaxations will not be sufficient to alleviate this problem, as the phenomenon has been observed empirically [3, 17, 15]. We include a small simulated example in the Appendix of the full version to illustrate the potential magnitude and frequency of such fairness violations.

### 3.2 Simple Fair Multiple-task Composition

Fortunately, there is a general purpose mechanism for the single slot composition problem which requires no additional information in learning each classifier and no additional coordination between the classifiers.<sup>8</sup> The rough procedure for `RandomizeThenClassify` (Algorithm 1) is to fix a fair classifier for each task, fix a probability distribution over the tasks, sample a task from the distribution, and then run the fair classifier for that task. `RandomizeThenClassify` has several nice properties: it requires no coordination in the training of the classifiers, it preserves the ordering and relative distance of elements by each classifier, and it can be implemented by a platform or other third party, rather than requiring the explicit cooperation of all classifiers. The primary downside of `RandomizeThenClassify` is that it reduces allocation (the total number of positive classifications) for classifiers trained with the expectation of being run independently.

## 4 Functional Composition

In *Functional Composition*, the outputs of multiple classifiers are combined through logical operations to produce a single output for a single task. A significant consideration in functional composition is determining which outcomes are relevant for fairness and at which point(s) fairness should be measured. For example, (possibly different) classifiers for admitting students to different colleges are composed to determine whether the student is accepted to at least one college. In this case, the function is “OR”, the classifiers are for the same task, and hence conform to the same metric, and this is the same metric one might use for defining

<sup>8</sup> See section Appendix Section 6.4 in the full version for another mechanism which requires coordination between the classifiers.

fairness of the system as a whole. Alternatively, the system may compose the classifier for admission with the classifier for determining financial aid. In this case the function is “AND”, the classifiers are for different tasks, with different metrics, and we may use scholastic ability or some other appropriate output metric for evaluating overall fairness of the system.

#### 4.1 Same-task Functional Composition

In this section, we consider the motivating example of college admissions. When secondary school students apply for college admission, they usually apply to more than one institution to increase their odds of admission to at least one college. Consider a universe of students  $U$  applying to college in a particular year, each with intrinsic qualification  $q_u \in [0, 1]$ ,  $\forall u \in U$ . We define  $\mathcal{D}(u, v) = |q_u - q_v| \forall u, v \in U$ .  $\mathcal{C}$  is the set of colleges and assume each college  $C_i \in \mathcal{C}$  admits students fairly with respect to  $\mathcal{D}$ . The system of schools is considered OR-fair if the indicator variable  $x_u$ , which indicates whether or not student  $u$  is admitted to at least one school, satisfies individual fairness under this same metric. More formally,

► **Definition 9 (OR Fairness).** Given a (universe, task) pair with metric  $\mathcal{D}$ , and a set of classifiers  $\mathcal{C}$  we define the indicator

$$x_u = \begin{cases} 1 & \text{if } \sum_{C_i \in \mathcal{C}} C_i(x) \geq 1 \\ 0 & \text{otherwise} \end{cases}$$

which indicates whether at least one positive classification occurred. Define  $\tilde{x}_u = \Pr[x_u = 1] = 1 - \prod_{C_i \in \mathcal{C}} (1 - \Pr[C_i(u) = 1])$ . Then the composition of the set of classifiers  $\mathcal{C}$  satisfies *OR Fairness* if  $\mathcal{D}(u, v) \geq d(\tilde{x}_u, \tilde{x}_v)$  for all  $u, v \in U$ .

The OR Fairness setting matches well to tasks where individuals primarily *benefit* from one positive classification for a particular task.<sup>9</sup> As mentioned above, examples of such tasks include gaining access to credit or a home loan, admission to university, access to qualified legal representation, access to employment, *etc.*<sup>10</sup> Although in some cases more than one acceptance may have positive impact, for example a person with more than one job offer may use the second offer to negotiate a better salary, the core problem is (arguably) whether or not at least one job is acquired.

Returning to the example of college admissions, even with the strong assumption that each college fairly evaluates its applicants, there are still several potential sources of unfairness in the resulting system. In particular, if students apply to different numbers of colleges or colleges with different admission rates, we would expect that their probabilities of acceptance to at least one college will be different. The more subtle scenario from the perspective of composition is when students apply to the *same* set of colleges.

Even in this restricted setting, it is still possible for a set of classifiers for the same task to violate OR fairness. The key observation is that for elements with positive distance, the difference in their expectation of acceptance by at least one classifier does not diverge linearly in the number of classifiers included in the composition. As the number of classifiers increases, the probabilities of positive classification by at least one classifier for any pair eventually converge. However, in practice, we expect students to apply to perhaps five or 10 colleges, so it is desirable to characterize when small systems are robust to such composition.

<sup>9</sup> We may conversely define NOR Fairness to take  $\neg x_u$ , and this setting more naturally corresponds to cases where not being classified as positive is desirable.

<sup>10</sup> [1] considers what boils down to AND-fairness for Equal Opportunity and presents an excellent collection of evocative example scenarios.

► **Theorem 10.** *For any (universe, task) pair with a non-trivial metric  $\mathcal{D}$ , there exists a set of individually fair classifiers  $\mathcal{C}$  which do not satisfy OR Fairness, even if each element in  $U$  is classified by all  $C_i \in \mathcal{C}$ .*

The proof of Theorem 10 follows from a straightforward analysis of the difference in probability of at least one positive classification.<sup>11</sup> The good news is that there exist non-trivial conditions for sets of small numbers of classifiers where OR Fairness is satisfied:

► **Lemma 11.** *Fix a set  $\mathcal{C}$  of fair classifiers, and let  $x_w$  for  $w \in U$  be the indicator variable as in Definition 9. If  $\mathbb{E}[x_w] \geq 1/2$  for all  $w \in U$ , then the set of classifiers  $\mathcal{C} \cup \{C'\}$  satisfies OR fairness if  $C'$  satisfies individual fairness under the same metric and  $\Pr[C'(w) = 1] \geq \frac{1}{2}$  for all  $w \in U$ .*

This lemma is useful for determining that a system is free from same-task divergence, as it is possible to reason about an “OR of ORs”, and more generally an “OR” of any fair components of sufficient weight.

Functional composition can also be used to reason about settings where classification procedures for different tasks are used to determine the outcome for a single task. For example, in order to attend a particular college, a student must be admitted *and* receive sufficient financial aid to afford tuition and living expenses. Financial need and academic qualification clearly have different metrics, and in such settings, a significant challenge is to understand how the input metrics relate to the relevant output metric. Without careful reasoning about the interaction between these tasks, it is very easy to end up with systems which violate individual fairness, even if they are constructed from individually fair components. (See Section 4.2 in the full version for more details.)

## 5 Dependent Composition

Thus far, we have restricted our attention to the mode of operation in which classifiers act on the entire universe of individuals at once and each individual’s outcome is decided independently. In practice, however, this is an unlikely scenario, as classifiers may be acting as a selection mechanism for a fixed number of elements, may operate on elements in arbitrary order, or may operate on only a subset of the universe. In this section, we consider the case in which the classification outcomes received by individuals are not independent. Slightly abusing the term “composition,” these problems can be viewed as a composition of the classifications of elements of the universe. We roughly divide these topics into Cohort Selection problems, when a set of exactly  $n$  individuals must be selected from the universe, and Universe Subset problems, when only a subset of the relevant universe for the task is under the influence of the classifier we wish to analyze or construct. Within these two problems we consider several relevant settings:

**Online versus offline:** Advertising decisions for online ads must be made immediately upon impression and employers must render employment decisions quickly or risk losing out on potential employees or taking too long to fill a position.

**Random versus adversarial ordering:** The order in which individuals apply for an open job may be influenced by their social connections with existing employees, which impacts how quickly they hear about the job opening.

<sup>11</sup> See Appendix Section 4 in the full version for the complete proof.

**Known versus unknown subset or universe size:** An advertiser may know the average number of interested individuals who visit a website on a particular day, but be uncertain on any particular day of the exact number.

**Constrained versus unconstrained selection:** In many settings there are arbitrary constraints placed on selection of individuals for a task which are unrelated to the qualification or metric for that task. For example, to cover operating costs, a college may need at least  $n/2$  of the  $n$  students in a class to be able to pay full tuition.

In dependent composition problems, it is important, when computing distances between distributions over outcomes, to pay careful attention to the source of randomness. Taking inspiration from the experiment setup found in many cryptographic definitions, we formally define two problems, Universe Subset Classification and Cohort Selection, (included in Definitions 13 and 14 in the Appendix). In particular, it is important to understand the randomness used to decide an ordering or a subset, as once an ordering or subset is fixed, reasoning about fairness is impossible, as a particular individual may be arbitrarily included or excluded.

## 5.1 Basic Offline Cohort Selection

First we consider the simplest version of the cohort selection problem: choosing a cohort of  $n$  individuals from the universe  $U$  when the entire universe is known and decisions are made offline. A simple solution is to choose a permutation of the elements in  $U$  uniformly at random, and then apply a fair classifier  $C$  until  $n$  are selected or selecting the last few elements from the end of the list if  $n$  have not yet been selected. With some careful bookkeeping, we show that this mechanism is individually fair for any individually fair input classifier. (See Algorithms 2 and 3 in the Appendix below; a complete analysis is included in Appendix Section 6 in the full version.)

## 5.2 More complicated settings

In this extended abstract, we omit a full discussion of the more complicated dependent composition scenarios, but briefly summarize several settings to build intuition.

► **Theorem 12.** *If the ordering of the stream is adversarial, but  $|U|$  is unknown, then there exists no solution to the online cohort selection problem.*

The intuition for the proof follows from imagining that a fair classification process exists for an ordering of size  $n$  and realizing that this precludes fair classification of a list of size  $n + 1$ , as the classification procedure cannot distinguish between the two cases.

### Constrained cohort selection

Next we consider the problem of selecting a cohort with an external requirement that some fraction of the selected set is from a particular subgroup. That is, given a universe  $U$ , and  $p \in [0, 1]$ , and a subset  $A \subset U$ , select a cohort of  $n$  elements such that at least a  $p$  fraction of the elements selected are in  $A$ . This problem captures situations in which external requirements cannot be ignored. For example, if a certain budget must be met, and only some members of the universe contribute to the budget, or if legally a certain fraction of people selected must meet some criterion (as in, demographic parity). In the full version, we characterize a broad range of settings where the constrained cohort selection problem cannot be solved fairly.

To build intuition, suppose the universe  $U$  is partitioned into sets  $A$  and  $B$ , where  $n/2 = |A| = |B|/5$ . Suppose further that the populations have the same distribution on ability, so that the set  $B$  is a “blown up” version of  $A$ , meaning that for each element  $u \in A$  there are 5 corresponding elements  $V_u = \{v_{u,1}, \dots, v_{u,5}\}$  such that  $\mathcal{D}(u, v_{u,i}) = 0$ ,  $1 \leq i \leq 5$ ,  $\forall u, u' \in A V_u \cap V_{u'} = \emptyset$ , and  $B = \cup_{u \in A} V_u$ . Let  $p = \frac{1}{2}$ . The constraint requires all of  $A$  to be selected; that is, each element of  $A$  has probability 1 of selection. In contrast, the average probability of selection for an element of  $B$  is  $\frac{1}{5}$ . Therefore, there exists  $v \in B$  with selection probability at most  $1/5$ . Letting  $u \in A$  such that  $v \in V_u$ , we have  $\mathcal{D}(u, v) = 0$  but the difference in probability of selection is at least  $\frac{4}{5}$ . We give a more complete characterization of the problem and impossibilities in the full version in Appendix Section 6.3 .

## 6 Extensions to Group Fairness

In general, the results discussed above for composition of individual fairness extend to group fairness definitions; however, there are several issues and technicalities unique to group fairness definitions which we now discuss.

### Technicalities

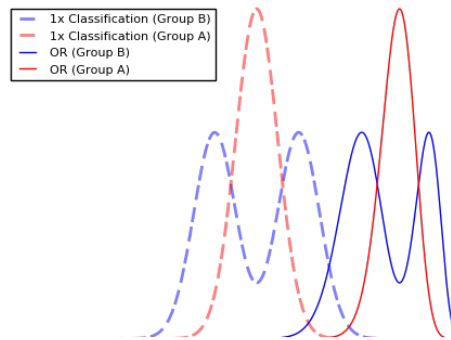

Consider the following simple universe: for a particular  $z \in \mathcal{Z}$ , group  $B$  is unimodal, having only elements with medium qualification  $q_m$ , while group  $A$  is bimodal, with half of its elements having low qualification  $q_l$  and half having high qualification  $q_h$ . Choosing  $p_h = 1$ ,  $p_m = .75$ , and  $p_l = .5$  satisfies Conditional Parity for a single application. However, for the OR of two applications, the squares diverge ( $.9375 \neq .875$ ), violating conditional parity (see Figure 1). Note, however, that all of the individuals with  $\mathbf{z} = z$  have been drawn closer together under composition, and none have been pulled further apart. This simple observation implies that in some cases we may observe failures under composition for conditional parity, even when individual fairness is satisfied. In order to satisfy Conditional Parity under OR-composition, the classifier could sacrifice accuracy by treating all individuals with  $\mathbf{z} = z$  equally. However, this necessarily discards useful information about the individuals in  $A$  to satisfy a technicality.

### Subgroup Subtleties

There are many cases where failing to satisfy conditional parity under task-competitive composition is clearly a violation of our intuitive notion of group fairness. However, conditional parity is not always a reliable test for fairness at the subgroup level under composition. In general, we expect conditional parity based definitions of group fairness to detect unfairness in multiple task compositions reasonably well when there is an obvious interaction between protected groups and task qualification, as observed empirically in [17] and [3]. For example, let’s return to our advertising example where home-goods advertisers have no protected set, but high-paying jobs have gender as a protected attribute. Under composition, home-goods out-bidding high-paying jobs ads for women will clearly violate the conditional parity condition for the job ads (see Figure 2).

However, suppose that, in response to gender disparity caused by task-competitive composition, classifiers iteratively adjust their bids to try to achieve Conditional Parity. This may cause them to *learn themselves* into a state that satisfies Conditional Parity with respect to gender, but behaves poorly for a socially meaningful subgroup (see Figure 3.) For example, if home goods advertisers aggressively advertise to women who are new parents

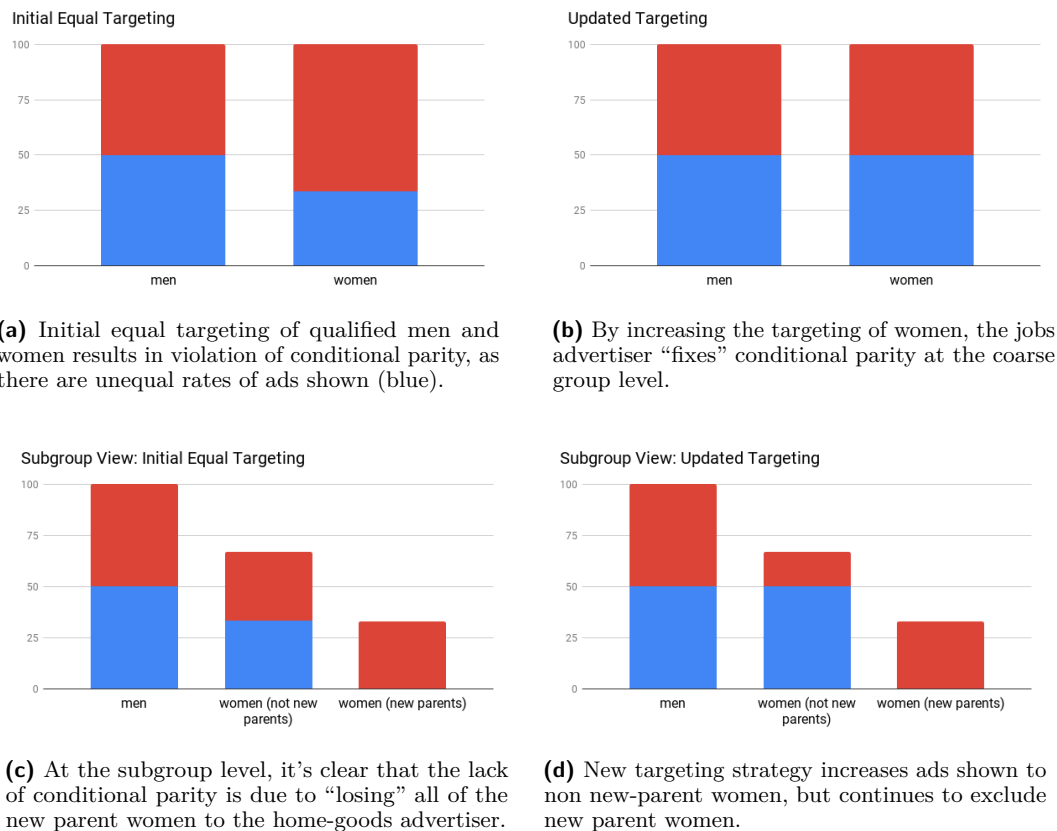

■ **Figure 1** An illustration of the shift in groups from a single classification to the OR of two applications of the same classifier. Although the two groups originally had the same mean probability of positive classification, this breaks down under OR composition.

■ **Figure 2 A.** When the two tasks are related, one will ‘claim’ a larger fraction of one gender than another, leading to a smaller fraction of men remaining for classification in the other task (shown in blue). Conditional parity will detect this unfairness. **B.** When the tasks are unrelated, one task may ‘claim’ the same fraction of people in each group, but potentially select a socially meaningful subgroup, eg parents. Conditional parity will fail to detect this subgroup unfairness, unless subgroups, including any subgroups targeted by classifiers composed with, are explicitly accounted for.

(because their life-time value ( $\mathcal{Z}$ ) to the advertiser is the highest of all universe elements), then a competing advertiser for jobs, noticing that its usual strategy of recruiting all people with skill level  $\mathbf{z}' = z'$  equally is failing to reach enough women, bids more aggressively on women. By bidding more aggressively, the advertiser increases the probability of showing ads to women (for example by outbidding low-value competition), but not to women who are bid for by the home goods advertiser (a high-value competitor), resulting in a high concentration of ads for women who are *not* mothers, while still failing to reach women who *are* mothers. Furthermore, the systematic exclusion of mothers from job advertisements can, over time, be even more problematic, as it may contribute to the stalling of careers. In this case, the system discriminates against mothers without necessarily discriminating against fathers.

Although problematic (large) subgroup semantics are part of the motivation for [11, 7] and exclusion of subgroups is not only a composition problem, the added danger in composition is that the features describing this subset may be missing from the feature set of the jobs classifier, rendering the protections proposed in [11] and [7] ineffective. In particular, we expect that sensitive attributes like parental status are unlikely to appear (or are illegal to collect) in employment-related training or testing datasets, but may be legitimately targeted by other competing advertisers.

■ **Figure 3** Home-goods advertisers aggressively target mothers, out-bidding the jobs advertiser. When the jobs advertiser bids more aggressively on “women” (b) the overall rate of ads shown to “women” increases, but mothers may still be excluded (d), so  $\Pr[\text{ad} \mid \text{qualified, woman}] > \Pr[\text{ad} \mid \text{qualified, mother}]$ .

## **A** Appendix

### **A.1** Algorithm for Task-Competitive Composition

RandomizeThenClassify, Algorithm 1 has several nice properties. First, it requires no coordination in the training of the classifiers. In particular, it does not require any sharing of objective functions. Second, it preserves the ordering of elements by each classifier. That is, if  $\Pr[C_i(u) = 1] > \Pr[C_i(v) = 1]$  then  $\Pr[\text{RandomizeThenClassify}(u)_i = 1] > \Pr[\text{RandomizeThenClassify}(v)_i = 1]$ . Finally, it can be implemented by a platform or other third party, rather than requiring the explicit cooperation of all classifiers. The primary downside of RandomizeThenClassify is that it drastically reduces allocation (the total number of positive classifications) for classifiers trained with the expectation of being run independently.

---

**Algorithm 1** RandomizeThenClassify.

---

**Input:** universe element  $u \in U$ , set of fair classifiers  $\mathcal{C}$  (possibly for distinct tasks) operating on  $U$ , probability distribution over tasks  $\mathcal{X} \in \Delta(\mathcal{C})$   
 $x \leftarrow 0^{|\mathcal{C}|}$   
 $C_t \sim \mathcal{X}$   
**if**  $C_t(u) = 1$  **then**  
     $x_t = 1$   
**end if**  
return  $x$

---

---

**Algorithm 2** PermuteThenClassify.

---

**Input:**  $n \leftarrow$  the number of elements to select  
 $C \leftarrow$  a classifier  $C : U \times \{0, 1\}^* \rightarrow \{0, 1\}$   
 $\pi \sim S_{|U|}$  a random permutation from the symmetric group on  $|U|$   
 $L \leftarrow \pi(U)$  An ordered set of elements  
 $M \leftarrow \emptyset$   
**while**  $|M| < n$ : **do**  
     $u \leftarrow \text{pop}(L)$   
    **if**  $C(u) = 1$  **then**  
         $M \leftarrow M \cup \{u\}$   
    **end if**  
    **if**  $n - |M| \geq |L|$  **then**  
        *// the end condition*  
         $M \leftarrow M \cup \{u\}$   
    **end if**  
**end while**  
return  $M$

---

## A.2 Algorithms for Cohort Selection

PermuteThenClassify, Algorithm 2, works through a list initialized to a random permutation  $\pi(U)$ , classifying elements one at a time and independently until either (1)  $n$  elements have been selected or (2) the number of remaining elements in the list equals the number of remaining spots to be filled. Case (2) is referred to as the “end condition”. Elements in the “end condition” are selected with probability 1.

WeightedSampling, Algorithm 3, chooses sets of elements with probability proportional to their weight under a fair classifier. This prevents the arbitrary behavior of the end condition in case the classifier is poorly tuned for the specific number of desired elements.

## A.3 Universe Subset Problems

► **Definition 13** (Universe Subset Classification Problem). Given a universe  $U$ , let  $\mathcal{Y}$  be a distribution over subsets of  $U$ . Let  $\mathcal{X} = \{\mathcal{X}(V)\}_{V \subseteq U}$  be a family of distributions, one for each subset of  $U$ , where  $\mathcal{X}(V)$  is a distribution on permutations of the elements of  $V$ . Let  $\Pi(2^U)$  denote the set of permutations on subsets of  $U$ . Formally, for a system  $\mathcal{S} : \Pi(2^U) \times \{0, 1\}^* \rightarrow U^*$ , we define **Experiment**( $\mathcal{S}, \mathcal{X}, \mathcal{Y}, u$ ) as follows:

1. Choose  $r \sim \{0, 1\}^*$
2. Choose  $V \sim \mathcal{Y}$

**Algorithm 3** WeightedSampling.

---

**Input:**  $n \leftarrow$  the number of elements to select  
 $C \leftarrow$  a classifier  $C : U \times r \rightarrow \{0, 1\}$   
 $L \leftarrow$  the set of all subsets of  $U$  of size  $n$   
**for**  $l \in L$  **do**  
     $w(l) \leftarrow \sum_{u \in l} \mathbb{E}[C(u)]$  // set the weight of each set  
    Define  $\mathcal{X} \in \Delta(L)$  such that  $\forall l \in L$ , the weight of  $l$  under  $\mathcal{X}$  is  $\frac{w(l)}{\sum_{l' \in L} w(l')}$   
     $M \sim \mathcal{X}$  // Sample a set of size  $n$  according to  $\mathcal{X}$   
**end for**  
return  $M$

---

3. Choose  $\pi \sim \mathcal{X}(V)$
4. Run  $\mathcal{S}$  on  $\pi$  with randomness  $r$ , and output 1 if  $u$  is selected (positively classified).

The system  $\mathcal{S}$  is individually fair and a solution to the Universe Subset Classification Problem for a particular  $(\mathcal{X}, \mathcal{Y})$  pair if for all  $u, v \in U$ ,

$$|\mathbb{E}[\text{Experiment}(\mathcal{S}, \mathcal{X}, \mathcal{Y}, u)] - \mathbb{E}[\text{Experiment}(\mathcal{S}, \mathcal{X}, \mathcal{Y}, v)]| \leq \mathcal{D}(u, v)$$

Note that for any distinct individuals  $u, v \in U$ , in any given run of the experiment  $V$  may contain  $u, v$ , neither or both.

► **Definition 14** (Cohort Selection Problem). The Cohort Selection Problem is identical to the Universe Subset Classification Problem, except the system is limited to choosing exactly  $n$  individuals.

► **Lemma 15.** *Given an instance of the universe subset classification problem (Definition 13) where  $\mathcal{Y}$  assigns positive weight to all elements  $w \in U$ , the following procedure applied to any individually fair classifier  $C$  which solely controls outcomes for a particular task will result in fair classification under the input distribution  $\mathcal{Y}$ .*

**Procedure:** for each  $w \in U$ , let  $q_w$  denote the probability that  $w$  appears in  $V$ . Let  $q_{\min} = \min_w q_w$ . For each element  $w \in V$ , with probability  $q_{\min}/q_w$  classify  $w$  normally, otherwise output the default for no classification.

**Proof.** Let  $u = \operatorname{argmin}_w(q_w)$ . Then  $u$  will be classified positively with probability  $p_u q_{\min}$  where probability is taken over  $\mathcal{Y}$  and  $C$ . All other elements  $v \in V$  will be classified positively with probability  $q_v(q_{\min}/q_v)p_v = p_v q_{\min}$ . As positive classification by  $C$  is the only way to get a positive outcome for the task, reasoning about  $|p_v - p_u|$  is sufficient to ensure fairness. Therefore, if  $|p_v - p_u| \leq \mathcal{D}(u, v)$ , then the distance under this procedure is also  $\leq \mathcal{D}(u, v)$ . ◀

## A.4 Construction of Fair Classifiers

► **Lemma 16.** *Let  $V$  be a (possibly empty) subset of  $U$ . If there exists a classifier  $C : V \times \{0, 1\}^* \rightarrow \{0, 1\}$  such that  $\mathcal{D}(u, v) \geq d(\tilde{C}(u), \tilde{C}(v))$  for all  $u, v \in V$ , then for any  $x \in U \setminus V$  there exists classifier  $C' : V \cup \{x\} \times \{0, 1\}^* \rightarrow \{0, 1\}$  such that  $\mathcal{D}(u, v) \geq d(\tilde{C}(u), \tilde{C}(v))$  for all  $u, v \in U$ , which has identical behavior to  $C$  on  $V$ .*

**Proof.** For  $V = \emptyset$ , any value  $p_x$  suffices to fairly classify  $x$ . For  $|V| = 1$ , choosing any  $p_x$  such that  $|p_v - p_x| \leq \mathcal{D}(v, x)$  for  $v \in V$  suffices.

---

**Algorithm 4** FairAddition( $\mathcal{D}, V, p_t, C, x$ ).

---

**Input:** metric  $\mathcal{D}$  for universe  $U$ , a subset  $V \subset U$ , target probability  $p_t$ , an individually fair classifier  $C : V \times \{0, 1\}^* \rightarrow \{0, 1\}$ , a target element  $x \in U \setminus V$  to be added to  $C$ .

Initialize  $L \leftarrow V$

$\hat{p}_x \leftarrow p_t$

**for**  $l \in L$  **do**

$dist \leftarrow \mathcal{D}(l, x)$

**if**  $dist < p_l - \hat{p}_x$  **then**

$\hat{p}_x \leftarrow p_l - dist$

**else if**  $dist < \hat{p}_x - p_l$  **then**

$\hat{p}_x \leftarrow p_l + dist$

**end if**

**end for**

**return**  $\hat{p}_x$

---

For  $|V| \geq 2$ , apply the procedure outlined in Algorithm 4 taking  $p_t$  to be the probability of positive classification of  $x$ 's nearest neighbor in  $V$  under  $C$ . As usual, we take  $p_w$  to be the probability that  $C$  positively classifies element  $w$ .

Notice that Algorithm 4 only modifies  $\hat{p}_x$ , and that  $\hat{p}_x$  is only changed if a distance constraint is violated. Thus it is sufficient to confirm that on each modification to  $\hat{p}_x$ , no distance constraints between  $x$  and elements in the opposite direction of the move are violated.

Without loss of generality, assume that  $\hat{p}_x$  is decreased to move within an acceptable distance of  $u$ , that is  $\hat{p}_x \geq p_u$ . It is sufficient to show that for all  $v$  such that  $p_v > \hat{p}_x$  that no distances are violated. Consider any such  $v$ . By construction  $\hat{p}_x - p_u = \mathcal{D}(u, x)$ , and  $p_v - p_u \leq \mathcal{D}(u, v)$ . From triangle inequality, we also have that  $\mathcal{D}(u, v) \leq \mathcal{D}(u, x) + \mathcal{D}(x, v)$ . Substituting, and using that  $p_v \geq \hat{p}_x \geq p_u$ :

$$\mathcal{D}(u, v) \leq \mathcal{D}(u, x) + \mathcal{D}(x, v)$$

$$\mathcal{D}(u, v) - \mathcal{D}(u, x) \leq \mathcal{D}(x, v)$$

$$\mathcal{D}(u, v) - (\hat{p}_x - p_u) \leq \mathcal{D}(x, v)$$

$$(p_v - p_u) - (\hat{p}_x - p_u) \leq \mathcal{D}(u, v) - (\hat{p}_x - p_u) \leq \mathcal{D}(x, v)$$

$$p_v - \hat{p}_x \leq \mathcal{D}(x, v)$$

Thus the fairness constraint for  $x$  and  $v$  is satisfied, and  $C'$  is an individually fair classifier for  $V \cup \{x\}$ . ◀

Lemma 16 allows us to build up a fair classifier in time  $O(|U|^2)$  from scratch, or to add to an existing fair classifier for a subset. We state several useful corollaries:

► **Corollary 17.** *Given a subset  $V \subset U$  and a classifier  $C : V \times \{0, 1\}^* \rightarrow \{0, 1\}$  such that  $\mathcal{D}(u, v) \geq d(\tilde{C}(u), \tilde{C}(v))$  for all  $u, v \in V$ , there exists an individually fair classifier  $C' : U \times \{0, 1\}^* \rightarrow \{0, 1\}$  which is individually fair for all elements  $u, v \in U$  and has identical behavior to  $C$  on  $V$ .*

Corollary 17 follows immediately from applying Algorithm 4 to each element of  $U \setminus V$  in arbitrary order.

## 33:20 Fairness Under Composition

► **Corollary 18.** *Given a metric  $\mathcal{D}$ , for any pair  $u, v \in U$ , there exists an individually fair classifier  $C : U \times \{0, 1\}^* \rightarrow \{0, 1\}$  such that  $d(\tilde{C}(u), \tilde{C}(v)) = \mathcal{D}(u, v)$ .*

Corollary 18 follows simply from starting from the classifier which is fair only for a particular pair and places them at their maximum distance under  $\mathcal{D}$  and then repeatedly applying Algorithm 4 to the remaining elements of  $U$ . From a distance preservation perspective, this is important; if there is a particular ‘axis’ within the metric where distance preservation is most important, then maximizing the distance between the extremes of that axis can be very helpful for preserving the most relevant distances.

► **Corollary 19.** *Given a metric  $\mathcal{D}$  and  $\alpha \in \mathbb{R}^+$ , for any pair  $u, v \in U$ , there exists an individually fair classifier  $C : U \times \{0, 1\}^* \rightarrow \{0, 1\}$  such that  $p_u/p_v = \alpha$ , where  $p_u = \mathbb{E}[C(u)]$  and likewise  $p_v = \mathbb{E}[C(v)]$ .*

Corollary 19 follows from choosing  $p_u/p_v = \alpha$  without regard for the difference between  $p_u$  and  $p_v$ , and then adjusting. Take  $\beta|p_v - p_u| = \mathcal{D}(u, v)$ , and choose  $\hat{p}_u = \beta p_u$  and  $\hat{p}_v = \beta p_v$  so that  $|\beta p_v - \beta p_u| = \beta|p_v - p_u| \leq \mathcal{D}(u, v)$ , but the ratio  $\frac{\beta p_u}{\beta p_v} = \frac{p_u}{p_v} = \alpha$  remains unchanged.

## Abstract

Let  $\kappa \in \mathbb{N}_+^\ell$  satisfy  $\kappa_1 + \dots + \kappa_\ell = n$ , and let  $\mathcal{U}_\kappa$  denote the *multislice* of all strings  $u \in [\ell]^n$  having exactly  $\kappa_i$  coordinates equal to  $i$ , for all  $i \in [\ell]$ . Consider the Markov chain on  $\mathcal{U}_\kappa$  where a step is a random transposition of two coordinates of  $u$ . We show that the log-Sobolev constant  $\varrho_\kappa$  for the chain satisfies

$$\varrho_\kappa^{-1} \leq n \cdot \sum_{i=1}^{\ell} \frac{1}{2} \log_2(4n/\kappa_i),$$

which is sharp up to constants whenever  $\ell$  is constant. From this, we derive some consequences for small-set expansion and isoperimetry in the multislice, including a KKL Theorem, a Kruskal–Katona Theorem for the multislice, a Friedgut Junta Theorem, and a Nisan–Szegedy Theorem.

## 1 Introduction

Suppose we have a deck of  $n$  cards, with  $\kappa_1$  of them colored red,  $\kappa_2$  of them colored blue, and  $\kappa_3$  of them colored green. If we “shuffle” the cards by repeatedly transposing random pairs of cards, how long does it take for the deck to get to a well-mixed configuration? This question is asking about the mixing time and expansion in a Markov chain known variously as the *multi-urn Bernoulli–Laplace diffusion process* or the *multislice*.

Let  $\ell \in \mathbb{N}_+$  denote a number of *colors* and let  $n \in \mathbb{N}_+$  denote a number of *coordinates* (or *positions*). Following computer science terminology, we refer to elements  $u \in [\ell]^n$  as

---

<sup>2</sup> Supported by NSF grant CCF-1717606. This material is based upon work supported by the National Science Foundation under grant numbers listed above. Any opinions, findings and conclusions or recommendations expressed in this material are those of the author and do not necessarily reflect the views of the National Science Foundation (NSF).

*strings.* Given a color  $i \in [\ell]$ , we write  $\#_i u$  for the number of coordinates  $j \in [n]$  for which  $u_j = i$ . The vector  $\kappa = (\#_1 u, \dots, \#_\ell u) \in \mathbb{N}^\ell$  is referred to as the *histogram* of  $u$ . In general, if  $\kappa \in \mathbb{N}_+^\ell$  satisfies  $\kappa_1 + \dots + \kappa_\ell = n$  (so  $\kappa$  is a *composition* of  $n$ ), we define the associated *multislice* to be

$$\mathcal{U}_\kappa = \{u \in [\ell]^n : \#_i u = \kappa_i \text{ for all } i \in [\ell]\}.$$

The terminology here is inspired by the well-studied case when  $\ell = 2$ , in which case  $\mathcal{U}_\kappa$  is a Hamming *slice* of the Boolean cube. We also remark that when  $\ell = n$  and  $\kappa = (1, 1, \dots, 1)$ , the set  $\mathcal{U}_\kappa$  is the set of all permutations of  $[n]$ .

### 1.1 The random transposition Markov chain

The symmetric group  $S_n$  acts on strings  $u \in [\ell]^n$  in the natural way, by permuting coordinates:  $(u^\sigma)_j = u_{\sigma(j)}$  for  $\sigma \in S_n$ . This action preserves each multislice  $\mathcal{U}_\kappa$ . This paper is concerned with the Markov chain on  $\mathcal{U}_\kappa$  generated by *random transpositions*. Let  $\text{Trans}(n) \subseteq S_n$  denote the set of transpositions on  $n$  coordinates. We will specifically be interested in the reversible, discrete-time Markov chain on state space  $\mathcal{U}_\kappa$  in which a step from  $u \in \mathcal{U}_\kappa$  consists of moving to  $u^\tau$ , where  $\tau \sim \text{Trans}(n)$  is chosen uniformly at random. (We always use **boldface** to denote random variables.) One also has the associated *Schreier graph*, with vertex set  $\mathcal{U}_\kappa$  and edges  $\{u, u^\tau\}$  for all  $u \in \mathcal{U}_\kappa$  and  $\tau \in \text{Trans}(n)$ . Since this graph is regular, it follows that the invariant distribution for the Markov chain is the uniform distribution on  $\mathcal{U}_\kappa$ . We will denote this distribution by  $\pi_\kappa$ , or just  $\pi$  if  $\kappa$  is clear from context.

### 1.2 Log-Sobolev inequalities

One of the most powerful ways to study mixing time and “small-set expansion” in Markov chains is through *log-Sobolev* inequalities (see, e.g., [25, 11]). For a subset  $A \subseteq \mathcal{U}_\kappa$ , define its *conductance* (or *expansion*) to be

$$\Phi[A] = \Pr_{\substack{\mathbf{u} \sim A \\ \tau \sim \text{Trans}(n)}} [\mathbf{u}^\tau \notin A].$$

Sets  $A$  with small conductance are natural bottlenecks for mixing in the Markov chain. An example when  $\ell = 2$  and  $\kappa = (n/2, n/2)$  is the “dictator” set  $A = \{u : u_1 = 1\}$ . It has expansion  $\Phi[A] = \frac{1}{n-1}$ , and indeed, if we start the random walk from a string  $u$  with  $u_1 = 1$ , it will take about  $n/2$  steps on average before there’s even a chance that  $u_1$  will change from 1.

One feature of this example is that the set  $A$  is “large”; its (*fractional*) *volume*,

$$\text{vol}(A) = |A|/|\mathcal{U}_\kappa| = \Pr_{\mathbf{u} \sim \pi} [\mathbf{u} \in A],$$

is bounded below by a constant. The “small-set expansion” phenomenon [28, 37, 47] (occurring most famously in the standard random walk on the Boolean cube  $\{0, 1\}^n$ ) refers to the possibility that all “small” sets have high conductance. Intuitively, if small-set expansion holds for a Markov chain, then a random walk with a deterministic starting point should mix rapidly in its early stages, with the possibility for slowdown occurring only when the chain is somewhat close to mixed.

A *log-Sobolev inequality* for the Markov chain is one way that such a phenomenon may be captured. In particular, if the *log-Sobolev constant* for the transposition chain on  $\mathcal{U}_\kappa$  is  $\varrho_\kappa$ , it follows that

$$\Phi[A] \geq \frac{1}{2} \varrho_\kappa \cdot \ln(1/\text{vol}(A)) \quad \text{for all nonempty subsets } A \subseteq \mathcal{U}_\kappa. \tag{1}$$

So sets of constant volume must have conductance  $\Omega(\varrho_\kappa)$ , but sets of volume  $2^{-\Theta(n)}$  (for example) must have conductance  $\Omega(n\varrho_\kappa)$ . A known further consequence of a log-Sobolev inequality is a *hypercontractive inequality*, which concerns expansion in the continuous-time version of the Markov chain. It implies that if  $\sigma$  is the random permutation generated by performing the continuous-time chain for  $t = \frac{\ln c}{2\varrho_\kappa}$  time – i.e.,

$\sigma$  is the product of Poisson  $\left(\frac{\ln c}{2\varrho_\kappa}\right)$  random transpositions,  $c \geq 1$

– then

$$\Pr_{\substack{\mathbf{u} \sim A \\ \sigma \sim \text{Trans}(n)}} [\mathbf{u}^\sigma \notin A] \geq 1 - \text{vol}(A)^{(c-1)/(c+1)} \quad \text{for all nonempty subsets } A \subseteq \mathcal{U}_\kappa.$$

Thus again, if  $\text{vol}(A)$  is small, then the Markov chain will almost surely exit  $A$  after running for  $\Theta(\varrho_\kappa^{-1})$  steps.

We remark that Inequality (1) is merely a *consequence* of the log-Sobolev constant being  $\varrho_\kappa$ . It is not the case that  $\varrho_\kappa$  is defined to be the largest constant for which Inequality (1) holds (for all  $A$ ) – though this is a reasonable intuition. Instead,  $\varrho_\kappa$  is defined to be the largest constant for which a certain generalization of Inequality (1) to nonnegative functions holds; namely,

$$\mathbf{E}_{\substack{\mathbf{u} \sim \pi \\ \tau \sim \text{Trans}(n)}} \left( \sqrt{\phi(\mathbf{u})} - \sqrt{\phi(\mathbf{u}^\tau)} \right)^2 \geq \varrho_\kappa \cdot \text{KL}(\phi\pi \parallel \pi) \quad \text{for all probability densities } \phi. \quad (2)$$

(Here a *probability density function* is a function  $\phi: \mathcal{U}_\kappa \rightarrow \mathbb{R}^{\geq 0}$  satisfying  $\mathbf{E}_\pi[\phi] = 1$ , and  $\text{KL}(\phi\pi \parallel \pi)$  denotes the *KL divergence* between distributions  $\phi\pi$  and  $\pi$ .) Inequality (2) includes Inequality (1) by taking  $\phi = 1_A/\text{vol}(A)$ .

Our main theorem in this work is a lower bound on the log-Sobolev constant for  $\mathcal{U}_\kappa$ :

► **Theorem 1.** *Let  $\kappa \in \mathbb{N}_+^\ell$  satisfy  $\kappa_1 + \dots + \kappa_\ell = n$ , and let  $\varrho_\kappa$  denote the log-Sobolev constant for the transposition chain on the multislice  $\mathcal{U}_\kappa$  (i.e., the largest constant for which Inequality (2) holds). Then*

$$\varrho_\kappa^{-1} \leq n \cdot \sum_{i=1}^{\ell} \frac{1}{2} \log_2(4n/\kappa_i).$$

The main case of interest for us is  $n \rightarrow \infty$  with  $\ell = O(1)$  and  $\kappa_i/n \geq \Omega(1)$  for each  $i$ ; in other words, when we are at a “middling” histogram of a high-dimensional multicube  $[\ell]^n$ . In this case our bound is  $\varrho_\kappa \geq \Omega(1/n)$ , which is the same bound that holds for the standard random walk on the Boolean cube. Thus for this parameter setting, the random transposition chain on the multislice enjoys all of the same small-set expansion properties as the Boolean cube (up to constants).

### 1.3 On the sharpness of Theorem 1

When  $\ell$  is considered to be a constant, Theorem 1 is sharp up to constant factors (which we did not attempt to optimize); i.e.,

$$\varrho_\kappa^{-1} = \Theta(n) \cdot \log \left( \frac{n}{\min_i \{\kappa_i\}} \right) \quad \text{for } \ell = O(1). \quad (3)$$

To see the upper bound on  $\varrho_\kappa$ , assume without loss of generality that  $\ell = \operatorname{argmin}_i \{\kappa_i\}$ , and take

$$A = \{u \in \mathcal{U}_\kappa : u_j = \ell \text{ for all } j \in [\kappa_\ell]\}.$$

It is easy to compute that  $\Phi[A] = \Theta(\kappa_\ell/n)$  and  $\operatorname{vol}(A) = \binom{n}{\kappa_\ell}^{-1}$  (hence  $\ln(1/\operatorname{vol}(A)) = \Theta(\kappa_\ell \log(n/\kappa_\ell))$ ). Putting this into Inequality (1) shows the claimed upper bound on  $\varrho_\kappa$ .

At the opposite extreme, when  $\ell = n$  and  $\kappa = (1, 1, \dots, 1)$ , we have the random transposition walk on the symmetric group  $S_n$ . In this case, Theorem 1 as stated gives the poor bound of  $\varrho_\kappa \geq \Omega(1/n^2 \log n)$ , whereas the optimal bound is  $\varrho_\kappa = \Theta(1/n \log n)$  [11, 35]. In fact, our proof of Theorem 1 (which generalizes that of [35]) can actually achieve the tight lower bound of  $\varrho_\kappa \geq \Omega(1/n \log n)$  in this case. However, we tailored our general bound for the case of  $\ell = O(1)$ , and did not try to optimize for the most general scenario of  $\ell$  varying with  $n$ . A reasonable prediction might be that Equation (3) always holds, up to universal constants, without the assumption of  $\ell = O(1)$ ; we leave investigation of this for future work.

## 2 Applications

There are many known applications of log-Sobolev and hypercontractive inequalities in combinatorics and theoretical computer science (see, e.g., [42, Ch. 9, 10]). In this paper we present four particular consequences of Theorem 1 for analysis/combinatorics of Boolean functions on the multislice. We anticipate the possibility of several more.

### 2.1 KKL and Kruskal–Katona for multislices

Throughout the remainder of this section, let us think of  $n$  as large, of  $\ell$  as constant, and let us fix a histogram  $\kappa$  (with  $\kappa_1 + \dots + \kappa_\ell = n$ ) satisfying  $\kappa_i/n \geq \Omega(1)$  for all  $i$ . For example, we might think of  $\ell = 3$  and  $\kappa = (n/3, n/3, n/3)$ , so that  $\mathcal{U}_\kappa$  consists of all ternary strings with an equal number of 1’s, 2’s, and 3’s. The *isoperimetric problem* for  $\mathcal{U}_\kappa$  would ask: for a given fixed  $0 < \alpha < 1$ , which subset  $A \subseteq \mathcal{U}_\kappa$  with  $\operatorname{vol}(A) = \alpha$  has minimal “edge boundary”, i.e., minimal  $\Phi[A]$ ? (Here “edge boundary” is with respect to performing a single transposition, although in our Kruskal–Katona application we will relate this to the size of  $A$ ’s “shadows” at neighboring multislices.)

We typically think of  $\alpha$  as “constant”, bounded away from 0 and 1. In our example with  $\kappa = (n/3, n/3, n/3)$ , when  $\alpha = 1/3$  the isoperimetric minimizer is a “dictator” set like  $A = \{u : u_1 = 1\}$ ; it has  $\Phi[A] = \frac{4/3}{n-1}$ . The “99% regime” version of the isoperimetric question would be: if  $\Phi[A]$  is within a factor  $1 + o(1)$  of minimal, must  $A$  be “ $o(1)$ -close” to a minimizer? This question will be considered in a companion paper. We will instead consider the “1% regime” version of the isoperimetric question: if  $\Phi[A]$  is at most  $O(1)$  times the minimum, must  $A$  at least “slightly resemble” a minimizer?

To orient ourselves, first note that for constant  $\alpha$  (bounded away from 0 and 1), the minimum possible value of  $\Phi[A]$  among  $A$  with  $\operatorname{vol}(A) = \alpha$  is  $\Theta(1/n)$ ; indeed, this follows from our Theorem 1 and Inequality (1). From this fact, we will derive a multislice variant of the **Kruskal–Katona Theorem**. Up to  $O(1)$  factors, this minimum is achieved not just by “dictator” sets like  $\{u \in \mathcal{U}_{(n/3, n/3, n/3)} : u_1 = 1\}$ , but also by any “junta” set, meaning a set  $A$  for which absence or presence of  $u \in A$  depends only on the colors  $(u_j : j \in J)$  for a set  $J \subseteq [n]$  of cardinality  $c = O(1)$ . It is not hard to see that if  $A \subseteq \mathcal{U}_\kappa$  is such a  $c$ -junta, then  $\Phi[A] \leq O(c/n)$ . We may now ask: if  $\Phi[A] \leq O(1/n)$ , must  $A$  at least slightly “resemble” a junta?

We give two closely related positive answers to this question, as a consequence of our log-Sobolev inequality. The first answer, a **KKL Theorem** for the multislice (cf. [28] and Talagrand’s strengthening of it [51]), follows immediately from previous work [43, 44]. It says that for any set with  $\Phi[A] \leq O(1/n)$ , there must exist some transposition  $\tau \in \text{Trans}(n)$  with at least constant *influence* on  $A$ , where the influence of the transposition  $\tau$  on  $A$  is defined to be

$$\text{Inf}_\tau[A] = \Pr_{\mathbf{u} \sim \pi} [1_A(\mathbf{u}) \neq 1_A(\mathbf{u}^\tau)].$$

Formally, Talagrand’s strengthening of the KKL theorem in this setting is:

► **Theorem 2.** *Let  $f: \mathcal{U}_\kappa \rightarrow \{0, 1\}$ . Then*

$$\text{avg}_{\tau \in \text{Trans}(n)} \left\{ \frac{\text{Inf}_\tau[f]}{\lg(2/\text{Inf}_\tau[f])} \right\} \gtrsim \rho_\kappa \cdot \mathbf{Var}_{\pi_\kappa}[f].$$

Substituting our lower bound on  $\rho_\kappa$  from Theorem 1 yields concrete new results. For example, consider our model scenario of  $n \rightarrow \infty$  with  $\ell = O(1)$  and  $\kappa_i/n \geq \Omega(1)$  for each  $i$ ; suppose further that  $f$  is “roughly balanced”, meaning  $\Omega(1) \leq \mathbf{Var}[f] \leq 1 - \Omega(1)$ . Then

$$\text{avg}_{\tau \in \text{Trans}(n)} \left\{ \frac{\text{Inf}_\tau[f]}{\lg(2/\text{Inf}_\tau[f])} \right\} \gtrsim \frac{1}{n},$$

and hence the maximum influence  $\mathcal{M}[f]$  satisfies

$$\mathcal{M}[f] \gtrsim \frac{\log n}{n}.$$

The latter statement here is the traditional conclusion of the KKL Theorem.

Let us record here one more concrete corollary of Theorem 2. In our model scenario, that theorem (roughly speaking) says that the energy  $\mathcal{E}[1_A] = \text{avg}_{\tau \in \text{Trans}(n)} \text{Inf}_\tau[1_A]$  is at least  $\Omega(\frac{\log n}{n})$  unless some transposition  $(i j)$  has a rather large influence, like  $1/n^{0.1}$ , on  $1_A$ .

► **Corollary 3.** *Let  $A \subseteq \mathcal{U}_\kappa$ . Assume  $\kappa_i \geq pn$  for all  $i \in [\ell]$  and that  $\epsilon \leq \text{vol}(A) \leq 1 - \epsilon$ . Then*

$$\mathcal{E}[1_A] \geq \Omega\left(\frac{\epsilon}{\ell \log(1/p)}\right) \cdot \frac{\log(1/\mathcal{M}[1_A])}{n}.$$

It is the hallmark of a junta  $A$  that every transposition  $\tau$  has either  $\text{Inf}_\tau[A] = 0$  or  $\text{Inf}_\tau[A] \geq \Omega(1)$ . Mirroring the original KKL Theorem, our work shows that: (i) if  $\Phi[A] \leq c/n$  then there exists  $\tau$  with  $\text{Inf}_\tau[A] \geq \exp(-O(c))$ ; (ii) for any  $A \subseteq \mathcal{U}_\kappa$  with  $\Omega(1) \leq \text{vol}(A) \leq 1 - \Omega(1)$ , there exists  $\tau$  with  $\text{Inf}_\tau[A] \geq \Omega(\frac{\log n}{n})$ .

From our KKL Theorem, we obtain various versions of the Kruskal–Katona Theorem for multislices. The classical Kruskal–Katona Theorem [50, 33, 29] concerns subsets of Hamming slices of the Boolean cube. To recall it, let us write a 2-color histogram  $\kappa \in \mathbb{N}_+^2$  as  $(\kappa_0, \kappa_1)$ , with  $n = \kappa_0 + \kappa_1$ . If  $A \subseteq \mathcal{U}_\kappa$ , then the (*lower*) *shadow* of  $A$  is defined to be

$$\partial A = \{v \in \mathcal{U}_{(\kappa_0+1, \kappa_1-1)} : v \leq u \text{ for some } u \in A\}.$$

It is not hard to show that  $\text{vol}(\partial A) \geq \text{vol}(A)$  always (here the fractional volume  $\text{vol}(\partial A)$  is vis-à-vis the containing slice  $\mathcal{U}_{(\kappa_0+1, \kappa_1-1)}$ ). The Kruskal–Katona Theorem improves this by giving an exactly sharp lower bound on  $\text{vol}(\partial A)$  as a function of  $\text{vol}(A)$ . The precise function is somewhat cumbersome to state, but the qualitative consequence, assuming that  $\text{vol}(A)$

and  $\kappa_0/n$  are bounded away from 0 and 1, is that  $\text{vol}(\partial A) \geq \text{vol}(A) + \Omega(1/n)$ . This is sharp, up to the constant in the  $\Omega(\cdot)$ , as witnessed by the “dictator set”  $A = \{u : u_1 = 0\}$ . See [43, Sec. 1.2] for more discussion.

To extend the Kruskal–Katona Theorem to multislices, we first need to extend the notion of neighboring slices and shadows. Fix an ordering on the colors,  $1 \prec 2 \prec \dots \prec \ell$ . This total order extends to a partial order on strings in  $[\ell]^n$  in the natural way.

► **Definition 4.** Let  $\kappa \in \mathbb{N}_+^\ell$  be a histogram. We say that histogram  $\kappa'$  is a *lower neighbor* of  $\kappa$ , and write  $\kappa' \triangleleft \kappa$ , if there exists some  $c \prec d \in [\ell]$  such that  $\kappa'_c = \kappa_c + 1$ ,  $\kappa'_d = \kappa_c - 1$ , and  $\kappa'_i = \kappa_i$  for all other colors  $i$ . In the opposite case, when  $c \succ d$ , we say  $\kappa'$  is an *upper neighbor* of  $\kappa$ , and write  $\kappa' \triangleright \kappa$ .

► **Definition 5.** Let  $A \subseteq \mathcal{U}_\kappa$ , and let  $\kappa' \triangleleft \kappa$ . The *lower shadow* of  $A$  at  $\kappa'$  is

$$\partial_{\kappa'} A = \{u \in \mathcal{U}_{\kappa'} : u \prec v \text{ for some } v \in A\}.$$

We similarly define upper shadows. We may use the same notation  $\partial_{\kappa'} A$  for both kinds of shadows, since whether a shadow is upper or lower is determined by whether  $\kappa' \triangleright \kappa$  or  $\kappa' \triangleleft \kappa$ .

► **Definition 6.** Given a histogram  $\kappa \in \mathbb{N}_+^\ell$ , we define a natural probability distribution  $\mathbf{lower}(\kappa)$  on the lower neighbors of  $\kappa$  as follows. To draw  $\kappa' \sim \mathbf{lower}(\kappa)$ : take an arbitrary  $u \in \mathcal{U}_\kappa$ ; choose  $\mathbf{j}, \mathbf{j}' \sim [n]$  independently and randomly, conditioned on  $u_{\mathbf{j}} \neq u_{\mathbf{j}'}$ ; let  $\mathbf{c}, \mathbf{d}$  denote the two colors  $u_{\mathbf{j}}, u_{\mathbf{j}'}$ , with the convention  $\mathbf{c} \prec \mathbf{d}$ ; finally, let  $\kappa'$  be the lower neighbor of  $\kappa$  with  $\kappa'_c = \kappa_c + 1$  and  $\kappa'_d = \kappa_c - 1$ .

We similarly define a probability distribution  $\mathbf{upper}(\kappa)$  on the upper neighbors of  $\kappa$  by interchanging the roles of  $\mathbf{c}$  and  $\mathbf{d}$ .

► **Theorem 7.** For  $A \subseteq \mathcal{U}_\kappa$  we have

$$\mathbf{E}_{\kappa' \sim \mathbf{lower}(\kappa)} [\text{vol}(\partial_{\kappa'} A)] \geq \text{vol}(A) + \frac{1}{n} \cdot \text{vol}(A) \ln(1/\text{vol}(A)) \cdot \left( \sum_{i=1}^n \log_2(4n/\kappa_i) \right)^{-1}.$$

In particular, at least one lower shadow of  $A$  has volume at least the right-hand side. The analogous statement for upper shadows also holds.

Thus in the model case when  $\text{vol}(A)$  and each  $\kappa_i/n$  is bounded away from 0 and 1, and  $\ell = O(1)$ , we get that the average lower shadow of  $A$  has volume at least  $\text{vol}(A) + \Omega(1/n)$ . Using our KKL Theorem (Corollary 3) we can get a “robust” version of this statement; the volume increase is in fact on the order of  $(\log n)/n$  unless there is a highly influential transposition for  $A$ :

► **Theorem 8.** Let  $A \subseteq \mathcal{U}_\kappa$ . Assume  $\kappa_i \geq pn$  for all  $i \in [\ell]$  and that  $\epsilon \leq \text{vol}(A) \leq 1 - \epsilon$ . Then for any  $\delta > 0$  we have

$$\mathbf{E}_{\kappa' \sim \mathbf{lower}(\kappa)} [\text{vol}(\partial_{\kappa'} A)] \geq \text{vol}(A) + \frac{\log n}{n} \cdot \Omega\left(\frac{\epsilon \delta}{\ell \log(1/p)}\right),$$

or else there exists  $\tau \in \text{Trans}(n)$  with  $\text{Inf}_\tau[A] \geq 1/n^\delta$ . The analogous statement for upper shadows also holds.

As in [43], we give a conceptual improvement to the “or else” clause in Theorem 8. Let us work with upper shadows rather than lower shadows going forward. The natural example for sets  $A$  with upper-shadow expansion “only”  $\Omega(1/n)$  are “dictator” sets such as  $A = \{u : u_1 = \ell\}$ . For such sets, all transpositions of the form  $(1\ j)$  indeed have huge

influence. However, it's not so natural to single out one such  $(1 j)$  as the “reason” for the small expansion; instead, we would prefer to say the reason is that  $A$  is highly “correlated” with coordinate 1:

► **Theorem 9.** *For  $n \rightarrow \infty$ , let  $A \subseteq \mathcal{U}_\kappa$ , with  $\ell = O(1)$ ,  $\kappa_i/n \geq \Omega(1)$  for all  $i \in [\ell]$  and  $\Omega(1) \leq \text{vol}(A) \leq 1 - \Omega(1)$ . Then*

$$\mathbf{E}_{\kappa' \sim \text{upper}(\kappa)}[\text{vol}(\partial_{\kappa'} A)] \geq \text{vol}(A) + \Omega\left(\frac{\log n}{n}\right),$$

or else there exists  $j \in [n]$  and colors  $c \prec d \in [\ell]$  with

$$\Pr_{\mathbf{u} \sim \pi_\kappa}[\mathbf{u} \in A \mid \mathbf{u}_j = d] - \Pr_{\mathbf{u} \sim \pi_\kappa}[\mathbf{u} \in A \mid \mathbf{u}_j = c] \geq 1/n^{0.01}.$$

## 2.2 Friedgut Junta Theorem for multislices

A closely related consequence of our work is a **Friedgut Junta Theorem** for the multislice (cf. [24]), which follows (using a small amount of representation theory) from work of Wimmer [53] (see also [18] for a different account). It states that for any  $A$  with  $\Phi[A] \leq c/n$ , and any  $\epsilon > 0$ , there is a genuine  $\exp(O(c/\epsilon))$ -junta  $A' \subseteq \mathcal{U}_\kappa$  that is  $\epsilon$ -close to  $A$ , meaning  $\text{vol}(A \Delta A') \leq \epsilon$ . The junta theorem can also be generalized to real-valued functions, following the work of Bouyrie [4], with a worse dependence on  $\epsilon$  in the exponent.

► **Theorem 10.** *Let  $f: \mathcal{U}_\kappa \rightarrow \{0, 1\}$  be such that  $\text{Inf}[f] \leq Kn$ . Write  $p_i = \kappa_i/n$ . Then for every  $\epsilon > 0$  there exists  $h: \mathcal{U}_\kappa \rightarrow \{0, 1\}$  depending on at most  $\left(\frac{1}{p_1 p_2 \dots p_\ell}\right)^{O(K/\epsilon)}$  coordinates such that  $\Pr_{\mathbf{u} \sim \pi_\kappa}[f(\mathbf{u}) \neq h(\mathbf{u})] \leq \epsilon$ .*

## 2.3 Nisan–Szegedy Theorem for multislices

Finally, with a little more representation theory effort, we are able to derive from Theorem 1 a **Nisan–Szegedy Theorem** for the multislice (cf. [41]), which is (roughly) an  $\epsilon = 0$  version of the Friedgut Junta Theorem; this generalizes previous work on the Hamming slice [20]. It says that if  $A \subseteq \mathcal{U}_\kappa$  is of “degree  $k$ ” – meaning that its indicator function can be written as a linear combination of  $k$ -junta functions – then  $A$  must be an  $\exp(O(k))$ -junta itself. (The  $k = 1$  case of this theorem, with the conclusion that  $A$  is a 1-junta, was proven recently in [21].)

More formally, the Nisan–Szegedy Theorem says that a degree- $k$  Boolean-valued function on the Hamming cube is a  $k2^k$ -junta. (We remark that the smallest quantity  $\gamma_2(k)$  that can replace  $k2^k$  here is now known [7] to satisfy  $3 \cdot 2^{k-1} - 2 \leq \gamma_2(k) < 22 \cdot 2^k$ .) Let us extend the definition of  $\gamma_2(k)$ ; we'll define  $\gamma_\ell(k)$  to be the least integer such that the following statement is true: Every degree- $k$  Boolean-valued function  $f: [\ell]^n \rightarrow \{0, 1\}$  on the “ $\ell$ -multicube” is a  $\gamma_\ell(k)$ -junta.

Here we say that  $f: [\ell]^n \rightarrow \mathbb{R}$  has degree at most  $k$  if it is a linear combination of  $k$ -juntas (as usual for functions on product spaces, see [42, Def. 8.32]). We can obtain the following Nisan–Szegedy Theorem:

► **Theorem 11.** *There is a universal constant  $C$  such that the following holds. For all  $k \in \mathbb{N}_+$  and all  $\kappa \in \mathbb{N}_+^\ell$  with  $\min_i \{\kappa_i\} \geq \ell^{Ck}$ , if  $f: \mathcal{U}_\kappa \rightarrow \{0, 1\}$  has degree at most  $k$ , then  $f$  is an  $\gamma_\ell(k)$ -junta.*

### 3 Context and prior work

In this section we review similar contexts where log-Sobolev inequalities and small-set expansion have been studied.

#### 3.1 The Boolean cube

The simplest and best-known setting for these kinds of results is the Boolean cube  $\{0, 1\}^n$  with the nearest-neighbour random walk. The optimal hypercontractive inequality in this setting was proven by Bonami [3]. Later, Gross [25] introduced log-Sobolev inequalities, showed that they were equivalent to hypercontractive inequalities in this setting, and determined the exact log-Sobolev constant for the Boolean cube, namely  $\varrho = 2/n$ . Gross also observed that all the same results also hold for Gaussian space in any dimension (recovering prior work of Nelson [40]); Gaussian space is in fact a “special case” of the Boolean cube, by virtue of the Central Limit Theorem. The Boolean cube also generalizes the well-studied *Ehrenfest model* of diffusion [15].

These inequalities for the Boolean cube, as well as the associated small-set expansion corollaries, have had innumerable applications in analysis, combinatorics, and theoretical computer science, in topics ranging from communication complexity to inapproximability; see, e.g., [34] or [42, Chapters 9–11].

A different line of work sought to determine the exact minimum value of  $\Phi[A]$  in terms of the size of  $A$ . This challenge, known as the *edge isoperimetric problem*, has been solved by Harper [26], Lindsey [36], Bernstein [2], and Hart [27], who have shown that the optimal sets are initial segments of a lexicographic ordering of the vertices of the Boolean cube. Recently Ellis, Keller and Lifshitz gave a new proof of the edge isoperimetric inequality using the Kruskal–Katona Theorem [16]. The same set of authors also recently proved a stability version of the edge isoperimetric inequality in the 99% regime [17].

Returning to log-Sobolev inequalities, an extraordinarily helpful feature of the random walk on the Boolean cube is that it is a *product Markov chain*, with a stationary distribution that is *independent* across the  $n$  coordinates. Because of this, a simple induction lets one immediately reduce the log-Sobolev (and hypercontractivity) analysis to the base case of  $n = 1$ .

#### 3.2 Other product chains

For *any* product Markov chain, one can similarly reduce the analysis to the  $n = 1$  case. In general, let  $\nu$  be a probability distribution of full support on  $[\ell]$ , and consider the Markov chain on  $[\ell]^n$  in which a step from  $u \in [\ell]^n$  consists of choosing a random coordinate  $j \sim [n]$  and replacing  $u_j$  with a random draw from  $\nu$ . The invariant distribution for this chain is the product distribution  $\nu^{\otimes n}$ . Though the  $n = 1$  case of this chain is, in a sense, trivial – it mixes perfectly in one step – it is not especially easy to work out the optimal log-Sobolev constant. Nevertheless, Diaconis and Saloffe-Coste [11] showed that for the  $n = 1$  chain, the log-Sobolev constant is

$$\varrho_\nu^{\text{triv}} = 2 \frac{q - p}{\ln q - \ln p}, \quad \text{where } p = \min_{i \in [\ell]} \{\nu(i)\}, \quad q = 1 - p.$$

It follows immediately that the log-Sobolev constant in the general- $n$  case is  $\varrho_\nu^{\text{triv}}/n$ . In particular, if  $\kappa_1 + \dots + \kappa_\ell = n$  and  $\nu(i) = \kappa_i/n$ , then  $\nu^{\otimes n}$  resembles the uniform distribution  $\pi_\kappa$  on  $\mathcal{U}_\kappa$ , and the product chain on  $[\ell]^n$  somewhat resembles the random transposition chain on  $\mathcal{U}_\kappa$ . This gives credence to the possibility that Equation (3) may hold with absolute constants for any  $\ell$ .

### 3.3 The Boolean slice / Bernoulli–Laplace model / Johnson graph

Significant difficulties arise when one moves away from product Markov chains. One of the simplest steps forward is to the Boolean slice. This is the  $\ell = 2$  case of the Markov chains studied in this paper, with the “balanced” case of  $\kappa = (n/2, n/2)$  being the most traditionally studied. This Markov chain is also equivalent to the Bernoulli–Laplace model for diffusion between two incompressible liquids, and to the standard random walk on *Johnson graphs*; taking multiple steps in the chain is similar to the random walk in *generalized Johnson graphs*. The chain has been studied in wide-ranging contexts, from genetics [38], to child psychology [45], to computational learning theory [43]. An asymptotically exact analysis of the time to stationarity of this Markov chain was given by Diaconis and Shahshahani [12], using representation theory. However, the log-Sobolev constant for the chain took a rather long time to be determined; it was left open in Diaconis and Saloff-Coste’s 1996 survey [11] before finally being determined (up to constants) by Lee and Yau in 1998 [35]. This sharp log-Sobolev inequality, and its attendant hypercontractivity and small-set expansion inequalities, have subsequently been used in numerous applications – for the Kruskal–Katona and Erdős–Ko–Rado theorems in combinatorics [43, 8, 22], for computational learning theory [52, 43], for property testing [39], and for generalizing classic “analysis of Boolean functions” results [43, 44, 18, 19, 23, 22, 5].

### 3.4 The Grassmann graph

One direction of generalization for the Johnson graphs are their “ $q$ -analogues”, the *Grassmann graphs*; understanding this Markov chain was posed as an open problem even in the early work of Diaconis and Shahshahani [12, Example 2]. For a finite field  $\mathbb{F}$  and integer parameters  $n \geq k \geq 1$ , the associated Grassmann graph has as its vertices all  $k$ -dimensional subspaces of  $\mathbb{F}^n$ , with two subspaces connected by an edge if their intersection has dimension  $k - 1$ . Understanding small-set expansion (and lack thereof) in the Grassmann graphs was central to the very recent line of work that positively resolved the 2-to-2 Conjecture [31, 14, 13, 1, 32] (with the analogous problems on the Johnson graphs serving as an important warmup [30]). Still, it seems fair to say that the mixing properties of the Grassmann graph are far from being fully understood.

### 3.5 The multislice

We now come to the multislice, the other natural direction of generalization for the Johnson graphs, and the subject of the present paper. One can see the multislice as a generalization of the Bernoulli–Laplace model, modeling diffusion between three or more liquids. As well, the space of functions  $f: \mathcal{U}_\kappa \rightarrow \mathbb{R}$ , together with the action of  $S_n$  on  $\mathcal{U}_\kappa$ , is precisely the *Young permutation module*  $M^\kappa$  arising in the representation theory of the symmetric group. Understanding the mixing properties of the  $\mathcal{U}_\kappa$  Markov chain with random transpositions was suggested as an open problem several times [12], [9, p. 59], [20]. The multislice has also played a key combinatorial role in problems in combinatorics, such as the Density Hales–Jewett problem (where  $\ell = 3$  was the main case under consideration) [46].

Although it might at first appear to be a simple generalization of the Boolean slice, there are several fundamental impediments that arise when moving from  $\ell = 2$  even to  $\ell = 3$ . These include: the fact that a Hamming slice disconnects the nearest-neighbour graph in  $[2]^\ell$  but not in  $[3]^\ell$ ; the fact that one can introduce just *one* variable per coordinate when representing functions  $[2]^\ell \rightarrow \mathbb{R}$  as multilinear polynomials; the fact that 2-row irreps of  $S_n$  (Young diagrams) are completely defined by the number of boxes not in the first

row; and, the fact that when  $\ell \geq 3$ , the decomposition of the permutation module  $M^\kappa$  into irreps has multiplicities. The last of these was the main difficulty to be overcome in Scarabotti's work [48] giving the asymptotic mixing time for the transposition walk on balanced multislices  $\mathcal{U}_{(n/\ell, \dots, n/\ell)}$  (see also [10, 49]). It also prevents the multislice from forming an association scheme.

For the purposes of this paper, the main difficulty that arises when analyzing the log-Sobolev inequality is the following: when  $\ell = 2$ , any nontrivial step in the Markov chain (switching a 1 and a 2) has the property that the histogram within  $[\ell]^{n-2}$  of the unswitched colors is always the same:  $(\kappa_1 - 1, \kappa_2 - 1)$ . By contrast, once  $\ell \geq 3$ , the multiple “kinds” of transpositions (switching a 1 and a 2, or a 1 and a 3, or a 2 and a 3, etc.) lead to differing histograms within  $[\ell]^{n-2}$  for the unswitched colors. This significantly complicates inductive arguments.

### 3.6 The symmetric group and beyond

Finally, we mention that analysis of the multislice can also be motivated simply as a necessary first step in a full understanding of spectral analysis on the symmetric group and other algebraic structures, an opinion also espoused in, e.g., [6]. Such structures include classical association schemes such as polar spaces and bilinear forms, matrix groups such as the general linear group, and the  $q$ -analog of the multislice.

## Abstract

We define new functions based on the Andreev function and prove that they require  $n^3/\text{polylog}(n)$  formula size to compute. The functions we consider are generalizations of the Andreev function using compositions with the majority function. Our arguments apply to composing a hard function with any function that agrees with the majority function (or its negation) on the middle slices of the Boolean cube, as well as iterated compositions of such functions. As a consequence, we obtain  $n^3/\text{polylog}(n)$  lower bounds on the (non-monotone) formula size of an explicit monotone function by combining the monotone address function with the majority function.

**2012 ACM Subject Classification** Theory of computation → Computational complexity and cryptography, Theory of computation → Circuit complexity

**Keywords and phrases** formula lower bounds, random restrictions, KRW conjecture, composition

**Digital Object Identifier** 10.4230/LIPIcs.ITCS.2019.35

**Acknowledgements** We thank an anonymous referee of a previous version of this paper for suggesting to apply our results to prove cubic formula size lower bounds for a monotone function.

## 1 Introduction

We study the problem of proving lower bounds on the De Morgan formula size of explicit functions.

While it is known that almost all Boolean functions of  $n$  variables require formula size exponential in  $n$ , proving lower bounds on the formula size of specific functions remains a major challenge. The current largest lower bounds on De Morgan formula size for explicitly defined functions are of the form  $n^{3-o(1)}$ . Lower bounds for general formula size are weaker, throughout this paper we only consider De Morgan formulas, but sometimes we just refer to them as “formulas”.

## History

Formula size lower bounds have a long history. One of the methods for proving formula size lower bounds is based on shrinkage of De Morgan formulas under random restrictions. This method was introduced by Subbotovskaya [17] who gave a  $\Omega(n^{1.5})$  lower bound on the De Morgan formula size of the parity function. The lower bound for parity has been improved by Khrapchenko [10] to  $\Omega(n^2)$ . However, it is also known that Khrapchenko's method cannot give larger than quadratic lower bounds. The method of random restrictions on the other hand has led to the currently known largest lower bounds on formula size. Andreev [1] used random restrictions to prove an  $\Omega(n^{2.5-o(1)})$  lower bound for a function obtained by composing parity with an arbitrary other function  $f$  where  $f$  is specified as part of the input. We give more formal definitions in Section 2. After improvements of the bound by [8, 13], Håstad [5] proved a lower bound of the form  $n^{3-o(1)}$  for the Andreev function. Tal [18] improved the lower order terms to give a  $\Omega\left(\frac{n^3}{(\log n)^2 \log \log n}\right)$  lower bound for the Andreev function, which is tight up to the  $\log \log n$  term. Tal [19] gave a slightly larger lower bound of the form  $\Omega\left(\frac{n^3}{\log n (\log \log n)^2}\right)$  for another function introduced by Komargodski and Raz [11]. This function is similar to the Andreev function, it still composes parity with other functions specified as part of the input. The difference is that instead of specifying the function  $f$  by its entire truth table as part of the input, an error correcting code is used to derive the truth table from the input. Bogdanov [2] showed that the same  $\Omega\left(\frac{n^3}{\log n (\log \log n)^2}\right)$  lower bound can also be obtained for any “small-biased” function, that is any randomized function whose distribution of truth tables is small biased. He also noted that standard constructions of small biased sets yield explicit families of such functions. [3, 12] showed that parity in Andreev's function can be replaced with any good enough bit fixing extractor, and the resulting function still requires  $n^3/\text{polylog}(n)$  formula size.

Other than Bogdanov's functions, the only explicit function with  $n^{3-o(1)}$  formula size lower bounds has been the Andreev function, and its variants using error correcting codes by [11, 19] or bit fixing extractors [3, 12].

Dinur and Meir [4] gave a new proof of  $n^{3-o(1)}$  formula size lower bounds for the Andreev function, based on information theoretic arguments. The bound obtained by their argument is of the form  $\Omega\left(\frac{n^3}{2^{\sqrt{\log n} \text{poly} \log \log n}}\right)$  which is weaker in the lower order terms than the bounds of Håstad [5] and Tal [18]. But their goal was to give a proof that could possibly generalize to other function compositions, which would be important in light of the KRW conjecture [9] (see Section 5). Our results can be viewed as a step in this direction.

## Our Results

In this paper we obtain  $n^3/\text{polylog}(n)$  lower bounds on a new class of functions. First we consider an extension of the Andreev function which we call “Generalized Andreev function with Majority”, using the majority function instead of parity in the function compositions. We define the function formally in Section 2. As far as we know this function has not been studied before, and previous approaches do not directly work to obtain our bounds.

Next we extend our results to composing a hard function with any function that agrees with the majority function (or its negation) on the middle slices of the Boolean cube, as well as iterated compositions of such functions. Since parity agrees with majority on the two middle slices of the Boolean cube, our argument also applies to parity (the original Andreev function), and composing parity with majority in various ways.

As another consequence, we prove  $n^3/\text{polylog}(n)$  lower bounds on the (non-monotone) formula size of the monotone function obtained by combining the monotone address function of Wegener [21] with the majority function.

It was pointed out to us by Pavel Pudlak [14], that for any function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$ , one can construct a function  $f' : \{0, 1\}^{2n} \rightarrow \{0, 1\}$  that is monotone, and has formula size at least as large as  $f$ . Consider inputs of the form  $(x, y)$  where  $x, y \in \{0, 1\}^n$  and simply let  $f'(x, y) = 1$  on all inputs of Hamming weight greater than  $n$ ,  $f'(x, y) = 0$  on all inputs of Hamming weight less than  $n$ , and  $f'(x, y) = f(x)$  on inputs  $(x, y)$  with Hamming weight  $n$ . Observe that  $f'$  has formula size at least as large as  $f$ : identifying for each  $i \in \{1, \dots, n\}$  the literals  $x_i$  and  $\neg y_i$ , and similarly  $\neg x_i$  and  $y_i$ , we get  $f$  from  $f'$ . However, as far as we know, our results give the first super-quadratic formula size lower bound with a direct proof for an explicitly defined monotone function.

Our argument gives a formal proof that the monotone formula size of the majority function is at least  $n^{\Gamma_{\text{mon}}}/\text{polylog } n$ , where  $\Gamma_{\text{mon}}$  denotes the shrinkage exponent of monotone formulas under random restrictions. It is a long standing open problem to determine the value of  $\Gamma_{\text{mon}}$ . It is also open to obtain tight bounds on the formula size of majority, both in the monotone and non-monotone case. The current best lower bound for both monotone and non-monotone formulas computing majority of  $n$  bits is  $\Omega(n^2)$ . The best upper bound on the De Morgan formula size of majority on  $n$  bits is  $\mathcal{O}(n^{3.91})$  [16]. Considering monotone formulas for majority, the best upper bound remains the  $\mathcal{O}(n^{5.3})$  bound by Valiant [20]. Håstad [5] noted that determining the value of  $\Gamma_{\text{mon}}$  is likely to yield improved lower bounds on the monotone formula size of the majority function. Our results make this connection explicit, independently of how the value  $\Gamma_{\text{mon}}$  is obtained.

Our argument is based on random restrictions and analyzing the shrinkage of formula size under restrictions. However, the main obstacle in applying previous arguments is that we need random restrictions that leave each Majority undetermined. Previously considered restrictions are far from achieving this. Instead of standard random restrictions, we use “staged” random restrictions, and adjust their results to enforce more structure. The idea of building restrictions in stages appears before in [7, 3, 12]. The main difference in our approach is that we maintain the structure of the composed hard function with majority after each stage by performing some clean-up procedure.

In addition to worst case formula size lower bounds, average case lower bounds have been shown in [3, 11, 12, 19]. These bounds are quantitatively weaker than the  $n^{3-o(1)}$  worst case bounds but provide high probability versions of the shrinkage results under certain structured random reductions. Tal [19] has shown that average case bounds can be used to obtain stronger worst case bounds, and in fact the current largest lower bounds of the form  $\Omega\left(\frac{n^3}{\log n(\log \log n)^2}\right)$  by Tal [19] and Bogdanov [2] were obtained this way.

## 2 Definitions and Background

Given an  $n$ -bit string  $\vec{x} = (x_1, \dots, x_n) \in \{0, 1\}^n$ , let  $\text{wt}(\vec{x})$  denote the Hamming weight of  $\vec{x}$ , defined as

$$\text{wt}(\vec{x}) = |\{i : x_i = 1\}|$$

Let  $\mathcal{B}_n = \{f : \{0, 1\}^n \rightarrow \{0, 1\}\}$  denote the set of all Boolean functions on  $n$  bits.

Given a  $bm$ -bit string  $\vec{x}$ , we can interpret  $\vec{x}$  as a  $b \times m$  matrix with rows  $\vec{x}_1, \dots, \vec{x}_b$  of  $m$  bits each. If  $f \in \mathcal{B}_b$  and  $g \in \mathcal{B}_m$  are arbitrary functions, let  $f \circ g : \{0, 1\}^{b \times m} \rightarrow \{0, 1\}$  denote

their composition, defined as

$$(f \circ g)(\vec{x}_1, \dots, \vec{x}_b) = f(g(\vec{x}_1), \dots, g(\vec{x}_b))$$

Given a function  $f \in \mathcal{B}_n$ , let  $\text{tt}(f)$  denote the truth table of  $f$ , defined as the string of length  $2^n$  specifying the output of  $f$  on all strings  $\vec{x} \in \{0, 1\}^n$  in lexicographic order. We use  $f$  and  $\text{tt}(f)$  interchangeably when  $f$  is an input to another function.

Let  $\oplus_m : \{0, 1\}^m \rightarrow \{0, 1\}$  denote the parity function on  $m$  bits.

Let  $\text{Maj}_m : \{0, 1\}^m \rightarrow \{0, 1\}$  denote the majority function on  $m$  bits, defined as

$$\text{Maj}_m(\vec{x}) = \begin{cases} 1 & \text{if } \text{wt}(\vec{x}) \geq \lceil \frac{m}{2} \rceil \\ 0 & \text{otherwise} \end{cases}$$

## 2.1 Andreev Function

Let  $\mathcal{A}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the Andreev function on  $2n$  bits. Let  $b = \log n$  and  $m = n/b = n/\log n$ . If  $f \in \mathcal{B}_b$ , then  $|\text{tt}(f)| = 2^b = 2^{\log n} = n$ .

The function  $\mathcal{A}_n$  takes two inputs: an  $n$ -bit string representing the truth table of a function  $f$  on  $b$  bits, and an  $n$ -bit string  $\vec{x}$ , interpreted as a  $b \times m$  matrix with rows  $\vec{x}_1, \dots, \vec{x}_b$ . Then,

$$\mathcal{A}_n(f, \vec{x}) = (f \circ \oplus_m)(\vec{x}) = f(\oplus_m(\vec{x}_1), \dots, \oplus_m(\vec{x}_b))$$

## 2.2 Generalized Andreev Function

Let  $b = \log n$  and  $m = n/b$  as before. If  $g_m \in \mathcal{B}_m$  is an arbitrary function on  $m$  bits, then let  $\mathcal{A}_n^{g_m} : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the generalized Andreev function on  $2n$  bits, defined analogously by

$$\mathcal{A}_n^{g_m}(f, \vec{x}) = (f \circ g_m)(\vec{x}) = f(g_m(\vec{x}_1), \dots, g_m(\vec{x}_b))$$

In particular,  $\mathcal{A}_n = \mathcal{A}_n^{\oplus_m}$ .

Let  $\mathcal{M}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the generalized Andreev function with  $\text{Maj}_m$  in place of  $g_m$ . That is

$$\mathcal{M}_n(f, \vec{x}) = \mathcal{A}_n^{\text{Maj}_m}(f, \vec{x}) = (f \circ \text{Maj}_m)(\vec{x}) = f(\text{Maj}_m(\vec{x}_1), \dots, \text{Maj}_m(\vec{x}_b))$$

If  $f \in \mathcal{B}_b$  is a fixed function, define  $\mathcal{M}_{n,f} : \{0, 1\}^n \rightarrow \{0, 1\}$  as

$$\mathcal{M}_{n,f}(\vec{x}) = \mathcal{M}_n(f, \vec{x})$$

or equivalently,  $\mathcal{M}_{n,f} = f \circ \text{Maj}_m$ .

## 2.3 De Morgan Formulas

Formulas are tree-like circuits, that is circuits where each gate has fan-out at most one. A De Morgan formula is a formula that uses only **AND**, **OR** and negation gates, where the gates have fan-in at most 2. Let  $f \in \mathcal{B}_n$  be an arbitrary function. Define  $\mathcal{L}(f)$  to be the formula complexity of  $f$ , which is the minimum number of leaves required by any De Morgan formula computing  $f$ .

It is known that almost all Boolean functions on  $n$  variables require De Morgan formula size at least  $\frac{2^n}{2 \log n}$  [15].

## 2.4 Random Restrictions and Shrinkage

Consider a function  $f \in \mathcal{B}_n$  and let  $S = \{x_1, \dots, x_n\}$  denote the variables of  $f$ . A restriction on  $S$  is a function  $\rho: S \rightarrow \{0, 1, \star\}$ . Let  $f \upharpoonright_\rho$  denote the function obtained from  $f$  by fixing inputs  $x_i$  to  $\rho(x_i)$  if  $\rho(x_i) \neq \star$ , which depends only on the inputs  $x_i$  for which  $\rho(x_i) = \star$ . Given arbitrary functions  $g \in \mathcal{B}_m$  and  $f \in \mathcal{B}_n$  for  $m \leq n$ , we say that  $f$  computes  $g$  as a sub-function if  $g$  can be achieved as a restriction of  $f$ .

A random  $p$ -restriction on  $S$  is a randomly generated restriction  $\rho$  where

$$\begin{aligned} \Pr(\rho(x_i) = \star) &= p \\ \Pr(\rho(x_i) = 0) &= \Pr(\rho(x_i) = 1) = \frac{1-p}{2} \end{aligned}$$

uniformly and independently for all  $x_i \in S$ . Let  $\mathcal{R}_p$  denote the distribution of all uniformly generated random  $p$ -restrictions.

Subbotovskaya [17] proved that for any Boolean function  $f \in \mathcal{B}_n$  it holds that

$$\mathbb{E}_{\rho \sim \mathcal{R}_p} \left[ \mathcal{L}(f \upharpoonright_\rho) \right] = \mathcal{O}(p^\Gamma \mathcal{L}(f))$$

for  $\Gamma = 3/2$ . The constant  $\Gamma$  is called the shrinkage exponent, which is the largest number for which the statement is true. After several improvements [8, 13], Håstad [5] proved that  $\Gamma = 2$ . The following version is due to Tal [18].

► **Theorem 2.1** (Shrinkage Lemma [18]). *Let  $f \in \mathcal{B}_n$  be an arbitrary function. Then,  $\forall p > 0$ ,*

$$\mathbb{E}_{\rho \sim \mathcal{R}_p} \left[ \mathcal{L}(f \upharpoonright_\rho) \right] \leq \mathcal{O}(1 + p^2 \mathcal{L}(f)) \quad (1)$$

► **Corollary 2.2.** *Let  $f \in \mathcal{B}_n$  be an arbitrary function. Then,  $\exists c > 0$  such that for  $\forall p > 0$  and large enough  $n$ ,*

$$\Pr_{\rho \sim \mathcal{R}_p} \left( \mathcal{L}(f \upharpoonright_\rho) \geq 10c(1 + p^2 \mathcal{L}(f)) \right) \leq \frac{1}{10} \quad (2)$$

**Proof.** Let  $c > 0$  be chosen such that  $\mathbb{E}_{\rho \sim \mathcal{R}_p} \left[ \mathcal{L}(f \upharpoonright_\rho) \right] \leq c(1 + p^2 \mathcal{L}(f))$ . Then, by Markov's inequality:  $\Pr_{\rho \sim \mathcal{R}_p} \left( \mathcal{L}(f \upharpoonright_\rho) \geq 10c(1 + p^2 \mathcal{L}(f)) \right) \leq \frac{1}{10}$ . ◀

## 2.5 Concentration Inequalities

We use the following result on bounds of sums of random variables.

► **Theorem 2.3** (Hoeffding's Inequality [6]). *Let  $X_1, \dots, X_n$  be independent random variables such that  $a_i \leq X_i \leq b_i$  for  $1 \leq i \leq n$  and let  $X = \sum_{i=1}^n X_i$ . Then,*

$$\Pr \left( \left| X - \mathbb{E}[X] \right| \geq t \right) \leq 2 \exp \left( \frac{-2t^2}{\sum_{i=1}^n (b_i - a_i)^2} \right) \quad (3)$$

## 3 Composition with Majority

Let  $\mathcal{M}_n$  be the generalized Andreev function with majority. Let  $b = \log n$  and  $m = n/b = n/\log n$  and assume  $b, m \in \mathbb{N}$ . Let  $h \in \mathcal{B}_b$  be a function of maximum formula complexity and consider  $\mathcal{M}_{n,h} = h \circ \text{Maj}_m$ . Since  $\mathcal{M}_{n,h}$  is a sub-function of  $\mathcal{M}_n$ , we

have  $\mathcal{L}(\mathcal{M}_n) \geq \mathcal{L}(\mathcal{M}_{n,h}) = \mathcal{L}(h \circ \text{Maj}_m)$ . Thus, it suffices to prove a lower bound on the formula complexity of  $h \circ \text{Maj}_m$ . Indeed, this will be our strategy (which is standard when proving lower bounds for Andreev-type functions). Our main result is the following general theorem, that may also be applied in other scenarios.

► **Theorem 3.1** (Formula Size of Composition with Majority). *Let  $b, m \in \mathbb{N}$  and  $h \in \mathcal{B}_b$  be non-constant. Then,*

$$\mathcal{L}(h \circ \text{Maj}_m) \geq \mathcal{L}(h) \cdot m^2 / \text{polylog}(b \cdot m)$$

Since the hardest functions on  $b = \log n$  bits have formula complexity at least  $\frac{n}{2 \log \log n}$  [15], Theorem 3.1 implies that

$$\mathcal{L}(\mathcal{M}_n) \geq \mathcal{L}(h \circ \text{Maj}_m) \geq \mathcal{L}(h) \cdot m^2 / \text{polylog}(b \cdot m) \geq n^3 / \text{polylog}(n)$$

The rest of this section is devoted to the proof of Theorem 3.1.

### Warmup

Let  $n = mb$ . The input  $\vec{x} = (x_1, \dots, x_n)$  is divided into  $b$  contiguous blocks  $B_1, \dots, B_b$  of  $m$  variables each. In order to apply a random restriction based argument to  $h \circ \text{Maj}_m$ , we wish to prove that there exists a restriction  $\rho$  that leaves each  $\text{Maj}_m$  undetermined and the resulting formula shrinks by a factor of  $\Omega(m^2 / \text{polylog}(bm))$ .

A single majority is left undetermined by  $\rho$  if the absolute difference between the number of variables assigned 0 and 1 is at most the number of unassigned variables. Otherwise, the majority value is already set and there are not enough remaining variables to flip it.

### 3.1 Random $p$ -Restrictions

Previous random restriction based arguments typically use random  $p$ -restrictions defined in Section 2.4. We start by some observations about them. Let  $\rho \in \mathcal{R}_p$  be a random  $p$ -restriction on  $S = \{x_1, \dots, x_n\}$  and let  $B_i = \{x_{i_1}, \dots, x_{i_m}\}$  be a fixed block of the input.

Let  $X_{ik}$  and  $Y_{ik}$  for  $1 \leq k \leq m$  be the following random variables:

$$X_{ik} = \begin{cases} 1 & \text{if } \rho(x_{i_k}) = \star \\ 0 & \text{otherwise} \end{cases} \quad Y_{ik} = \begin{cases} 1 & \text{if } \rho(x_{i_k}) = 0 \\ -1 & \text{if } \rho(x_{i_k}) = 1 \\ 0 & \text{if } \rho(x_{i_k}) = \star \end{cases}$$

Then,

$$\begin{aligned} X_i &= \sum_{k=1}^m X_{ik} & Y_i &= \sum_{k=1}^m Y_{ik} \\ \mathbb{E}[X_i] &= \sum_{k=1}^m \mathbb{E}[X_{ik}] = mp & \mathbb{E}[Y_i] &= \sum_{k=1}^m \mathbb{E}[Y_{ik}] = 0 \end{aligned}$$

We note that  $X_i$  and  $Y_i$  are not necessarily independent, since for any  $\ell \geq 0$

$$X_i \geq \ell \implies |Y_i| \leq m - \ell$$

Since  $0 \leq X_{ik} \leq 1$ , Theorem 2.3 gives:

$$\Pr_{\rho \in \mathcal{R}_p} (|X_i - mp| > t) \leq 2 \exp(-2t^2/m)$$

To obtain lower bounds of the form  $\mathcal{L}(h) \cdot \frac{m^2}{\text{polylog}(mb)}$  by a single round of  $p$ -restrictions, one would need  $p = \mathcal{O}(\text{polylog}(mb)/m)$ , thus  $X_i = \Theta(\text{polylog}(mb))$  would hold with high probability. Since  $|Y_i|$  is typically  $\Omega(\sqrt{m})$ , it is likely that  $\text{Maj}_m(B_i \upharpoonright_\rho)$  is constant.

Since one  $p$ -restriction cannot shrink the formula size sufficiently and leave each majority undetermined, we will build such a restriction incrementally instead.

### 3.2 Staged $p$ -Restrictions

**Proof of Theorem 3.1.** Let  $c'$  be a large constant to be defined later. We first deal with the case that  $\mathcal{L}(h) \leq 2c'$ . Then, since for non-constant  $h$ ,  $\text{Maj}_m$  (or its negation) is a sub-function of  $h \circ \text{Maj}_m$  and since  $\mathcal{L}(\text{Maj}_m) \geq \Omega(m^2)$  ([10]) we get

$$\mathcal{L}(h \circ \text{Maj}_m) \geq \mathcal{L}(\text{Maj}_m) \geq \Omega(m^2) \geq \Omega(\mathcal{L}(h) \cdot m^2)$$

which completes the proof in this case. In the following, we shall assume that  $\mathcal{L}(h) > 2c'$ .

We define the following procedure that runs in  $t$  stages: in the  $j$ -th stage, we generate a  $p_j$ -restriction  $\rho_j$  such that, with high probability, the formula has enough unrestricted variables to balance the number of 0's and 1's and leave enough variables unrestricted for stage  $j + 1$ .

#### Setting Up Parameters

We set

$$m_1 = m$$

and

$$m_{j+1} = m_j^{0.6}$$

for  $j \geq 1$  as long as  $m_j \geq \log^5(4b)$ . Let  $t$  be the last  $j$  such that  $m_j \geq \log^5(4b)$ . A small calculation shows that  $t \leq 2 \log \log m$ . For  $j = 1, \dots, t$  we set

$$p_j = 4m_j^{-0.4} = 4m_{j+1}/m_j$$

#### Shrinkage In $t$ Stages

Denote by  $\varphi_1 = h \circ \text{Maj}_m$ . For  $j = 1, \dots, t$ , we show how to construct  $\varphi_{j+1}$  over variables  $S_{j+1}$  from  $\varphi_j$  over  $S_j$ . We show by induction that  $\varphi_{j+1} = h \circ \text{Maj}_{m_{j+1}}$  (up to a renaming of the variables) and that

$$\mathcal{L}(\varphi_{j+1}) \leq c \cdot \left( \frac{m_{j+1}}{m_j} \right)^2 \cdot \mathcal{L}(\varphi_j),$$

for some large enough universal constant  $c > 0$ .

Let  $j \in \{1, \dots, t\}$ . Let  $\rho_j \in \mathcal{R}_{p_j}$  be a random  $p_j$ -restriction over  $S_j$ . Let

$$X_i^j = \sum_{k=1}^{m_j} X_{ik}^j \qquad Y_i^j = \sum_{k=1}^{m_j} Y_{ik}^j$$

for  $i = 1, \dots, b$  be defined analogously as in the previous section for block  $B_i$ . Then,

$$\mathbb{E}[X_i^j] = m_j p_j = 4m_{j+1}$$

Let  $E_{j,i}$  denote the event that  $|X_i^j - m_j p_j| \leq \frac{1}{4} m_j p_j$  and let  $F_{j,i}$  denote the event that  $|Y_i^j| \leq \frac{1}{2} m_j p_j$ . By Theorem 2.3, using the assumption  $m_j \geq \log^5(4b)$ ,

$$\Pr_{\rho_j \in \mathcal{R}_{p_j}} (E_{j,i}) \geq 1 - 2e^{-2 \frac{m_j^2}{m_j}} = 1 - 2e^{-2m_j^{0.2}} \geq 1 - \frac{1}{4b} \quad (4)$$

$$\Pr_{\rho_j \in \mathcal{R}_{p_j}} (F_{j,i}) \geq 1 - 2e^{-2 \frac{(2m_j+1)^2}{4m_j}} = 1 - 2e^{-2m_j^{0.2}} \geq 1 - \frac{1}{4b} \quad (5)$$

By Corollary 2.2, there exists some constant  $c' > 0$  such that

$$\Pr_{\rho_j \in \mathcal{R}_{p_j}} \left( \mathcal{L}(\varphi_j \upharpoonright_{\rho_j}) \leq c'(1 + p_j^2 \mathcal{L}(\varphi_j)) \right) \geq 0.9$$

Let  $H_j$  denote the event that  $\mathcal{L}(\varphi_j \upharpoonright_{\rho_j}) \leq c' \cdot (1 + p_j^2 \cdot \mathcal{L}(\varphi_j))$ . Thus  $\Pr[H_j] \geq 0.9$ . By the union bound, there exists a restriction  $\rho_j$  for which  $H_j$  and all  $E_{j,i}, F_{j,i}$  for  $i = 1, \dots, b$  hold simultaneously. Fix such a restriction  $\rho_j$ . Now, since  $E_{j,i}$  holds, then

$$X_i^j \geq \frac{3}{4} m_j p_j$$

Since  $F_{j,i}$  also holds, then we can make the number of 0's and 1's equal by fixing at most  $\frac{1}{2} m_j p_j$  variables appropriately, leaving at least  $\frac{1}{4} m_j p_j = m_{j+1}$  unrestricted variables in the block. We restrict the remaining variables further to leave exactly  $m_{j+1}$  unrestricted variables by assigning an equal number of them 0 and 1 in some arbitrary process. Take  $\varphi_{j+1}$  to be the restricted function.

Since  $H_j$  holds, we get

$$\mathcal{L}(\varphi_{j+1}) \leq \mathcal{L}(\varphi_j \upharpoonright_{\rho_j}) \leq c' \cdot (1 + p_j^2 \cdot \mathcal{L}(\varphi_j))$$

However, since  $h$  is a sub-function of  $\varphi_{j+1}$  and since we assumed that  $\mathcal{L}(h) > 2c'$ , we get that  $c' < \frac{1}{2} \mathcal{L}(\varphi_{j+1})$ . Thus,

$$\mathcal{L}(\varphi_{j+1}) < \frac{1}{2} \mathcal{L}(\varphi_{j+1}) + c' \cdot p_j^2 \cdot \mathcal{L}(\varphi_j)$$

which implies that  $\mathcal{L}(\varphi_{j+1}) < 2c' \cdot p_j^2 \cdot \mathcal{L}(\varphi_j)$  and we get

$$\mathcal{L}(\varphi_{j+1}) \leq 2c' \cdot \left( \frac{4m_{j+1}}{m_j} \right)^2 \cdot \mathcal{L}(\varphi_j) = c \cdot \left( \frac{m_{j+1}}{m_j} \right)^2 \cdot \mathcal{L}(\varphi_j)$$

for any  $j \in \{1, \dots, t\}$  by setting  $c = 2c' \cdot 16$ . Overall, we get

$$\mathcal{L}(\varphi_{t+1}) \leq c^t \cdot \left( \frac{m_{t+1}}{m} \right)^2 \cdot \mathcal{L}(\varphi)$$

Since  $h$  is a sub-function of  $\varphi_{t+1}$ , the formula size of  $\varphi_{t+1}$  is at least  $\mathcal{L}(h)$ , which gives

$$\mathcal{L}(\varphi) \geq c^{-t} \cdot \left( \frac{m}{m_{t+1}} \right)^2 \cdot \mathcal{L}(h)$$

Using  $m_{t+1} < \log^5(4b)$  and  $t \leq 2 \log \log m$  we get

$$\mathcal{L}(\varphi) \geq c^{-2 \log \log m} \cdot \left( \frac{m}{\log^5(4b)} \right)^2 \cdot \mathcal{L}(h) \geq \mathcal{L}(h) \cdot m^2 / \text{polylog}(b \cdot m) \quad \blacktriangleleft$$

In the above proof, we only use two facts about the majority function. First, we use that the values of the  $m$ -bit majority function are 0 on inputs  $\vec{x}$  with Hamming weight  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil - 1$  and 1 on inputs with  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil$ . In addition, (at the beginning of our proof) we use that  $\mathcal{L}(\text{Maj}_m) \geq \Omega(m^2)$  [10]. Thus our argument extends to any function with these two properties. It turns out that the first condition we need implies the second. Let  $g_m \in \mathcal{B}_m$  be any function such that  $g_m(\vec{x}) = 0$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil - 1$ , and  $g_m(\vec{x}) = 1$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil$ . Then by Khrapchenko's theorem [10] the De Morgan formula size of  $g_m$  is at least  $\Omega(m^2)$ .

One can also think of such functions as a partial function that generalizes both Majority and Parity. We obtain the following.

► **Theorem 3.2.** *Let  $m = \frac{n}{\log n}$  and let  $g_m \in \mathcal{B}_m$  be any function such that  $g_m(\vec{x}) = 0$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil - 1$ , and  $g_m(\vec{x}) = 1$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil$ . Then,*

$$\mathcal{L}(\mathcal{A}_n^{g_m}) \geq n^3 / \text{polylog}(n)$$

## 4 Consequences

### 4.1 Composition with Other Threshold Functions

We also obtain lower bounds for compositions with arbitrary threshold functions  $\text{Th}_{m,k}$  instead of  $\text{Maj}_m$ . We use that  $\text{Th}_{2k+1,k}$  is a subfunction of  $\text{Th}_{m,k}$ . Fixing arbitrary  $m - (2k + 1)$  bits to 0 in each block, our results immediately imply that  $\mathcal{L}(h \circ \text{Th}_{m,k}) \geq \mathcal{L}(h) \cdot k^2 / \text{polylog}(k, b)$ . We get stronger bounds by noticing that fixing the  $m - (2k + 1)$  heaviest variables in each block, the formula shrinks by a factor of  $(2k + 1)/m$ . Thus, we get

$$\mathcal{L}(h \circ \text{Th}_{m,k}) \geq \mathcal{L}(h) \cdot m \cdot k / \text{polylog}(k, b)$$

This implies the following:

► **Theorem 4.1.** *Let  $m = \frac{n}{\log n}$  and  $k \leq m/2$ . Then*

$$\mathcal{L}(\mathcal{A}_n^{\text{Th}_{m,k}}) \geq n^2 \cdot k / \text{polylog}(n)$$

### 4.2 Iterated Compositions

Since the composed function “Parity of Parities” is just Parity, considering iterated compositions in place of Parity in the original lower bound arguments for Andreev function did not give new functions. But taking iterated compositions of Majorities yield new functions, such as “Majority of Majorities”, “Parity of Majorities”, “Majority of Parities” and so on. Our results extend to the generalized Andreev function with iterated compositions in place of  $g_m$ . We obtain additional functions with cubic formula size lower bounds.

► **Theorem 4.2.** *Let  $\mathcal{G}_m$  denote the set of functions  $g_m \in \mathcal{B}_m$  such that  $g_m(\vec{x}) = 0$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil - 1$ , and  $g_m(\vec{x}) = 1$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil$ ; or the other way around, that is  $g_m(\vec{x}) = 1$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil - 1$ , and  $g_m(\vec{x}) = 0$  when  $\text{wt}(\vec{x}) = \lceil \frac{m}{2} \rceil$ .*

*Let  $m = \frac{n}{\log n}$  and let  $u \geq 2$  and  $v \geq 2$  be integers such that  $uv = m$ . For any functions  $f_u \in \mathcal{G}_u$  and  $g_v \in \mathcal{G}_v$*

$$\mathcal{L}(\mathcal{A}_n^{f_u \circ g_v}) \geq n^3 / \text{polylog}(n)$$

**Proof.** Let  $h \in \mathcal{B}_{\log n}$  be a function of maximum formula complexity. By Theorem 3.1

$$\mathcal{L}(h \circ f_u) \geq \mathcal{L}(h) \cdot u^2 / \text{polylog}(b \cdot u)$$

where  $b = \log n$ . Let  $b' = b \cdot u$ . By Theorem 3.1

$$\mathcal{L}(h \circ f_u \circ g_v) \geq \mathcal{L}(h \circ f_u) \cdot v^2 / \text{polylog}(b' \cdot v)$$

Thus,

$$\mathcal{L}(h \circ f_u \circ g_v) \geq \mathcal{L}(h) \cdot \frac{u^2}{\text{polylog}(b \cdot u)} \cdot \frac{v^2}{\text{polylog}(b \cdot u \cdot v)} \geq \mathcal{L}(h) \cdot \frac{m^2}{\text{polylog}(n)} \geq \frac{n^3}{\text{polylog}(n)} \quad \blacktriangleleft$$

The argument extends to repeated iterations. As the proof shows, we lose a  $\text{polylog}(n)$  factor from the  $n^3$  lower bound at each iteration.

### 4.3 Cubic Formula Size Lower Bounds for an Explicit Monotone Function

A function  $h : \{0, 1\}^b \rightarrow \{0, 1\}$  is called a *slice function* if on inputs  $\vec{z} \in \{0, 1\}^b$ ,  $h(\vec{z}) = 1$  if  $\text{wt}(\vec{z}) \geq \lfloor \frac{b}{2} \rfloor + 1$ , and  $h(\vec{z}) = 0$  if  $\text{wt}(\vec{z}) < \lfloor \frac{b}{2} \rfloor$ . Note that every slice function is monotone, and slice functions differ from each other only on inputs in the middle layer of the Boolean cube, that is on inputs with weight exactly  $\lfloor \frac{b}{2} \rfloor$ .

The *monotone address function* defined by Wegener [21] takes  $b + n$  input bits where  $n = \binom{b}{\lfloor \frac{b}{2} \rfloor}$ . The  $n$  bits are interpreted to specify a slice function  $h$  on  $b$  bits. We denote by  $h$  both the  $n$ -bit string and the slice function specified by it. Then, on input  $(z, h)$  where  $z \in \{0, 1\}^b$  and  $h \in \{0, 1\}^n$ , the output of the monotone address function is  $h(z)$ . Note that the monotone address function itself is monotone.

We are now ready to define a monotone function that requires cubic formula size. Let  $n = \binom{b}{\lfloor b/2 \rfloor}$ , and let  $m = n/b$ . Similarly to the Generalized Andreev Function, we define a function  $\mathcal{F}_n : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  on  $2n$  bits.

The function  $\mathcal{F}_n$  takes two inputs: an  $n$ -bit string representing a slice function  $h$  on  $b$  bits, and an  $n$ -bit string  $\vec{x}$ , interpreted as a  $b \times m$  matrix with rows  $\vec{x}_1, \dots, \vec{x}_b$ . Then,

$$\mathcal{F}_n(h, \vec{x}) = (h \circ \text{Maj}_m)(\vec{x}) = h(\text{Maj}_m(\vec{x}_1), \dots, \text{Maj}_m(\vec{x}_b))$$

We can further generalize this as follows: If  $g_m \in \mathcal{B}_m$  is an arbitrary function on  $m$  bits, then let  $\mathcal{F}_n^{g_m} : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$  denote the function on  $2n$  bits, defined analogously by

$$\mathcal{F}_n^{g_m}(h, \vec{x}) = (h \circ g_m)(\vec{x}) = h(g_m(\vec{x}_1), \dots, g_m(\vec{x}_b))$$

In particular,  $\mathcal{F}_n = \mathcal{F}_n^{\text{Maj}_m}$ . Note that for any monotone function  $g_m$ , the function  $\mathcal{F}_n^{g_m}$  is also monotone.

Since the number of De Morgan formulas of size  $s$  on  $b$  input bits is at most  $(cb)^s$  for some constant  $c$  [15], and the number of different slice functions on  $b$  input bits is  $2^n$  where  $n = \binom{b}{\lfloor b/2 \rfloor}$ , by a standard counting argument, there are slice functions on  $b$  bits that require formula size at least  $\Omega(\frac{n}{\log b}) = \Omega(\frac{n}{\log \log n})$ .

This implies the following bound on the formula size of the monotone function  $\mathcal{F}_n$ .

► **Theorem 4.3.**

$$\mathcal{L}(\mathcal{F}_n) \geq n^3 / \text{polylog}(n)$$

#### 4.4 Monotone Formula Size of Majority

Our results highlight again the question of determining the shrinkage exponent for monotone formulas, raised by Håstad [5]. It was pointed out by Håstad [5], that determining the shrinkage exponent for monotone formulas could potentially yield improved lower bounds on the monotone formula size of the Majority function. Our results make this connection explicit, without any dependence on how the value of the shrinkage exponent is obtained. More precisely, our arguments imply the following.

► **Theorem 4.4.** *Let  $\Gamma_{\text{mon}}$  denote the shrinkage exponent of monotone formulas. Then  $\mathcal{L}_{\text{mon}}(\text{Maj}_n) \geq n^{\Gamma_{\text{mon}}} / \text{polylog } n$ , where  $\mathcal{L}_{\text{mon}}$  denotes monotone formula complexity.*

**Proof.** To see this, notice that our argument in the proof of Theorem 3.1 can also be carried out when  $b = 1$  and  $h : \{0, 1\}^1 \rightarrow \{0, 1\}$  is the identity function, that is  $h \circ \text{Maj}_m = \text{Maj}_m$ , and we apply our staged restrictions on just one block.

Let  $\Gamma = \Gamma_{\text{mon}}$ . Then by definition,

$$\mathbb{E}_{\rho \sim \mathcal{R}_p} \left[ \mathcal{L}_{\text{mon}} \left( f \upharpoonright_{\rho} \right) \right] = \mathcal{O} \left( 1 + p^{\Gamma} \mathcal{L}_{\text{mon}}(f) \right)$$

Let  $c'$  be a constant such that

$$\mathbb{E}_{\rho \sim \mathcal{R}_p} \left[ \mathcal{L}_{\text{mon}} \left( f \upharpoonright_{\rho} \right) \right] \leq c' \cdot \left( 1 + p^{\Gamma} \mathcal{L}_{\text{mon}}(f) \right)$$

Let  $m_1 = m = n$ . As in the proof of Theorem 3.1, we set  $m_{j+1} = m_j^{0.6}$  for  $j \geq 1$ . Let  $t$  be the last  $j$  such that  $m_j \geq 32$  and  $\mathcal{L}_{\text{mon}}(\text{Maj}_{m_{j+1}}) \geq 2c'$  both hold. (Recall that  $b = 1$ , thus  $\log^5(4b) = 2^5 = 32$ .)

A small calculation shows that  $t \leq \frac{1}{\log(10/6)} \log \log m \leq 2 \log \log m$ . For  $j = 1, \dots, t$  we set  $p_j = 4m_j^{-0.4} = 4m_{j+1}/m_j$ .

As in the proof of Theorem 3.1, our staged restrictions ensure that  $\varphi_j = \text{Maj}_{m_j}$ . Similarly to our previous argument, setting  $c = 2c' \cdot 16$ , and using that

$$\mathcal{L}_{\text{mon}}(\varphi_{j+1}) = \mathcal{L}_{\text{mon}}(\text{Maj}_{m_{j+1}}) \geq 2c'$$

for  $j = 1, \dots, t$ , we get

$$\mathcal{L}_{\text{mon}}(\varphi_{t+1}) \leq c^t \cdot \left( \frac{m_{t+1}}{m} \right)^{\Gamma} \cdot \mathcal{L}_{\text{mon}}(\varphi_1)$$

Thus, we obtain

$$\mathcal{L}_{\text{mon}}(\text{Maj}_n) \geq c^{-t} \cdot \left( \frac{n}{m_{t+1}} \right)^{\Gamma} \cdot \mathcal{L}_{\text{mon}}(\text{Maj}_{m_{t+1}})$$

By the definition of  $t$  above, at least one of  $m_{t+1} < 32$  or  $\mathcal{L}_{\text{mon}}(\text{Maj}_{m_{t+2}}) < 2c'$  must hold. The latter implies that  $m_{t+2} < 2c'$ , hence  $m_{t+1} = m_{t+2}^{10/6} < (2c')^{10/6}$  and for  $c'' = \max\{32, (2c')^{10/6}\}$  we have  $m_{t+1} < c''$ . Since  $m_t \geq 32$  we also have  $m_{t+1} \geq 8$ . Using  $8 \leq m_{t+1} < c''$  and  $t \leq 2 \log \log m$  we get

$$\mathcal{L}_{\text{mon}}(\text{Maj}_n) \geq c^{-2 \log \log m} \cdot \left( \frac{n}{c''} \right)^{\Gamma} \cdot \mathcal{L}_{\text{mon}}(\text{Maj}_{m_{t+1}}) \geq n^{\Gamma} / \text{polylog } n \quad \blacktriangleleft$$

## 5 Future Directions

A possible extension of our result would be to verify the KRW conjecture [9] for composing arbitrary functions with the majority function. The KRW conjecture essentially states that the formula size of composed functions is the product of their formula sizes, e.g.  $\mathcal{L}(h \circ g) \geq \Omega(\mathcal{L}(h) \cdot \mathcal{L}(g))$ . The conjecture has been verified for composing arbitrary functions with parity. Unfortunately, getting asymptotically tight bounds on the formula size of majority is still open. Currently, the best upper bound on the De Morgan formula size of majority is  $\mathcal{O}(n^{3.91})$  [16]. Our lower bound would verify the conjecture for composing arbitrary functions with majority if  $\mathcal{L}(\text{Maj}_n) = \mathcal{O}(n^2)$ .

Another interesting direction is studying the average-case hardness of the Generalized Andreev function with Majority. Here, we expect a different behavior than the standard Andreev function that is hard to compute on  $1/2 + \exp(-n^{\Omega(1)})$  fraction of the inputs [11] (under the uniform distribution). For  $\mathcal{M}_n$  we could not hope to get such strong average-case hardness, as we argue next. Observe that a Majority function on the  $\{x_1, \dots, x_m\}$  agrees with the dictator function of  $x_1$  on  $1/2 + \Omega(1/\sqrt{m})$  fraction of the inputs. Replacing each majority in  $\mathcal{M}_n$  with the appropriate dictator yields the address function, which has formula complexity  $\Theta(n)$ . A small calculation shows that that a linear size formula (computing the address function) has agreement at least  $1/2 + \Omega(1/\sqrt{m})^{\log n} \geq 1/2 + 2^{-\log^2(n)}$  with  $\mathcal{M}_n$ . We conjecture that getting a much better agreement with  $\mathcal{M}_n$ , say  $1/2 + 1/\text{poly}(n)$ , or even  $1/2 + 2^{-o(\log^2 n)}$ , requires almost cubic formula complexity.

## Abstract

We consider the following game between two players Alice and Bob, which we call the mirror game. Alice and Bob take turns saying numbers belonging to the set  $\{1, 2, \dots, N\}$ . A player loses if they repeat a number that has already been said. Otherwise, after  $N$  turns, when all the numbers have been spoken, both players win. When  $N$  is even, Bob, who goes second, has a very simple (and memoryless) strategy to avoid losing: whenever Alice says  $x$ , respond with  $N + 1 - x$ . The question is: does Alice have a similarly simple strategy to win that avoids remembering all the numbers said by Bob?

The answer is no. We prove a linear lower bound on the space complexity of any deterministic winning strategy of Alice. Interestingly, this follows as a consequence of the Eventown-Oddtown theorem from extremal combinatorics. We additionally demonstrate a randomized strategy for Alice that wins with high probability that requires only  $\tilde{O}(\sqrt{N})$  space (provided that Alice has access to a random matching on  $K_N$ ).

We also investigate lower bounds for a generalized mirror game where Alice and Bob alternate saying 1 number and  $b$  numbers each turn (respectively). When  $1 + b$  is a prime, our linear lower bounds continue to hold, but when  $1 + b$  is composite, we show that the existence of a  $o(N)$  space strategy for Bob (when  $N \not\equiv 0 \pmod{1 + b}$ ) implies the existence of exponential-sized matching vector families over  $\mathbb{Z}_{1+b}^N$ .

## 1 Introduction

### 1.1 The Mirror Game and Mirror Strategies

Consider the following simple game. Alice and Bob take turns saying numbers belonging to the set  $\{1, 2, \dots, N\}$ . If either player says a number that has previously been said, they lose. Otherwise, after  $N$  turns, all the numbers in the set have been spoken aloud, and both players win. Alice says the first number.

If  $N$  is even, there is a very simple and computationally efficient strategy that allows Bob to win this game, regardless of Alice's strategy: whenever Alice says  $x$ , Bob replies with  $N + 1 - x$ . This is an example of a *mirror strategy* (and for this reason, we refer to the game above as the *mirror game*). Mirror strategies are an effective tool for figuring out who wins

in a variety of combinatorial games (for example, two-pile Nim [2]). More practically, mirror strategies can be applied when playing more complex games, such as chess or go (to varying degrees of success). From a computational perspective, mirror strategies are interesting as they require very limited computational resources - most mirror strategies can be described via a simple transformation of the preceding action.

Returning to the game above, this leads to the following natural question: does Alice have a simple strategy to avoid losing when  $N$  is even? Since both players have access to the same set of actions, one may be tempted to believe that the answer is yes - in fact, if  $N$  is odd, then Alice can start by saying the number  $N$  and then adopt the mirror strategy for Bob described above for a set of  $N - 1$  elements. However, when  $N$  is even, the mirror strategy as stated does not work.

To answer the above question, we need to formalize what we mean by simple; after all, Alice has plenty of strategies such as “say the smallest number which has not yet been said”. One useful metric of simplicity is the metric of *space complexity*, the amount of memory a player requires to implement their strategy (we formalize this in Section 2). Note that Bob needs only  $O(\log N)$  bits of memory to implement his mirror strategy, whereas the naive strategy for Alice (remembering everything) requires  $O(N)$  bits.

In this paper, we show that this gap is necessary; any successful, deterministic strategy for Alice requires at least  $\Omega(N)$  bits of memory:

► **Theorem 1** (Restatement of Theorem 11). *If  $N$  is even, then any winning strategy for Alice in the mirror game requires at least  $(\log_2 5 - 2)N - o(N)$  bits of space.*

## 1.2 Eventown and Oddtown

While many tools exist in the computer science literature for showing space lower bounds (e.g. communication complexity, information theory, etc.), one interesting feature of this problem absent from many others is that any proof of Theorem 1 *must depend crucially on the parity* of  $N$ .

In the study of set families in extremal combinatorics, an “Oddtown” is a collection of subsets of  $\{1, 2, \dots, N\}$  where every subset has even cardinality but each pair of distinct subsets has an intersection of odd cardinality. Likewise, an “Eventown” is a collection of subsets of  $\{1, 2, \dots, N\}$  where every subset has even cardinality but each pair of distinct subsets has an intersection of even cardinality. In 1969, Berlekamp [3], answering a question of Erdős, showed that while there exist Eventowns containing up to  $2^{N/2}$  subsets, any Oddtown contains at most  $N$  subsets.

It turns out that this exponential gap between the size of Oddtowns and the size of Eventowns is directly responsible for the exponential gap between the space complexity of Alice’s strategy and the space complexity of Bob’s strategy! (One way to see this connection is that, just as Bob’s  $O(\log N)$ -space strategy involves pairing up the numbers of  $\{1, 2, \dots, N\}$ , one way to construct an Eventown of size  $2^{N/2}$  is to perform a similar pairing, and then consider all subsets formed by unions of pairs).

The Eventown-Oddtown theorem figures into our proof of Theorem 1 in the following way. At a given turn, for each possible state of memory of Alice, label the state with the possible subsets of numbers that could have possibly been said before this turn. We show (Lemma 13) that these subsets must form an Oddtown, or else Bob has some strategy that can force Alice to lose. Since there are a large (exponential) number of total possible subsets (Corollary 10), and since each Oddtown contains at most  $N$  subsets, this implies that Alice’s memory must be large.

### 1.3 Randomized Strategies for Alice

A natural followup to Theorem 1 is whether these lower bounds continue to hold if Alice instead uses a randomized strategy, which only needs to succeed with high probability.

We provide some evidence to show that this might not be the case. We demonstrate an  $O(\sqrt{N} \log^2 N)$ -space algorithm for Alice that succeeds with probability  $1 - O(1/N)$ , as long as Alice is provided access to a uniformly chosen perfect matching on the complete graph on  $N$  vertices ( $K_N$ ) (Theorem 18). In addition, even with  $O(\log N)$ -space (and access to a uniformly chosen perfect matching on  $K_N$ ), Alice can guarantee success with probability  $\Omega(1/N)$ .

In both of these algorithms, Alice attempts the mirror strategy of Bob, hoping that Bob does not choose the number with no match. In the  $O(\sqrt{N} \log^2 N)$  algorithm, Alice decreases her probability of failure by maintaining a set of  $\tilde{O}(\sqrt{N})$  possible “backup” points she can switch to if Bob identifies the unmatched point. This lets Alice survive until turn  $N - \tilde{O}(\sqrt{N})$ , whereupon Alice can reconstruct the remaining  $O(\sqrt{N})$  elements by maintaining  $O(\sqrt{N})$  power sums during the computation.

Since Alice cannot store a perfect matching on  $K_N$  in  $o(N)$  space, this unfortunately does not give any  $o(N)$ -space strategies for Alice. In addition, our lower bound techniques from Theorem 1 fail to give non-trivial guarantees in the randomized model. Demonstrating non-trivial algorithms or non-trivial lower bounds for the general case is an interesting open problem.

### 1.4 General Mirror Games

It is possible to generalize the mirror game presented earlier to the case where in each turn Alice says  $a$  numbers and Bob says  $b$  numbers. We refer to this game as the  $(a, b)$ -mirror game.

By a generalization of the Oddtown theorem that works modulo prime  $p$ , our proof of Theorem 1 immediately carries over to show that if  $N$  is not divisible by  $p$ , then any winning strategy for Bob in the  $(1, p - 1)$ -mirror game requires  $\Omega(N)$  space (Theorem 20).

The natural generalization of the Oddtown theorem is known not to hold modulo composite  $m$ . Grolmusz showed [9] that if  $m$  is composite, there exists a set family of quasipolynomial size such that every set has cardinality divisible by  $m$ , but the intersection of any two distinct sets has cardinality not divisible by  $m$ . The best known upper bounds for the size of such a set family are of the form  $2^{O(N)}$ , and improving these to any bound of the form  $2^{o(N)}$  is an important open problem, with applications in coding theory to the construction of matching vector families [5, 4].

As long as the size of a modulo  $m$  Oddtown is bounded above by  $2^{o(N)}$ , the proof of Theorem 20 still achieves an  $\Omega(N)$  lower bound on the space complexity of Bob’s strategy. It follows that finding any  $o(N)$ -space winning strategy for Bob in the  $(1, m - 1)$  mirror game implies the existence of a  $2^{\Omega(N)}$ -size modulo  $m$  Oddtown, and hence similarly sized matching vector families (Theorem 22). Admittedly, Bob may not have an  $o(N)$ -space winning strategy in this game for unrelated reasons; it is interesting whether it is possible to show a converse result, constructing a low-space strategy for Bob from any  $2^{\Omega(N)}$ -size modulo  $m$  Oddtown.

For other  $(a, b)$ -mirror games, we understand much less about the complexity of winning strategies (if  $a + b$  is prime, then depending on the residue of  $N$  modulo  $a + b$  it is occasionally possible to show an  $\Omega(N)$  lower bound on the lower bound of a winning strategy).

## 2 Definitions and Preliminaries

### 2.1 The Mirror Game

The *mirror game on  $N$  elements* as discussed before is a game between two players, Alice and Bob. Alice and Bob take turns (Alice going first) saying a number in  $[N]$  ( $[N]$  indicates the set  $\{1, 2, \dots, N\}$ ). If a player says a number that has previously been said (either by the other player or by themselves) they lose and the other player wins. In addition, after  $N$  successful turns (so no numbers in  $[N]$  remain unsaid), both players are declared winners.

With unbounded memory, it is clear that both players can easily win this game. We therefore restrict our attention to strategies with bounded memory. A *strategy computable in memory  $m$*  for Alice in the mirror game is defined by an initial memory state  $s_0 \in [2^m]$  and a pair of transition functions  $f : [N] \times [2^m] \times [N] \rightarrow [2^m]$  and  $g : [2^m] \rightarrow [N]$  computable in  $SPACE(m)$  (see [1] for an introduction to bounded space complexity). The function  $f$  takes in the previous reply  $b \in [N]$  of Bob, Alice's current memory state  $s \in [2^m]$ , and the current turn  $t \in [N]$ , and returns Alice's new memory state  $s' \in [2^m]$ ; the function  $g$  takes in Alice's current memory state  $s \in [2^m]$  (after updating it based on Bob's move), and outputs her next move  $a$ . We say a strategy for Alice is a *winning strategy* if Alice is guaranteed to win regardless of Bob's choice of actions.

By removing the constraint that the transition function  $f$  is computable in  $SPACE(m)$ , we obtain a larger class of strategies, which we refer to as strategies *weakly computable in memory  $m$* . Our lower bounds in Theorems 1 and 20 continue to hold for this larger class of strategies.

### 2.2 Eventown and Oddtown

In this section we review the known literature on the Eventown-Oddtown problem. Note that while in the introduction we only defined the terms "Eventown" and "Oddtown", there are actually four different classes of set system depending on the parity of cardinalities of the subsets and the parity of the cardinality of the intersection.

► **Definition 2.** A collection of subsets  $\mathcal{F} \subseteq [N]$  forms an *(Odd, Even)-town* of sets if:

1. For every  $F \in \mathcal{F}$ ,  $|F| \equiv 1 \pmod{2}$ .
2. For every  $F_1 \neq F_2 \in \mathcal{F}$ ,  $|F_1 \cap F_2| = 0 \pmod{2}$ .

We define *(Odd, Odd)-towns*, *(Even, Odd)-towns*, and *(Even, Even)-towns* similarly.

Note that there exist (Even, Even)-towns and (Odd, Odd)-towns containing exponentially (in  $N$ ) many sets; one simple construction of an (Even, Even)-town is to partition the ground set into pairs (possibly with a leftover element), and consider all sets formed by taking unions of these pairs. In contrast, (Even, Odd)-towns and (Odd, Even)-towns each contain at most  $N$  sets.

► **Lemma 3.** Any *(Odd, Even)-town*  $\mathcal{F}$  has size at most  $N$  i.e.  $|\mathcal{F}| \leq N$ . [3, 12]

For completeness, we give the proof below.

**Proof.** Let  $\mathcal{F}$  be  $\{F_1, F_2, \dots, F_k\}$ . Let  $v_i \in \{0, 1\}^N$  be the characteristic function of  $F_i$  i.e.  $v_i[l] = 1 \iff l \in F_i$ . We know that  $v_i^T v_j \pmod{2} = 1$  for  $i = j$  and 0 otherwise. We claim that  $v_1, v_2, \dots, v_k$  are linearly independent over  $\mathbb{F}_2$  (where  $\mathbb{F}_2$  is the field with 2 elements) and hence,  $k \leq N$ . We prove this claim by contradiction. If they are not linearly independent, then  $\exists \lambda_1, \lambda_2, \dots, \lambda_k \in \{0, 1\}$  not all zero such that  $\sum_{i=1}^k \lambda_i v_i = 0 \pmod{2}$ . Without loss of generality, assume  $\lambda_1 \neq 0$ . As  $v_1^T (\sum_{i=1}^k \lambda_i v_i) = \lambda_1$  over  $\mathbb{F}_2$ , this implies  $\lambda_1 = 0$ ; a contradiction. ◀

► **Corollary 4.** *Any (Even, Odd)-town contains at most  $N$  sets.*

**Proof.** We prove an upper bound of  $N + 1$  sets by reduction to Lemma 3. Given an (Even, Odd)-town  $\mathcal{B} = \{B_1, \dots, B_m\}$ , construct an (Odd, Even)-town in space  $[N + 1]$  from sets  $B_1 \cup \{N + 1\}, B_2 \cup \{N + 1\}, \dots, B_m \cup \{N + 1\}$ . Using Lemma 3, we get  $m \leq N + 1$ . For a stronger upper bound of  $N$ , refer to [3, 12]. ◀

By adapting the above linear algebraic arguments to the field  $\mathbb{F}_p$  ( $p$  is prime and  $\mathbb{F}_p$  refers to field over  $p$  elements), it is possible to show similar upper bounds on the size of set families with cardinality constraints modulo  $p$ . We will use the following lemma, due to Frankl and Wilson.

► **Lemma 5 ([8]).** *Let  $p$  be a prime and  $L$  be a set of  $s$  integers. Let  $B_1, B_2, \dots, B_m \subseteq [N]$  be a family of subsets such that:*

1.  $|B_i| \bmod p \notin L, \forall i \in [m]$ .
2.  $|B_i \cap B_j| \bmod p \in L, \forall i \neq j$ .

Then

$$m \leq \sum_{i=0}^s \binom{N}{s}$$

We call such family of subsets a  $(p, L)$ -Modtown.

Interestingly, by a result of Grolmusz, there is no straightforward generalization of these results modulo a composite number  $k$ .

► **Theorem 6.** *Let  $k$  be a positive integer with  $r > 1$  different prime divisors. Then there exists a  $c > 0$ , such that for every  $N$ , there exists a family of subsets  $B_1, B_2, \dots, B_m$  such that:*

1.  $m \geq \exp(c(\log N)^r / (\log \log N)^{r-1})$ ,
2.  $|B_i| \equiv 0 \pmod{k}, \forall i$ ,
3.  $|B_i \cap B_j| \not\equiv 0 \pmod{k}, \forall i \neq j$ .

**Proof.** See [9]. ◀

This type of set family is captured in coding theory by the definition of a matching vector family.

► **Definition 7.** A *matching vector family* [4] over  $\mathbb{Z}_m^n$  of size  $t$  is a pair of ordered lists  $U = \{u_1, u_2, \dots, u_t\}$  and  $V = \{v_1, v_2, \dots, v_t\}$  where  $u_i, v_j \in \mathbb{Z}_m^n$  such that for all  $i$ ,  $u_i^T v_i = 0$ , and for all  $i \neq j$ ,  $u_i^T v_j \neq 0$ .

By taking  $u_i = v_i$  to be the characteristic vector of  $B_i$  above, it is clear that a family of subsets of size  $m$  in Theorem 6 gives rise to a Matching Vector family of size  $m$ . Matching vector families have deep applications to many problems in coding theory, such as private information retrieval and locally decodable codes [6, 7]. Understanding the maximum possible size of a matching vector family is an important open problem in coding theory.

### 3 Alice Requires Linear Space

In this section we prove that Alice requires linear space to win the mirror game when  $N$  is even. To do this, we will show that if Alice is at a specific memory state, then the possible sets of numbers that have been said till that point in time must form an (Even, Odd)-town (and hence there are at most  $N$  such sets for any memory state).

Before we get into the main proof, we will define and lower-bound the size of what we call a “covering collection” of subsets (this will later allow us to lower bound the total number of possible sets of numbers said by round  $t$  ( $2t$  turns)).

► **Definition 8.** A collection of subsets  $\mathcal{C}$  of  $[N]$  is  $(p, r)$ -covering if:

1. each  $S \in \mathcal{C}$  has  $|S| = pr$ .
2. for every  $T \subset [N]$  with  $|T| = r$ , there exists a  $S \in \mathcal{C}$  with  $T \subset S$ .

► **Lemma 9.** Every  $(p, r)$ -covering collection  $\mathcal{C}$  has size at least  $\frac{\binom{N}{r}}{\binom{pr}{r}}$ .

**Proof.** Every set in this collection contains at most  $\binom{pr}{r}$  sets  $T$  with cardinality  $r$ . There are  $\binom{N}{r}$  possible sets  $T$ . ◀

When  $p = 2$ , it turns out that the lower bound in Lemma 9 is maximized when  $r = N/5$ .

► **Corollary 10.** When  $r = N/5$ , every  $(2, r)$ -covering collection has size at least  $2^{(\log_2 5 - 2)N - o(N)}$ .

We now prove our main theorem.

► **Theorem 11.** If  $N$  is even, then any winning strategy in the mirror game for Alice requires at least  $(\log_2 5 - 2)N - o(N)$  bits of space.

**Proof.** Fix a winning strategy for Alice. Assume this strategy uses  $m$  bits of memory, and thus has  $M = 2^m$  distinct states of memory.

Call a subset  $S$  of  $[N]$   $r$ -occurring if it is possible that immediately after turn  $2r$  ( $r$  rounds), the set of numbers that have been said is equal to  $S$ . Let  $\mathcal{S}_r$  be the collection of all  $r$ -occurring sets. Before diving into the main proof, for any fixed deterministic strategy of Alice, we prove a lower bound on  $\mathcal{S}_r$  i.e. the number of different subsets of numbers that could have been said in the first  $2r$  turns over various strategies of Bob.

► **Lemma 12.**  $\mathcal{S}_r$  is  $(2, r)$ -covering.

**Proof.** Since  $2r$  numbers have been said immediately after turn  $2r$ , every set in  $\mathcal{S}_r$  has cardinality  $2r$ . We must show that for any  $T \subset [N]$  with  $|T| = r$ , that there exists an  $S$  in  $\mathcal{S}_r$  with  $T \subset S$ .

Consider the following strategy for Bob: “say the smallest number in  $T$  which has not yet been said”. Note that if Bob follows this strategy, then the set of numbers said by turn  $2r$  must contain the entire set  $T$ . This set belongs to  $\mathcal{S}_r$ , and it follows that  $\mathcal{S}_r$  is  $(2, r)$ -covering. ◀

Write  $N = 2n$ , and fix a value  $r \in [n]$ . For a memory state  $x$  out of the  $M$  possible memory states and an  $r$ -occurring set  $S$ , label  $x$  with  $S$  if it is possible that Alice is at memory state  $x$  when the set of numbers that have been said is equal to  $S$ . Each state of memory may be labeled with several or none  $r$ -occurring sets, but each  $r$ -occurring set must exist as a label to some state of memory (by definition). Let  $\mathcal{U}_x$  be the collection of  $r$ -occurring labels for memory state  $x$ . We want to upper bound the size of  $\mathcal{U}_x$ . Following lemma along with (Even, Odd)-town Lemma (Corollary 4) helps us in doing exactly that.

► **Lemma 13.** *If  $S_1$  and  $S_2$  belong to  $\mathcal{U}_x$ , then  $|S_1 \setminus S_2|$  is odd.*

**Proof.** Let  $D = S_1 \Delta S_2$ , let  $D_1 = S_1 \setminus S_2$ , and let  $D_2 = S_2 \setminus S_1$ . Assume to the contrary that  $|D_1|$  is even. Note then that  $|D_2|$  is also even (since  $|S_1| = |S_2| = 2r$ ) and that  $|D| = 2|D_1|$ . We'll consider two possible cases for the state of the game after turn  $2r$ : 1. Alice is at state  $x$ , and the set of numbers that have been said is  $S_1$ , and 2. Alice is at state  $x$ , and the set of numbers that have been said is  $S_2$ .

Consider the following strategy that Bob can play in either of these cases: “say the smallest number that has not been said and is not in  $D$ ”. We claim that if Bob uses this strategy, Alice will be the first person (after turn  $2r$ ) to say an element of  $D$ . Note that Bob will not say an element of  $D$  until after turn  $2n - |D|/2$ ; this is since:

1. If we are in case 1, then all of the numbers in  $D_1$  have been said but none of the numbers in  $D_2$  have been said. There are therefore  $|D_2| = |D|/2$  numbers in  $D$  which have not been said, so Bob can avoid saying an element of  $D$  till turn  $2n - |D|/2$ .
2. Likewise, if we are in case 2, the argument proceeds symmetrically.

On the other hand, if no element of  $D$  is spoken by either player between turn  $2r$  and turn  $2n - |D|/2$ , then at turn  $2n - |D|/2 + 1$ , the only remaining elements belong to  $D$  (the set of remaining elements is either  $D_1$  or  $D_2$ , depending on which case we are in). If  $|D_1| = |D|/2$  is even, then it is Alice's turn to speak at turn  $2n - |D|/2 + 1$ . It follows that Alice will be the first person after turn  $r$  to say an element of  $D$ .

Let  $y_1$  be the memory state of Alice when she first speaks an element of  $D$  in case 1, and define  $y_2$  similarly. We claim that  $y_1 = y_2$ . Indeed, since Alice's strategy is deterministic and starts from  $x$  in both cases 1 and 2, Bob's strategy plays identically in both case 1 and case 2 until an element of  $D$  has been spoken. It follows that Alice must speak the same element of  $D$  in both cases. But if this element is in  $D_1$ , and they are in case 1, then this element has already been said before; similarly, if this element is in  $D_2$ , and they are in case 2, then this element has also been said before. Regardless of which element in  $D$  Alice speaks at this state, there is some case where she loses, which contradicts the fact that Alice's strategy is successful. It follows that  $|D_1|$  must be odd, as desired. ◀

► **Claim 14.**  $|\mathcal{U}_x| \leq N$

**Proof.** We claim the sets in  $\mathcal{U}_x$  form an (Even, Odd)-town, from which this conclusion follows (Corollary 4). Each set in  $\mathcal{U}_x$  has cardinality  $2r$ , so all sets have even cardinality. By Lemma 13, any pair of distinct sets  $S_1, S_2 \in \mathcal{U}_x$  has odd  $|S_1 \setminus S_2|$ . Note that since  $|S_1 \cap S_2| = |S_1| - |S_1 \setminus S_2|$ , and since  $|S_1|$  is even, it follows that  $|S_1 \cap S_2|$  is odd, so any pair of sets have an odd cardinality intersection. ◀

Choose  $r = N/5$ . By Corollary 10,  $\mathcal{S}_r$  must have cardinality at least  $2^{(\log_2 5 - 2)N - o(N)}$ . Since each element in  $\mathcal{S}_r$  belongs to at least one collection  $\mathcal{U}_x$ , and since each collection  $\mathcal{U}_x$  has cardinality at most  $N$  (Claim 14), the number  $M$  of memory states  $x$  is at least  $2^{(\log_2 5 - 2)N - o(N)} / (N + 1) = 2^{(\log_2 5 - 2)N - o(N)}$ . It follows that  $m = \log M \geq (\log_2 5 - 2)N - o(N)$ , as desired. This proves Theorem 11. ◀

## 4 Randomized Strategies for Alice

In this section, we consider randomized strategies for Alice. A *randomized strategy computable in memory  $m$*  is defined similarly as in Section 2, with the exception that the transition function no longer needs to be deterministic and need only be computable in  $RSPACE(m)$ ;

i.e. it must be computable by a space  $m$  Turing machine with access to a  $\text{poly}(N, m)$ -sized read-once random tape. We say a randomized strategy wins with probability  $p$  if Alice wins with probability at least  $p$  against every possible strategy for Bob.

Unfortunately, we do not know any randomized strategies with sublinear memory which win with high probability. We therefore relax the definition of randomized strategy above and consider randomized strategies where Alice has oracle access to a perfect matching  $M$  chosen uniformly at random from all perfect matchings on  $K_N$  where  $K_N$  is the complete graph on  $N$  vertices (we assume here that  $N$  is even). Calling this oracle with  $x \in [N]$  returns  $x$ 's match  $M(x)$  in this matching, and  $M$  may be called arbitrarily many times during the computation of  $f$ .

One way to interpret the following upper bounds is as a source of difficulty for proving strong lower bounds for randomized strategies (of the form “you need linear space to succeed with high probability”), since a randomized strategy with memory  $m$  with access to a random matching can be viewed as a convex combination of deterministic strategies weakly computable in memory  $m$ . This means that any attempt to extend aforementioned strong lower bounds against randomized strategies must fail against this stronger class of randomized strategies.

Another way to interpret this model of computation is as a specific case of the setting where Alice has arbitrary read access to her random tape (as opposed to read-once access). It is known [11] that having arbitrary read access to randomness is more powerful than read-once access as long as certain probabilistic space classes do not collapse. Proving a strong lower bound for randomized strategies would provide more evidence for this separation (this time in the setting of streaming games).

We begin by showing that with only logarithmic space (and access to a random perfect matching), Alice can already win with probability  $\Omega(1/N)$ . In contrast, without access to a random matching, we know no logarithmic space strategy that succeeds with better than an exponentially small probability.

► **Theorem 15.** *When  $N$  is even, there exists a randomized strategy (with access to a uniformly random perfect matching  $M$  on  $K_N$ ) for Alice with space complexity  $O(\log N)$  which succeeds with probability  $\Omega(1/N)$ .*

**Proof.** Consider the following strategy for Alice. She begins by sampling a uniform element  $x$  from  $[N]$ . On her first turn, Alice says  $x$ . On subsequent turns, if Bob has just previously said  $y$ , Alice replies with  $M(y)$ .

Note that with this strategy, Alice wins playing against Bob if the last number said by Bob on turn  $N$  is  $M(x)$ . This follows since  $M$  is a matching, so there is no other number  $y \neq M(x)$  that Bob can say where  $M(y)$  has also already been said. It follows that if Bob says  $M(x)$  at turn  $N$ , then Alice is guaranteed to win.

What is the probability Bob says  $M(x)$  before turn  $N$ ? We will show it is less than  $1 - 1/N$ . To do this, we first claim that any winning strategy for Bob (i.e. any strategy that doesn't repeat previously said elements) has the same probability of saying  $M(x)$  before turn  $N$ . This follows from symmetry: since a uniformly random perfect matching conditioned on containing a submatching is still a uniformly random perfect matching on the remaining vertices, at any point in the protocol, if  $M(x)$  has not been said yet, it has an equally likely chance of being any of the unsaid elements. Therefore, without loss of generality, assume Bob is playing according to the strategy where each turn he says the smallest number that has not been said so far.

Now, note that if  $M(x) = N$ , Bob will not say  $M(x)$  before turn  $N$  (there will always be a smaller unsaid element). But this happens with probability  $1/N$ , and therefore Alice succeeds with probability at least  $1/N$ . ◀

We will next show how to extend this idea to construct an  $\tilde{O}(\sqrt{N})$  strategy for Alice which succeeds with high probability. To do this, we will need the following folklore result on determining missing elements from a set in a streaming setting.

► **Definition 16.** The “missing  $k$  numbers problem” is a streaming problem where a subset  $S$  of cardinality  $N - k$  is chosen from  $[N]$ , and Alice is shown the elements of  $S$  one at a time, in some order. Alice’s goal is to output the set  $[N] \setminus S$ .

► **Lemma 17.** *There exists an  $O(k \log N)$ -space deterministic algorithm for the missing  $k$  numbers problem.*

**Proof.** See [10]. For completeness, we include the proof here.

Choose a prime  $q \in (N, 2N]$ . We will perform all subsequent computations over the field  $\mathbb{F}_q$ . For a subset  $T$  of  $[N]$ , define  $p_i(T) = \sum_{x \in T} x^i$ . We first claim that if  $|T| \leq k$ , then Alice can recover the elements of  $T$  given the values of  $p_i(T)$  for  $1 \leq i \leq k$ .

To show this, define  $e_i(T)$  to be the value of  $i$ th elementary symmetric polynomial over the elements of  $T$  (that is,  $e_i(T) = \sum_{T' \subseteq T, |T'|=i} \prod_{x \in T'} x$ ). Newton’s identities allow us to compute (in space  $O(\log N)$ ) the values of  $e_i(T)$  for  $1 \leq i \leq k$  from the values of  $p_i(T)$  for  $1 \leq i \leq k$  (since  $k < N < q$ , all of these operations are valid over  $\mathbb{F}_q$ ). Now, each element  $x$  of  $T$  is a root of the polynomial

$$x^k - e_1(T)x^{k-1} + e_2(T)x^{k-2} - \dots + (-1)^k e_k(T) = 0.$$

We can factor this in space  $O(\log N)$  by trying all possible  $x \in [N]$ , and therefore recover the original set  $T$ .

To solve the missing  $k$  numbers problem, Alice first computes  $p_i(S)$  for each  $1 \leq i \leq k$  using  $O(k \log N)$  space, updating each count every time she receives a new element from  $S$ . This allows her to compute  $p_i([N] \setminus S)$  via  $p_i([N] \setminus S) = p_i([N]) - p_i(S)$ . Finally, since  $|[N] \setminus S| = k$ , she can use the previous algorithm to recover the set  $[N] \setminus S$ . ◀

► **Theorem 18.** *When  $N$  is even, there exists a randomized strategy (with access to a uniformly random perfect matching  $M$  on  $K_N$ ) for Alice with space complexity  $O(\sqrt{N} \log^2 N)$  which succeeds with probability  $1 - O(1/N)$ .*

**Proof.** Consider the following strategy for Alice. Alice begins by sampling  $r = \sqrt{N}$  distinct elements  $X = \{x_1, x_2, \dots, x_r\}$  uniformly at random from all  $\binom{N}{r}$  subsets of  $r$  elements of  $N$  (and stores them in memory).

At every point in the game, Alice uses her  $O(\sqrt{N} \log^2 N) = O(r \log^2 N)$  bits of memory to keep track of: i) which elements of  $X$  have already been said, and ii) the first  $k = r \log N$  power sums of the elements said so far, modulo some prime  $q \in (N, 2N]$  (as per the proof of Lemma 17).

Alice begins by choosing a random element of  $X$  and saying it. Her algorithm in later rounds is defined as follows:

1. If less than or equal to  $k$  elements remain unchosen (i.e., this is turn  $N - k$  or later), Alice uses the  $O(k \log n)$ -space algorithm from Lemma 17 to compute the remaining unsaid elements. She then says one of these elements, chosen arbitrarily.
2. Otherwise, if Bob has just said  $y$ , Alice checks if  $M(y)$  belongs to  $X$ .
  - If it does not belong to  $X$ , Alice says  $M(y)$ .

## 36:10 The Space Complexity of Mirror Games

- If  $M(y)$  belongs to  $X$  but has not been said yet, Alice says  $M(y)$  and marks down  $M(y)$  as having been said.
- If  $M(y)$  belongs to  $X$  and has already been said, Alice chooses an element of  $X$  uniformly at random from the elements of  $X$  which have not yet been said (if there are no such elements, Alice gives up and says a random element). She then marks this element as having been said.

Let  $T$  be the random variable denoting the first turn in which all of the elements of  $X$  have been said. We first claim that if  $T \geq N - k$ , then Alice succeeds. Indeed, since the algorithm of Lemma 17 always succeeds, Alice is guaranteed to succeed if she makes it to turn  $N - k$ . On the other hand, the only way for Alice to fail before turn  $N - k$  is if all of the elements of  $X$  have already been said, and Alice is forced to say a random element.

We now claim that with high probability,  $T \geq N - k$ . To see this, note that, similarly as in the proof of Theorem 15, any non-trivial strategy of Bob will give rise to the same distribution over  $T$ . This follows from the fact that at any point in the protocol, each unsaid element has the same probability of belonging to the set  $X$ .

We can therefore assume that Bob is playing under the strategy where on his turn, he says the smallest number that has not been said so far. Note that under this strategy, Bob will only say numbers less than or equal to  $i$  on turn  $i$ ; it follows that if there exists any  $x_i$  such that  $x_i \geq N - k$ , then also  $T \geq N - k$ .

We can thus compute

$$\begin{aligned}
 \Pr[T < N - k] &\leq \Pr[\forall i, x_i \leq N - k] \\
 &= \frac{\binom{N-k}{r}}{\binom{N}{r}} \\
 &\leq \left(\frac{N-k}{N}\right)^r \\
 &= \left(1 - \frac{\log N}{\sqrt{N}}\right)^{\sqrt{N}} \\
 &= O(1/N).
 \end{aligned}$$

It follows that Alice wins with probability at least  $1 - O(\frac{1}{N})$ , as desired. ◀

Note that the same upper bound holds when Alice does not have an oracle access to a random matching but Bob's strategy is to choose a random number in  $[N]$  in every turn.

### 5 The $(a, b)$ -Mirror Game

Consider the following generalization of the mirror game, where Alice says  $a$  numbers each turn, and Bob says  $b$  numbers each turn. We call this new game the  $(a, b)$ -mirror game.

As with the regular  $(1, 1)$ -mirror game, mirror strategies exist for the class of  $(1, b)$ -mirror games (and similarly, the  $(a, 1)$ -mirror games).

► **Theorem 19.** *If  $N$  is divisible by  $b + 1$ , then Bob has a winning strategy computable in  $O(\log N)$  memory for the  $(1, b)$ -mirror game.*

**Proof.** Divide the  $N$  elements of  $[N]$  into  $N/(b+1)$  consecutive  $(b+1)$ -tuples. Any time Alice says an element in a  $(b+1)$ -tuple, Bob says all the remaining elements in that  $(b+1)$ -tuple. ◀

Unlike in the  $(1,1)$ -mirror game, we cannot rule out the existence of low space winning strategies for other games and other choices of  $N$ . In this section, we summarize what we know about low-space winning strategies for  $(a,b)$ -mirror games.

### 5.1 $a + b$ is Prime

We begin by considering the set of  $(a,b)$ -mirror games where  $a + b$  is a prime,  $p$ . The Frankl-Wilson Lemma (Lemma 5) allows us to extend some of our proof techniques from Theorem 11 to this case.

In the case where  $a = 1$ , we have the following analogue to Theorem 11, fully characterizing the  $N$  where Bob has a low space winning strategy (Theorem 19) and where Bob requires linear space.

► **Theorem 20.** *Let  $p$  be a prime. If  $N$  is not divisible by  $p$ , then any winning strategy for Bob in the  $(1, p - 1)$ -mirror game requires  $\Omega(N)$  space.*

**Proof.** See Appendix A. ◀

When  $a > 1$ , our proof techniques no longer allow us completely characterize the set of  $N$  where Bob requires  $\Omega(N)$  space to win. Instead, we only have the following partial characterization.

► **Theorem 21.** *Let  $p$  be a prime. If  $a + b = p$ , and  $N \bmod p \in \{a, a + 1, \dots, p - 1\}$ , then any winning strategy for Bob in the  $(a,b)$ -mirror game requires  $\Omega(N)$  space.*

**Proof.** See Appendix A. ◀

### 5.2 $a + b$ is Composite

The failure of the Frankl-Wilson lemma (Lemma 5) to hold modulo composite numbers prevents us from directly applying our proof techniques in this case. Gromulz's construction (Theorem 6) shows that there exist  $(m, L)$ -Modtown families containing a superpolynomial in  $N$  number of sets when  $m$  is composite.

However, a sufficiently small superpolynomial upper bound on the size of such a family would still allow us to prove the analogue of Theorem 20. In fact, any upper bound of  $F$  on the size of such a family leads to a lower bound of  $\log(2^{\Omega(n)}/F) = \Omega(n) - \log F$  on Bob's memory. This implies the following "contrapositive" to Theorem 20:

► **Theorem 22.** *If Bob has a  $o(N)$ -space winning strategy in a  $(1, m - 1)$  game when  $N \equiv k \not\equiv 0 \pmod{m}$ , then there exists  $2^{\Omega(N)}$  sized matching vector families over  $\mathbb{Z}_m^N$  (for sufficiently large  $N$ ).*

**Proof.** See Appendix A. ◀

## 6 Open Problems

Our understanding of the space complexity aspects of mirror games is still very rudimentary. We conclude by listing some open problems we find interesting.

1. **When do low-space winning strategies exist?** Does either Alice or Bob ever have a low-space winning strategy for any  $(a,b)$  game when  $a$  and  $b$  are both larger than 1 (e.g., the  $(2,2)$  game)? Are there any cases where the best deterministic winning strategy

has space complexity strictly between  $O(\log N)$  and  $O(N)$  (e.g.  $O(\sqrt{N})$ ), or does the best winning strategy always fit into one of these two extremes? Is it ever the case that both Alice and Bob simultaneously have  $O(\log N)$  winning strategies?

2. **Beating low-space with low-space.** In order to show that Alice needs  $\Omega(N)$  space, our adversarial strategy for Bob also requires  $\Omega(N)$  space. Given a deterministic low-memory  $m$  strategy for Bob, is there a low-memory strategy for Alice which wins against it?
3. **Lower bounds for randomized strategies.** Can we prove any sort of lower bound against randomized strategies that win with high probability? What about against randomized strategies with additional power, such as access to a uniformly chosen matching or with multiple read access to the random tape? Is our upper bound of  $\tilde{O}(\sqrt{N})$  tight in the latter contexts?
4. **Composite  $a + b$ .** Is it possible to show some sort of converse to Theorem 22, that any large enough matching vector family gives rise to a low space strategy for Bob? Or is it possible to show linear space lower bounds for composite  $a + b$  via some other approach?
5. **More general mirror games.** One of the great successes of the theory of combinatorial games [2] is that its techniques apply to essentially all sequential two-player games with perfect information. Is there a more general class of games beyond the family of  $(a, b)$ -mirror games with similar space complexity phenomena? One possible other family of such games with mirror strategies comes from a generalization of the combinatorial game “Cram”, where Alice and Bob take turn placing dominoes (more generally, an element of some set of “symmetric” polyominoes) onto a  $w$  by  $h$  grid (more generally, some high dimensional grid, or any “symmetric” subset of a high-dimensional grid). For example, the original mirror game can be thought of as Cram on a 1 by  $N$  board, where players take turn placing unit squares. Can we say anything about the space complexity of playing Cram, or its generalizations?

---

## A

 Omitted Proofs

### Proof of Theorem 20

Theorem 20 is a special case of Theorem 21 setting  $a = 1$ . Hence, we go on to prove that.

### Proof of Theorem 21

**Proof.** We proceed similarly to the proof of Theorem 11. As before, call a subset  $S$  of  $[N]$   $r$ -occurring if it is possible that immediately after turn  $2r$ , the set of numbers that have been said is equal to  $S$ . Let  $\mathcal{S}_r$  be the collection of all  $r$ -occurring sets. As before,  $\mathcal{S}_r$  is  $(p, r)$ -covering and we can choose  $r$  such that  $|\mathcal{S}_r| \geq 2^{\Omega(N)}$ .

Write  $N = pm + k$ ,  $k \in \{a, a + 1, \dots, p - 1\}$ , and fix a value  $r \in [n]$ . For a memory state  $x$  out of the  $M$  possible memory states of Bob and an  $r$ -occurring set  $S$ , label  $x$  with  $S$  if it is possible that Bob is at memory state  $x$  when the set of numbers that have been said is equal to  $S$ . Each state of memory may be labelled with several  $r$ -occurring sets or none, but each  $r$ -occurring set must exist as a label to some state of memory (by definition). Let  $\mathcal{U}_x$  be the collection of  $r$ -occurring labels for memory state  $x$ .

► **Lemma 23.** *If  $S_1$  and  $S_2$  belong to  $\mathcal{U}_x$ , then  $|S_1 \setminus S_2| \bmod p \in \{k - a + 1, \dots, k - 1, k, \dots, p - 1\}$ .*

**Proof.** Let  $D = S_1 \Delta S_2$ , let  $D_1 = S_1 \setminus S_2$ , and let  $D_2 = S_2 \setminus S_1$ . Assume to the contrary that  $|D_1| \equiv k_1 \pmod p$  where  $k_1 \in \{0, 1, \dots, k - a\}$ . Note then that  $|D_2| = |D_1|$  (since  $|S_1| = |S_2|$ ) and that  $|D| = 2|D_1|$ . We'll consider two possible cases for the state of the game after turn  $2r$  (each turn, either Alice says  $a$  numbers or Bob says  $b$  numbers): 1. Bob is at state  $x$ , and the set of numbers that have been said is  $S_1$ , and 2. Bob is at state  $x$ , and the set of numbers that have been said is  $S_2$ .

Consider the following strategy that Alice can play in either of these cases: “say the smallest number that has not been said that is not in  $D$ ”. We claim that if Alice uses this strategy, Bob will be the first person (after turn  $2r$ ) to say an element of  $D$ . Note that Alice will not say an element of  $D$  until turn  $2\lfloor \frac{N - |D_1|}{p} \rfloor + 1$ ; this is since:

1. If we are in case 1, then all of the numbers in  $D_1$  have been said but none of the numbers in  $D_2$  have been said. There are therefore  $|D_2| = |D_1|$  numbers in  $D$  which have not been said, so Alice can avoid saying an element of  $D$  until turn  $2\lfloor \frac{N - |D_1|}{p} \rfloor + 1$  as the number of numbers remaining before Alice's turn would be  $|D_1| + k - k_1 \geq |D_1| + a$ . Hence, Alice can say  $a$  numbers not belonging to the set  $D_1$ .
2. Likewise, if we are in case 2, the argument proceeds symmetrically.

On the other hand, if no element of  $D$  is spoken by either player between turn  $2r$  and turn  $2\lfloor \frac{N - |D_1|}{p} \rfloor + 1$ , then at turn  $2\lfloor \frac{N - |D_1|}{p} \rfloor + 2$ , Bob has to say  $b$  elements from  $|D_1| + k - k_1 - a$  elements and hence, there would be intersection with elements of  $D$  (as  $k - k_1 - a \leq p - 1 - a = b - 1$ ).

Let  $y_1$  be the memory state of Bob when he first speaks an element of  $D$  in case 1, and define  $y_2$  similarly. We claim that  $y_1 = y_2$ . Indeed, since Bob's strategy is deterministic and starts from  $x$  in both cases 1 and 2, Alice's strategy plays identically in both case 1 and case

2 until an element of  $D$  has been spoken. It follows that Bob must speak the same element of  $D$  in both cases. But if this element is in  $D_1$ , and they are in case 1, then this element has already been said before; similarly, if this element is in  $D_2$ , and they are in case 2, then this element has also been said before. Regardless of which element in  $D$ , Bob speaks at this state, there is some case where he loses, which contradicts the fact that Bob's strategy is successful. It follows that  $|D_1| \bmod p \in \{k - a + 1, \dots, k - 1, k, \dots, p - 1\}$ , as desired. ◀

► **Claim 24.**  $|\mathcal{U}_x| \leq p \binom{N}{p-1}$ .

**Proof.** We claim the sets in  $\mathcal{U}_x$  form a  $(p, \{1, 2, \dots, p-1\})$ -Modtown, from which this conclusion follows (Lemma 5). Each set in  $\mathcal{U}_x$  has cardinality  $pr \equiv 0 \pmod p$ . By Lemma 23, any pair of distinct sets  $S_1, S_2 \in \mathcal{U}_x$  has  $|S_1 \setminus S_2| \bmod p \in \{k - a + 1, \dots, k - 1, k, \dots, p - 1\} \subseteq \{1, 2, \dots, p - 1\}$  (as  $k \geq a$ ). Note that since  $|S_1 \cap S_2| = |S_1| - |S_1 \setminus S_2|$ , it follows that  $|S_1 \cap S_2| \bmod p$  also belongs to  $\{1, 2, \dots, p - 1\}$ . ◀

We established that for some  $r$ ,  $\mathcal{S}_r$  must have cardinality at least  $2^{\Omega(N)}$ . Since each element in  $\mathcal{S}_r$  belongs to at least one collection  $\mathcal{U}_x$ , and since each collection  $\mathcal{U}_x$  has cardinality at most  $pN^p$  (Claim 24), the number  $M$  of memory states  $x$  is at least  $2^{\Omega(N)}/(pN^p)$ . It follows that  $m = \log M \geq \Omega(N)$ , as desired. This proves Theorem 21. ◀

## Proof of Theorem 22

**Proof.** In proof of Theorem 21, we use the fact that  $p$  is prime only to bound the size of  $\mathcal{U}_x$  and thus, Lemma 23 ( $a = 1$ ) hold even for composite  $m$ . As  $\mathcal{S}_r$  must have cardinality at least  $2^{\Omega(N)}$  and there are at most  $2^{o(N)}$  memory states  $x$ , by pigeonhole principle, there exists  $x'$  with  $|\mathcal{U}_{x'}| \geq 2^{\Omega(N)}$ . Let's define the set of vectors  $U$  based on  $\mathcal{U}_{x'}$ . For every subset  $S \in \mathcal{U}_{x'}$ , we add a vector  $v_S \in \{0, 1\}^N$  to  $U$  where  $v_S$  is the characteristic vector of  $S$  ( $v_S(l) = 1 \iff l \in S$ ). Clearly,  $|U| = |\mathcal{U}_{x'}|$  and  $U \subseteq \{0, 1\}^N$ . We claim the  $U$  and  $U$  form a Matching Vector family as  $v_S^T v_S = |S| \bmod m = 0$ , for all  $S$  and  $v_{S_1}^T v_{S_2} = |S_1 \cap S_2| \not\equiv 0 \pmod m$ ,  $\forall S_1 \neq S_2$  by Lemma 23 (when  $N \equiv k \not\equiv 0 \pmod m$ ). Hence, we have a exponential sized Matching Vector family  $(U, U)$  over  $\mathbb{Z}_m^N$ . ◀

# The Subgraph Testing Model

## Abstract

---

We initiate a study of testing properties of graphs that are presented as subgraphs of a fixed (or an explicitly given) graph. The tester is given free access to a base graph  $G = ([n], E)$ , and oracle access to a function  $f : E \rightarrow \{0, 1\}$  that represents a subgraph of  $G$ . The tester is required to distinguish between subgraphs that possess a predetermined property and subgraphs that are far from possessing this property.

We focus on bounded-degree base graphs and on the relation between testing graph properties in the subgraph model and testing the same properties in the bounded-degree graph model. We identify cases in which testing is significantly easier in one model than in the other as well as cases in which testing has approximately the same complexity in both models. Our proofs are based on the design and analysis of efficient testers and on the establishment of query-complexity lower bounds.

## 1 Introduction

Property testing refers to probabilistic algorithms with sub-linear complexity for deciding whether a given object has a predetermined property or is far from any object having this property. Such algorithms, called testers, obtain local views of the object by *performing queries* and their performance guarantees are stated with respect to a distance measure that (combined with a distance parameter) determines what objects are considered far from the property.

In the last couple of decades, the area of property testing has attracted significant attention (see, e.g., [13, 31, 32, 14]). Much of this attention was devoted to testing graph properties in a variety of models ranging from the dense graph model [15], to the bounded-degree graph model [17], and to the sparse and general graph models [30, 24].<sup>1</sup> These models differ in two main parameters: the *types of queries* that potential testers can make, and the *distance measure* against which their performance is measured.

---

<sup>1</sup> These models are surveyed in Chapters 8, 9, and 10 of the textbook [14].

In all aforementioned models, the input graph is arbitrary, except for its size (and possibly its degree, in the case of the bounded-degree graph model). The same holds with respect to the graphs that are used to determine the distance of the input from the property. While some prior works (see, e.g., [3, 22, 6, 20, 9, 7, 29, 5]) restrict the input graph in certain natural ways, the restrictions considered so far were expressed in terms of general (“uniform”) graph properties (such as degree bound, hyperfiniteness, planarity, etc). See further discussion in Section 1.5.1.

In contrast, we envision circumstances in which the input is restricted to be a subgraph of some fixed graph that is known beforehand. For example, the fixed graph may represent an existing (or planned) network, and the subgraph represents the links that are actually in operation (or actually constructed). Alternatively, the graph may represent connections between data items that may exist under some known constraints, and the edges of the subgraph represent connections that actually exist. Either way, the input is a subgraph of some fixed graph, and the distance to having the property is measured with respect to subgraphs of the same fixed graph.

## 1.1 The model

In accordance with the foregoing discussion, in the **subgraph testing model**, there is a fixed **base graph**, denoted  $G = ([n], E)$ , and the tester is given oracle access to a function  $f : E \rightarrow \{0, 1\}$  that represents a subgraph of  $G$  in the natural manner (i.e.,  $f$  represents the subgraph  $([n], \{e \in E : f(e) = 1\})$ ). Alternatively, the base graph  $G$  is not fixed, but the tester is given free access to  $G$ .

► **Definition 1.1** (subgraph tester). Fixing  $G = ([n], E)$  and  $\Pi_G \subseteq \mathcal{F}_G \stackrel{\text{def}}{=} \{f : E \rightarrow \{0, 1\}\}$ , a **subgraph tester** for  $\Pi_G$  is a probabilistic oracle machine, denoted  $T$ , that, on input a (proximity) parameter  $\epsilon$ , and oracle access to a function  $f : E \rightarrow \{0, 1\}$ , outputs a binary verdict that satisfies the following two conditions.

1.  $T$  *accepts inputs in*  $\Pi_G$ : For every  $\epsilon > 0$ , and for every  $f \in \Pi_G$ , it holds that  $\Pr[T^f(\epsilon) = 1] \geq 2/3$ .
2.  $T$  *rejects inputs that are  $\epsilon$ -far from*  $\Pi$ : For every  $\epsilon > 0$ , and for every  $f : E \rightarrow \{0, 1\}$  that is  $\epsilon$ -far from  $\Pi_G$  it holds that  $\Pr[T^f(\epsilon) = 0] \geq 2/3$ , where  $f$  is  $\epsilon$ -far from  $\Pi_G$  if for every  $h \in \Pi_G$  it holds that  $|\{e \in E : f(e) \neq h(e)\}| > \epsilon \cdot |E|$ .

If the first condition holds with probability 1 (i.e.,  $\Pr[T^f(\epsilon) = 1] = 1$  for  $f \in \Pi_G$ ), then we say that  $T$  has **one-sided error**; otherwise, we say that  $T$  has **two-sided error**.

In the alternative formulation, the subgraph tester is given  $G$  as an explicit input (along with  $\epsilon$ ). In this case, the random variable being considered is  $T^f(G, \epsilon)$ .

Definition 1.1 falls within the framework of massively parameterized property testing (cf. [28]). The massive parameter is the base graph  $G = ([n], E)$ , and the actual input is a function  $f : E \rightarrow \{0, 1\}$  (which represents a subgraph of  $G$ ).

(The subgraph testing model is syntactically identical to the *orientation model* [21], but semantically these models are fundamentally different; see further discussion in Section 1.5.2.)

As usual in the area, our primary focus is on the query complexity of such testers, and our secondary focus is on their time complexity. Both complexities are stated as a function of the proximity parameter  $\epsilon$  and the base graph  $G$ . Indeed, the dependency of these complexities on  $G$ , or rather on some parameters of  $G$ , will be of major interest.

As an illustration, consider the problem of testing whether the subgraph is bipartite. If the base graph is bipartite, then this problem is trivial (since every subgraph is bipartite).

■ **Figure 1** For  $n \geq 6$ , the  $n$ -vertex path is oriented by the additional edge  $\{n-3, n-1\}$ .

If the base graph is  $\mathcal{M}$ -minor free<sup>2</sup>, for any fixed family of graphs  $\mathcal{M}$ , then testing (with distance parameter  $\epsilon$ ) can be done in  $\text{poly}(1/\epsilon)$ -time (see Proposition 2.2). Lastly, if the base graph is of bounded-degree, then testing can be done in  $\text{poly}(1/\epsilon) \cdot \tilde{O}(\sqrt{n})$ -time (see Theorem 1.2), and this result is optimal in general (i.e., for arbitrary bounded-degree base graphs, see Part 1 of Theorem 1.4).

Our main focus will be on the case that the base graph is sparse (e.g., of bounded-degree). Furthermore, we shall be interested in cases in which the subgraph testing model is different from other testing models. Still, let us make a couple of comments regarding cases in which the subgraph testing model coincides with other testing models.

**The dense graph model is a special case of subgraph testing.** For the base graph  $G = K_n$  (i.e., the  $n$ -vertex clique), the subgraph testing model coincides with the dense graph model. This is the case since adjacency queries (as in the dense graph model) correspond to edges of the base graph  $G$ , and the distance measure used in both models is the same.

**General property testing as a special case of subgraph testing.** If the base graph  $G$  is sparse and asymmetric (i.e., its automorphism group consists solely of the identity permutation), then the subgraph testing model captures property testing (for Boolean functions) at large. This is shown as follows.

For  $n \geq 6$ , consider an  $n$ -vertex graph  $G'$  consisting of an  $n$ -vertex long path augmented with the edge  $\{n-3, n-1\}$  (see Figure 1). Observe that the only automorphism of this graph is the identity permutation, and augment  $G'$  with self-loops on each of the  $n$  vertices, deriving a base graph  $G$  with  $2n$  edges. (We note that the construction can be modified so that self-loops are avoided, by replacing them with disjoint cycles of length 3.) Lastly, associate any function  $f : [n] \rightarrow \{0, 1\}$  with a subgraph of  $G$  that contains  $G'$  as well as the self-loop on vertices in  $f^{-1}(1)$ . Note that, by the asymmetry of  $G'$ , there is a bijection between the set of Boolean functions over  $[n]$  and the subgraphs of  $G$  that contain  $G'$ , and that distances between the two models are preserved up to a factor of 2.<sup>3</sup>

**On our terminology: Testing graph properties in the subgraph model.** Unless the base graph  $G = ([n], E)$  is closed under all possible relabelings of  $[n]$  (which happens if and only if  $G$  is either the complete graph or the empty graph),<sup>4</sup> we cannot expect a (non-empty) set of

<sup>2</sup> Recall that a graph  $M$  is a minor of graph  $G$  if  $M$  can be obtained from  $G$  by vertex deletions, edge deletions and edge contractions; a graph  $G$  is  $\mathcal{M}$ -minor free for a family of graphs  $\mathcal{M}$ , if no graph in  $\mathcal{M}$  is a minor of  $G$ .

<sup>3</sup> The argument extends to any sparse graph  $G'$  that is asymmetric. Recall that almost all (bounded degree) graphs are asymmetric (cf. [10, 25]). On the other hand, an asymmetric graph cannot contain two isolated vertices, and thus it must contain at least a linear number of edges.

<sup>4</sup> Indeed, the  $n$ -vertex complete graph and the empty ( $n$ -vertex) graph are closed under all possible relabelings of  $[n]$ . On the other hand, if  $G$  is neither the complete graph nor the empty graph, then  $G$  is not closed under all possible relabelings of  $[n]$ . To see this observe that  $G$  must contain a vertex  $w$  that has degree in  $[n-2]$ ; that is, its neighbor set, denoted  $\Gamma_G(w)$ , is neither empty nor contains all other vertices in  $G$ . Picking  $u \in \Gamma_G(w)$  and  $v \notin \Gamma_G(w)$ , observe that the permutation  $\pi$  that switches  $u$

its subgraphs,  $\Pi_G$ , to constitute a graph property (i.e., to be closed under all relabelings of  $[n]$ ). That is, in the general case, the property  $\Pi_G \subseteq \mathcal{F}_G$  is not a graph property, since it is not closed under isomorphism (because  $\mathcal{F}_G$  is not closed under isomorphism). Nevertheless, for any base graph  $G$  and every graph property  $\Pi$ , we shall refer to  $\Pi_G = \mathcal{F}_G \cap \Pi$  as a graph property.

Throughout this paper, we assume that  $G$  contains no isolated vertices. This can be assumed without loss of generality, because, for every graph  $G'$  that is obtained from the graph  $G = ([n], E)$  by adding isolated vertices, it holds that  $\mathcal{F}_G = \mathcal{F}_{G'}$ , since in both cases the subgraphs are represented by Boolean functions on the same edge-set (i.e.,  $E$ ).

## 1.2 Results

Throughout this paper, the base graph  $G$  is viewed as a varying parameter, which may grow when other parameters (e.g., the degree bound  $d$ ) are fixed. We focus on bounded-degree base graphs and on the relation between testing graph properties in the subgraph model and testing the same properties in the bounded-degree graph (BDG) model.

Recall that in the BDG model [17], the tester is explicitly given three parameters:  $n$ ,  $d$ , and  $\epsilon$ . Its goal is to distinguish with probability at least  $2/3$  between the case that a graph  $G = ([n], E)$  (of maximum degree bounded by  $d$ ) has a prespecified property  $\Pi$ , and the case that  $G$  is  $\epsilon$ -far from having the property  $\Pi$ , where a graph is said to be  $\epsilon$ -far from having  $\Pi$  if more than  $\epsilon \cdot d \cdot n$  edge modifications (additions or removals) are required in order to obtain a graph (of maximum degree bounded by  $d$ ) that has  $\Pi$ . To this end the tester can perform queries of the form “who is the  $i^{\text{th}}$  neighbor of vertex  $v$ ?”, for  $v \in [n]$  and  $i \in [d]$ .<sup>5</sup> Unless stated explicitly otherwise, the degree bound  $d$  is a constant.

Obviously, the relationship between the subgraph model and the BDG model depends on the property being tested as well as on the base graph used in the subgraph model. We identify cases in which testing is significantly easier in one model than in the other as well as cases in which testing has approximately the same complexity in both models.

More specifically, we distinguish *downward-monotone* graph properties from other graph properties, where a graph property is called *downward-monotone* if it is preserved under omission of edges (i.e., if  $G = ([n], E)$  has the property, then so does  $G' = ([n], E')$  for every  $E' \subset E$ ).

For each of the theorems stated in this section, we provide either a proof outline or a proof idea in Section 1.3. Full proofs of Theorems 1.2, 1.3, and 1.7 (as well as Propositions 1.6 and 2.1) appear in Section 2. The proofs of our other results can be found in our technical report [19].

### 1.2.1 Downward-monotone properties

We first observe that, for every bounded-degree graph  $G = ([n], E)$  and any downward-monotone graph property  $\Pi$ , testing  $\Pi \cap \mathcal{F}_G$  in the subgraph model (w.r.t. the base graph  $G$ ) reduces to testing  $\Pi$  in the BDG model.

► **Theorem 1.2** (a general upper bound on the complexity of testing downward-monotone properties (see Section 2.1)). *Let  $\Pi$  be a downward-monotone graph property that is testable with query complexity  $Q_d(\cdot, \cdot)$  in the bounded-degree graph model, where  $d \geq 2$  denotes the*

---

and  $v$ , while keeping all other vertices intact, does not preserve the graph  $G$  (i.e.,  $\pi(G) \neq G$ ).

<sup>5</sup> If  $v$  has less than  $i$  neighbors, then a special symbol is returned. It is sometimes assumed that the algorithm can also query the degree of any vertex of its choice, but this assumption saves at most a multiplicative factor of  $\log d$  in the complexity of the algorithm.

degree bound, and  $Q_d$  is a function of the proximity parameter and (possibly) the size of the graph. Then, for every base graph  $G = ([n], E)$  of degree  $d$ , testing whether a subgraph of  $G$  satisfies  $\Pi$  (with proximity parameter  $\epsilon$ ) can be done with query complexity  $d \cdot Q_d(\epsilon', n)$ , where  $\epsilon' = \epsilon/d$ . The same holds with respect to the time complexity. Furthermore, one-sided error is preserved.

(Note that, for constant  $d$ , it holds that  $\epsilon' = \Omega(\epsilon)$ .) Properties covered by Theorem 1.2 include bipartiteness, cycle-freeness, and all subgraph-freeness and minor-freeness properties. Hence, testers known for these properties in the BDG model (see [14, Chap. 9]) get translated to testers of similar complexity for the subgraph testing model.

While Theorem 1.2 asserts that testing downward-monotone graph properties in the subgraph model is not harder than testing these properties in the BDG model, it raises the question of whether the former task may be easier.

**Testing in the subgraph model may be trivial.** A trivial positive answer holds in case the base graph itself has the property (i.e.,  $G \in \Pi$ ). In this case, by the downward-monotonicity of  $\Pi$ , every subgraph of  $G$  has the property  $\Pi$ , which means that testing  $\Pi \cap \mathcal{F}_G$  in the subgraph model (w.r.t. the base graph  $G$ ) is trivial.

**Testing in the subgraph model may be easier (than in the BDG model).** A more interesting case in which testing in the subgraph model may be easier than in the BDG model occurs when the base graph is not in  $\Pi$ , but has some suitable property  $\Pi'$  that is not related to  $\Pi$ . In particular, if the base graph is  $\mathcal{M}$ -minor free, for some fixed set of graphs  $\mathcal{M}$ , then, for any downward-monotone graph property  $\Pi$ , testing  $\Pi \cap \mathcal{F}_G$  in the subgraph model has complexity that is independent of the size of the tested graph, whereas testing  $\Pi$  in the BDG model may require query complexity that depends on the size of the tested graph. More generally, we consider *hyperfinite* families of graphs [8], where an  $n$ -vertex graph  $G$  is  $t$ -hyperfinite for  $t : (0, 1) \rightarrow \mathbb{N}$  if, for every  $\epsilon > 0$ , removing at most  $\epsilon n$  edges from  $G$  results in a graph with no connected component of size exceeding  $t(\epsilon)$ . We mention that minor-free (bounded-degree) graphs are hyperfinite (with  $t(\epsilon) = O(1/\epsilon^2)$ ).

► **Theorem 1.3** (on the complexity of testing downward-monotone properties of subgraphs of hyperfinite base graphs (see Section 2.2)). *Let  $\Pi$  be a downward-monotone graph property and  $\mathcal{G}$  be a family of  $t$ -hyperfinite graphs. Then, for every bounded-degree base graph  $G = ([n], E)$  in  $\mathcal{G}$ , testing whether a subgraph of  $G$  satisfies  $\Pi$  can be done in time that depends only on the proximity parameter  $\epsilon$ . Furthermore, if  $\Pi$  is additive (i.e., a graph is in  $\Pi$  iff all its connected components are in  $\Pi$ ), then its query complexity is  $O(t(\epsilon/4)/\epsilon)$  and the tester has one-sided error.*<sup>6</sup>

Note that by Theorem 1.3, testing bipartiteness of subgraphs of any (bounded-degree) planar graph  $G$  has complexity  $\text{poly}(1/\epsilon)$ , whereas (by [17]) testing bipartiteness of  $n$ -vertex graphs in the BDG model has complexity  $\Omega(\sqrt{n})$ .<sup>7</sup>

**Testing in the subgraph model may not be easier (than in the BDG model).** On the other hand, there are cases in which the testers provided by Theorem 1.2 are essentially the best possible. Indeed, these cases correspond to base graphs that are not hyperfinite.

<sup>6</sup> In general, the tester has two-sided error and the query complexity is at most exponential in  $O(t(\epsilon/4)^2)$ .

<sup>7</sup> As discussed in Section 1.5.1, weaker results may be obtained by using testers for the BDG model that work under the corresponding promise.

► **Theorem 1.4** (testing  $c$ -colorability of subgraphs of general bounded-degree base graphs (see [19, Sec. 3])).

1. *There exist explicit bounded-degree graphs  $G = ([n], E)$  such that testing whether a subgraph of  $G$  is bipartite, with proximity parameter  $1/\text{poly}(\log |E|)$ , requires  $\tilde{\Omega}(\sqrt{|E|})$  queries.*
2. *There exist bounded-degree graphs  $G = ([n], E)$  such that testing whether a subgraph of  $G$  is 3-colorable, with constant proximity parameter, requires  $\Omega(|E|)$  queries.*

Item 2 asserts that the complexity of testing 3-Colorability in the subgraph model may be linear, just as in the BDG model. Item 1 should be contrasted with the tester obtained by applying Theorem 1.2 to the known tester for the BDG model [16]. The derived tester has complexity  $\text{poly}(1/\epsilon) \cdot \tilde{O}(\sqrt{|E|})$ , where  $\epsilon$  denotes the proximity parameter, whereas Item 1 implies that one cannot obtain better complexity in terms of  $\epsilon$  and  $|E|$  (e.g., complexity  $\text{poly}(1/\epsilon) \cdot Q(|E|)$  is possible only for  $Q(n) = \tilde{\Omega}(\sqrt{n})$ ).

### 1.2.2 Other properties (i.e., non downward-monotone properties)

When turning to graph properties that are not downward-monotone, the statement of Theorem 1.2 no longer holds. There exist graph properties that are significantly harder to test in the subgraph model than in the BDG model. Specifically:

► **Theorem 1.5** (testing in the subgraph model may be harder than in the BDG model (see [19, Sec. 4])). *There exists a property of graphs  $\Pi$  for which the following holds. On one hand,  $\Pi$  is testable in  $\text{poly}(1/\epsilon)$ -time in the bounded-degree graph model. On the other hand, there exist explicit graphs  $G = ([n], E)$  of constant degree such that testing whether a subgraph of  $G$  satisfies  $\Pi$  requires  $\Omega(\log \log n)$  queries. Furthermore, the property  $\Pi$  is (upwards) monotone, and the family of base graphs is hyperfinite.<sup>8</sup>*

The first part of the furthermore-clause implies that a result analogous to Theorem 1.2 does not hold for monotone (rather than downward-monotone) graph properties. The second part of the furthermore-clause implies that also a result analogous to Theorem 1.3 does not hold for monotone graph properties.

We comment that the property  $\Pi$  used in Theorem 1.5 is related to being Eulerian, and the base graphs are related to a cyclic grid. Hence, it is interesting to note that testing whether subgraphs of a cyclic grid are Eulerian can be done in complexity that only depends on the proximity parameters (see [19, Prop. 4.2]).

Turning back to monotone graph properties, we first note the trivial case in which the base graph  $G$  does not have the property (which implies that all its subgraphs lack this property as well). A non-trivial case is that of testing minimum degree (see Proposition 2.1). A more interesting case is that of connectivity.

► **Proposition 1.6** (testing connectivity in the subgraph model – see Section 2.1). *For every base graph  $G = ([n], E)$ , testing whether a subgraph of  $G$  is connected can be done in  $\text{poly}(1/\epsilon)$ -time.*

We mention that even the case of 2-edge connectivity, which has an efficient tester in the BDG model, seems challenging in the subgraph testing model (see Problem 1.9).

---

<sup>8</sup> See the definition of hyperfinite graphs preceding Theorem 1.3.

**A relatively general positive result.** We next state a result for a class of properties that are not downward-monotone (and not necessarily monotone either). This result is of the flavor of Theorem 1.2, but introduces an overhead that is logarithmic in the number of vertices. Specifically, we refer to the class of all graph properties that have proximity-oblivious testers of constant query complexity (in the BDG model) [18, Sec. 5]. We mention that such properties are “local” in the sense that satisfying them can be expressed as the conjunction of conditions that refer to constant-distance neighborhood in the graph (see Definition 2.4).

► **Theorem 1.7** (testing local properties in the subgraph model (see Section 2.3)). *Let  $\Pi$  be a local property and suppose that the base graph  $G$  is outerplanar and of bounded degree. Then, testing whether a subgraph of  $G = ([n], E)$  has property  $\Pi$  can be done using  $O(\epsilon^{-1} \log n)$  queries.*

The result stated in Theorem 1.7 extends to every graph having constant-size separating sets (the dependence on the size of the separating sets is given explicitly in Theorem 2.5).

**Testing in the subgraph model may be easier than in the BDG model.** Lastly we note that moving from the BDG model to the subgraph testing model makes the testing task *potentially* easier, since the subgraph tester knows *a priori* the possible locations of edges. This is reflected by the following result, which refers to any (bounded-degree) base graph.

► **Theorem 1.8** (a property that is extremely easier in the subgraph model). *For every constant  $d$ , there exists a graph property  $\Pi_d$  that requires linear query complexity in the bounded-degree model but can be tested using  $O(1/\epsilon)$  queries in the subgraph model w.r.t. every base graph of maximum degree  $d$ .*

Since the proof of Theorem 1.8 is short and simple, we provide it next.

**Proof.** Fixing  $d$ , let  $\Pi_d$  be a set of  $d$ -regular graphs such that testing  $\Pi_d$  in the BDG model (with degree bound  $d$ ) requires a linear number of queries (e.g.,  $\Pi_d$  is the set of 3-colorable  $d$ -regular graphs [4]). To establish the upper bound in the subgraph model, observe that for any base graph  $G$  that has maximum degree  $d$ , the only subgraph of  $G$  that may be  $d$ -regular is  $G$  itself. Therefore, if the base graph  $G$  is not in  $\Pi_d$ , then the subgraph-tester can reject without performing any queries. If  $G \in \Pi_d$ , then the subgraph-tester simply tests whether the subgraph of  $G$  is  $G$  itself (by performing  $O(1/\epsilon)$  queries). ◀

The proof of Theorem 1.8 begs the question of whether the theorem holds also for downward-monotone properties, and more generally, which properties  $\Pi_d$  can be tested using  $O(1/\epsilon)$  queries in the subgraph model *w.r.t. every base graph of maximum degree  $d$* ? Alternatively, one may reverse the order of quantifiers and ask whether there exists a graph property  $\Pi$  that satisfies the conclusion of Theorem 1.8 *for any constant  $d$* .

### 1.3 Techniques

Some of the testers (algorithms) presented in this paper (e.g., Theorems 1.3 and 1.7) are based on structural properties of the base graph. In some cases (e.g., Theorem 1.3) these structural properties, which are inherited by the subgraphs, make the testing task (in the subgraph model) easier than in the BDG model. The proofs of the lower bounds constitute the more technically challenging part of the paper. Typically, the challenge is emulating lower bounds obtained for other testing models on the subgraph testing model. The brief overviews, especially those referring to the lower bounds, are merely intended to give a flavor of the techniques (and are not supposed to convince the reader of the validity of the claims).

### 1.3.1 Algorithms

The tester used in proving Theorem 1.2 is a simple emulation of the BDG-model tester by the subgraph tester, and its analysis is based on the observation that the distance between a graph  $G'$  and a downward-monotone graph property  $\Pi$  equals the number of edges that should be omitted from  $G'$  in order to place the resulting graph in  $\Pi$ . Proposition 1.6 is also proved by a simple emulation of the BDG-model tester, but the analysis of the resulting tester relies on special features of connectivity (and does not extend to 2-connectivity; see Problem 1.9).

The proofs of Theorems 1.3 and 1.7 are more interesting. In both cases we reduce testing subgraphs of the base graph  $G$  to testing subgraphs of a fixed subgraph  $G'$  of  $G$  such that  $G'$  is close to  $G$  and testing subgraphs of  $G'$  is (or seems) relatively easier. Such a reduction is valid since the property that we test is downward-monotone, and the subgraph  $G'$  is found without making any queries.

In the proof of Theorem 1.3 the fixed subgraph  $G'$  consists of small connected components. Hence, in the special case of Theorem 1.3 (i.e., properties that are determined by their connected components), it suffices to test that the subgraphs induced by the connected components of the base graph have the relevant property. In the general case, we follow Newman and Sohler [29] in estimating the frequency of the various graphs that are seen in these induced subgraphs. We stress that, unlike in [29], we do not use a *partition oracle of the tested graph* (which may be implemented based on standard queries (following Hassidim et al. [22])), but rather determine such a *partition of the base graph* (without making any queries).

Theorem 1.7 is proved by applying a recursive decomposition of the base graph using constant-size separating sets. Essentially, in addition to checking the local neighborhood of random vertices, we also check the local neighborhoods of the vertices in the separating sets that correspond to the path in the recursion tree (i.e., the tree of recursive decomposition) that isolates the chosen vertices. Actually, we check that all these local neighborhoods are consistent with some subgraph that has the property. These additional checks are used in the analysis in order to establish the consistency of the various local neighborhoods (i.e., not only those examined in the same execution).

We highlight the fact that the foregoing testers are non-adaptive. This is remarkable, because the corresponding testers for the BDG model (which in some cases are actually emulated by our testers) are inherently adaptive. However, these “BDG model testers” utilize their adaptivity only for conducting local searches in the input graph, whereas in the subgraph testing model the input is a subgraph of a fixed (or *a priori* known) graph, and so the queries that support these local searches can be determined non-adaptively.

### 1.3.2 Lower bounds

The lower bound on testing 3-colorability of a subgraph (asserted in Part 2 of Theorem 1.4) is established by combining the query complexity lower bound of [2] with a variant of the standard reduction of 3SAT to 3COL (cf. [12, Prop. 2.27]). Recall that Ben-Sasson et al. [2] prove the existence of (sparse) 3CNF formulae for which testing satisfiability of a given assignment requires linear query complexity. We reduce this testing problem, which refers to an explicitly given 3CNF formula (viewed as a massive parameter), to testing 3-colorability of a subgraph of a base graph. That is, we view the NP-reduction of 3SAT to 3COL as a mapping of a parameter (i.e., 3CNF formula) of one testing problem to a parameter (i.e., base graph) of another testing problem. In addition, we establish a one-to-one correspondence between

■ **Figure 2** A subgraph of the 2-by-8 grid that misses 4 edges. The subgraph is marked by solid lines, the missing edges by dashed lines, and an external edge that makes this subgraph 2-connected is dotted.

the bits of the assignment and part of the edges in the base graph, while considering only subgraphs that contain all other edges of the base graph (i.e., those not in correspondence to the bits of the assignment).

The proof of Item 1 of Theorem 1.4 (which refers to testing 2-colorability of a subgraph) is more complicated. The basic idea is to emulate the lower bound on bipartite testing established in the BDG model [17]. The obvious question is what should be the base graph. It is natural to pick a base graph that allows an embedding of any bounded-degree graph in it such that edges of the embedded graph are mapped to short vertex-disjoint paths. Furthermore, the mapping of edges to paths should be determined in a local manner. We use a base graph that is related to a routing network of logarithmic depth, and employ (randomized) oblivious routing on it. This allows us to map bipartite graphs (of the BDG model) to bipartite subgraphs of the base graph, while mapping graphs that are far from bipartite (in the BDG model) to subgraphs that are far from bipartite (in the subgraph testing model). The actual analysis of this construction is quite complicated (as evident from the length of [19, Sec. 3.1]), because we have to *locally emulate* a subgraph of the base graph (by making few queries to the input graph in the BDG model).

The proof of Theorem 1.5 uses a reduction from testing Eulerian orientations of cyclic grids in the orientation model. As discussed in Section 1.5.2, the orientation model (presented by Halevy et al. [21]) is related but different from the subgraph testing model. Our reduction maps the (cyclic) grid, used in the lower bound of Fischer et al. [11], to a base graph that looks like such a grid, except that edges are replaced by small gadgets. The orientations of edges in the orientation model are mapped to choices of subgraphs of the corresponding gadgets. In this case, it is easy to locally emulate a subgraph of the base graph by making queries to the orientation oracle, and the claimed  $\Omega(\log \log n)$  lower bound follows (from the analogous lower bound of [11]). On the other hand, the property at the image of the reduction is local, and so it is testable within  $\text{poly}(1/\epsilon)$  queries in the BDG model.

## 1.4 Open problems

Moving from the BDG model to the subgraph testing model makes the testing task potentially easier, since the subgraph tester knows *a priori* the possible locations of edges. But, when dealing with properties that are not downward-monotone, there is an opposite effect that arises from the fact that the distance to the set of subgraphs (of  $G$ ) that have graph property  $\Pi$  may be much bigger than the distance to the set of (bounded-degree) graphs that have property  $\Pi$ . This may require the subgraph tester to reject the input (since its distance to  $\Pi \cap \mathcal{F}_G$  is large), whereas the BDG model tester may be allowed to accept the input (since its distance  $\Pi$  is small). This difficulty is reflected in the following open problems.

► **Problem 1.9** (testing 2-connectivity of subgraphs). *Is the query complexity of testing 2-edge-connectivity in the subgraph testing model independent of the size of the graph? What about  $c$ -edge-connectivity for any constant  $c \in \mathbb{N}$ ?*

Recall that  $c$ -connectivity is testable in the BDG model within complexity that depends only on the proximity parameter [17]. We note that a straightforward emulation of the BDG-model tester (for 2-connectivity) calls for trying to find a small 2-connected component that has a cut of size at most 1 to the rest of the graph. But this approach fails when considering a base graph that is a 2-by- $n$  grid (since, as illustrated in Figure 2, any subgraph that misses at most one horizontal edge of each vertex (of degree 4) is  $O(1/n)$ -close to being 2-connected but may be far from any 2-connected subgraph of the 2-by- $n$  grid).

The straightforward emulation of the BDG-model tester also fails for testing whether a subgraph of the  $n$ -cycle is a perfect matching (i.e., is 1-regular), but a tester that considers the locations of edges in the subgraph does work (we discuss this shortly at the very end of [19, Sec. 4]). Testers of complexity that does not depend on the graph size do exist for this property when the base graph is a tree (since each tree has at most one perfect matching)<sup>9</sup>, but we do not know if they exist when the graph is outerplanar.

► **Problem 1.10** (testing whether the subgraph is a perfect matching). *What is the complexity of testing 1-regularity when the base graph is outerplanar? What about the case that the base graph is planar (e.g., a grid)? And what about testing degree-regularity?*

Note that  $c$ -connectivity, degree-regularity, and Eulerianity are the only properties covered in [14, Chap. 9] that are not downward-monotone. Also note that [19, Prop. 4.2] refers to the complexity of testing the Eulerian property for a base graph that is a grid, and it is clear that the underlying ideas apply to base graphs of “similar structure” (as arising in the proof of [19, Prop. 4.2]). But what about going beyond that?

► **Problem 1.11** (testing whether the subgraph is Eulerian). *What is the complexity of testing the Eulerian property in any base graph of bounded degree?*

The foregoing problems are all rooted in the difficulties that are introduced by the fact that distances under the subgraph model may be significantly larger than under the BDG model, which makes the task of the tester potentially harder. On the other hand, the fact that the base graph is known to the tester makes its task potentially easier. Recalling that only the latter effect is relevant in the case of downward-monotone properties, begs the following question.

► **Problem 1.12** (a property that is always easier in the subgraph model). *Does there exist a downward-monotone graph property  $\Pi$  such that testing  $\Pi$  in the bounded-degree model has higher query complexity than testing  $\Pi$  in the subgraph model w.r.t. every base graph of bounded-degree?*

Recall that Theorem 1.8 refers to an upward-monotone property (which depends on the degree bound).

The foregoing problems are aimed at concretizing the abstract challenge of making better use of the knowledge of the base graph that is available to the tester. Although Theorem 1.4 indicates that this extra knowledge is not always helpful, other results point out to cases in which it is helpful. We would like to see more such cases and more substantial use of the knowledge of the base graph.

---

<sup>9</sup> This perfect matching is determined by a pruning process (started at the leaves), and the tester just checks that the subgraph equals this perfect matching (if it exists). Note that, also in this case, the tester does not emulate the BDG-model tester (which just samples vertices and checks their degree); such an emulation will fail poorly (even when the base graph is a path).

## 1.5 Related models

### 1.5.1 Testing under a promise

As mentioned earlier, testing graph properties under the promise that the tested graph has some (other) property was considered before (see discussion in [14, Sec. 12.2]). In fact, the bounded-degree graph model itself may be viewed as postulating such a promise. More conspicuous cases include the study of testing under the promise that the graph is hyperfinite [29] or more specifically planar [3], or with bounded tree-width [7]. In continuation to Theorem 1.2, we observe that testing downward-monotone graph properties in the subgraph model can be reduced to testing the same property under a promise that contains the base graph.

► **Theorem 1.13** (a generalization of Theorem 1.2). *Let  $\mathcal{G}$  and  $\Pi$  be downward-monotone graph properties such that  $\mathcal{G}$  contains graphs of degree at most  $d$ . Suppose that, when promised that the tested graph is in  $\mathcal{G}$ , the property  $\Pi$  is testable (in the bounded-degree graph model) with query complexity  $Q_{\mathcal{G}}(\cdot, \cdot)$ , where  $Q_{\mathcal{G}}$  is a function of the proximity parameter and (possibly) the size of the graph. Then, for every base graph  $G = ([n], E)$  in  $\mathcal{G}$ , testing whether a subgraph of  $G$  satisfies  $\Pi$  (with proximity parameter  $\epsilon$ ) can be done with query complexity  $d \cdot Q_{\mathcal{G}}(\epsilon', n)$ , where  $\epsilon' = \epsilon/d$ .*

Hence, results weaker than Theorem 1.3 may be obtained by combining Theorem 1.13 with the tester provided in [29] (see discussion in Section 2.2). Indeed, the improved results are due to the fact that in the subgraph model the tester is given the base graph for free. In the current case (of hyperfinite graphs), the tester does not need to query the tested graph in order to obtain a partition oracle of the tested graph; it may just use an adequate partition of the base graph. In general, a main challenge in the study of the subgraph model is in how to utilize the knowledge of the base graph in order to improve the complexity of testing.

### 1.5.2 The orientation model

A property testing model that is related to the subgraph model is the *orientation model*, which was introduced by Halevy et al. [21]. Similarly to the subgraph model, in the orientation model there is a fixed (undirected) base graph  $G = ([n], E)$ . However, the goal in the latter model is to test properties of *directed graphs* (digraphs) that are defined by *orientations* of the edges of  $G$ . That is, for each edge  $\{u, v\} \in E$ , either the edge is directed from  $u$  to  $v$ , or from  $v$  to  $u$ , and the algorithm may perform queries in order to obtain the orientation of edges of its choice. For a property  $\Pi$  of digraphs, the algorithm should distinguish (with probability at least  $2/3$ ) between the case that the tested orientation  $\vec{G}$  has the property  $\Pi$  and the case in which the orientation of more than  $\epsilon \cdot |E|$  edges should be flipped in order to obtain the property.

While the subgraph model and the orientation model are syntactically identical, the semantics are very different, as we explain next. Similarly to the subgraph model, an orientation  $\vec{G} = ([n], \vec{E})$  of  $G$  is defined by a function  $f : E \rightarrow \{0, 1\}$ . Here,  $f(e) = 1$  indicates that in  $\vec{G}$  the edge  $e$  is directed from its smaller (id) endpoint to its larger endpoint. Querying the orientation of an edge hence corresponds to querying  $f$ , and distance between two functions  $f$  and  $f'$  (representing two different digraphs) is simply the Hamming distance between the functions.

The fundamental difference in the semantic between the two models is reflected in the fact that natural properties of digraphs in the orientation model do not correspond to nature properties of graphs in the subgraph testing model, and vice versa. For example, the functions

$f$  that define Eulerian orientations of an undirected graph  $G = ([n], E)$  (as described above) do not necessarily define subgraphs of  $G$  (i.e., in which  $f(e) = 1$  indicates that  $e$  belongs to the subgraph) that are Eulerian. Hence, natural properties in one model do not necessarily translate to natural properties in the other model. Still, it may be possible to emulate or reduce testing properties in one model to testing properties in the other model, as we do in the proof of Theorem 1.5.

## 2 Algorithms

In this section we prove Theorems 1.2, 1.3, and 1.7 (as well as Propositions 1.6 and 2.1). These results refer to different types of base graphs and different classes of properties. We have organized them according to the type of the base graph. Recall that  $G$  is assumed to have no isolated vertices, so that  $|E| \geq n/2$ .

### 2.1 General bounded-degree base graphs

In this section  $d \geq 2$  is a fixed constant, and the base graph  $G$  is an arbitrary graph in which each vertex has degree at most  $d$  (and at least 1).

#### 2.1.1 Testing downward-monotone properties

We first consider any graph property  $\Pi$  that is preserved under edge omission. Such properties are called *downward-monotone* or *downwards monotone*. We prove Theorem 1.2, which asserts that *for every graph  $G = ([n], E)$  of degree at most  $d$  and any downward-monotone graph property  $\Pi$ , testing  $\Pi \cap \mathcal{F}_G$  in the subgraph model (w.r.t. the base graph  $G$ ) is not harder than testing  $\Pi$  in the bounded-degree graph (BDG) model.*

**Proof of Theorem 1.2.** Given oracle access to  $f : E \rightarrow \{0, 1\}$ , the subgraph tester invokes the tester of the BDG model, and emulates an incidence oracle for the subgraph of  $G$  represented by  $f$  in the natural manner. That is, the query  $(v, i) \in [n] \times [d]$  is answered with the  $i^{\text{th}}$  vertex in the set  $\Gamma_f(v) = \{u : \{u, v\} \in E \ \& \ f(u, v) = 1\}$ , where vertices are ordered arbitrarily (e.g., by lexicographic order), and the answer is  $\perp$  if  $|\Gamma_f(v)| < i$ . This means that each query  $(v, i)$  of the BDG model tester, denoted  $T$ , is answered by first retrieving  $\Gamma_f(v)$ , which in turn amounts to making at most  $d$  queries to  $f$  (i.e., querying all edges incident to  $v$  in  $G$ ). Hence, the subgraph tester emulates the execution of  $T$  on the graph  $G^f = ([n], \{e \in E : f(e) = 1\})$ .

In the analysis, downward monotonicity is used to associate distance from  $\Pi$  in each of the two models with the number of edges that should be omitted from the subgraph. Specifically, in both cases, the distance from the property reflects the number of edges that should be omitted in order to make the graph satisfy the property (because adding edges never decreases that distance). Specifically, if  $f \in \Pi \cap \mathcal{F}_G$ , then  $G^f \in \Pi$ , and  $T$  accepts (with probability at least  $2/3$  in general, and with probability 1 if  $T$  has one-sided error). On the other hand, if  $f : E \rightarrow \{0, 1\}$  is  $\epsilon$ -far from  $\Pi \cap \mathcal{F}_G$ , then (by downward-monotonicity of  $\Pi$ ) any graph in  $\Pi$  that is closest to  $G^f$  must be a subgraph of  $G^f$  (i.e., is in  $\Pi \cap \mathcal{F}_G$  and so differs from  $G^f$  on more than  $\epsilon \cdot |E|$  edges). It follows that  $G^f$  is  $\epsilon'$ -far from  $\Pi$  for  $\epsilon' = \frac{\epsilon \cdot |E|}{dn/2} \geq \frac{\epsilon}{d}$ .  $\blacktriangleleft$

**Proof of Theorem 1.13.** The proof is identical to the proof of Theorem 1.2, except that here we rely on the hypothesis that  $\mathcal{G}$  is downward-monotone.  $\blacktriangleleft$

### 2.1.2 Testing monotone properties

Theorem 1.2 does not apply to monotone properties. Still, several such properties are quite easy to test in the subgraph testing model. One simple example is the property of having a specified minimal degree.

► **Proposition 2.1** (testing minimal degree in the subgraph model). *For  $d' \geq 1$ , testing whether all vertices in the subgraph have degree at least  $d'$  can be done in time  $O(d/\epsilon)$ .*

**Proof.** If  $d'$  is bigger than the minimum degree of the base graph  $G = ([n], E)$ , then the tester rejects without performing any queries. Otherwise, the tester selects  $\Theta(1/\epsilon)$  vertices, uniformly at random, and computes their degrees in the tested subgraph  $G^f$ , by querying all their incident edges in  $G$ . The tester accepts if and only if all sampled vertices have degree at least  $d'$ .

Hence, the tester makes  $O(d/\epsilon)$  queries, and always accepts subgraphs that have the property. To prove that it rejects subgraphs that are  $\epsilon$ -far from having the property with probability at least  $2/3$ , we establish the contrapositive statement. Consider a graph  $G^f$  that is accepted with probability at least  $1/3$ . This implies that the number of vertices in  $G^f$  whose degree is smaller than  $d'$  is at most  $(\epsilon/2) \cdot n$ . Since in  $G$  every vertex has degree at least  $d'$ , it is possible to add edges to  $G^f$  in order to obtain a subgraph that has the property, whereas the number of required added edges is at most  $(\epsilon n/2) \cdot d' \leq \epsilon \cdot |E|$ . ◀

**Proof of Proposition 1.6.** We now turn to the proof of Proposition 1.6, which asserts a  $\text{poly}(d/\epsilon)$ -time tester for connectivity in the subgraph model. If the base graph  $G = ([n], E)$  is not connected, then testing is trivial (since all subgraphs of  $G$  are disconnected). Otherwise (i.e., the base graph  $G$  is connected), connectivity of the input  $f \in \mathcal{F}_G$  can be tested by emulating the tester used for the BDG model [17]. This tester samples vertices and explores their local neighborhood in search of small connected components.

The analysis is even simpler than the original (bounded-degree) one since we can add edges without worrying about the degree bound (similarly to the analysis of testing connectivity in the sparse (unbounded-degree) model [30]). Specifically, we use the fact that if  $f$  represents a subgraph with  $t$  connected components, then by modifying  $f$  at one entry we can obtain a function that represents a subgraph with  $t - 1$  connected components. (This relies on the fact that  $G$  must contain edges between the connected components of  $G^f$ .) ◀

As noted in the introduction (see Section 1.4), the argument does not extend to 2-connectivity. The reason is that in that case the known tester for the BDG model [17] does not search for arbitrary 2-connected components but rather for 2-connected components that are connected to the rest of the graph by at most one edge. The problem with that tester is that its analysis requires the ability to add edges between any given pair of such 2-connected components, whereas we can only add edges that exist in the base graph.

## 2.2 Hyperfinite base graphs

A graph  $G = ([n], E)$  is said to have an  $(\epsilon, t)$ -partition if its vertex set can be partitioned into connected components of size at most  $t$  such that the number of edges between these components is at most  $\epsilon n$ .

Recall that a graph  $M$  is called a **minor** of a graph  $G$  if  $M$  is isomorphic to a graph that can be obtained by (zero or more) edge contractions on a subgraph of  $G$ . A graph  $G$  is  $M$ -minor free if  $M$  is not a minor of  $G$ . If  $G$  has degree at most  $d$  and is minor-free (i.e.,  $G$  is  $M$ -minor free for some fixed subgraph  $M$ ), then it has an  $(\epsilon, O((d/\epsilon)^2))$ -partition, for every  $\epsilon > 0$  (the size of  $M$  is “hidden” in the  $O(\cdot)$  notation – see [1, 22]).

More generally, Theorem 1.3 refers to any family of hyperfinite graphs, where a family of graph  $\mathcal{G}$  is hyperfinite if there exists a function  $t : (0, 1) \rightarrow \mathbb{N}$  such that, for every  $\epsilon > 0$ , every graph in the family has an  $(\epsilon, t(\epsilon))$ -partition. We shall first prove the second clause in the theorem, which refers to downward-monotone properties that are additive (i.e., determined by the connected components of the graph).

**A special case of interest.** We say that a graph property  $\Pi$  is additive if it holds that a graph is in  $\Pi$  if and only if all its connected components are in  $\Pi$ . We comment that not every downward-monotone graph property is additive. For example, consider the graph property  $\Pi$  that consists of all graphs that either constitute of a single (Hamiltonian) cycle or consist of a collection of isolated paths and vertices. Note that  $\Pi$  is closed under omission of edges and vertices, but a graph that consists of several isolated cycles is not in  $\Pi$  (i.e.,  $\Pi$  is not additive).<sup>10</sup>

► **Proposition 2.2** (testing downward-monotone properties that are additive). *Let  $\Pi \neq \emptyset$  be a downward-monotone graph property that is additive. Let  $G = ([n], E)$  be a graph of maximum degree  $d$ , and  $t : (0, 1) \rightarrow \mathbb{N}$  be such that, for every  $\epsilon > 0$ , the graph  $G$  has an  $(\epsilon, t(\epsilon))$ -partition. Then, testing whether a subgraph of  $G$  is in  $\Pi$  can be done by performing  $O(d^2 \cdot t(\epsilon/4)/\epsilon)$  queries. Furthermore, the tester is non-adaptive and has one-sided error.*

In particular, Proposition 2.2 implies that, for every fixed graph  $M$ , testing bipartiteness of a subgraph of  $G$ , when  $G$  is  $M$ -minor free, can be done in  $\text{poly}(d/\epsilon)$ -time, when given an  $(\epsilon/4, O((d/\epsilon)^2))$ -partition of  $G$ .<sup>11</sup> This is much more efficient than testing bipartiteness in the bounded-degree model, for which the query complexity is  $\Omega(\sqrt{n})$  [17]. It is also more efficient than testing bipartiteness of bounded-degree graphs under the promise that the graph is minor-free, let alone under the weaker promise that the graph is  $t$ -hyperfinite. Indeed, under these promises, the tester may implement an  $(\epsilon/4, t(\epsilon/4))$ -partition oracle of the tested subgraph, but such an implementation requires more than  $\text{poly}(t(\epsilon/4))$  queries. Specifically, in the special case of minor-free graphs the best implementation known uses  $O(d/\epsilon)^{O(\log(1/\epsilon))}$  queries [26], whereas in the general ( $t$ -hyperfinite) case the best implementation known uses  $\exp(d^{O(t(\text{poly}(1/\epsilon)))})$  queries [22],

**Proof Sketch.** Let  $(C_1, \dots, C_r)$  be an  $(\epsilon/4, t(\epsilon/4))$ -partition of  $G$ . Given query access to  $f : E \rightarrow \{0, 1\}$ , which represents the subgraph  $G^f = ([n], \{e \in E : f(e) = 1\})$ , we select at random  $\Theta(d/\epsilon)$  vertices, and for each selected vertex  $v$  we inspect all edges in the subgraph of  $G = ([n], E)$  induced by the part  $C_i$  that contains  $v$  (i.e., we query all pairs  $(u, w) \in E \cap (C_i \times C_i)$ ). We accept if and only if all the retrieved subgraphs are in  $\Pi$ ; that is, we accept if and only if for each inspected  $C_i$  it holds that the subgraph of  $G^f$  induced by  $C_i$  is in  $\Pi$ .

Using the fact that  $\Pi$  is preserved by omission of edges (and omission of connected components), we observe that if  $G^f$  is in  $\Pi$ , then so are the subgraphs of  $G^f$  induced by the  $C_i$ 's. Hence, our tester accepts  $G^f \in \Pi$  with probability 1. On the other hand, if  $G^f$  is  $\epsilon$ -far from  $\Pi$ , then the subgraph of  $G^f$  obtained by omitting all edges between the  $C_i$ 's is  $(\epsilon/2)$ -far from  $\Pi$  (since  $(\epsilon/4)n \leq (\epsilon/2)|E|$ ). Denoting the latter subgraph by  $\hat{G}^f$ , we claim that at least  $(\epsilon/4)n/d$  of its vertices reside in connected components that are not in  $\Pi$ , and it follows that the tester rejects  $G^f$  with high probability (since each connected component is contained in one of the  $C_i$ 's).

<sup>10</sup> Indeed, if a graph is in (this)  $\Pi$ , then all its connected are in  $\Pi$ , but the converse does not hold.

<sup>11</sup> Such a partition can be found in polynomial-time [1].

The foregoing claim is proved by relying on the hypothesis that  $\Pi$  is additive. Specifically, if less than  $(\epsilon/4)n/d$  vertices reside in connected components that are not in  $\Pi$ , then by omitting less than  $(\epsilon/4)n < (\epsilon/2)|E|$  edges we can make all connected components reside in  $\Pi$  (since  $\Pi$  contains the graph consisting of a single vertex). This implies that the graph consisting of these modified connected components is in  $\Pi$ , which in turn contradicts the hypothesis that  $\hat{G}^f$  is  $(\epsilon/2)$ -far from  $\Pi$ . ◀

**Greater generality at larger cost.** A more general result refers to graph properties  $\Pi$  that are only preserved under edge omission (and to hyperfinite base graphs  $G$ ). The cost of this generalization is an increase in the query complexity of the tester, as asserted next.

► **Proposition 2.3** (testing general downward-monotone properties). *Suppose that  $\Pi$  is a downward-monotone graph property and that, for some  $t : [0, 1] \rightarrow \mathbb{N}$  and every  $\epsilon > 0$ , the graph  $G = ([n], E)$  has an  $(\epsilon, t(\epsilon))$ -partition. Then, we can test whether a subgraph of  $G$  is in  $\Pi$  with query complexity  $O(d^2 \cdot \exp(t(\epsilon/4)^2)/\epsilon^2)$ .*

We mention that the exponential dependence on  $t$  of query complexity of the foregoing tester is unavoidable (in the general case of downward-monotone graph properties). Consider, for example, the case that the base graph is an  $\sqrt{n}$ -by- $\sqrt{n}$  grid augmented by diagonal edges in each small square, and the following downward-monotone property  $\Pi$ : A graph is in  $\Pi$  if there exists a  $k$  such that the graph consists of connected component that are each a  $k$ -by- $k$  grid augmented by some of the foregoing diagonal edges such that at most half of the possible patterns occur in these small grids. Now, on proximity parameter  $\epsilon > 0$ , consider the task of distinguishing the case that the subgraph consists of  $0.1/\epsilon$ -by- $0.1/\epsilon$  grids in which half of the possible patterns occur from the case in which all patterns occur. A lower bound that is a square root of the number of patterns follows from a birthday paradox argument (and a lower bound that is almost linear follows from [34, 33]).

**Proof Sketch.** By the premise of the proposition, for every  $\epsilon > 0$ , the base graph  $G$  has an  $(\epsilon/4, t(\epsilon/4))$ -partition. Let  $g \in \mathcal{F}_G$  denote the all-ones function, and let  $g'$  be  $\epsilon/2$ -close to  $g$  and describe a subgraph of  $G$  in which each connected component has size at most  $t(\epsilon/4)$ . Hence,  $G^{g'}$  is a subgraph of  $G$  that is obtained from  $G$  by removing the at most  $(\epsilon/4)n \leq (\epsilon/2)|E|$  edges between parts in the  $(\epsilon/4, t(\epsilon/4))$ -partition.

By the closure of  $\Pi$  to edge omissions, every function  $f \in \mathcal{F}_G \cap \Pi$  is  $0.5\epsilon$ -close to the function  $f' \in \mathcal{F}_G \cap \Pi$  such that  $f'(e) = f(e) \wedge g'(e)$ . Let  $\Pi'_G$  denote the set of graphs obtained in this way; that is,  $\Pi'_G = \{f \wedge g' : f \in \mathcal{F}_G \cap \Pi\}$ . Since  $\Pi$  is a graph property, it follows that  $\Pi'_G = \mathcal{F}_G \cap \Pi'$ , where  $\Pi'$  is the set of all graphs that are isomorphic to graphs that appear in  $\Pi'_G$ . Hence, the set  $\Pi'_G$  is closed under all automorphisms of the graph  $G$ .

Recalling that  $\Pi'_G$  and likewise  $\Pi'$  contain only graphs that consist of connected components of size at most  $t = t(\epsilon/4)$ , it follows  $\Pi'$  is characterized by the frequencies in which the various graphs of size at most  $t$  appear as connected components. Hence,  $f \in \mathcal{F}_G$  describes a graph in  $\Pi$  if and only if  $f' = f \wedge g'$  is in  $\mathcal{F}_G \cap \Pi'$ , where  $\Pi'$  is characterized in terms of the number of connected component that are isomorphic to each of the graphs with at most  $t(\epsilon/4)$  vertices (and contain no smaller connected components). It follows that testing with proximity parameter  $\epsilon$  whether subgraphs of  $G$  satisfy  $\Pi$  can be performed by estimating these numbers in the subgraph described by  $f \wedge g'$ , where  $f$  is the tested function. Lastly, we note that estimating the frequencies in which the various  $t(\epsilon/4)$ -vertex graphs appear as connected components can be done using  $O(d^2 \cdot \exp(t(\epsilon/4)^2)/\epsilon^2)$  queries, where  $\exp(t(\epsilon/4)^2)$  account for the number of  $t(\epsilon/4)$ -vertex graphs. ◀

### 2.3 Local properties and base graphs with small separators

Loosely speaking, a graph property is called *local* if satisfying it can be expressed as the conjunction of local conditions, where each local condition refers to a constant-distance neighborhood of one of the graph's vertices. A precise definition is given next.

► **Definition 2.4.** For a constant  $\ell \in \mathbb{N}$ , the  $\ell$ -neighborhood of a vertex  $v$  in a graph  $G$  is the subgraph of  $G$  induced by all vertices that are at distance at most  $\ell$  from  $v$ . A property  $\Pi$  of  $n$ -vertex graphs is called  $\ell$ -local if there exists a graph property  $\Pi'$  such that  $G$  is in  $\Pi$  if and only if the  $\ell$ -neighborhood of each vertex in  $G$  is in  $\Pi'$ . (Actually,  $\Pi'$  is a set of rooted graphs, where the root corresponds to the “center” of the  $\ell$ -neighborhood.)<sup>12</sup> A graph property  $\Pi = \bigcup_n \Pi_n$  is local if there exists a constant  $\ell$  such that  $\Pi_n$  is an  $\ell$ -local property of  $n$ -vertex graphs.

We mention that this definition coincides with [18, Def. 5.2], and that (in the bounded degree graph model) every graph property that has a proximity-oblivious tester of constant query complexity is local [18, Sec. 5].

For  $s : \mathbb{N} \rightarrow \mathbb{N}$  we say that a graph  $G = ([n], E)$  has separating sets of size  $s$  if for every set of vertices  $U \subseteq [n]$  there exists a subset  $S \subseteq U$  of at most  $s(|U|)$  vertices such that the subgraph of  $G$  induced by  $U \setminus S$  has no connected component of size greater than  $\frac{2}{3} \cdot |U|$ . For example, every tree has separating sets of size 1, every outerplanar graph has separating sets of size 2 [23, Lem. 3], and  $n$ -vertex planar graphs have separating sets of size  $O(\sqrt{n})$  [27].

► **Theorem 2.5** (Theorem 1.7, generalized). *Let  $\Pi$  be an  $\ell$ -local property and let  $s : \mathbb{N} \rightarrow \mathbb{N}$ . Suppose that the base graph  $G$  is of bounded degree  $d$  and has separators of size  $s$ . Then, testing whether a subgraph of  $G = ([n], E)$  has property  $\Pi$  can be done by performing  $O(\epsilon^{-1} s(n) \log n \cdot d^{\ell+1})$  queries. Furthermore, the tester is non-adaptive and has one-sided error.*

**Proof.** We consider a recursive decomposition of the graph  $G$ , obtained by applying the guaranteed separators, and a tree that corresponds to these applications. Specifically, the root of the tree corresponds to the separating set, denoted  $S_\lambda$ , that disconnects the graph  $G_\lambda \stackrel{\text{def}}{=} G$ . Collecting the resulting connected components into two subgraphs, each containing at most two-thirds of  $G$ 's vertices, we proceed to obtain separating sets, denoted  $S_0$  and  $S_1$ , for each of these two subgraphs, denoted  $G_0$  and  $G_1$ , respectively. In general, an internal node in the tree is labeled by a string  $\alpha$  and corresponds to the subgraph  $G_\alpha$  as well as to a separating set  $S_\alpha$  for  $G_\alpha$ . The children of this node correspond to subgraphs  $G_{\alpha 0}$  and  $G_{\alpha 1}$  that result from removing  $S_\alpha$  from  $G_\alpha$  (where the number of vertices in each of these subgraphs is at most two-thirds of the number of vertices in  $G_\alpha$ ). When the subgraph reaches some constant size, the process stops. Hence, the leaves of the tree correspond to subgraphs of constant size. For a leaf labeled by  $\alpha$ , we let  $S_\alpha$  be the set of vertices of the subgraph  $G_\alpha$ .

For the sake of clarity, we reserve the term ‘node’ for nodes in the tree (describing the recursive decomposition), and the term ‘vertex’ for the vertices of  $G$ . We shall never talk of edges of the (rooted) tree, but only of the descendance and ancestry relations induced by it. Recall that each node in the tree is associated with a set of vertices of  $G$ , and note that these sets form a partition of the vertex set of  $G$ . We say that vertex  $v$  resides in a node labeled by  $\alpha$  if  $v \in S_\alpha$ . Observe that edges of the graph  $G$  can connect vertices that reside in

<sup>12</sup>Marking the root is important only in case that the center of the graph of radius  $\ell$  cannot be uniquely determined.

the same node and vertices that reside in nodes that are in an ancestry relation, but *cannot* connect vertices that reside in nodes that are not in an ancestry relation (equiv., reside in nodes  $\alpha'0\alpha''$  and  $\alpha'1\alpha'''$  for any  $\alpha', \alpha'', \alpha''' \in \{0, 1\}^*$ ).

We are now ready to describe the tester for  $\Pi$ , which is an  $\ell$ -local property for some constant  $\ell \in \mathbb{N}$ . Given a fixed based graph  $G = ([n], E)$  and oracle access to a subgraph represented by  $f : E \rightarrow \{0, 1\}$ , the tester repeats the following procedure  $\Theta(d/\epsilon)$  times, where if no invocation of the procedure causes rejection, then it accepts.

1. Uniformly select a vertex that resides in one of the leaves of the decomposition tree. (Note that a constant fraction of the vertices of  $G$  resides in leaves of the tree.)
2. For each vertex  $v$  of  $G$  that resides in a node on the path from the selected leaf to the root (including both the leaf and the root), explore the  $\ell$ -neighborhood of  $v$  in  $G$  (i.e., query  $f$  on each of the edges in that neighborhood).
3. If the subgraph discovered in the previous step is not consistent with any  $n$ -vertex subgraph of  $G$  that has property  $\Pi$ , then reject.

Note that the aforementioned discovered subgraph includes not only the explored edges but also indication that certain edges do not exist in the subgraph (i.e., the latter include all non-edges of  $G$  as well as some edges of  $G$  that were queried by the procedure and answered by the value 0).

The query complexity of this procedure is  $O(s(n) \log n \cdot d^\ell)$ , where  $d$  is the degree-bound of  $G$ . Clearly, the tester always accepts subgraphs of  $G$  that have the property  $\Pi$ . It remains to show that if the subgraph is  $\epsilon$ -far from  $\Pi$ , then the probability that a single invocation of the procedure causes rejection is  $\Omega(\epsilon/d)$ .

We establish the contrapositive statement. Suppose that the foregoing procedure rejects with probability  $\rho < 1$ . We show that it suffices to modify an  $O(\rho \cdot d)$  fraction of the edges in  $G$  in order to obtain a graph that satisfies  $\Pi$ . We say that a leaf of the tree is **good** if the procedure does not reject when it selects a vertex that resides in this leaf. We say that an internal node of the tree is **good** if it appears on the path from some good leaf to the root. Note that  $\rho < 1$  implies that there exist good leaves, and hence the root of the tree is good. More generally, if a node is good, then all its ancestors are good. Also note that each vertex that resides in a good node has an  $\ell$ -neighborhood in  $G^f$  that satisfies the local condition (i.e., the  $\ell$ -neighborhood is in  $\Pi'$ ), where recall that  $G^f$  denotes the subgraph of  $G$  defined by  $f$ .

Hence, we only need to modify the neighborhoods of vertices residing in bad nodes, and we should do so without harming the neighborhoods of vertices that reside in good nodes. But before explaining how this is done, we note that the number of vertices that reside in internal nodes belonging to the subtree rooted in node  $\alpha$  is only a constant factor larger than the number of vertices that reside in the leaves of this subtree. On the other hand, considering the set of bad nodes that have good parents, we note that  $\rho$  equals the fraction of vertices that reside in leaves of the subtrees rooted at these bad nodes.

Consider an arbitrary bad node, denoted  $\alpha\sigma$ , that has a good parent, denoted  $\alpha$ . Then, the  $\ell$ -neighborhoods of the vertices residing in node  $\alpha$  satisfy the local condition (in the subgraph  $G^f$ ). We claim that the  $\ell$ -neighborhoods of vertices in  $G_{\alpha\sigma}$  can be modified so that they satisfy the local conditions as well without modifying the  $\ell$ -neighborhoods of any vertex that resides in a good node. To verify this claim observe the intersection of the  $\ell$ -neighborhoods of vertices in  $G_{\alpha\sigma}$  and the  $\ell$ -neighborhoods of vertices that reside in good nodes is contained in the intersection of the  $\ell$ -neighborhoods of vertices in  $G_{\alpha\sigma}$  and the  $\ell$ -neighborhoods of vertices that reside either in node  $\alpha$  or in one of its ancestors. The reasoning is that if vertex  $v$  in  $G_{\alpha\sigma}$  is adjacent in  $G$  to a vertex  $u$ , then either  $u$  is in  $G_{\alpha\sigma}$  or  $u$  is in  $S_{\alpha'}$  such that  $\alpha'$  is a (not necessarily proper) prefix of  $\alpha$ .

Recall that by Item 3 of the procedure (based on which the notion of good node is defined) the fact that node  $\alpha$  is good, implies that the  $\ell$ -neighborhoods of vertices in  $G_{\alpha\sigma}$  can be modified to satisfy  $\Pi'$  in a manner that is consistent with the  $\ell$ -neighborhoods of all vertices that reside in node  $\alpha$  and its ancestors, and so with the  $\ell$ -neighborhoods of all vertices that reside in good nodes. It follows that by modifying  $f$  on  $G_{\alpha\sigma}$ , while maintaining the  $\ell$ -neighborhoods of vertices in  $S_\alpha$  (as well as  $S_{\alpha'}$  for each  $\alpha'$  that is an ancestor of  $\alpha$ ) intact, we can “fix” the  $\ell$ -local neighborhood of all vertices in  $G_{\alpha\sigma}$ .

The foregoing process modifies  $f$  into a function that describes a subgraph of  $G$  that is in  $\Pi$ , while modifying  $O(\rho \cdot d \cdot n) = O(\rho \cdot d \cdot |E|)$  edges. The theorem follows. ◀

## Abstract

*Separations:* We introduce a monotone variant of XOR-SAT and show it has exponential monotone circuit complexity. Since XOR-SAT is in  $\text{NC}^2$ , this improves qualitatively on the monotone vs. non-monotone separation of Tardos (1988). We also show that monotone span programs over  $\mathbb{R}$  can be exponentially more powerful than over finite fields. These results can be interpreted as separating subclasses of TFNP in communication complexity.

*Characterizations:* We show that the communication (resp. query) analogue of PPA (subclass of TFNP) captures span programs over  $\mathbb{F}_2$  (resp. Nullstellensatz degree over  $\mathbb{F}_2$ ). Previously, it was known that communication FP captures formulas (Karchmer–Wigderson, 1988) and that communication PLS captures circuits (Razborov, 1995).

## 1 Our Results

We study the complexity of *monotone* boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ , that is, functions satisfying  $f(x) \leq f(y)$  for every pair  $x \leq y$  (coordinate-wise). (An excellent introduction to monotone complexity is the textbook [36].) Our main results are new **separations** of monotone models of computation and **characterizations** of those models in the language of query/communication complexity. At the core of these results are two conceptual innovations.

1. We introduce a natural *monotone* encoding of the usual CSP satisfiability problem (Subsection 1.1). This definition unifies many other monotone functions considered in the literature.
2. We extend and make more explicit an intriguing connection between *circuit complexity* and *total NP search problems* (TFNP) via communication complexity. Several prior characterizations [37, 55] can be viewed in this light. This suggests a potentially useful organizational principle for circuit complexity measures; see Section 2 for our survey.

### 1.1 Monotone $\mathcal{C}$ -Sat

The basic conceptual insight in this work is a new simple definition: a *monotone encoding* of the usual constraint satisfaction problem (CSP). For any finite set of constraints  $\mathcal{C}$ , we introduce a monotone function  $\mathcal{C}$ -SAT. A general definition is given in Section 3, but for now, consider as an example the set  $\mathcal{C} = 3\text{XOR}$  of all ternary parity constraints

$$3\text{XOR} := \{ (v_1 \oplus v_2 \oplus v_3 = 0), (v_1 \oplus v_2 \oplus v_3 = 1) \}.$$

We define  $3\text{XOR-SAT}_n: \{0, 1\}^N \rightarrow \{0, 1\}$  over  $N := |\mathcal{C}|n^3 = 2n^3$  input bits as follows. An input  $x \in \{0, 1\}^N$  is interpreted as (the indicator vector of) a set of  $3\text{XOR}$  constraints over  $n$  boolean variables  $v_1, \dots, v_n$  (there are  $N$  possible constraints). We define  $3\text{XOR-SAT}_n(x) := 1$  iff the set  $x$  is *unsatisfiable*, that is, no boolean assignment to the  $v_i$  exists that satisfies all constraints in  $x$ . This is indeed a monotone function: if we flip any bit of  $x$  from 0 to 1, this means we are adding a new constraint to the instance, thereby making it even harder to satisfy.

**Prior work.** Our  $\mathcal{C}$ -SAT encoding generalizes several previously studied monotone functions.

**(NL)** Karchmer and Wigderson [37] (also [29, 49, 56] and textbooks [39, 36]) studied the NL-complete *st-connectivity* problem. This is equivalent to a  $\mathcal{C}$ -SAT problem with  $\mathcal{C}$  consisting of a binary implication ( $v_1 \rightarrow v_2$ ) and unit clauses ( $v_1$ ) and ( $\neg v_1$ ).

**(P)** Raz and McKenzie [52] (also [14, 15, 25, 18, 56, 48]) studied a certain P-complete *generation* problem. In hindsight, this is simply HORN-SAT, that is,  $\mathcal{C}$  consists of *Horn clauses*: clauses with at most one positive literal, such as ( $\neg v_1 \vee \neg v_2 \vee v_3$ ).

**(NP)** Göös and Pitassi [25] and Oliveira [45, §3] (also [47, 48]) studied the NP-complete (dual of) CNF-SAT problem, where  $\mathcal{C}$  consists of bounded-width clauses.

These prior works do not exhaust all interesting classes of  $\mathcal{C}$ , as is predicted by various classification theorems for CSPs [59, 20, 11, 63]. In this work, we focus on *linear* constraints over finite fields  $\mathbb{F}_p$  (for example,  $3\text{XOR-SAT}$  corresponding to  $\mathbb{F}_2$ ) and over the reals  $\mathbb{R}$ .

### 1.2 Separations

First, we show that  $3\text{XOR-SAT}_n$  cannot be computed efficiently with monotone circuits.

► **Theorem 1.**  $3\text{XOR-SAT}_n$  requires monotone circuits of size  $2^{n^{\Omega(1)}}$ .

This theorem stands in contrast to the fact that there exist fast parallel (non-monotone) algorithms for linear algebra [44]. In particular, 3XOR-SAT is in  $\text{NC}^2$ . Consequently, our result improves qualitatively on the monotone vs. non-monotone separation of Tardos [61] who exhibited a monotone function in  $\text{P}$  (computed by solving a semidefinite program) with exponential monotone circuit complexity. For further comparison, another famous candidate problem to witness a monotone vs. non-monotone separation is the *perfect matching* function: it is in  $\text{RNC}^2$  [40] while it is widely conjectured to have exponential monotone circuit complexity (a quasipolynomial lower bound was proved by Razborov [53]).

**Span programs.** The computational easiness of  $3\text{XOR-SAT}_n$  can be stated differently: it can be computed by a linear-size monotone  $\mathbb{F}_2$ -span program. Span programs are a model of computation introduced by Karchmer and Wigderson [38] (see also [36, §8] for exposition) with an extremely simple definition. An  $\mathbb{F}$ -span program, where  $\mathbb{F}$  is a field, is a matrix  $M \in \mathbb{F}^{m \times m'}$  each row of which is labeled by a literal,  $x_i$  or  $\neg x_i$ . We say that the program accepts an input  $x \in \{0, 1\}^n$  iff the rows of  $M$  whose labels are consistent with  $x$  (literals evaluating to true on  $x$ ) span the all-1 row vector. The *size* of a span program is its number of rows  $m$ . A span program is *monotone* if all its literals are positive; in this case the program computes a monotone function.

A corollary of Theorem 1 is that monotone  $\mathbb{F}_2$ -span programs cannot be simulated by monotone circuits without exponential blow-up in size. This improves on a separation of Babai, Gál, and Wigderson [3] who showed that monotone circuit complexity can be quasipolynomially larger than monotone  $\mathbb{F}_2$ -span program size.

Furthermore, Theorem 1 holds more generally over *any* field  $\mathbb{F}$ : an appropriately defined function  $3\text{LIN}(\mathbb{F})\text{-SAT}_n$  (ternary  $\mathbb{F}$ -linear constraints; see Section 3) is easy for monotone  $\mathbb{F}$ -span programs, but exponentially hard for monotone circuits. No such separation, even superpolynomial, was previously known for fields of characteristic other than 2.

This brings us to our second theorem.

► **Theorem 2.**  $3\text{LIN}(\mathbb{R})\text{-SAT}_n$  requires monotone  $\mathbb{F}_p$ -span programs of size  $2^{n^{\Omega(1)}}$  for any prime  $p$ .

In other words: monotone  $\mathbb{R}$ -span programs can be exponentially more powerful than monotone span programs over finite fields. This separation completes the picture for the relative powers of monotone span programs over distinct fields, since the remaining cases were exponentially separated by Pitassi and Robere [48].

Finally, our two results above yield a bonus result in proof complexity as a byproduct: the Nullstellensatz proof system (over any field) can be exponentially more powerful than the Cutting Planes proof system (see Subsection 4.2).

**Techniques.** The new lower bounds are applications of the lifting theorems for monotone circuits [23] and monotone span programs [48]. We show that, generically, if some unsatisfiable formula composed of  $\mathcal{C}$  constraints is hard to refute for the Resolution (resp. Nullstellensatz) proof system, then the  $\mathcal{C}$ -SAT problem is hard for monotone circuits (resp. span programs). Hence we can invoke (small modifications of) known Resolution and Nullstellensatz lower bounds [8, 10, 1]. The key conceptual innovation here is a reduction from unsatisfiable  $\mathcal{C}$ -CSPs (or their lifted versions) to the monotone Karchmer–Wigderson game for  $\mathcal{C}$ -SAT. This reduction is extremely slick, which we attribute to having finally found the “right” definition of  $\mathcal{C}$ -SAT.

### 1.3 Characterizations

There are two famous “top-down” characterizations of circuit models (both monotone and non-monotone variants) using the language of communication complexity; these characterizations are naturally related to communication analogues of subclasses of TFNP.

**(FP)** Karchmer and Wigderson [37] showed that the logarithm of the (monotone) formula complexity of a (monotone) function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  is equal, up to constant factors, to the communication complexity of the (monotone) *Karchmer–Wigderson game*:

$$\begin{array}{l} \text{Search problem } \mathbf{KW}(f) \\ \text{[resp. } \mathbf{KW}^+(f)\text{]} \end{array} = \begin{array}{l} \text{input: a pair } (x, y) \in f^{-1}(1) \times f^{-1}(0) \\ \text{output: an } i \in [n] \text{ with } x_i \neq y_i \text{ [resp. } x_i > y_i\text{]} \end{array}$$

We summarize this by saying that *the communication analogue of FP captures formulas*. Here  $\text{FP} \subseteq \text{TFNP}$  is the classical (Turing machine) class of total NP search problems efficiently solved by deterministic algorithms [42].

**(PLS)** Razborov [55] (see also [50, 60]) showed that the logarithm of the (monotone) circuit complexity of a function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  is equal, up to constant factors, to the least cost of a PLS-protocol solving the  $\text{KW}(f)$  (or  $\text{KW}^+(f)$ ) search problem. Here a PLS-protocol (Definition 14 in Appendix A) is a natural communication analogue of  $\text{PLS} \subseteq \text{TFNP}$  [35]. We summarize this by saying that *the communication analogue of PLS captures circuits*.

We contribute a third characterization of this type: *the communication analogue of PPA captures  $\mathbb{F}_2$ -span programs*. The class PPA [46] is a well-known subclass of TFNP embodying the combinatorial principle “every graph with an odd degree vertex has another”. Informally, a search problem is in PPA if for every  $n$ -bit input  $x$  we may describe implicitly an undirected graph  $G_x = (V, E)$  (typically of size exponential in  $n$ ; the edge relation is computed by a polynomial-size circuit) such that  $G$  has degree at most 2, there is a distinguished degree-1 vertex  $v^* \in V$ , and every other degree-1 vertex  $v \in V$  is associated with a feasible solution to the instance  $x$  (that is, the solution can be efficiently computed from  $v$ ).

**Communication PPA.** The communication analogue of PPA is defined canonically by letting the edge relation be computed by a (deterministic) communication protocol. Specifically, first fix a two-party search problem  $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$ , that is, Alice gets  $x \in \mathcal{X}$ , Bob gets  $y \in \mathcal{Y}$ , and their goal is to find a *feasible solution* in  $S(x, y) := \{o \in \mathcal{O} : (x, y, o) \in S\}$ . A PPA-protocol  $\Pi$  solving  $S$  consists of a vertex set  $V$ , a distinguished vertex  $v^* \in V$ , and for each vertex  $v \in V$  there is an associated solution  $o_v \in \mathcal{O}$  and a protocol  $\Pi_v$  (taking inputs from  $\mathcal{X} \times \mathcal{Y}$ ). Given an input  $(x, y)$ , the protocols  $\Pi_v$  implicitly describe a graph  $G = G_{x,y}$

on the vertex set  $V$  as follows. The output of protocol  $\Pi_v$  on input  $(x, y)$  is interpreted as a subset  $\Pi_v(x, y) \subseteq V$  of size at most 2. We define  $\{u, v\} \in E(G)$  iff  $u \in \Pi_v(x, y)$  and  $v \in \Pi_u(x, y)$ . The correctness requirements are:

(C1) if  $\deg(v^*) \neq 1$ , then  $o_{v^*} \in S(x, y)$ .

(C2) if  $\deg(v) \neq 2$  for  $v \neq v^*$ , then  $o_v \in S(x, y)$ .

The *cost* of  $\Pi$  is defined as  $\log |V| + \max_v |\Pi_v|$  where  $|\Pi_v|$  is the communication cost of  $\Pi_v$ . Finally, define  $\text{PPA}^{\text{cc}}(S)$  as the least cost of a PPA-protocol that solves  $S$ .

For a (monotone) function  $f$ , define  $\text{SP}_{\mathbb{F}}(f)$  (resp.  $\text{mSP}_{\mathbb{F}}(f)$ ) as the least size of a (monotone)  $\mathbb{F}$ -span program computing  $f$ . Our characterization is in terms of  $S := \text{KW}(f)$ .

► **Theorem 3.** *For any boolean function  $f$ , we have  $\log \text{SP}_{\mathbb{F}_2}(f) = \Theta(\text{PPA}^{\text{cc}}(\text{KW}(f)))$ . Furthermore, if  $f$  is monotone, we have  $\log \text{mSP}_{\mathbb{F}_2}(f) = \Theta(\text{PPA}^{\text{cc}}(\text{KW}^+(f)))$ .*

**Query PPA.** Our second characterization concerns the *Nullstellensatz* proof system; see Section 3 for the standard definition. Span programs and Nullstellensatz are known to be connected via interpolation [51] and lifting [48]. Given our first characterization (Theorem 3), it is no surprise that a companion result should hold in query complexity: *the query complexity analogue of PPA captures the degree of Nullstellensatz refutations over  $\mathbb{F}_2$ .*

The query analogue of PPA is defined in the same way as the communication analogue, except we replace protocols by (deterministic) decision trees. In fact, query PPA was already studied by Beame et al. [6] who separated query analogues of different subclasses of TFNP. To define it, first fix a search problem  $S \subseteq \{0, 1\}^n \times \mathcal{O}$ , that is, on input  $x \in \{0, 1\}^n$  the goal is to find a *feasible solution* in  $S(x) := \{o \in \mathcal{O} : (x, o) \in S\}$ . A *PPA-decision tree*  $\mathcal{T}$  solving  $S$  consists of a vertex set  $V$ , a distinguished vertex  $v^* \in V$ , and for each vertex  $v \in V$  there is an associated solution  $o_v \in \mathcal{O}$  and a decision tree  $\mathcal{T}_v$  (querying bits of an  $n$ -bit input). Given an input  $x \in \{0, 1\}^n$ , the decision trees  $\mathcal{T}_v$  implicitly describe a graph  $G = G_x$  on the vertex set  $V$  as follows. The output of  $\mathcal{T}_v$  on input  $x$  is interpreted as a subset  $\mathcal{T}_v(x) \subseteq V$  of size at most 2. We then define  $\{u, v\} \in E(G)$  iff  $u \in \mathcal{T}_v(x)$  and  $v \in \mathcal{T}_u(x)$ . The correctness requirements are the same as before, 1 and 2. The *cost* of  $\mathcal{T}$  is defined as the maximum over all  $v \in V$  and all inputs  $x$  of the number of queries made by  $\mathcal{T}_v$  on input  $x$ . Finally, define  $\text{PPA}^{\text{dt}}(S)$  as the least cost of a PPA-decision tree that solves  $S$ .

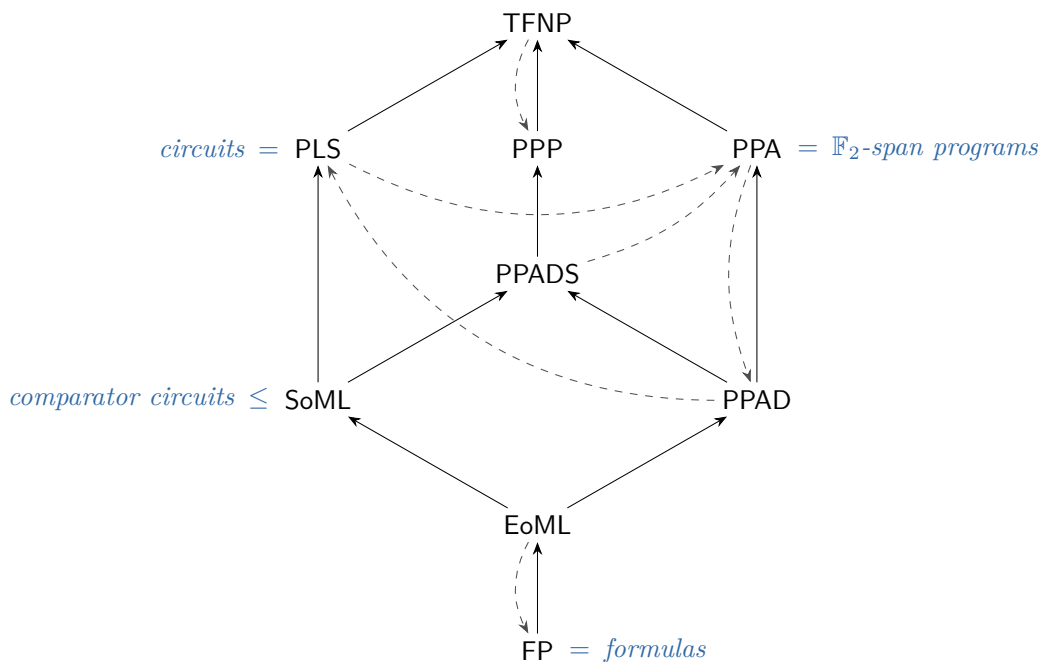

With any unsatisfiable  $n$ -variate boolean CSP  $F$  one can associate a canonical search problem:

**CSP search problem  $S(F)$**  = *input*: an  $n$ -variate truth assignment  $x \in \{0, 1\}^n$   
*output*: constraint  $C$  of  $F$  falsified by  $x$  (i.e.,  $C(x) = 0$ )

► **Theorem 4.** *The  $\mathbb{F}_2$ -Nullstellensatz degree of an  $k$ -CNF formula  $F$  equals  $\Theta(\text{PPA}^{\text{dt}}(S(F)))$ .*

The easy direction of this characterization is that Nullstellensatz degree lower bounds  $\text{PPA}^{\text{dt}}$ . This fact was already observed and exploited by Beame et al. [6] to prove lower bounds for  $\text{PPA}^{\text{dt}}$ . Our contribution is to show the other (less trivial) direction.

Let us finally mention a related result in Turing machine complexity due to Belovs et al. [9]: a circuit-encoded version of Nullstellensatz is PPA-complete. Their proof is highly nontrivial whereas our characterizations admit relatively short proofs, owing partly to us working with simple nonuniform models of computation.

■ **Figure 1** The landscape of communication search problem classes (uncluttered by the usual ‘cc’ superscripts). A solid arrow  $C_1 \rightarrow C_2$  denotes  $C_1 \subseteq C_2$ , and a dashed arrow  $C_1 \dashrightarrow C_2$  denotes  $C_1 \not\subseteq C_2$  (in fact, an exponential separation). Some classes can characterize other models of computation (printed in blue). See Appendix A for definitions.

## 2 Survey: Communication TFNP

Given the results in Section 1, it is natural to examine other communication analogues of subclasses of TFNP. The goal in this section is to explain the current state of knowledge as summarized in Figure 1. The formal definitions of the communication classes appear in Appendix A.

**TFNP.** As is customary in structural communication complexity [2, 30, 27] we formally define  $\text{TFNP}^{\text{cc}}$  (resp.  $\text{PLS}^{\text{cc}}$ ,  $\text{PPA}^{\text{cc}}$ , etc.) as the class of all total two-party  $n$ -bit search problems that admit a nondeterministic protocol<sup>5</sup> (resp. PLS-protocol, PPA-protocol, etc.) of communication cost  $\text{polylog}(n)$ . For example, Karchmer–Wigderson games  $\text{KW}(f)$  and  $\text{KW}^+(f)$ , for an  $n$ -bit boolean function  $f$ , have efficient nondeterministic protocols: guess a  $\log n$ -bit coordinate  $i \in [n]$  and check that  $x_i \neq y_i$  or  $x_i > y_i$ . Hence these problems are in  $\text{TFNP}^{\text{cc}}$ . In fact, a converse holds: any total two-party search problem with nondeterministic complexity  $c$  can be reduced to  $\text{KW}^+(f)$  for some  $2^c$ -bit *partial* monotone function  $f$ , see [21, Lemma 2.3]. In summary, the study of total NP search problems in communication complexity is equivalent to the study of monotone Karchmer–Wigderson games for *partial* monotone functions.

<sup>5</sup> That is, for any input  $(x, y)$ , every accepting computation of the nondeterministic protocol outputs a feasible solution  $o \in \mathcal{O}$  for  $(x, y)$ . An alternative, more restrictive definition of  $\text{TFNP}^{\text{cc}}$  (which is closer to how the classical class is defined) is to require that there is an efficient deterministic protocol that on input  $(x, y)$  decides whether  $o \in \mathcal{O}$  is feasible for  $(x, y)$ . In this paper we stick with the stronger (and simpler) definition for convenience. All results hold equally well under the more restrictive definition.

Sometimes a *partial* function  $f$  can be canonically extended into a *total* one  $f'$  without increasing the complexity of  $\text{KW}(f)$  (or  $\text{KW}^+(f)$ ). This is possible whenever  $\text{KW}(f)$  lies in a communication class that captures some associated model of computation. For example, if  $\text{KW}(f)$  is solved by a deterministic protocol (resp. PLS-protocol, PPA-protocol) then the Karchmer–Wigderson connection can build us a corresponding formula (resp. circuit,  $\mathbb{F}_2$ -span program) that computes some total extension  $f'$  of  $f$ . Consequently, separating two communication classes that capture two monotone models is *equivalent* to separating the monotone models themselves.

**FP.** Raz and McKenzie [52] showed an exponential separation between monotone formula size and monotone circuit size. This can be rephrased as  $\text{PLS}^{\text{cc}} \not\subseteq \text{FP}^{\text{cc}}$ . Their technique is much more general: they develop a query-to-communication lifting theorem for deterministic protocols (see also [26] for exposition). By plugging in known query complexity lower bounds against the class  $\text{EoML}$  (combinatorial subclass of  $\text{CLS}$  [17] introduced by [32, 19]), one can obtain a stronger separation  $\text{EoML}^{\text{cc}} \not\subseteq \text{FP}^{\text{cc}}$ .

A related question is whether *randomization* helps in solving  $\text{TFNP}^{\text{cc}}$  problems. Lower bounds against randomized protocols have applications in proof complexity [34, 7, 33, 25] and algorithmic game theory [58, 5, 28, 57, 22, 4]. In particular, some of these works (for finding Nash equilibria) have introduced a communication analogue of the PPAD-complete END-OF-LINE problem, which we will continue to study in Subsection 4.2.

**PLS.** Razborov’s [54] famous monotone circuit lower bound for the *clique/coloring* problem (which is in  $\text{PPP}^{\text{cc}}$ ) can be interpreted as an exponential separation  $\text{PPP}^{\text{cc}} \not\subseteq \text{PLS}^{\text{cc}}$ . We show a stronger separation  $\text{PPAD}^{\text{cc}} \not\subseteq \text{PLS}^{\text{cc}}$  using the END-OF-LINE problem in Subsection 4.2. Note that this is even slightly stronger than Theorem 1, which only implies  $\text{PPA}^{\text{cc}} \not\subseteq \text{PLS}^{\text{cc}}$ .

**PPApD.** In light of our characterization of  $\text{PPA}^{\text{cc}}$ , we may interpret the inability of monotone  $\mathbb{F}_2$ -span program to efficiently simulate monotone circuits [48] as a separation  $\text{PLS}^{\text{cc}} \not\subseteq \text{PPA}^{\text{cc}}$ . We show an incomparable separation  $\text{PPADS}^{\text{cc}} \not\subseteq \text{PPA}^{\text{cc}}$  in Subsection 4.3.

In the other direction, prior work implies  $\text{PPA}^{\text{cc}} \not\subseteq \text{PPAD}^{\text{cc}}$  as follows. Pitassi and Robere [48] exhibit a monotone  $f$  (in hindsight, one can take  $f := 3\text{XOR-SAT}_n$ ) computable with a small monotone  $\mathbb{F}_2$ -span program (hence  $\text{KW}^+(f) \in \text{PPA}^{\text{cc}}$ ) and such that  $\text{KW}^+(f)$  has an exponentially large  $\mathbb{R}$ -partition number (see Section 3 for a definition); however, we observe that all problems in  $\text{PPAD}^{\text{cc}}$  have a small  $\mathbb{R}$ -partition number (see Remark 9).

**PPP.** There are no lower bounds against  $\text{PPP}^{\text{cc}}$  for an *explicit* problem in  $\text{TFNP}^{\text{cc}}$ . However, we can show non-constructively the existence of  $\text{KW}(f) \in \text{TFNP}^{\text{cc}}$  such that  $\text{KW}(f) \notin \text{PPP}^{\text{cc}}$ , which implies  $\text{PPP}^{\text{cc}} \neq \text{TFNP}^{\text{cc}}$ . Indeed, we argue in Remark 8 that every  $S$  reduces to  $\text{KW}^+(3\text{CNF-SAT}_N)$  over  $N := \exp(O(\text{PPP}^{\text{cc}}(S)))$  variables. Applying this to  $S := \text{KW}(f)$  for an  $n$ -bit  $f$ , we conclude that  $f$  is a (non-monotone) projection of  $3\text{CNF-SAT}_N$  for  $N := \exp(O(\text{PPP}^{\text{cc}}(\text{KW}(f))))$ . In particular, if  $\text{KW}(f) \in \text{PPP}^{\text{cc}}$  (i.e.,  $\text{PPP}^{\text{cc}}(\text{KW}(f)) \leq \text{polylog}(n)$ ), then  $f$  is in non-uniform quasipoly-size NP. Therefore  $\text{KW}(f) \notin \text{PPP}^{\text{cc}}$  for a random  $f$ .

**EoML, SoML, and comparator circuits.** One prominent circuit model that currently lacks a characterization via a  $\text{TFNP}^{\text{cc}}$  subclass is *comparator circuits* [41, 16]. These circuits are composed only of *comparator gates* (taking two input bits and outputting them in sorted order) and input literals (positive literals in the monotone case).

We can show an upper bound better than  $\text{PLS}^{\text{cc}}$  for comparator circuits. Indeed, we introduce a new class  $\text{SoML}$  generalizing  $\text{EoML}$  [32, 19] as follows. Recall that  $\text{EoML}$  is the class of problems reducible to  $\text{END-OF-METERED-LINE}$ : we are given a directed graph of in/out-degree at most 1 with a distinguished source vertex  $v^*$  (in-degree 0), and moreover, each vertex is labeled with an integer “meter” that is strictly decreasing along directed paths; a solution is any sink or source distinct from  $v^*$ . The complete problem defining  $\text{SoML}$  is  $\text{SINK-OF-METERED-LINE}$ , which is the same as  $\text{END-OF-METERED-LINE}$  except only sinks count as solutions. It is not hard (left as an exercise) to adapt the characterization of circuits via  $\text{PLS}^{\text{cc}}$  [55, 50, 60] to show that  $\text{KW}(f)$  is in  $\text{SoML}^{\text{cc}}$  if  $f$  is computed by a small comparator circuit. However, we suspect that the converse ( $\text{SoML}$ -protocol for  $\text{KW}(f)$  implies a comparator circuit) is false.

## 2.1 Open problems

In query complexity, the relative complexities of TFNP subclasses are almost completely understood [6, 12, 43]. In communication complexity, by contrast, there are huge gaps in our understanding as can be gleaned from Figure 1. For example:

- (1) There are no lower bounds against classes  $\text{PPADS}^{\text{cc}}$  and  $\text{PPP}^{\text{cc}}$  for an explicit problem in  $\text{TFNP}^{\text{cc}}$ . For starters, show  $\text{PLS}^{\text{cc}} \not\subseteq \text{PPADS}^{\text{cc}}$  or  $\text{PPA}^{\text{cc}} \not\subseteq \text{PPADS}^{\text{cc}}$ .
- (2) Find computational models captured by  $\text{EoML}^{\text{cc}}$ ,  $\text{SoML}^{\text{cc}}$ ,  $\text{PPAD}^{\text{cc}}$ ,  $\text{PPADS}^{\text{cc}}$ ,  $\text{PPP}^{\text{cc}}$ .
- (3) Query-to-communication lifting theorems are known for  $\text{FP}$  [52],  $\text{PLS}$  [23],  $\text{PPA}$  [48]. Prove more. (This is one way to attack Question 1 if proved for  $\text{PPADS}$ .)
- (4) Prove more separations. For example, can our result  $\text{PPADS}^{\text{cc}} \not\subseteq \text{PPA}^{\text{cc}}$  be strengthened to  $\text{SoML}^{\text{cc}} \not\subseteq \text{PPA}^{\text{cc}}$ ? This is closely related to whether monotone comparator circuits can be more powerful than monotone  $\mathbb{F}_2$ -span programs (no separation is currently known).

## 3 Preliminaries

**C-Sat.** Fix an alphabet  $\Sigma$  (potentially infinite, e.g.,  $\Sigma = \mathbb{R}$ ). Let  $\mathcal{C}$  be a finite set of  $k$ -ary predicates over  $\Sigma$ , that is, each  $C \in \mathcal{C}$  is a function  $C: \Sigma^k \rightarrow \{0, 1\}$ . We define a monotone function  $\mathcal{C}\text{-SAT}_n: \{0, 1\}^N \rightarrow \{0, 1\}$  over  $N = |\mathcal{C}|n^k$  input bits as follows. An input  $x \in \{0, 1\}^N$  is interpreted as a  $\mathcal{C}$ -CSP instance, that is,  $x$  is (the indicator vector of) a set of  $\mathcal{C}$ -constraints, each applied to a  $k$ -tuple of variables from  $v_1, \dots, v_n$ . We define  $\mathcal{C}\text{-SAT}_n(x) := 1$  iff the  $\mathcal{C}$ -CSP  $x$  is *unsatisfiable*: no assignment  $v \in \Sigma^n$  exists such that  $C(v) = 1$  for all  $C \in x$ .

For a field  $\mathbb{F}$ , we define  $k\text{LIN}(\mathbb{F})$  as the set of all  $\mathbb{F}$ -linear equations of the form

$$\sum_{i \in [k]} a_i v_i = a_0, \quad \text{where } a_i \in \{0, \pm 1\}.$$

In particular, we recover  $3\text{XOR-SAT}_n$  defined in Section 1 essentially as  $3\text{LIN}(\mathbb{F}_2)\text{-SAT}_n$ . We could have allowed the  $a_i$  to range over  $\mathbb{F}$  when  $\mathbb{F}$  is finite, but we stick with the above convention as it ensures that the set  $k\text{LIN}(\mathbb{R})$  is always finite.

**Boolean alphabets.** We assume henceforth that all alphabets  $\Sigma$  contain distinguished elements 0 and 1. We define  $\mathcal{C}_{\text{bool}}$  to be the constraint set obtained from  $\mathcal{C}$  by restricting each  $C \in \mathcal{C}$  to the boolean domain  $\{0, 1\}^k \subseteq \Sigma^k$ . Moreover, if  $F$  is a  $\mathcal{C}$ -CSP, we write  $F_{\text{bool}}$  for the  $\mathcal{C}_{\text{bool}}$ -CSP obtained by restricting the constraints of  $F$  to boolean domains. Consequently, any  $S(F_{\text{bool}})$  associated with a  $\mathcal{C}$ -CSP  $F$  is a *boolean* search problem.

**Algebraic partitions.** We say that a subset  $A \subseteq \mathcal{X} \times \mathcal{Y}$  is *monochromatic* for a two-party search problem  $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$  if there is some  $o \in \mathcal{O}$  such that  $o \in S(x, y)$  for all  $(x, y) \in A$ . Moreover, if  $M \in \mathbb{F}^{\mathcal{X} \times \mathcal{Y}}$  is a matrix, we say  $M$  is *monochromatic* if the support of  $M$  is monochromatic. For any field  $\mathbb{F}$ , an  $\mathbb{F}$ -*partition* of a search problem  $S$  is a set  $\mathcal{M}$  of rank-1 matrices  $M \in \mathbb{F}^{\mathcal{X} \times \mathcal{Y}}$  such that  $\sum_{M \in \mathcal{M}} M = \mathbb{1}$  and each  $M \in \mathcal{M}$  is monochromatic for  $S$ . The *size* of the partition is  $|\mathcal{M}|$ . The  $\mathbb{F}$ -*partition number*  $\chi_{\mathbb{F}}(S)$  is the least size of an  $\mathbb{F}$ -partition of  $S$ . In the following characterization, recall that we use  $\text{SP}_{\mathbb{F}}$  and  $\text{mSP}_{\mathbb{F}}$  to denote (monotone) span program complexity.

► **Theorem 5** ([21]). *For any boolean function  $f$  and any field  $\mathbb{F}$ ,  $\text{SP}_{\mathbb{F}}(f) = \chi_{\mathbb{F}}(\text{KW}(f))$ . Furthermore, if  $f$  is monotone then  $\text{mSP}_{\mathbb{F}}(f) = \chi_{\mathbb{F}}(\text{KW}^+(f))$ .*

**Nullstellensatz.** Let  $P := \{p_1 = 0, p_2 = 0, \dots, p_m = 0\}$  be an unsatisfiable system of polynomial equations in  $\mathbb{F}[z_1, z_2, \dots, z_n]$  for a field  $\mathbb{F}$ . An  $\mathbb{F}$ -*Nullstellensatz refutation* of  $P$  is a sequence of polynomials  $q_1, q_2, \dots, q_m \in \mathbb{F}[z_1, z_2, \dots, z_n]$  such that  $\sum_{i=1}^m q_i p_i = 1$  where the equality is syntactic. The *degree* of the refutation is  $\max_i \deg(q_i p_i)$ . The  $\mathbb{F}$ -*Nullstellensatz degree* of  $P$ , denoted  $\text{NS}_{\mathbb{F}}(P)$ , is the least degree of an  $\mathbb{F}$ -Nullstellensatz refutation of  $P$ .

Moreover, if  $F$  is a  $k$ -CNF formula (or a boolean  $k$ -CSP), we often tacitly think of it as a polynomial system  $P_F$  by using the standard encoding (e.g.,  $(z_1 \vee \neg z_2) \rightsquigarrow (1 - z_1)z_2 = 0$ ) and also including the *boolean axioms*  $z_i^2 - z_i = 0$  in  $P_F$  if we are working over  $\mathbb{F} \neq \mathbb{F}_2$ .

**Lifting theorems.** Let  $S \subseteq \{0, 1\}^n \times \mathcal{O}$  be a boolean search problem and  $g: \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  a two-party function, usually called a *gadget*. The composed search problem  $S \circ g^n \subseteq \mathcal{X}^n \times \mathcal{Y}^n \times \mathcal{O}$  is defined as follows: Alice holds  $x \in \mathcal{X}^n$ , Bob holds  $y \in \mathcal{Y}^n$ , and their goal is to find an  $o \in S(z)$  where  $z := g^n(x, y) = (g(x_1, y_1), \dots, g(x_n, y_n))$ . We focus on the usual *index gadget*  $\text{IND}_m: [m] \times \{0, 1\}^m \rightarrow \{0, 1\}$  given by  $\text{IND}_m(x, y) := y_x$ .

The main results of [23, 48] can be summarized as follows (we define more terms below).

► **Theorem 6.** *Let  $k \geq 1$  be a constant and let  $m = m(n) := n^C$  for a large enough constant  $C \geq 1$ . Then for any an unsatisfiable boolean  $n$ -variate  $k$ -CSP  $F$ ,*

$$\begin{aligned} [23]: \quad & \text{PLS}^{\text{cc}}(S(F) \circ \text{IND}_m^n) = \text{PLS}^{\text{dt}}(S(F)) \cdot \Theta(\log n), \\ [48]: \quad & \text{PPA}^{\text{cc}}(S(F) \circ \text{IND}_m^n) = \text{PPA}^{\text{dt}}(S(F)) \cdot \Theta(\log n), \\ [48]: \quad & \log \chi_{\mathbb{F}}(S(F) \circ \text{IND}_m^n) = \text{NS}_{\mathbb{F}}(F) \cdot \Theta(\log n), \quad \forall \mathbb{F} \in \{\mathbb{F}_p, \mathbb{R}\}. \end{aligned}$$

For aesthetic reasons, we have used  $\text{PLS}^{\text{dt}}(S(F))$  here to denote the *Resolution width* of  $F$  (introduced in [10]), which is how the result of [23] was originally stated. (But one can check that the query analogue of PLS, obtained by replacing protocols with decision trees in Definition 14, is indeed equivalent to Resolution width.) We also could not resist incorporating our new characterizations of  $\text{PPA}^{\text{cc}}$  and  $\text{PPA}^{\text{dt}}$  to interpret the result of [48] specialized to  $\mathbb{F}_2$ .

## 4 Proofs of Separations

In this section, we show lower bounds for  $\mathcal{C}$ -SAT against monotone circuits (Theorem 1) and monotone span programs (Theorem 2), plus some bonus results ( $\text{PPAD}^{\text{cc}} \not\subseteq \text{PLS}^{\text{cc}}$ ,  $\text{PPADS}^{\text{cc}} \not\subseteq \text{PPA}^{\text{cc}}$ , Nullstellensatz degree vs. Cutting Planes).

## 4.1 Reduction

The key to our lower bounds is a new reduction. We show that a lifted version of  $S(F_{\text{bool}})$ , where  $F$  is an unsatisfiable  $\mathcal{C}$ -CSP, reduces to the monotone Karchmer–Wigderson game for  $\mathcal{C}$ -SAT. Note that we require  $F$  to be unsatisfiable over its original alphabet  $\Sigma$ , but the reduction is from the booleanized (and hence easier-to-refute) version of  $F$ .

► **Lemma 7.** *Let  $F$  be an unsatisfiable  $\mathcal{C}$ -CSP. Then  $S(F_{\text{bool}}) \circ \text{IND}_m^n$  reduces to  $\text{KW}^+(\mathcal{C}\text{-SAT}_{nm})$ .*

**Proof.** Suppose the  $\mathcal{C}$ -CSP  $F$  consists of  $k$ -ary constraints  $C_1, \dots, C_t$  applied to variables  $z_1, \dots, z_n$ . We reduce  $S(F_{\text{bool}}) \circ \text{IND}_m^n \subseteq [m]^n \times (\{0, 1\}^m)^n \times [t]$  to the problem  $\text{KW}^+(f) \subseteq f^{-1}(1) \times f^{-1}(0) \times [N]$  where  $f := \mathcal{C}\text{-SAT}_{mn}$  over  $N := |\mathcal{C}|(mn)^k$  input bits. The two parties compute locally as follows.

**Alice:** Given  $(x_1, \dots, x_n) \in [m]^n$ , Alice constructs a  $\mathcal{C}$ -CSP over variables  $\{v_{i,j} : (i, j) \in [n] \times [m]\}$  that is obtained from  $F$  by renaming its variables  $z_1, \dots, z_n$  to  $v_{1,x_1}, \dots, v_{n,x_n}$  (in this order). Since  $F$  was unsatisfiable, so is Alice’s variable-renamed version of it. Thus, when interpreted as an indicator vector of constraints, Alice has constructed a 1-input of  $\mathcal{C}\text{-SAT}_{mn}$ .

**Bob:** Given  $y \in (\{0, 1\}^m)^n$ , Bob constructs a  $\mathcal{C}$ -CSP over variables  $\{v_{i,j} : (i, j) \in [n] \times [m]\}$  as follows. We view  $y$  naturally as a boolean assignment to the variables  $v_{i,j}$ . Bob includes in his  $\mathcal{C}$ -CSP instance all possible  $\mathcal{C}$ -constraints  $C$  applied to the  $v_{i,j}$  such that  $C$  is satisfied under the assignment  $y$  (i.e.,  $C(y) = 1$ ). This is clearly a satisfiable  $\mathcal{C}$ -CSP instance, as the assignment  $y$  satisfies all Bob’s constraints. Thus, when interpreted as an indicator vector of constraints, Bob has constructed a 0-input of  $\mathcal{C}\text{-SAT}_{mn}$ .

It remains to argue that any solution to  $\text{KW}^+(\mathcal{C}\text{-SAT}_{mn})$  gives rise to a solution to  $S(F_{\text{bool}}) \circ \text{IND}_m^n$ . Indeed, a solution to  $\text{KW}^+(\mathcal{C}\text{-SAT}_{mn})$  corresponds to a  $\mathcal{C}$ -constraint  $C$  that is present in Alice’s  $\mathcal{C}$ -CSP but not in Bob’s. By Bob’s construction, such a  $C$  must be violated by the assignment  $y$  (i.e.,  $C(y) = 0$ ). Since all Alice’s constraints involve only variables  $v_{1,x_1}, \dots, v_{n,x_n}$ , the constraint  $C$  must in fact be violated by the partial assignment to the said variables, which is  $z = \text{IND}_m^n(x, y)$ . Thus the constraint of  $F$  from which  $C$  was obtained via renaming is a solution to  $S(F_{\text{bool}}) \circ \text{IND}_m^n$ . ◀

► **Remark 8 (Generic reduction to CNF-SAT).** We claim that any problem  $S \subseteq \mathcal{X} \times \mathcal{Y} \times \mathcal{O}$  that lies in one of the known subclasses of  $\text{TFNP}^{\text{cc}}$  (as listed in Section 2) reduces efficiently to  $\text{KW}^+(k\text{CNF-SAT}_n)$  for constant  $k$  (one can even take  $k = 3$  by standard reductions). Let us sketch the argument for  $S \in \text{PPP}^{\text{cc}}$ ; after all, better reductions are known for  $\text{PLS}^{\text{cc}}$  and  $\text{PPA}^{\text{cc}}$ , namely to  $\text{HORN-SAT}$  and  $3\text{XOR-SAT}$ .

**Proof Sketch.** Let  $\Pi := (V, v^*, o_v, \Pi_v)$  be a PPP-protocol solving  $S$  of cost  $c := \text{PPP}^{\text{cc}}(S)$ . We may assume wlog that all the  $\Pi_v$  have constant communication cost  $k \leq O(1)$  by embedding the protocol trees of the  $\Pi_v$  as part of the implicitly described bipartite graph. In particular, we view each  $\Pi_v$  as a function  $\mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}^k$  where the output is interpreted according to some fixed map  $\{0, 1\}^k \rightarrow V$ . Consider a set of  $n := k|V|$  ( $|V| \leq 2^c$ ) boolean variables  $\{z_{v,i} : (v, i) \in V \times [k]\}$  with the intuitive interpretation that  $z_{v,i}$  is the  $i$ -th output bit of  $\Pi_v$ . We may encode the correctness conditions for  $\Pi$  as an unsatisfiable  $2k$ -CNF formula  $F$  over the  $z_{v,i}$  that has, for each  $\{v, u\} \in \binom{V}{2}$ , clauses requiring that the outputs of  $\Pi_v$  and  $\Pi_u$  (as encoded by the  $z_{v,i}$ ) should point to distinct vertices. Finally, we note that computing the  $i$ -th output bit  $(\Pi_v)_i : \mathcal{X} \times \mathcal{Y} \rightarrow \{0, 1\}$  reduces to a large enough constant-size index gadget  $\text{IND}_{O(1)}$  (which embeds any two-party function of communication complexity  $k \leq O(1)$ ). Therefore  $S$  naturally reduces to  $S(F) \circ \text{IND}_{O(1)}^n$ , which by Lemma 7 reduces to  $\text{KW}^+(2k\text{CNF-SAT}_{O(n)})$ , as desired. ◀

## 4.2 Monotone circuit lower bounds

**Xor-Sat.** The easiest result to prove is Theorem 1: an exponential monotone circuit lower bound for 3XOR-SAT<sub>n</sub>. By the characterization of [55] it suffices to show

$$\text{PLS}^{\text{cc}}(\text{KW}^+(\text{3XOR-SAT}_n)) \geq n^{\Omega(1)}. \quad (1)$$

Urquhart [62] exhibited unsatisfiable  $n$ -variate 3XOR-CSPs  $F$  (aka *Tseitin formulas*) requiring linear Resolution width, that is,  $\text{PLS}^{\text{dt}}(S(F)) \geq \Omega(n)$  in our notation. Hence Theorem 6 implies that  $\text{PLS}^{\text{cc}}(S(F) \circ \text{IND}_m^n) \geq \Omega(n)$  for some  $m = n^{O(1)}$ . By the reduction in Lemma 7, we get that  $\text{PLS}^{\text{cc}}(\text{KW}^+(\text{3XOR-SAT}_{nm})) \geq \Omega(n)$ . (Note that 3XOR has a boolean alphabet, so  $F = F_{\text{bool}}$ .) This yields the claim (1) by reparameterizing the number of variables.

**Lin(F)-Sat.** More generally, we can prove a similar lower bound over any field  $\mathbb{F} \in \{\mathbb{F}_p, \mathbb{R}\}$ :

$$\text{PLS}^{\text{cc}}(\text{KW}^+(\text{3LIN}(\mathbb{F})\text{-SAT}_n)) \geq n^{\Omega(1)}. \quad (2)$$

Fix such an  $\mathbb{F}$  henceforth. This time we start with a  $k\text{LIN}(\mathbb{F})$ -CSP introduced in [13] for  $\mathbb{F} = \mathbb{F}_p$  (aka *mod- $p$  Tseitin formulas*), but the definition generalizes to any field. The CSP is constructed based on a given directed graph  $G = (V, E)$  that is *regular*:  $\text{in-deg}(v) = \text{out-deg}(v) = k/2$  for all  $v \in V$ . Fix also a distinguished vertex  $v^* \in V$ . Then  $F = F_{G, \mathbb{F}}$  is defined as the following  $k\text{LIN}(\mathbb{F})$ -CSP over variables  $\{z_e : e \in E\}$ :

$$\forall v \in V : \sum_{(v,u) \in E} z_{(v,u)} - \sum_{(u,v) \in E} z_{(u,v)} = \mathbf{1}_{v^*}(v), \quad (F_{G, \mathbb{F}})$$

where  $\mathbf{1}_{v^*}(v^*) = 1$  and  $\mathbf{1}_{v^*}(v) = 0$  for  $v \neq v^*$ . This system is unsatisfiable because the sum over  $v \in V$  of the RHS equals 1 whereas the sum of the LHS equals 0 (each variable appears once with a positive sign, once with a negative sign).

We claim that the booleanized  $k$ -CSP  $F_{\text{bool}}$  (more precisely, its natural  $k$ -CNF encoding) has linear Resolution width, that is,  $\text{PLS}^{\text{dt}}(S(F_{\text{bool}})) \geq \Omega(n)$  in our notation. Indeed, the constraints of  $F_{\text{bool}}$  are  $k/2$ -robust in the sense that if a partial assignment  $\rho \in \{0, 1, *\}^k$  fixes the value of a constraint of  $F_{\text{bool}}$ , then  $\rho$  must set more than  $k/2$  variables. Alekhovich et al. [1, Theorem 3.1] show that if  $k$  is a large enough constant, there exist regular expander graphs  $G$  such that  $F_{\text{bool}}$  (or any  $k$ -CSP with  $\Omega(k)$ -robust constraints) has Resolution width  $\Omega(n)$ , as desired.

Combining the above with the lifting theorem in Theorem 6 and the reduction in Lemma 7 yields  $\text{PLS}^{\text{cc}}(k\text{LIN}(\mathbb{F})\text{-SAT}_n) \geq n^{\Omega(1)}$  for large enough  $k$ . Finally, we can reduce the arity from  $k$  to 3 by a standard trick. For example, given the linear constraint  $a_1v_1 + a_2v_2 + a_3v_3 + a_4v_4 = a_0$  we can introduce a new auxiliary variable  $u$  and two equations  $a_1v_1 + a_2v_2 + u = 0$  and  $-u + a_3v_3 + a_4v_4 = a_0$ . In general, we replace each equation on  $k > 3$  variables with a collection of  $k - 2$  equations by introducing  $k - 3$  auxiliary variables to create an equisatisfiable instance. This shows that  $k\text{LIN}(\mathbb{F})\text{-SAT}_n$  reduces to (i.e., is a monotone projection of)  $3\text{LIN}(\mathbb{F})\text{-SAT}_{kn}$ , which concludes the proof of (2).

**PPAD<sup>cc</sup>  $\not\leq$  PLS<sup>cc</sup> via End-of-Line.** Consider the  $\mathbb{R}$ -linear system  $F = F_{G, \mathbb{R}}$  defined above. We observe that  $S(F_{\text{bool}})$  is in fact equivalent to (a query version of) the PPAD-complete END-OF-LINE problem. In the END-OF-LINE problem, we are given a directed graph of in/out-degree at most 1 and a distinguished source vertex  $v^*$  (in-degree 0); the goal is to find a sink or a source distinct from  $v^*$  (cf. Definition 15). On the other hand, in  $S(F_{\text{bool}})$

we are given a boolean assignment  $z \in \{0, 1\}^E$ , which can be interpreted as (the indicator vector of) a subset of edges defining a (spanning) subgraph  $G_z$  of  $G$ ; the goal is to find a vertex  $v \in V$  such that either

- (1)  $v = v^*$  and  $\text{out-deg}(v) \neq \text{in-deg}(v) + 1$  in  $G_z$ ; or
- (2)  $v \neq v^*$  and  $\text{out-deg}(v) \neq \text{in-deg}(v)$  in  $G_z$ .

The only essential difference between  $S(F_{\text{bool}})$  and END-OF-LINE is that the graph  $G_z$  can have in/out-degree a large constant  $k/2$  rather than 1. But there is a standard reduction between the two problems [46]: we may locally interpret a vertex  $v \in V(G_z)$  with  $\text{out-deg}(v) = \text{in-deg}(v) = \ell$  as  $\ell$  distinct vertices of in/out-degree 1. This reduction also shows that the lifted problem  $S(F_{\text{bool}}) \circ \text{IND}_m$  for  $m = n^{O(1)}$  admits a  $O(\log n)$ -cost PPAD-protocol, and is thus in  $\text{PPAD}^{\text{cc}}$ . By contrast, we proved above that this problem is not in  $\text{PLS}^{\text{cc}}$  (for appropriate  $G$ ).

► **Remark 9 (Algebraic partitions for  $\text{PPAD}^{\text{cc}}$ ).** We claim that every problem  $S \in \text{PPAD}^{\text{cc}}$  admits a small  $\mathbb{Z}$ -partition, and hence a small  $\mathbb{F}$ -partition over any field  $\mathbb{F}$ . More precisely, we argue that  $\log \chi_{\mathbb{Z}}(S) \leq O(\text{PPAD}^{\text{cc}}(S))$ . Indeed, let  $\Pi := (V, v^*, o_v, \Pi_v)$  be an optimal PPAD-protocol for  $S$ . We define a  $\mathbb{Z}$ -partition  $\mathcal{M}$  by describing it as a nondeterministic protocol for  $S$  whose accepting computations output weights in  $\mathbb{Z}$  (interpreted as values of the entries of an  $M \in \mathcal{M}$ ): On input  $(x, y)$ , guess a vertex  $v \in V$ ; if  $v$  is a sink in  $G_{x,y}$ , accept with weight 1; if  $v$  is a source distinct from  $v^*$ , accept with weight  $-1$ ; otherwise reject (i.e., weight 0). This protocol accepts with overall weight  $\#(\text{sinks}) - \#(\text{non-distinguished sources}) = 1$  on every input  $(x, y)$ , as desired.

A similar argument yields an analogous query complexity bound  $\text{NS}_{\mathbb{Z}}(F) \leq O(\text{PPAD}^{\text{dt}}(S(F)))$  where  $\text{PPAD}^{\text{dt}}(S)$  is the least cost of a PPAD-*decision tree* (Definition 15) solving  $S$ .

**Nullstellensatz vs. Cutting Planes.** By the above remark,  $F_{\text{bool}}$  for  $F = F_{G,\mathbb{F}}$  admits a low-degree – in fact, constant-degree – Nullstellensatz refutation over any field  $\mathbb{F}$ . Nullstellensatz degree behaves well with respect to compositions: if we compose  $F_{\text{bool}}$  with a gadget  $\text{IND}_m^n$ ,  $m = n^{O(1)}$  (see, e.g., [23, §8] how this can be done), the Nullstellensatz degree can only increase by the query complexity of the gadget, which is  $O(\log n)$  for  $\text{IND}_m^n$ . This gives us an  $n^{O(1)}$ -variate boolean  $k$ -CSP  $F' := F_{\text{bool}} \circ \text{IND}_m^n$  (where  $k$  is constant [23, §8]) such that  $\text{NS}_{\mathbb{F}}(F') \leq O(\log n)$ . On the other hand, we can invoke the strong version of the main result of [23]: if  $F$  has Resolution width  $w$ , then  $F \circ \text{IND}_m^n$  requires Cutting Planes refutations of length  $n^{\Omega(w)}$ . In summary,  $F'$  witnesses that  $\mathbb{F}$ -Nullstellensatz can be exponentially more powerful than log of Cutting Planes length.

### 4.3 Monotone span program lower bounds

Let us prove Theorem 2:  $3\text{LIN}(\mathbb{R})\text{-SAT}_n$  requires exponential-size monotone  $\mathbb{F}_p$ -span programs, that is,

$$\chi_{\mathbb{F}_p}(\text{KW}^+(3\text{LIN}(\mathbb{R})\text{-SAT}_n)) \geq n^{\Omega(1)}. \tag{3}$$

Using Theorem 6 and Lemma 7 similarly as in Subsection 4.2, it suffices to show that  $\text{NS}_{\mathbb{F}_p}(F_{\text{bool}}) \geq n^{\Omega(1)}$ , for some unsatisfiable  $k\text{LIN}(\mathbb{R})$ -CSP  $F$  where  $k$  is a constant. To this end, we consider an  $\mathbb{R}$ -linear system  $F = F_{G,U,\mathbb{R}}$  that generalizes  $F_{G,\mathbb{R}}$  defined above:

$$\forall v \in V : \sum_{(v,u) \in E} z_{(v,u)} - \sum_{(u,v) \in E} z_{(u,v)} = \mathbf{1}_U(v), \tag{F_{G,U,\mathbb{R}}}$$

where  $\mathbb{1}_U: V \rightarrow \{0, 1\}$  is the indicator function for  $U \subseteq V$ . This is unsatisfiable as long as  $U \neq \emptyset$ . Combinatorially, the boolean search problem  $S(F_{\text{bool}})$  can be interpreted as an END-OF- $\ell$ -LINES problem for  $\ell := |U|$ : given a graph with distinguished source vertices  $U$ , find a sink or a source not in  $U$ . It is important to have many distinguished sources,  $|U| \geq n^{\Omega(n)}$ , as otherwise  $S(F_{\text{bool}})$  is in  $\text{PPAD}^{\text{dt}}$  [31] and hence  $F_{\text{bool}}$  has too low an  $\mathbb{F}_p$ -Nullstellensatz degree (by Remark 9).

**Nullstellensatz lower bound.** To show  $\text{NS}_{\mathbb{F}_p}(F_{\text{bool}}) \geq n^{\Omega(1)}$  for an appropriate  $F = F_{G,U,\mathbb{R}}$ , we adapt a result of Beame and Riis [8]. They proved a Nullstellensatz lower bound for a related *bijective pigeonhole* principle  $P_n$  whose underlying graph has *unbounded* degree; we obtain a bounded-degree version of their result by a reduction.

► **Lemma 10** ([8, §8]). *Fix a prime  $p$ . The following system of polynomial equations over variables  $\{x_{ij} : (i, j) \in D \times R\}$ , where  $|D| = n$  and  $|R| = n - n^{\Omega(1)}$ , requires  $\mathbb{F}_p$ -Nullstellensatz degree  $n^{\Omega(1)}$ :*

$$\begin{array}{llll}
(i) & \forall i \in D : & \sum_{j \in R} x_{ij} = 1 & \text{“each pigeon occupies a hole”,} \\
(ii) & \forall j \in R : & \sum_{i \in D} x_{ij} = 1 & \text{“each hole houses a pigeon”,} \\
(iii) & \forall i \in D, \{j, j'\} \in \binom{R}{2} : & x_{ij}x_{ij'} = 0 & \text{“no pigeon occupies two holes”,} \\
(iv) & \forall j \in R, \{i, i'\} \in \binom{D}{2} : & x_{ij}x_{i'j} = 0 & \text{“no hole houses two pigeons”.}
\end{array} \tag{P_n}$$

We construct a natural bounded-degree version  $G$  of the complete bipartite graph  $D \times R$  and show that each constraint of  $F_{\text{bool}}$  for  $F = F_{G,U,\mathbb{R}}$  is a low-degree  $\mathbb{F}_p$ -Nullstellensatz consequence of  $P_n$ . Hence, if  $F_{\text{bool}}$  admits a low-degree  $\mathbb{F}_p$ -Nullstellensatz proof, so does  $P_n$  (see, e.g., [13, Lemma 1] for composing proofs), which contradicts Lemma 10.

The directed graph  $G = (V, E)$  is obtained from the complete bipartite graph  $D \times R$  as illustrated in Figure 2 (for  $|D| = 4$  and  $|R| = 3$ ). Specifically, each vertex of degree  $d$  in  $D \times R$  is replaced with a binary tree of height  $\log d$ . The result is a layered graph with the first and last layers identified with  $D$  and  $R$ , respectively. We also add a “feedback” edge from each vertex in  $R$  to a vertex in  $D$  according to some arbitrary injection  $R \rightarrow D$  (dashed edges in Figure 2). The vertices in  $D$  not incident to feedback edges will form the set  $U$  (singleton in Figure 2).

This defines a boolean 3-CSP  $F_{\text{bool}}$  for  $F = F_{G,U,\mathbb{R}}$  over variables  $\{z_e : e \in E\}$ . In order to reduce  $P_n$  to  $F_{\text{bool}}$ , we define an affine map between the variables  $x_{ij}$  of  $P_n$  and  $z_e$  of  $F_{\text{bool}}$ . Namely, for a feedback edge  $e$  we set  $z_e := 1$ , and for every other  $e = (v, u)$  we set

$$z_{(v,u)} := \sum_{i \in D_v} \sum_{j \in R_u} x_{ij},$$

$$\begin{aligned}
\text{where } D_v &:= \{i \in D : v \text{ is reachable from } i \text{ without using feedback edges}\}, \\
R_u &:= \{j \in R : j \text{ is reachable from } u \text{ without using feedback edges}\}.
\end{aligned}$$

Note in particular that this map naturally identifies the edge-variables  $z_e$  in the middle of  $G$  (yellow edges) with the variables  $x_{ij}$  of  $P_n$ . The other variables  $z_e$  are simply affinely dependent on the middle edge-layer. We then show that from the equations of  $P_n$  we can derive each constraint of  $F_{\text{bool}}$ . Recall that the constraint for  $v \in V$  requires that the *out-flow*  $\sum_{(v,u) \in E} z_{(v,u)}$  equals the *in-flow*  $\sum_{(u,v) \in E} z_{(u,v)}$  (plus 1 iff  $v \in U$ ).

$v \notin D \cup R$ : Suppose  $v$  is on the left side of  $G$  (right side is handled similarly) so that  $z_{(v,u)} = \sum_{j \in R_u} x_{ij}$  for some fixed  $i \in D$ . The out-flow is

$$\sum_{(v,u) \in E} z_{(v,u)} = \sum_{(v,u) \in E} \sum_{j \in R_u} x_{ij} = \sum_{j \in R_v} x_{ij}. \tag{4}$$

■ **Figure 2** Graph  $G = (V, E)$ , a bounded-degree version of the biclique  $D \times R$ .

On the other hand,  $v$  has a unique incoming edge  $(u^*, v)$  so the in-flow is  $\sum_{(u,v) \in E} z_{(u,v)} = z_{(u^*,v)} = \sum_{j \in R_v} x_{ij}$ , which equals (4).

$v \in D$ : (Case  $v \in R$  is handled similarly). The in-flow equals 1 (either  $v \in U$  so that we have the +1 term from  $\mathbb{1}_U(v)$ ; or  $v \notin U$  and the value of a feedback-edge variable gives +1).

The out-flow equals  $\sum_{j \in R_v} x_{ij} = \sum_{j \in R} x_{ij} = 1$  by (4),  $R_v = R$ , and (ii).

Finally, we can verify the boolean axioms  $z_e^2 = z_e$ . This holds trivially for feedback edges  $e$ . Let  $e = (v, u)$  be an edge in the left side of  $G$  (right side is similar) so that  $z_e = \sum_{j \in R_u} x_{ij}$  for some fixed  $i \in D$ . We have  $z_e^2 = (\sum_{j \in R_u} x_{ij})^2 = \sum_{j \in R_u} x_{ij}^2 = \sum_{j \in R_u} x_{ij} = z_e$  by (iii) and the boolean axioms for  $P_n$ .

This concludes the reduction and hence the proof of (3).

**PPADS<sup>cc</sup>  $\not\subseteq$  PPA<sup>cc</sup> via End-of- $\ell$ -Lines.** It is straightforward to check that  $F_{\text{bool}}$  for  $F = F_{G,U,\mathbb{R}}$  is in the query class PPADS<sup>dt</sup> (Definition 16). In particular, in the PPADS–decision tree, we can define the distinguished vertex  $v^*$  as being associated with any vertex from  $U$ . Similarly, the lifted problem  $S' := S(F_{\text{bool}}) \circ \text{IND}_n^m$  for  $m = n^{O(1)}$  is in the communication class PPADS<sup>cc</sup>. By contrast, we just proved that  $\chi_{\mathbb{F}_2}(S') \geq n^{\Omega(1)}$ , which implies that  $S' \notin \text{PPA}^{\text{cc}}$ .

## 5 Proofs of Characterizations

Due to space constraints, the proofs of Theorem 3 and Theorem 4 are omitted from this extended abstract. See the full version [24] for complete proofs.

## A Appendix: TFNP Class Definitions

For each TFNP subclass there is a canonical definition of its communication or query analogue: we simply let communication protocols or decision trees (rather than circuits) implicitly define the objects that appear in the original Turing machine definition. Each communication class  $C^{cc}$  (resp. query class  $C^{dt}$ ) is defined via a  $C$ -protocol (resp.  $C$ -decision tree) that solves a two-party search problem  $S \subseteq \{0, 1\}^{n/2} \times \{0, 1\}^{n/2} \times \mathcal{O}$  (resp.  $S \subseteq \{0, 1\}^n \times \mathcal{O}$ ). The class  $C^{cc}$  (resp.  $C^{dt}$ ) is then defined as the set of all  $n$ -bit search problems  $S$  that admit a polylog( $n$ )-cost  $C$ -protocol (resp.  $C$ -decision tree). We only define the communication analogues below with the understanding that a query version can be obtained by replacing mentions of a protocol  $\Pi_v(x, y)$  by a decision tree  $\mathcal{T}_v(x)$ ; the *cost* of a  $C$ -decision tree is defined as  $\max_{v,x} \#(\text{queries made by } \mathcal{T}_v(x))$ . In what follows, *sink* means out-degree 0, and *source* means in-degree 0.

### ► Definition 11. (FP)

**Syntax:**  $\Pi$  is a (deterministic) protocol outputting values in  $\mathcal{O}$ .

**Object:**  $n/a$

**Correctness:**  $\Pi(x, y) \in S(x, y)$ .

**Cost:**  $|\Pi| :=$  communication cost of  $\Pi$ .

► **Definition 12.** (EoML)

**Syntax:**  $V$  is a vertex set with a distinguished vertex  $v^* \in V$ . For each  $v \in V$ :  $o_v \in \mathcal{O}$  and

$\Pi_v$  is a protocol outputting a tuple  $(s_v(x, y), p_v(x, y), \ell_v(x, y)) \in V \times V \times \mathbb{Z}$ .

**Object:** Dag  $G_{x,y} = (V, E)$  where  $(v, u) \in E$  iff  $s_v(x, y) = u$ ,  $p_u(x, y) = v$ ,  $\ell_v(x, y) > \ell_u(x, y)$ .

**Correctness:** If  $v^*$  is a sink or non-source in  $G_{x,y}$ , then  $o_{v^*} \in S(x, y)$ .

If  $v \neq v^*$  is a sink or source in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 13.** (SoML)

**Syntax:** Same as in Definition 12.

**Object:** Same as in Definition 12.

**Correctness:** If  $v^*$  is a sink or non-source in  $G_{x,y}$ , then  $o_{v^*} \in S(x, y)$ .

If  $v \neq v^*$  is a sink in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 14.** (PLS)

**Syntax:**  $V$  is a vertex set. For each  $v \in V$ :  $o_v \in \mathcal{O}$  and  $\Pi_v$  is a protocol outputting a pair

$(s_v(x, y), \ell_v(x, y)) \in V \times \mathbb{Z}$ .

**Object:** Dag  $G_{x,y} = (V, E)$  where  $(v, u) \in E$  iff  $s_v(x, y) = u$  and  $\ell_v(x, y) > \ell_u(x, y)$ .

**Correctness:** If  $v$  is a sink in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 15.** (PPAD)

**Syntax:**  $V$  is a vertex set with a distinguished vertex  $v^* \in V$ . For each  $v \in V$ :  $o_v \in \mathcal{O}$  and

$\Pi_v$  is a protocol outputting a pair  $(s_v(x, y), p_v(x, y)) \in V \times V$ .

**Object:** Digraph  $G_{x,y} = (V, E)$  where  $(v, u) \in E$  iff  $s_v(x, y) = u$  and  $p_u(x, y) = v$ .

**Correctness:** If  $v^*$  is a sink or non-source in  $G_{x,y}$ , then  $o_{v^*} \in S(x, y)$ .

If  $v \neq v^*$  is a sink or source in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 16.** (PPADS)

**Syntax:** Same as in Definition 15.

**Object:** Same as in Definition 15.

**Correctness:** If  $v^*$  is a sink or non-source in  $G_{x,y}$ , then  $o_{v^*} \in S(x, y)$ .

If  $v \neq v^*$  is a sink in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 17.** (PPA)

**Syntax:**  $V$  is a vertex set with a distinguished vertex  $v^* \in V$ . For each  $v \in V$ :  $o_v \in \mathcal{O}$  and

$\Pi_v$  is a protocol outputting a subset  $\Pi_v(x, y) \subseteq V$  of size at most 2.

**Object:** Undirected graph  $G_{x,y} = (V, E)$  where  $\{v, u\} \in E$  iff  $v \in \Pi_u(x, y)$  and  $u \in \Pi_v(x, y)$ .

**Correctness:** If  $v^*$  has degree  $\neq 1$  in  $G_{x,y}$ , then  $o_{v^*} \in S(x, y)$ .

If  $v \neq v^*$  has degree  $\neq 2$  in  $G_{x,y}$ , then  $o_v \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

► **Definition 18.** (PPP)

**Syntax:**  $V$  is a vertex set with a distinguished vertex  $v^* \in V$ . For each unordered pair

$\{v, u\} \in \binom{V}{2}$ :  $o_{\{v,u\}} \in \mathcal{O}$ . For each  $v \in V$ :  $\Pi_v$  is a protocol outputting values in  $V - v^*$ .

**Object:** Bipartite graph  $G_{x,y} = (V \times (V - v^*), E)$  where  $(v, w) \in E$  iff  $\Pi_v(x, y) = w$ .

**Correctness:** If  $(v, w)$  and  $(u, w)$ ,  $v \neq u$ , are edges in  $G_{x,y}$ , then  $o_{\{v,u\}} \in S(x, y)$ .

**Cost:**  $\log |V| + \max_v |\Pi_v|$ .

## Abstract

Using a mild variant of polar codes we design linear compression schemes compressing Hidden Markov sources (where the source is a Markov chain, but whose state is not necessarily observable from its output), and to decode from Hidden Markov channels (where the channel has a state and the error introduced depends on the state). We give the first polynomial time algorithms that manage to compress and decompress (or encode and decode) at input lengths that are polynomial *both* in the gap to capacity and the mixing time of the Markov chain. Prior work achieved capacity only asymptotically in the limit of large lengths, and polynomial bounds were not available with respect to either the gap to capacity or mixing time. Our results operate in the setting where the source (or the channel) is *known*. If the source is *unknown* then compression at such short lengths would lead to effective algorithms for learning parity with noise – thus our results are the first to suggest a separation between the complexity of the problem when the source is known versus when it is unknown.

## 1 Introduction

We study the problem of designing coding schemes, specifically encoding and decoding algorithms, that overcome errors caused by stochastic, but not memoryless, channels. Specifically we consider the class of “(hidden) Markov channels” that are stateful, with the states evolving according to some Markov process, and where the distribution of error depends on

■ **Figure 1** A Markovian Channel: The Nice state flips bits with probability  $\delta$  whereas the Noisy state flips with probability  $1/2 - \delta$ . The stationary probability of the Nice state is  $q/p$  times that of the Noisy state.

the state.<sup>4</sup> Such Markovian models capture many natural settings of error, such as bursty error models. (See for example, Figure 1.) Yet they are often less understood than their memoryless counterparts (or even “explicit Markov models” where the state is completely determined by the actions of the channel). For instance (though this is not relevant to our work) even the capacity of such channels is not known to have a closed form expression in terms of channel parameters. (In particular the exact capacity of the channel in Figure 1 is not known as a function of  $\delta$ ,  $p$  and  $q$ !)

In this work we aim to design coding schemes that achieve rates arbitrarily close to capacity. Specifically given a channel of capacity  $C$  and gap parameter  $\varepsilon > 0$ , we would like to design codes that achieve a rate of at least  $C - \varepsilon$ , that admit polynomial time algorithms even at small block lengths  $n \geq \text{poly}(1/\varepsilon)$ . Even for the memoryless case such coding schemes were not known till recently. In 2008, Arikan [1] invented a completely novel approach to constructing codes based on “channel polarization” for communication on binary-input memoryless channels, and proved that they enable achieving capacity in the limit of large code lengths with near-linear complexity encoding and decoding. In 2013, independent works by Guruswami and Xia [5] and Hassani et al. [6] gave a finite-length analysis of Arikan’s polar codes, proving that they approach capacity fast, at block lengths bounded by  $\text{poly}(1/\varepsilon)$  where  $\varepsilon > 0$  is the difference between the channel capacity and code rate.

The success of polar codes on the memoryless channels might lead to the hope that maybe these codes, or some variants, might lead to similar coding schemes for channels with memory. But such a hope is not easily justified: the analysis of polar codes relies heavily on the fact that errors introduced by the channel are independent and this is exactly what is not true for channels with memory. Despite this seemingly insurmountable barrier, Şaşıoğlu [4] and later Şaşıoğlu and Tal [9] showed, quite surprisingly, that the analysis of polar codes can be carried out even with Markovian channels (and potentially even broader classes of channels). Specifically they show that these codes converge to capacity and even the probability of decoding error, under maximum likelihood decoding, drops exponentially fast in the block length (specifically as  $2^{-n^{\Omega(1)}}$  on codes of length  $n$ ; see also [10], where exponentially fast polarization was also shown at the high entropy end). An extension of Arikan’s successive cancellation decoder from the memoryless case was also given by [12], building on an earlier version [13] specific to intersymbol interference channels, leading to efficient decoding algorithms.

<sup>4</sup> We use the term *hidden* to emphasize the fact that the state itself is not directly observable from the actions of the channel, though in the interest of succinctness we will omit this term for most of the rest of this section.

However, none of the works above give small bounds on the block length of the codes as a function of the gap to capacity, and more centrally to this work, on the mixing time of the Markov chain. The latter issue gains importance when we turn to the issue of “compressing Markov sources” which turns out to be an intimately related task to that of error-correction for Markov channels as we elaborate below and which is also the central task we turn to in this paper. We start by describing Markov source and the (linear) compression problem.

A (hidden) Markov source over alphabet  $\Sigma$  is given by a Markov chain on some finite state space where each state  $s$  has an associated distribution  $D_s$  over  $\Sigma$ . The source produces information by performing a walk on the chain and at each time step  $t$ , outputting a letter of  $\Sigma$  drawn according to the distribution associated with the state at time  $t$  (independent of all previous choices, and previous states).<sup>5</sup> In the special case of additive Markovian channels where the output of the channel is the sum of the transmitted word with an error vector produced by a Markov source, a well-known correspondence shows that error-correction for the additive Markov channel reduces to the task of designing a compression and decompression algorithm for Markovian sources, with the compression being *linear*. Indeed in this paper we only focus on this task: our goal turns into that of compressing  $n$  bits generated by the source to its entropy upto an additive factor of  $\varepsilon n$ , while  $n$  is only polynomially large in  $1/\varepsilon$ .

A central issue in the task of compressing a source is whether the source is *known* to the compression algorithm or not. While ostensibly the problem should be easier in the “known” setting than in the “unknown” one, we are not aware of any formal results suggesting a difference in complexity. It turns out that compression in the setting where the source is unknown is at least as hard as “learning parity with noise” (we argue this in Appendix B), *if* the compression works at lengths polynomial in the mixing time and gap to capacity. This suggests that the unknown source setting is hard (under some current beliefs). No corresponding hardness was known for the task of compressing sources when they are known, but no easiness result seems to have been known either (and certainly no linear compression algorithm was known). This leads to the main question addressed (positively) in this work.

## Our Results

Our main result is a construction of codes for *additive Markov channels* that gets  $\varepsilon$  close to capacity at block lengths polynomial in  $1/\varepsilon$  and the mixing time of the Markov chain, with polynomial (in fact near-linear) encoding and decoding time. Informally additive channels are those that map inputs from some alphabet  $\Sigma$  to outputs over  $\Sigma$  with an abelian group defined on  $\Sigma$  and the channel generates an error sequence independent of the input sequence, and the output of the channel is just the coordinatewise sum of the input sequence with the error sequence. (In our case the alphabet  $\Sigma$  is a finite field of prime cardinality.) The exact class of channels is described in Definition 4, and Theorem 10 states our result formally. We stress that we work with additive channels only for conceptual simplicity and that our results should extend to more general symmetric channels though we don’t do so here. Prior to this work no non-trivial Markov channel was known to achieve efficient encoding and decoding at block lengths polynomial in either parameter (gap to capacity or mixing time).

Our construction and analyses turn out to be relatively simple given the works of Şaşıoğlu and Tal [4, 9] and the work of Blasiok et al. [2]. The former provides insights on how to work with channels with memory, whereas the latter provides tools needed to get short block

---

<sup>5</sup> The phrase “hidden” emphasizes the fact that the output produced by the source does not necessarily reveal the sequence of states visited.

length and cleaner abstractions of the efficient decoding algorithm that enable us to apply it in our setting. Our codes are a slight variant of polar codes, where we apply the polar transforms independently to blocks of inputs. This enables us to apply the analysis of [2] in an essentially black box manner, benefiting both from its polynomially fast convergence guarantee to capacity as well as its generality covering all polarizing matrices over any prime alphabet (and not just the basic Boolean  $2 \times 2$  transform covered in [9]).

We give a more detailed summary of how our codes are obtained and how we analyze them in Section 3 after stating our results and main theorem formally.

## 2 Definitions and Main Results

### 2.1 Notation and Definitions

We will use  $\mathbb{F}_q$  to denote the finite field with  $q$  elements. Throughout the paper, we will deal only with the case when  $q$  is a prime. (This restriction in turn comes from the work of [2] whose results we use here.)

We use several notations to index matrices. For a matrix  $M \in \mathbb{F}_q^{m \times n}$ , the entry in the  $i$ th row,  $j$ th column is denoted  $M_{i,j}$  or  $M_{(i,j)}$ . Columns are denoted by superscripts, i.e.,  $M^j \in \mathbb{F}_q^m$  denotes the  $j$ th column of  $M$ . Note that  $M_i^j = M_{(i,j)}$ . We also use the indices as sets in the natural way. For example  $M^{\leq j} \in \mathbb{F}_q^{m \times j}$  denotes the first  $j$  columns of  $M$ .  $M_{\leq i}^{\leq j}$  denotes the submatrix of elements in the first  $j$  columns and first  $i$  rows.  $M_{\prec(i,j)}$  denotes the set of elements of  $M$  indexed by lexicographically smaller indices than  $(i, j)$ . Multiplication of a matrix  $M \in \mathbb{F}_q^{m \times n}$  with a vector  $v \in \mathbb{F}_q^n$  is denoted  $Mv$ .

For a finite set  $S$ , let  $\Delta(S)$  denote the set of probability distributions over  $S$ . For a random variable  $X$  and event  $E$ , we write  $X|E$  to denote the conditional distribution of  $X$ , conditioned on  $E$ . For example, we may write  $X|\{X_1 = 0\}$ .

The *total-variation distance* between two distributions  $p, q \in \Delta(U)$  is

$$\|p - q\|_1 := \sum_i |p(i) - q(i)|$$

We consider compression schemes, as a map  $\mathbb{F}_q^n \rightarrow \mathbb{F}_q^m$ . The *rate* of a compression scheme  $\mathbb{F}_q^n \rightarrow \mathbb{F}_q^m$  is the ratio  $m/n$ .

For a random variable  $X \in [q]$ , the (*non-normalized*) *entropy* is denoted  $H(X)$ , and is

$$H(X) := - \sum_i \Pr[X = i] \log(\Pr[X = i])$$

and the *normalized entropy* is denoted  $\bar{H}(X)$ , and is

$$\bar{H}(X) := \frac{1}{\log(q)} H(X)$$

► **Definition 1.** A *Markov chain*  $\mathcal{M} = (\ell, \Pi, \pi_0)$  is given by an  $\ell$  representing the state space  $[\ell]$ , a transition matrix  $\Pi \in \mathbb{R}^{\ell \times \ell}$ , and a distribution on initial state  $\pi_0 \in \Delta([\ell])$ . The rows of  $\Pi$ , denoted  $\Pi_1, \dots, \Pi_\ell$  are thus elements of  $\Delta([\ell])$ . A Markov chain generates a random sequence of states  $X_0, X_1, X_2, \dots$  determined by letting  $X_0 \sim \pi_0$ , and  $X_t \sim \Pi_{X_{t-1}}$  for  $t > 0$  given  $X_0, \dots, X_{t-1}$ . The stationary distribution  $\pi \in \Delta([\ell])$  is the distribution such that if  $X_0 \sim \pi$ , then all  $X_t$ 's are marginally identically distributed as  $\pi$ .

We consider only Markov chains which are irreducible and aperiodic, and hence have a stationary distribution to which they converge in the limit. The rate of convergence is measured by the mixing time, defined below.

► **Definition 2.** The *mixing time* of a Markov chain is the constant  $\tau > 0$  such that for every initial state  $s_0$  of the Markov chain, the distribution of state  $s_\ell$  is  $\exp(-\ell/\tau)$ -close in total variation distance to the stationary distribution  $\pi$ .

► **Definition 3.** A *(stationary, hidden) Markov source*  $\mathcal{H} = (\Sigma, \mathcal{M}, \{\mathcal{S}_1, \dots, \mathcal{S}_\ell\})$  is specified by an alphabet  $\Sigma$ , a Markov chain  $\mathcal{M}$  on  $\ell$  states and distributions  $\{\mathcal{S}_i \in \Delta(\Sigma)\}_{i \in [\ell]}$ . The output of the source is a sequence  $Z_1, Z_2, \dots$ , of random variables obtained by first sampling a sequence  $X_0, X_1, X_2, \dots$  according to  $\mathcal{M}$  and then sampling  $Z_i \sim \mathcal{S}_{X_i}$  independently for each  $i$ . We let  $\mathcal{H}_t$  the distribution of output sequences of length  $t$ , and  $\mathcal{H}_t^{\otimes s}$  denote the distribution of  $s$  i.i.d. samples from  $\mathcal{H}_t$ .

Similarly, we define an *additive Markov channel* as a channel which adds noise from a Markov source.

► **Definition 4.** An *additive Markov channel*  $\mathcal{C}_{\mathcal{H}}$ , specified by a Markov source  $\mathcal{H}$  over alphabet  $\mathbb{F}_q$ , is a randomized map  $\mathcal{C}_{\mathcal{H}} : \mathbb{F}_q^* \rightarrow \mathbb{F}_q^*$  obtained as follows: On channel input  $X_1, \dots, X_n$ , the channel outputs  $Y_1, \dots, Y_n$  where  $Y_i = X_i + Z_i$  where  $Z = (Z_1, \dots, Z_n) \sim \mathcal{H}_n$ .

► **Definition 5.** A *linear code* is a linear map  $C : \mathbb{F}_q^k \rightarrow \mathbb{F}_q^n$ . The *rate* of a code is the ratio  $k/n$ .

► **Definition 6.** For all sets  $A, B$ , a *constructive source over  $(A|B)$  samplable in time  $T$*  is a distribution  $\mathcal{D} \in \Delta(A \times B)$  such that  $(a, b) \sim \mathcal{D}$  can be sampled efficiently in time at most  $T$ , and for every fixed  $b \in B$ , the conditional distribution  $A|\{B = b\}$  can be sampled efficiently in time at most  $T$ .

► **Proposition 7.** *Every Markov source with state space  $[\ell]$  is a constructive source samplable in time  $\mathcal{O}(n\ell^2)$ . That is, for every  $n$ , let  $Y_1, \dots, Y_n$  be the random variables generated by the Markov source. Then, the sequence  $Y_1, \dots, Y_n$  can be sampled in time at most  $\mathcal{O}(n\ell^2)$ , and moreover for every setting of  $Y_{<n} = y_{<n}$ , the distribution  $(Y_n|Y_{<n} = y_{<n})$  can be sampled in time  $\mathcal{O}(n\ell^2)$ .*

**Proof.** Sampling  $Y_1, \dots, Y_n$  can clearly be done by simulating the Markov chain, and sampling from the conditional distribution  $(Y_n|Y_{<n} = y_{<n})$  is possible using the standard *Forward Algorithm* for inference in Hidden Markov Models, which we describe for completeness in Appendix A. ◀

Finally, we will use the following notion of *mixing matrices* from [7, 2], characterizing which matrices lead to good polar codes. In the study of polarization it is well-known that lower-triangular matrices do not polarize at all, and the polarization characteristics of matrices are invariant under column permutations. Mixing matrices are defined to be those that avoid the above cases.

► **Definition 8.** For prime  $q$  and  $M \in \mathbb{F}_q^{k \times k}$ ,  $M$  is said to be a *mixing matrix* if  $M$  is invertible and for every permutation of the columns of  $M$ , the resulting matrix is not lower-triangular.

## 2.2 Main Theorems

We are now ready to state the main results of this work formally. We begin with the statement for compressing the output of a hidden Markov model.

► **Theorem 9.** *For every prime  $q$  and mixing matrix  $M \in \mathbb{F}_q^{k \times k}$  there exists a preprocessing algorithm (POLAR-PREPROCESS, Algorithm 6.3), a compression algorithm (POLAR-COMPRESS, Algorithm 4.1), a decompression algorithm (POLAR-DECOMPRESS, Algorithm 4.2) and a polynomial  $p(\cdot)$  such that for every  $\varepsilon > 0$ , the following properties hold:*

1. POLAR-PREPROCESS is a randomized algorithm that takes as input a Markov source  $\mathcal{H}$  with  $\ell$  states, and  $t \in \mathbb{N}$ , and runs in time  $\text{poly}(n, \ell, 1/\varepsilon, q)$  where  $n = k^{2t}$  and outputs auxiliary information for the compressor and decompressor (for  $\mathcal{H}_n$ ).
2. POLAR-COMPRESS takes as input a sequence  $Z \in \mathbb{F}_q^n$  as well as the auxiliary information output by the preprocessor, runs in time  $\mathcal{O}(n \log n)$ , and outputs a compressed string  $\tilde{U} \in \mathbb{F}_q^{\overline{H}(Z)+\varepsilon n}$ . Further, for every auxiliary input, the map  $Z \rightarrow \tilde{U}$  is a linear map.
3. POLAR-DECOMPRESS takes as input a Markov source  $\mathcal{H}$  a compressed string  $\tilde{U} \in \mathbb{F}_q^{\overline{H}(Z)+\varepsilon n}$  and the auxiliary information output by the preprocessor, runs in time  $\mathcal{O}(n^{3/2}\ell^2 + n \log n)$  and outputs  $\hat{Z} \in \mathbb{F}_q^n$ .<sup>6</sup>

The guarantee provided by the above algorithms is that with probability at least  $1 - \exp(-\Omega(n))$ , the Preprocessing Algorithm outputs auxiliary information  $S$  such that

$$\Pr_{Z \sim \mathcal{H}_n} [\text{POLAR-DECOMPRESS}(\mathcal{H}, S; \text{POLAR-COMPRESS}(Z; S)) \neq Z] \leq \mathcal{O}\left(\frac{1}{n^2}\right),$$

provided  $n > p(\tau/\varepsilon)$  where  $\tau$  is the mixing time of  $\mathcal{H}$ .

(In the above  $\mathcal{O}(\cdot)$  hides constants depending  $k$  and  $q$ , but not on  $\ell$  or  $n$ .)

The above linear compression directly yields channel coding for additive Markov channels, via a standard reduction (the details of which are in Section 7.)

► **Theorem 10.** For every prime  $q$  and mixing matrix  $M \in \mathbb{F}_q^{k \times k}$  there exists a randomized preprocessing algorithm PREPROCESS, an encoding algorithm ENC, a decoding algorithm DEC, and a polynomial  $p(\cdot)$  such that for every  $\varepsilon > 0$ , the following properties hold:

1. PREPROCESS is a randomized algorithm that takes as input an additive Markov channel  $\mathcal{C}_{\mathcal{H}}$  described by Markov source  $\mathcal{H}$  with  $\ell$  states, and  $t \in \mathbb{N}$ , and runs in time  $\text{poly}(n, \ell, 1/\varepsilon)$  where  $n = k^{2t}$ , and outputs auxiliary information for  $\mathcal{H}_n$ .
2. ENC takes as input a message  $x \in \mathbb{F}_q^r$ , where  $r \geq n(1 - \frac{\overline{H}(Z)}{n} - \varepsilon)$ , as well as auxiliary information from the preprocessor and outputs and computes  $\text{ENC}(x) \in \mathbb{F}_q^n$  in  $\mathcal{O}(n \log n)$  time.
3. DEC takes as input the Markov source  $\mathcal{H}$ , auxiliary information from the preprocessor and a string  $z \in \mathbb{F}_q^n$ , runs in time  $\mathcal{O}_q(n^{3/2}\ell^2 + n \log n)$ , and outputs an estimate  $\hat{x} \in \mathbb{F}_q^r$  of the message  $x$ .<sup>7</sup>

The guarantee provided by the above algorithms is that with probability at least  $1 - \exp(-\Omega(n))$ , the Preprocessing algorithm outputs  $S$  such that for all  $x \in \mathbb{F}_q^r$  we have

$$\Pr_{\mathcal{C}_{\mathcal{H}}} [\text{DEC}(\mathcal{H}; \mathcal{C}_{\mathcal{H}}(\text{ENC}(C; x))) \neq x] \leq \mathcal{O}\left(\frac{1}{n^2}\right),$$

provided  $n > p(\tau/\varepsilon)$  where  $\tau$  is the mixing time of  $\mathcal{H}$ .

(In the above  $\mathcal{O}(\cdot)$  hides constants that may depend on  $k$  and  $q$  but not on  $\ell$  or  $n$ .)

Theorem 10 follows relatively easily from Theorem 9 and so in the next section we focus on the overview of the proof of the latter.

<sup>6</sup> The runtime of the decompression algorithm can be improved to a runtime of  $\mathcal{O}(n^{1+\delta}\ell^2 + n \log n)$  by a simple modification. In particular, by taking the input matrix  $Z$  to be  $n^{1-\delta} \times n^\delta$  instead of  $n^{1/2} \times n^{1/2}$ . In fact we believe the decoding algorithm can be improved to an  $\mathcal{O}(n \log n)$  time algorithm with some extra bookkeeping though we don't do so here.

<sup>7</sup> This can similarly be improved to a runtime of  $\mathcal{O}_q(n^{1+\delta}\ell^2 + n \log n)$ .

### 3 Overview of our construction

**Basics of polarization.** We start with the basics of polarization in the setting of compressing samples from an i.i.d. source. To compress a sequence  $Z \in \mathbb{F}_2^n$  drawn from some source, the idea is to build an invertible linear function  $P$  such that for all but  $\varepsilon$  fraction of the output coordinates  $i \in [n]$ , the conditional entropy  $H(P(Z)_i | P(Z)_{<i})$  is close to 0 and or close to 1. (Such an effect is called *polarization*, as the entropies are driven to polarize toward the two extreme values.) Since a deterministic invertible transformation preserves the total entropy, it follows that roughly  $H(Z)$  output coordinates can have entropy close to 1 and  $n - H(Z)$  coordinates have (conditional) entropy close to 0. Letting  $S$  denote the coordinates whose conditional entropies that are not close to zero, the compression function is simply  $Z \mapsto P(Z)_S$ , the projection of the output  $P(Z)$  onto the coordinates in  $S$ .

Picking a random linear function  $P$  would satisfy the properties above with high probability, but this is not known (and unlikely) to be accompanied by efficient algorithms. To get the algorithmics (how to compute  $P$  efficiently, to determine  $S$  efficiently, and to decompress efficiently) one uses a recursive construction of  $P$ . For our purposes the following explanation works best: Let  $n = m^2$  and view  $Z = (Z_{11}, Z_{12}, \dots, Z_{mm})$  and as an  $m \times m$  matrix over  $\mathbb{F}_2$ , where the elements of  $Z$  arrive one row at a time. Let  $P_m^{\text{row}}(\cdot)$  denote the operation mapping  $\mathbb{F}_2^{m \times m}$  to  $\mathbb{F}_2^{m \times m}$  that applies  $P_m$  to each row of separately. Let  $P_m^{\text{column}}(\cdot)$  denote the operation that applies  $P_m$  to each column separately. Then  $P_n(Z) = P_m^{\text{column}}(P_m^{\text{row}}(Z))^T$ . The base case is given by  $P_2(U, V) = (U + V, V)$ .

Intuitively, when the elements of  $Z$  are *independent* and identical, the operation  $P_m$  already polarizes the outputs somewhat and so a moderate fraction of the outputs of  $P_m^{\text{row}}(Z)$  have conditional entropies moderately close to 0 or 1. The further application of  $P_m^{\text{column}}(\cdot)$  further polarizes the output bringing a larger fraction of the conditional entropies of the output even closer to 0 or 1.

**Polarization for Markovian Sources.** When applied to source  $Z$  with memory, roughly the analysis in [9], reinterpreted to facilitate our subsequent modification of the above polar construction, goes as follows: Since the elements of the row  $Z_i$  are not really independent one cannot count on the polarization effects of  $P_m^{\text{row}}$ . But, letting  $U = P_m^{\text{row}}(Z)$  one can show that most elements of the column of  $U^j$  are almost independent of each other, provided  $m$  is much larger than the mixing time of the source. (Here we imagine that the entries of  $Z$  arrive row-by-row, so that the source outputs within each row are temporally well-separated from most entries of the previous row, when  $m$  is large.) Further, this almost independence holds even when conditioning on the columns  $U^{<j}$  for most values of  $j$ . Thus the operation  $P_m^{\text{column}}(\cdot)$  continues to have its polarization effects and this is good enough to get a qualitatively strong polarization theorem (about the operator  $P_n$ !).

The above analysis is asymptotic, proving that in the limit of  $n \rightarrow \infty$ , we get optimal compression. However, we do not know how to give an effective finite-length analysis of the polarization process for Markovian process, as the analysis in [5, 6] crucially rely on independence which we lack within a row.

**Our Modified Code and Ingredients of Analysis.** To enable a finite-length analysis, we make a minor, but quite important, alteration to the polar code: Instead of using  $P_n(Z) = P_m^{\text{column}}(P_m^{\text{row}}(Z))^T$  we simply use the transformation  $\tilde{P}_n = P_m^{\text{column}}(Z)^T$  (or in other words, we replace the inner function  $P_m^{\text{row}}(\cdot)$  in the definition of  $P_n$  by the identity function). This implies that we lose whatever polarization effects of  $P_m^{\text{row}}$  we may have been counting on, but as pointed out above, for Markov sources, we weren't counting on polarization here anyway!

The crucial property we identify and exploit in the analysis is the following: the Markovian nature of the source plus the row-by-row arrival ordering of  $Z$ , implies that the distribution of the  $j$ 'th source column  $Z^j$  conditioned on the previous columns  $Z^{<j} = z^{<j}$ , is a *close to a product distribution*, for all but the last few (say  $\varepsilon m$ ) columns.<sup>8</sup>

It turns out that the analysis of the polar transform  $P_m$  only needs independent inputs, which however need not be identically distributed. We are then able to apply the recent analysis from [2], essentially as black box, to argue that  $P_m$  will compress each of the conditioned sources  $Z^j|Z^{<j} = z^{<j}$  to its respective entropy, and also establish fast convergence via quantitatively strong polynomial (in the gap to capacity) upper bounds on the  $m$  needed to achieve this. Further, we automatically benefit from the generality of the analysis in [2], which applies not only to the  $2 \times 2$  transform  $P_2$  at the base case, but in fact any  $k \times k$  transform (satisfying some minimal necessary conditions) over an arbitrary prime field  $\mathbb{F}_q$ . Previous works on polar coding for Markovian sources [4, 9, 12] only applied for Boolean sources.

We remark that the use of the identity transform for the rows in  $\tilde{P}_n$  is quite counterintuitive. It implies that the compression matrix is a block diagonal matrix (after some permutation of the rows and columns) – and in turn this seems to suggest that we are compressing different parts of the input sequence “independently”. However this is not quite true. The relationship between the blocks ends up influencing the final set  $S$  of the bits of  $\tilde{P}_n(Z)$  that are output by the compression algorithm. Furthermore the decompression relies on the information obtained from the decompression of the blocks corresponding to  $Z^{<j}$  to compute the block  $Z^j$ .

**Decompression algorithm.** Our alteration to apply the identity transform for the rows also helps us with the task of decompression. Toward this, we build on a decompression algorithm for memoryless sources from [2] that is somewhat different looking from the usual ones in the polar coding literature. This algorithm aims to compute  $U = P_m^{\text{row}}(Z)$  one *column* at a time, given  $P_n(Z)|_S$ . Given the first  $j - 1$  columns  $U^{<j} = u^{<j}$ , the algorithm first computes the conditional distribution of  $U^j$  conditioned on  $U^{<j} = u^{<j}$  and then uses a recursive decoding algorithm for  $P_m$  to determine  $U^j$ . The key to the recursive use is again that the decoding algorithm works as long as the input variables are independent (and in particular, does not need them to be identically distributed).

In our Markovian setting, we now have to compute the conditional distribution of  $Z^j$  conditioned on  $Z^{<j} = z^{<j}$ . But as mentioned above, this conditional distribution is close to a product distribution, say  $D_j(z^{<j})$  (except for the last few columns  $j$  where decompression is trivial as we output the entire column). Further, the marginals of this product distribution are easily computed using dynamic programming (via what is called the “Forward Algorithm” for hidden Markov models, described for completeness in Appendix A). We can then determine the  $j$ 'th column  $Z^j$  (having already recovered the first  $j - 1$  columns as  $z^{<j}$ ) by running (in a black box fashion) the polar decompressor from [2] for the memoryless case, feeding this product distribution  $D_j(z^{<j})$  as the source distribution.

**Computing the output indices.** Finally we need one more piece to make the result fully constructive. This is the preprocessing needed to compute the subset  $S$  of the coordinates of  $\tilde{P}_n(Z)$  that have noticeable conditional entropy. For the memoryless case these computations

---

<sup>8</sup> We handle the non-independence in the last few columns, by simply outputting those columns  $P_m(Z^j)$  in entirety, rather than only a set  $S_j$  of entropy-carrying positions. This only adds an  $\varepsilon$  fraction to the output length, which we can afford.

**Algorithm 4.1** POLAR-COMPRESS.**Constants:**  $M \in \mathbb{F}_q^{k \times k}$ ,  $m = k^t$ ,  $n = m^2$ **Input:**  $Z = (Z_{11}, Z_{12}, \dots, Z_{mm}) \in \mathbb{F}_q^n$ , and sets  $S_j \subseteq [m]$  for  $j \in [m]$ **Output:**  $U_{S_j}^j \in \mathbb{F}_q^{s_j}$  for all  $j \in [m]$   $\triangleright s_j := |S_j|$  for  $j \leq (1 - \varepsilon)m$ , and  $s_j := m$  otherwise.

---

```

1: procedure POLAR-COMPRESS( $Z; \{S_j\}_{j \in [m]}$ )
2:   for all  $j \in [m]$  do
3:     Compute  $U^j := P_m(Z^j)$ .
4:     If  $j \leq (1 - \varepsilon)m$  then
5:       Output  $U_{S_j}^j$ 
6:     else
7:       Output  $U^j$ 

```

---

were shown to be polynomial time computable in the works of [8, 5, 11]. We manage to extend the ideas from Guruswami and Xia [5] to the case of Markovian channels as well. It turns out the only ingredients needed to make this computation work are, again, the ability to compute the distributions of  $Z^j$  conditioned on  $Z^{<j} = z^{<j}$  for typical values of  $z^{<j}$ . We note that unlike in the setting of memoryless channels (or i.i.d. sources) our preprocessing step is randomized. We believe this is related to the issue that there is no “closed” form solutions to basic questions related to Markovian sources and channels (such as the capacity of the channel in Figure 1) and this forces us to use some random sampling and estimation to compute some of the conditional entropies needed by our algorithms.

**Organization of rest of the paper.** In the next section (Section 4) we describe our compression and decompression algorithms. In Section 5 we describe a notion of “nice”-ness for the preprocessing stage and show that if the preprocessing algorithm returns a nice output, then the compression and decompression algorithm work correctly with moderately high probability (over the message produced by the source). In Section 6 we describe our preprocessing algorithm that returns a nice set with all but exponentially small failure probability (over its internal coin tosses). Finally in Section 7 we give the formal proofs of Theorems 9 and 10.

## 4 Construction

### 4.1 Compression Algorithm

Our compression, decompression and preprocessing algorithms are defined with respect to arbitrary mixing matrices  $M \in \mathbb{F}_q^{k \times k}$ . (Recall that mixing matrices were defined in Definition 8.) Though a reader seeking simplicity may set  $k = 2$  and  $M = \begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}$ . Given integer  $t$ , let  $m = k^t$  and let  $P_m = P_{m,M} : \mathbb{F}_q^m \rightarrow \mathbb{F}_q^m$  be the polarization transform given by  $P_m = M^{\otimes t}$ .

### 4.2 Fast Decompressor

The decompressor below makes black-box use of the FAST-DECODER from [2, Algorithm 4].

The FAST-DECODER takes as input the description of a *product distribution*  $\mathcal{D}_Z$  on inputs in  $\mathbb{F}_q^m$ , as well as the specified coordinates of the compression  $U$ . It is intended to decode from the encoding  $U' \in \{\mathbb{F}_q \cup \{\perp\}\}^m$ , where  $U := M^{\otimes t}Z$ , coordinates of  $Z$  are independent,

---

**Algorithm 4.2** POLAR-DECOMPRESS.
 

---

**Constants:**  $M \in \mathbb{F}_q^{k \times k}$ ,  $m = k^t$ ,  $n = m^2$ 
**Input:** Markov Source  $\mathcal{H}$  and  $U_{S_1}^1, U_{S_2}^2, \dots, U_{S_m}^m \in \mathbb{F}_q^m$ 
**Output:**  $\hat{Z} \in \mathbb{F}_q^{m \times m}$ 

```

1: procedure POLAR-DECOMPRESS( $\mathcal{H}; U_{S_1}^1, U_{S_2}^2, \dots, U_{S_m}^m$ )
2:   for all  $j \in [m]$  do
3:     If  $j \leq (1 - \varepsilon)m$  then
4:       Compute the distribution  $\mathcal{D}_{z^j | \hat{z}^{<j}} \equiv \bar{Z}^j | \{\bar{Z}^{<j} = \hat{Z}^{<j}\}$ , using the Forward Algorithm on Markov Source  $\mathcal{H}$ .
5:       Define  $U^j \in \{\mathbb{F}_q \cup \{\perp\}\}^m$  by extending  $U_{S_j}^j$  using  $\perp$  in the unspecified coordinates.
6:       Set  $\hat{Z}^j \leftarrow \text{FAST-DECODER}(\mathcal{D}_{z^j | \hat{z}^{<j}}; U^j)$ 
7:     else
8:       Set  $\hat{Z}^j \leftarrow (M^{-1})^{\otimes t} \hat{U}_{S_j}^j$  ▷ Note here  $S_j = [m]$ 
9:   Return  $\hat{Z}$ 

```

---

and  $U'$  is defined by  $U$  on the high-entropy coordinates of  $U$  (and  $\perp$  otherwise). It outputs an estimate  $\hat{Z}$  of the input  $Z$ .

Note that, for a Markov source  $\mathcal{H}$  on  $\ell$  states, Line 4 takes time  $\mathcal{O}_q(m^2 \ell^2)$  (time  $\mathcal{O}_q(m \ell^2)$  per coordinate of  $\bar{Z}^j$ , using the Forward Algorithm). The FAST-DECODER call in Line 6 takes time  $\mathcal{O}_q(m \log m)$ . Thus, the total runtime is  $\mathcal{O}_q(m^3 \ell^2 + m^2 \log m) = \mathcal{O}_q(n^{3/2} \ell^2 + n \log n)$ .

## 5 Analysis

The goal of this section is to prove that the decompressor works correctly, with high probability, provided the preprocessing stage returns the appropriate sets  $\{S_j\}$ . Specifically, we prove Theorem 12 as stated below. But first we need a definition of “nice” sets  $\{S_j\}$ : We will later show that pre-processing produces such sets and compression and decompression work correctly (w.h.p.) given nice sets.

► **Definition 11** ( $(\varepsilon, \zeta)$ -niceness). Let  $\mathcal{H}$  be a Markov source. For every  $m \in \mathbb{N}$  and  $n = m^2$ , let  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$  be the corresponding “independent” distribution. Let  $\bar{U} := P_m^{\text{column}}(\bar{Z})$ .

We call sets  $S_1, S_2, \dots, S_m \subseteq [m]$  “ $(\varepsilon, \zeta)$ -nice” if they satisfy the following:

1.  $\sum_j |S_j| \leq \bar{H}(Z) + \varepsilon n$
2.  $\forall j \in [m], i \notin S_j : \bar{H}(\bar{U}_{(i,j)} | \bar{U}_{\prec(i,j)}) < \zeta$

Now, the rest of this section will show the following.

► **Theorem 12.** *There exists a polynomial  $p(\cdot)$  such that for every  $\varepsilon > 0$ ,  $\tau > 0$ , and  $n = m^2 > p(\tau/\varepsilon)$  the following holds:*

*Let  $\mathcal{H}$  be an aperiodic irreducible Markov source with alphabet  $\mathbb{F}_q$ , mixing time  $\tau$  and underlying state space  $[\ell]$ . Define random variables  $Z = (Z_{11}, Z_{12}, \dots, Z_{mm}) \sim \mathcal{H}_{m^2}$  as generated by  $\mathcal{H}$ . Then, for all sets  $S_1, S_2, \dots, S_m \subseteq [m]$  that are  $(\varepsilon, \zeta)$ -nice as per Definition 11, we have:*

$$\Pr_Z[\text{POLAR-DECOMPRESS}(\text{POLAR-COMPRESS}(Z; \{S_j\}_{j \in [m]})) \neq Z] \leq n\zeta + m \exp(-\varepsilon m/\tau)$$

## 5.1 Proof Overview

Throughout this section, let  $\mathcal{H}$  be a stationary Markov source with alphabet  $\mathbb{F}_q$  and mixing-time  $\tau$ . The key part of the analysis is showing that compression and decompression succeed when applied to the “independent” distribution  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$ . To do this, we first show that the compression transform “polarizes” entropies, which follows directly from the results of [2, 3]. Then we show that, provided “nice” sets can be computed (low-entropy sets, a la Definition 11), the compression and decompression succeed with high probability. This also follows essentially in a black-box fashion from the results of [2]. Finally, we argue that the compression and decompression also work for the actual distribution  $Z \sim \mathcal{H}_{m^2}$ , simply by observing that the involved variables are close in distribution.

We later describe how such “nice” sets can be computed in polynomial time, given the description of the Markov source  $\mathcal{H}$ .

## 5.2 Polarization

In this section, we show that the compression transform  $P_m^{\text{column}}$  polarizes entropies.

► **Lemma 13.** *Let  $\mathcal{H}$  be a Markov source, and let  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$ . Let  $\bar{U} = P_m^{\text{column}}(\bar{Z})$ .*

*Then, there exists a polynomial  $p(\cdot)$  such that for every  $\varepsilon > 0$ , there exists  $\beta > 0$  such that if  $m > p(1/\varepsilon)$ , the following holds: For all but  $\varepsilon$ -fraction of indices  $i, j \in [m] \times [m]$ , the normalized entropy*

$$\bar{H}(\bar{U}_{i,j} | \bar{U}_{\prec(i,j)}) \notin (\exp(-m^\beta), 1 - \varepsilon)$$

**Proof.** We will show that for each column  $\bar{U}^j$ , all but  $\varepsilon$ -fraction of indices  $i \in [m]$  have entropies

$$\bar{H}(\bar{U}_i^j | \bar{U}_{\prec i}^j, \bar{U}^{\prec j}) \notin (\exp(-m^\beta), 1 - \varepsilon)$$

Indeed, this follows directly from the analysis in [3]. For each  $j$ , the set of variables  $(\bar{Z}_1^j, \bar{Z}_1^{\prec j}), (\bar{Z}_2^j, \bar{Z}_2^{\prec j}), \dots, (\bar{Z}_m^j, \bar{Z}_m^{\prec j})$  are independent and identically distributed. Thus, Theorem 14 from [3] (reproduced below) implies that the conditional entropies are polarized. Specifically, let  $p(\cdot)$  and  $\beta$  be as guaranteed by Theorem 14, for the distribution  $\mathcal{D} \equiv (\bar{Z}_1^j, \bar{Z}_1^{\prec j})$ . Then, since  $P_m = M^{\otimes t}$ , we have

$$\begin{aligned} \bar{H}(\bar{U}_i^j | \bar{U}_{\prec i}^j, \bar{U}^{\prec j}) &= \bar{H}(\bar{U}_i^j | \bar{U}_{\prec i}^j, P_m(\bar{Z}^{\prec j})) && \text{(by definition)} \\ &= \bar{H}(\bar{U}_i^j | \bar{U}_{\prec i}^j, \bar{Z}^{\prec j}) && (P_m \text{ is invertible}) \\ &\notin (\exp(-m^\beta), 1 - \varepsilon) && \text{(Theorem 14)} \end{aligned}$$

◀

The following theorem is direct from the works [3].

► **Theorem 14.** *For every  $k \in \mathbb{N}$ , prime  $q$ , mixing-matrix  $M \in \mathbb{F}_q^{k \times k}$ , discrete set  $\mathcal{Y}$ , and any distribution  $\mathcal{D} \in \Delta(\mathbb{F}_q \times \mathcal{Y})$ , the following holds. Define the random vectors  $A := (A_1, A_2, \dots, A_n)$  and  $B := (B_1, B_2, \dots, B_n)$  where  $n = k^t$  and each component  $(A_i, B_i)$  is independent and identically distributed  $(A_i, B_i) \sim \mathcal{D}$ .*

*Let  $X := M^{\otimes t} A$ . Then, the conditional entropies of  $X$  are polarized: There exists a polynomial  $p(\cdot)$  and  $\beta > 0$  such that for every  $\varepsilon > 0$ , if  $n = k^t > p(1/\varepsilon)$ , then all but  $\varepsilon$ -fraction of indices  $i \in [n]$  have normalized entropy*

$$\bar{H}(X_i | X_{\prec i}, B) \notin (\exp(-n^\beta), 1 - \varepsilon).$$

### 5.3 Independent Analysis

Now we bound the failure probability of the Polar Compressor and Decompressor, when applied to the “independent” input distribution  $\bar{Z}$ .

► **Claim 15.** *Let  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$  and  $\bar{U} := P_m^{\text{column}}(\bar{Z})$ . Then, for all sets  $S_1, S_2, \dots, S_m \subseteq [m]$ ,*

$$\Pr_{\bar{U} \leftarrow P_m^{\text{column}}(\bar{Z})} [\text{POLAR-DECOMPRESS}(U_{S_1}^1, U_{S_2}^2, \dots, U_{S_m}^m) \neq \bar{U}] \leq \sum_{j \in [m], i \notin S_j} \bar{H}(\bar{U}_i^j | \bar{U}_{<i}^j, \bar{U}^{<j})$$

**Proof.** Appears in the full version of this paper. ◀

### 5.4 Proof of Main Theorem

At this point, we can show the entire process of compression and decompression succeeds with high probability, proving Theorem 12.

First, we argue  $\mathcal{H}_{m^2}$  and  $\mathcal{H}_m^{\otimes m}$  are close in the appropriate sense.

► **Lemma 16.** *Let  $Z \sim \mathcal{H}_{m^2}$  and  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$ . Then, for every  $\ell \in [m]$ , the distribution of  $Z^{<m-\ell}$  and  $\bar{Z}^{<m-\ell}$  are  $m \cdot \exp(-\ell/\tau)$ -close in  $L_1$ .*

**Proof.** We proceed by a sequence of  $m$  hybrids, changing one row at a time to being independent. Let the  $i$ -th hybrid be  $H_i := Z_{\leq i}^{<m-\ell} \circ \bar{Z}_{>i}^{<m-\ell}$ , that is, the first  $i$  rows of  $Z$ , with the remaining rows replaced by iid copies of  $Z_1$ .

Consider moving from  $H_{i+1}$  to  $H_i$ . Conditioned on the first  $i$  rows of  $Z^{<m-\ell}$ , the distribution of the hidden state of the Markov source, at the beginning of the  $(i+1)$ th row, is  $\exp(-\ell/\tau)$ -close to its stationary distribution  $\pi$  (since  $\ell$  steps pass between  $Z_{i,m-\ell}$  and  $Z_{i+1,1}$ ). Recall that the distribution of  $Z_1$  is generated by the Markov source starting from  $\pi$ . Thus, the distribution of the  $(i+1)$ th row of  $Z$ , conditioned on the first  $i$  rows of  $Z^{<m-\ell}$ , is  $\exp(-\ell/\tau)$ -close to the distribution of  $Z_1$ . So,  $|H_{i+1} - H_i|_1 \leq \exp(-\ell/\tau)$ . Since we pass through  $m$  hybrids, the total  $L_1$  distance is at most  $m \cdot \exp(-\ell/\tau)$ . ◀

**Proof of Theorem 12.** First, we show the corresponding claim about the “independent” distribution  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$ :

► **Claim 17.** *For  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$ , we have:*

$$\Pr_{\bar{U} \leftarrow P_m^{\text{column}}(\bar{Z})} [\text{POLAR-DECOMPRESS}(\bar{U}_{S_1}^1, \bar{U}_{S_2}^1, \dots, \bar{U}_{S_m}^m) \neq \bar{Z}] \leq n\zeta$$

or equivalently,

$$\Pr_{\bar{Z} \sim \mathcal{H}_m^{\otimes m}} [\text{POLAR-DECOMPRESS}(\text{POLAR-COMPRESS}(\bar{Z}; \{S_j\}_{j \in [m]})) \neq \bar{Z}] \leq n\zeta$$

**Proof.** By Claim 15, we have

$$\begin{aligned} \Pr_{\bar{U} \leftarrow P_m^{\text{column}}(\bar{Z})} [\text{POLAR-DECOMPRESS}(\bar{U}_{S_1}^1, \bar{U}_{S_2}^1, \dots, \bar{U}_{S_m}^m) \neq \bar{Z}] &\leq \sum_{j \in [m], i \notin S_j} \bar{H}(\bar{U}_i^j | \bar{U}_{<i}^j, \bar{U}^{<j}) \\ &\leq n\zeta \quad (\text{by } (\varepsilon, \zeta)\text{-niceness}) \end{aligned} \quad \blacktriangleleft$$

Continuing the proof of Theorem 12, notice that the composition of POLAR-COMPRESS and POLAR-DECOMPRESS always operate as the identity transform on the inputs  $Z^j$  for  $j > (1-\varepsilon)m$ . Thus, it suffices to consider the behavior of this composition on inputs  $Z^{\leq (1-\varepsilon)m}$ . In this case, Lemma 16 guarantees that the distributions of  $\bar{Z}^{\leq (1-\varepsilon)m}$  and  $Z^{\leq (1-\varepsilon)m}$  are close in  $L_1$ , and thus we may conclude by Claim 17:

$$\begin{aligned}
& \Pr_{Z \sim \mathcal{H}_{m^2}} [\text{POLAR-DECOMPRESS}(\text{POLAR-COMPRESS}(Z; \{S_j\}_{j \in [m]})) \neq Z] \\
& \leq \Pr_{\bar{Z} \sim \mathcal{H}_m^{\otimes m}} [\text{POLAR-DECOMPRESS}(\text{POLAR-COMPRESS}(\bar{Z}; \{S_j\}_{j \in [m]})) \neq \bar{Z}] + m \exp(-\varepsilon m / \tau) \\
& \leq n\zeta + m \exp(-\varepsilon m / \tau) \quad (\text{Claim 17}) \quad \blacktriangleleft
\end{aligned}$$

## 6 Preprocessing

In this section, we describe a pre-processing algorithm to find the  $(\varepsilon, \zeta)$ -nice sets, as defined in Definition 11, that are required by the compression and decompression algorithms. Recall the notion of a mixing matrix (Definition 8). The following theorem shows that for every prime alphabet  $\mathbb{F}_q$  and mixing matrix  $M \in \mathbb{F}_q^{k \times k}$ , there is an efficient algorithm that can find nice sets in polynomial time. Specifically, we prove the following theorem.

► **Theorem 18.** *For every prime  $q$  and mixing-matrix  $M \in \mathbb{F}_q^{k \times k}$ , there exists a polynomial  $p(\cdot)$  and a polynomial time preprocessing algorithm POLAR-PREPROCESS (Algorithm 6.3), such that for every  $\varepsilon > 0$  and  $m > p(1/\varepsilon)$ , the following holds:*

*Let  $\mathcal{H}$  be a Markov source with mixing-time  $\tau$ , alphabet  $\mathbb{F}_q$ , and underlying state space  $[\ell]$ . Let  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$  for  $m = k^t$ , and  $\bar{U} := P_m^{\text{column}}(\bar{Z})$ .*

*Let*

$$S_1, S_2, \dots, S_m \leftarrow \text{POLAR-PREPROCESS}(q, k, t, M, \mathcal{H})$$

*Then, except with probability  $\exp(-\Omega(m))$  over the randomness of the algorithm, the output sets  $S_1, S_2, \dots, S_m \subseteq [m]$  are  $(\varepsilon, \zeta = \mathcal{O}(\frac{1}{n^3}))$ -nice for  $\mathcal{H}$ . Further, the algorithm runs in time  $\text{poly}_q(m, \ell, 1/\varepsilon)$ .*

Our main goal will be to estimate the conditional entropies

$$\bar{H}(\bar{U}_{(i,j)} | \bar{U}_{\prec(i,j)}) = \bar{H}(\bar{U}_{i,j} | \bar{U}_{\prec i,j}, \bar{U}^{\prec j}) = \bar{H}(\bar{U}_{i,j} | \bar{U}_{\prec i,j}, \bar{Z}^{\prec j})$$

for  $\bar{Z} \sim \mathcal{H}_m^{\otimes m}$  and  $\bar{U} := P_m^{\text{column}}(\bar{Z})$ . Then, we will construct the “nice” sets by defining, for each  $j$ ,  $S_j$  as the set of indices with high entropy:  $S_j := \{i \in [m] : \bar{H}(\bar{U}_{i,j} | \bar{U}_{\prec i,j}, \bar{Z}^{\prec j}) > \frac{1}{n^3}\}$ . By Polarization (Lemma 13), these sets have size at most  $\sum_j |S_j| \leq \bar{H}(Z) + \varepsilon n$ , since they must have conditional entropies close to 1 (except possibly for some  $\varepsilon$  fraction of indices  $(i, j) \in [m] \times [m]$ ).

We will estimate conditional entropies  $\bar{H}(\bar{U}_{i,j} | \bar{U}_{\prec i,j}, \bar{Z}^{\prec j})$  by approximately tracking the distribution of variables as we apply successive tensor-powers of  $M$ . Since we are only interested in conditional entropies, it is sufficient to “quantize” the true distribution of, for example  $U_i | U_{\prec i}$ , into an approximation  $U_i | A$ , such that  $H(U_i | U_{\prec i}) \approx H(U_i | A)$ . This algorithm follows the same high-level strategy of [5], of approximating the conditional distributions via quantized bins. It turns out that this strategy can be implemented for Markov sources, using the fact that Markov sources are constructive. We define our notions of approximation, and formalize this strategy below.

### 6.1 Notation and Preliminaries

► **Definition 19** (Associated Conditional Distribution). Let  $X$  be a random variable taking values in universe  $U$ , and let  $W$  be an arbitrary random variable. Let  $\mathcal{D}_{X|w} \in \Delta(U)$  denote the conditional distribution of  $X | \{W = w\}$ . Let  $\mathbb{D}_{X|W} \in \Delta(\Delta(U))$  be the distribution over  $\mathcal{D}_{X|w}$  defined by sampling  $w \sim W$ . We call  $\mathbb{D}_{X|W}$  the *associated conditional distribution to  $X|W$* .

As above, we use boldface  $\mathbb{D}$  to denote objects of type  $\Delta(\Delta(U))$ . Note that we can operate on conditional distributions as we would on their underlying random variables. For example, for random variables  $(A_1, W)$  and  $(A_2, Y)$  such that  $A_1, A_2 \in \mathbb{F}_q$  and  $(A_1, W)$  is independent from  $(A_2, Y)$ , the associated conditional distribution of  $A_1 + A_2|Y, W$  can be computed from the associated conditional distributions of  $A_1|Y$  and  $A_2|W$ . To more easily describe such operations on conditional distributions (which may not always arise from underlying random variables), we define the *implicit random variables* associated to a conditional distribution:

► **Definition 20** (Implicit Random Variables Associated to Conditional Distribution). For every  $\mathbb{D}_{X|W} \in \Delta(\Delta(U))$ , define *implicit random variables*  $X, W$  associated to  $\mathbb{D}_{X|W}$  as random variables  $(X, W)$  such that the associated conditional distribution to  $X|W$  is exactly  $\mathbb{D}_{X|W}$ . Note that there is not a unique choice of such random variables.

Using this, we can naturally define (for example)  $\mathbb{D}_{A_1+A_2|W, Y}$  and  $\mathbb{D}_{A_2|W, Y, A_1+A_2}$  from any  $\mathbb{D}_{A_1, W}, \mathbb{D}_{A_2, Y} \in \Delta(\Delta(\mathbb{F}_q))$ . Note that we will always be performing such operations assuming independence of the involved implicit random variables, ie  $(A_1, W)$  and  $(A_2, Y)$ .

► **Definition 21** (Conditional Distance). Let  $(X, W)$  and  $(Y, Z)$  be two joint distributions, such that  $X$  and  $Y$  take values in the same universe  $U$ . Let  $\mathbb{D}_{X|W}$  and  $\mathbb{D}_{Y|Z}$  be the associated distributions in  $\Delta(\Delta(U))$ . Then, define the *conditional distance*

$$d_C(\mathbb{D}_{X|W}, \mathbb{D}_{Y|Z}) := \min_{\substack{(A, B): \text{a distribution in } \Delta(\Delta(U) \times \Delta(U)) \\ \text{s.t. marginals of } A \text{ match } \mathbb{D}_{X|W}, \text{ and} \\ \text{marginals of } B \text{ match } \mathbb{D}_{Y|Z}}} \mathbb{E}_{(D_A, D_B) \sim (A, B)} [\|D_A - D_B\|_1]$$

Note that  $d_C$  can be equivalently defined as an optimal transportation cost between two distributions in  $\Delta(\Delta(U))$ , where the cost of moving a unit of mass between points  $D_i, D_j \in \Delta(U)$  is  $\|D_i - D_j\|_1$ .

This metric behaves naturally under post-processing:

► **Claim 22.** For all  $\mathbb{D}_{X|W}, \mathbb{D}_{X'|W'} \in \Delta(\Delta(U))$ , and any  $f: U \rightarrow V$ ,

$$d_C(\mathbb{D}_{f(X)|W}, \mathbb{D}_{f(X')|W'}) \leq d_C(\mathbb{D}_{X|W}, \mathbb{D}_{X'|W'})$$

For computational purposes, we represent the space of distributions using  $\varepsilon$ -nets:

► **Definition 23** ( $\varepsilon$ -nets). For every set  $U$  and any  $\varepsilon > 0$ , let  $T_\varepsilon(U) \subseteq \Delta(U)$  be an  $\varepsilon$ -net of  $\Delta(U)$  with respect to  $L_1$ . That is, for every  $\mathcal{D} \in \Delta(U)$ , there exists  $\hat{\mathcal{D}} \in T_\varepsilon(U)$  such that  $\|\mathcal{D} - \hat{\mathcal{D}}\|_1 \leq \varepsilon$ .

Note that for  $|U| = |\mathbb{F}_q| = q$ ,  $T_\varepsilon(U)$  can be chosen such that  $|T_\varepsilon(U)| \leq \left(\frac{q}{\varepsilon} + q\right) \leq \left(\frac{2q}{\varepsilon}\right)^q = \text{poly}_q(1/\varepsilon)$ .

Moreover,  $\Delta(T_\varepsilon(U))$  is an  $\varepsilon$ -net of  $\Delta(\Delta(U))$  under the  $d_C$ -metric.

## 6.2 Conditional Distribution Approximation

The below procedure takes as input a conditional distribution  $\mathbb{D}_{Z|W} \in \Delta(\Delta(\mathbb{F}_q))$ , and computes an approximation to the conditional distribution of  $U_I|(U_{\setminus I}, W_1, \dots, W_{k^t})$ , for an index  $I \in [k]^t$ , where  $U := M^{\otimes t}Z$  and  $\{(Z_i, W_i)\}_{i \in [k^t]}$  are independently defined by  $\mathbb{D}_{Z|W}$ .

Note that if the input  $\mathbb{D}_{Z|W}$  is specified in an  $\varepsilon$ -net  $\Delta(T_\varepsilon(\mathbb{F}_q))$ , then the above procedure runs in time  $\text{poly}_q(m, 1/\varepsilon)$  for  $m = k^t$ .

**Algorithm 6.1** Conditional Distribution Approximation.

---

**Input:** Conditional distribution on inputs  $\mathbb{D}_{Z|W} \in \Delta(\Delta(\mathbb{F}_q))$ ,  $\varepsilon > 0$ ,  $t \in \mathbb{N}$ , index  $I \in [k]^t$ , and  $M \in \mathbb{F}_q^{k \times k}$

**Output:** Conditional distribution  $\tilde{\mathbb{D}}_{U|W} \in \Delta(\Delta(\mathbb{F}_q))$ , an approximation to  $U_I | (U_{\prec I}, W_1, \dots, W_{k^t})$  for  $U := M^{\otimes t} Z$  and  $\{(Z_i, W_i)\}_{i \in [k^t]}$  independently defined by  $\mathbb{D}_{Z|W}$ .

- 1: **procedure** APPROXDIST( $\mathbb{D}_{Z|W}, \varepsilon, t, I = (I_1, \dots, I_t), M$ )
- 2:   **If**  $t = 0$  **then**
- 3:     **Return**  $\mathbb{D}_{Z|W}$
- 4:   **else**
- 5:      $\hat{\mathbb{D}}_{Z|Y} \leftarrow$  APPROXDIST( $\mathbb{D}_{Z|W}, \varepsilon/(2k), t-1, I_{\prec t} = (I_1, \dots, I_{t-1}), M$ )
- 6:      $j \leftarrow I_t$ .
- 7:     Explicitly compute the following conditional distribution  $\hat{\mathbb{D}}_{U_j | U_{\prec j}, Y_1, \dots, Y_k} \in \Delta(\Delta(\mathbb{F}_q))$ :
- 8:       Let  $(Z, Y)$  be the implicit random variables associated to  $\hat{\mathbb{D}}_{Z|Y}$ .
- 9:       Let  $\{(Z_i, Y_i)\}_{i \in [k]}$  be independent random variables distributed identically to  $(Z, Y)$ .
- 10:       Define random vector  $U := M \cdot Z'$ , Where  $Z' = (Z_1, \dots, Z_k)$ .
- 11:       Let  $\hat{\mathbb{D}}_{U_j | U_{\prec j}, Y_1, \dots, Y_k}$  be the associated conditional distribution to  $U_j | U_{\prec j}, Y_1, \dots, Y_k$ .
- 12:       Round  $\hat{\mathbb{D}}_{U_j | U_{\prec j}, Y_1, \dots, Y_k}$  to  $\tilde{\mathbb{D}}_{U|Y} \in \Delta(T_{\varepsilon/2}(\mathbb{F}_q))$ , a point in the  $\varepsilon/2$ -net of  $\Delta(\Delta(\mathbb{F}_q))$  under  $d_C$ .
- 13:     **Return**  $\tilde{\mathbb{D}}_{U|Y}$ .

---

► **Lemma 24.** For all  $\mathbb{D}_{Z|W} \in \Delta(\Delta(U))$ ,  $\varepsilon > 0$ ,  $t \in \mathbb{N}$ ,  $M \in \mathbb{F}_q^{k \times k}$ , and  $I \in [k]^t$ , we have

$$d_C(\text{APPROXDIST}(\mathbb{D}_{Z|W}, \varepsilon, t, I, M), \mathbb{D}_{U_I | U_{\prec I}, W_1, \dots, W_{k^t}}) \leq \varepsilon$$

where  $\mathbb{D}_{U_I | U_{\prec I}, W_1, \dots, W_{k^t}}$  is the associated conditional distribution to the random variables defined as follows. Let  $(Z, W)$  be the implicit random variables associated to  $\mathbb{D}_{Z|W}$ . Let  $\{(Z_i, W_i)\}_{i \in [k^t]}$  be independent random variables distributed identically to  $(Z, W)$ . Finally, define random vector  $U := M^{\otimes t} \cdot Z'$ , where  $Z' = (Z_1, \dots, Z_{k^t})$ .

**Proof.** Appears in the full version of this paper. ◀

### 6.3 Approximating Conditional Entropies

Here we use Algorithm 6.1 directly to approximate conditional entropies:

► **Theorem 25.** For every field  $\mathbb{F}_q$ , conditional distribution  $\mathbb{D}_{Z|W} \in \Delta(\Delta(\mathbb{F}_q))$ , matrix  $M \in \mathbb{F}_q^{k \times k}$ ,  $t \in \mathbb{N}$ ,  $m = k^t$ , and  $\gamma > 0$ , consider the random variable  $U := M^{\otimes t} Z$  where each  $\{(Z_i, W_i)\}_{i \in [m]}$  is sampled independently from  $\mathcal{D}_{Z,W}$ .

Then, Algorithm 6.2 outputs  $\hat{h}_1, \dots, \hat{h}_m \leftarrow$  APPROXENTROPY( $\mathbb{D}_{Z|W}, \gamma, t, M$ ) such that

$$\forall i \in [m] : \hat{h}_i = \overline{H}(U_i | U_{\prec i}, W_1, \dots, W_m) \pm \gamma$$

Further, if the input  $\mathbb{D}_{Z|W}$  is specified in an  $\varepsilon$ -net  $\Delta(T_\varepsilon(\mathbb{F}_q))$ , then the above procedure runs in time  $\text{poly}_q(m, 1/\varepsilon, 1/\gamma)$ .

**Algorithm 6.2** Entropy Approximation.

---

**Input:**  $\gamma > 0$ ,  $t \in \mathbb{N}$ , Conditional distribution  $\mathbb{D}_{Z|W} \in \Delta(\Delta(\mathbb{F}_q))$ , and  $M \in \mathbb{F}_q^{k \times k}$

**Output:**  $\{\hat{h}_i \in \mathbb{R}\}_{i \in [k^t]}$

- 1: **procedure** APPROXENTROPY( $\mathbb{D}_{Z|W}, \gamma, t, M$ )
- 2:    $m \leftarrow k^t$
- 3:    $\varepsilon \leftarrow \frac{\gamma^2}{16 \log(q)}$
- 4:   **for all**  $I \in [k]^t$  **do**
- 5:      $\mathbb{D}_{U|Y} \leftarrow \text{APPROXDIST}(\mathbb{D}_{Z|W}, \varepsilon, t, I, M)$
- 6:      $\hat{h}_I \leftarrow \overline{H}(U|Y)$ , the conditional entropy of the implicit random variables  $(U, Y)$  associated to  $\mathbb{D}_{U|Y}$ .
- 7:   **Return**  $\{\hat{h}_i\}_{i \in [k^t]}$                     $\triangleright$  Abusing notation by identifying  $[k]^t$  with  $[k^t]$ .

---

**Algorithm 6.3** POLAR-PREPROCESS.

---

**Input:**  $q, k, t \in \mathbb{N}$  with  $q$  prime,  $M \in \mathbb{F}_q^{k \times k}$ , and Markov source  $\mathcal{H}$                     $\triangleright m = k^t, n = m^2$

**Output:** Sets  $S_1, S_2, \dots, S_m \subseteq [m]$

- 1: **procedure** POLAR-PREPROCESS( $q, k, t, M, \mathcal{H}$ )
- 2:    $m \leftarrow k^t$ ;  $\gamma \leftarrow \frac{1}{n^{10}}$ ;  $N \leftarrow |T_\gamma(\mathbb{F}_q)|$ ;  $R \leftarrow n(N/\gamma)^2$                     $\triangleright N \leq \text{poly}_q(1/\gamma)$
- 3:   **for all**  $j \in [m]$  **do**
- 4:     **for all**  $i = 1, 2, \dots, R$  **do**
- 5:       Sample a sequence  $w_i := (y_1, y_2, \dots, y_{j-1})$  from  $\mathcal{H}$ .
- 6:       Compute  $\mathcal{D}_{w_i} \in \Delta(\mathbb{F}_q)$ , the distribution of  $Y_j | Y_{<j} = w_i$ , using the Forward Algorithm A.1 for  $\mathcal{H}$ .
- 7:       Let  $\tilde{\mathbb{D}}_{Y|W} \in \Delta(\Delta(\mathbb{F}_q))$  be the empirical distribution of  $\mathcal{D}_w$ , from the samples  $\mathcal{D}_{w_i}$  above.
- 8:        $\{\hat{h}_1, \dots, \hat{h}_m\} \leftarrow \text{APPROXENTROPY}(\tilde{\mathbb{D}}_{Y|W}, \gamma = \frac{1}{n^4}, t, M)$
- 9:        $S_j \leftarrow \{i \in [m] : \hat{h}_i > \frac{1}{n^3}\}$
- 10: **Return**  $S_1, S_2, \dots, S_j$ .

---

**Proof of Theorem 25.** Correctness of Algorithm 6.2 follows from the fact that  $O(\frac{\gamma^2}{\log(q)})$ -closeness in the  $d_C$ -metric implies  $\gamma$ -closeness of conditional entropies. Thus, using Algorithm 6.1 to approximate the conditional distributions within  $O(\frac{\gamma^2}{\log(q)})$  is sufficient. See the full version of this paper for details.  $\blacktriangleleft$

## 6.4 Nice Subset Selection

Now we can describe how to find “nice” sets. We first approximate the conditional distribution  $\mathbb{D}_{Z_t|Z_{<t}} \in \Delta(\Delta(\mathbb{F}_q))$  for  $Z_1, \dots, Z_t \sim \mathcal{H}_t$ , by sampling. This crucially relies on the fact that  $\mathcal{H}$  is a constructive source (ie, using the Forward Algorithm). Then we use Algorithm 6.2 to estimate conditional entropies, and select high-entropy indices.

The correctness of this algorithm (proof of Theorem 18) appears in the full version of this paper.

## 7 Proofs of Theorems 9 and 10

Combining Theorem 18 (to compute nice sets) with Theorem 12 (compressing and decompressing assuming nice sets), Theorem 9 follows immediately.

**Proof of Theorem 9.** The algorithms claimed are Algorithm 6.3 for preprocessing, Algorithm 4.1 for compressing and Algorithm 4.2 for decompression. Theorem 18 asserts that Algorithm 6.3 returns a nice sequence of sets  $S_1, \dots, S_m$  with all but exponentially small probability in  $n$ . And Theorem 12 asserts that if  $S_1, \dots, S_m$  are nice then Algorithm 4.1 and 4.2 compress and decompress correctly with high probability over the output of the Markovian source. This yields the theorem. ◀

Finally we show how Theorem 10 follows from Theorem 9.

**Proof of Theorem 10.** Let  $H \in \mathbb{F}_q^{s \times n}$  be the matrix specifying the (linear) compression scheme given by the Preprocessing Algorithm in Theorem 9, when applied to Markov source  $\mathcal{H}$ . The code  $C$  for the additive Markov Channel  $\mathcal{C}_{\mathcal{H}}$  is simply specified by the nullspace of  $H$ , ie encoding is given by  $C(x) := Nx$  where  $N \in \mathbb{F}_q^{n \times n-s}$  spans  $\text{Null}(A)$ .

Note that due to the structure of  $H$ , a nullspace matrix  $N$  can be applied in  $\mathcal{O}_q(n \log n)$  time. In particular,  $H$  is a subset of rows of the block-diagonal matrix  $P \in \mathbb{F}_q^{n \times n}$ , where each  $\sqrt{n} \times \sqrt{n}$  block is the tensor-power  $M^{\otimes t}$ . Thus,  $P^{-1}$  is also block-diagonal with blocks  $(M^{-1})^{\otimes t}$ , and so can be applied in time  $\mathcal{O}_q(n \log n)$ . The matrix  $N$  can be chosen as just a subset of columns of  $P^{-1}$ , and hence can also be applied in time  $\mathcal{O}_q(n \log n)$ .

Let  $y_1, y_2, \dots, y_n \in \mathbb{F}_q$  be distributed according to  $\mathcal{H}$ , and  $y := (y_1, \dots, y_n) \in \mathbb{F}_q^n$ . To decode from  $z = Nx + y$ , the decoder first applies  $H$  (by running the compression algorithm of Theorem 9), to compute  $H z = H N x + H y = H y$ . Then, the decoder runs the decompression algorithm of Theorem 9 on  $H y$  to determine  $y$ . Finally, the decoder can compute  $y - z$  to find the codeword sent ( $Nx$ ), and thus determine  $x$ . (Again using the structure of  $P$ , as above, to determine  $x$  from  $Nx$  in  $\mathcal{O}_q(n \log n)$  time). ◀

## A Forward Algorithm

---

**Algorithm A.1** Forward Algorithm.

---

**Input:**  $n \in \mathbb{N}$ . Markov source  $\mathcal{H}$  with state-space  $[\ell]$ , alphabet  $\Sigma$ , stationary distribution  $\pi \in \Delta([\ell])$ , transition matrix  $\Pi \in \mathbb{R}^{\ell \times \ell}$ , and output distributions  $\{\mathcal{S}_i \in \Delta(\Sigma)\}_{i \in [\ell]}$ . And  $y = (y_1, y_2, \dots, y_{n-1})$  for  $y_i \in \Sigma$ .

**Output:** Distribution  $Y_n \in \Delta(\Sigma)$

- 1: **procedure** FORWARDINFER( $\mathcal{H} = (\ell, \Sigma, \pi, \Pi, \{\mathcal{S}_i\}), n, y$ )
  - 2:    $s_0 \leftarrow \pi$ .
  - 3:   **for all**  $t = 1, 2, \dots, n - 1$  **do**
  - 4:     Define  $s_t \in \Delta([\ell])$  by  $s_t(i) \leftarrow \frac{(\Pi s_{t-1})_i \cdot \mathcal{S}_i(y_t)}{\sum_{j \in [\ell]} (\Pi s_{t-1})_j \cdot \mathcal{S}_j(y_t)}$  ▷ Treating  $s_{t-1}$  as a vector in the probability simplex embedded in  $\mathbb{R}^\ell$
  - 5:    $s_n \leftarrow \Pi s_{n-1}$ .
  - 6:   **Return** The distribution  $Y_n := \mathbb{E}_{i \sim s_n}[\mathcal{S}_i]$ .
- 

► **Claim 26.** For every Markov source  $\mathcal{H} = (\ell, \Sigma, \pi, \Pi, \{\mathcal{S}_i\})$ , let random variables  $Y_1, \dots, Y_n \sim \mathcal{H}_n$ . For every setting  $y = (y_1, y_2, \dots, y_{n-1})$  for  $y_i \in \Sigma$ , let  $\mathcal{D}_{Y_n | Y_{<n}=y}$  denote the distribution of  $Y_n$  conditioned on  $Y_{<n} = y$ . Then,

$$\text{FORWARDINFER}(\mathcal{H}, n, y) \equiv \mathcal{D}_{Y_n | Y_{<n}=y}$$

This follows inductively, from the fact that  $s_t$  as maintained by the algorithm is exactly the distribution of  $S_t | \{Y_{\leq t} = y_{\leq t}\}$ , where  $S_t$  is the hidden state of  $\mathcal{H}$  after  $t$  steps.

## B Connection to Learning Parity with Noise

The problem of learning parity with noise (LPN) is the following. Fix an (unknown) string  $a \in \mathbb{F}_2^\ell$  and  $\eta > 0$  and let  $D_{a,\eta}$  be the distribution on  $\mathbb{F}_2^{\ell+1}$  whose samples  $(x, y)$  are generated as follows: Draw  $x \in \mathbb{F}_2^\ell$  uniformly and let  $z \in \text{Bern}(\eta)$  be drawn independent of  $x$  and let  $y = \langle a, x \rangle + z$  where  $\langle a, x \rangle = \sum_{i=1}^\ell a_i x_i$ . Given samples  $(x_1, y_1), \dots, (x_m, y_m)$  drawn i.i.d. from such a distribution, the LPN problem is the task of “learning”  $a$ .

It is well known that  $a$  is uniquely determined by  $O(\ell)$  samples (i.e.,  $m = O(\ell)$ ) where the constant in the  $O(\cdot)$  depends on  $\eta < 1/2$ . However no polynomial time algorithms are known that work with  $m = \text{poly}(\ell)$  and determine  $a$  for any  $\eta > 0$  and indeed this is believed to be a hard task in learning. We refer to this hardness assumption as the LPN hypothesis.

The connection to learning Markovian sources comes from the fact that samples from the distribution  $D_{a,\eta}$  can be generated by an  $O(\ell)$ -state Markov chain. (Briefly the states are indexed  $(i, b, c)$  indicating  $\sum_{j=1}^{i-1} a_j x_j = b$  and  $x_i = c$ . For  $i < \ell$  the state  $(i, b, c)$  outputs  $c$  and transitions to  $(i+1, b+c, 0)$  w.p.  $1/2$  and to  $(i+1, b+c, 1)$  w.p.  $1/2$ . When  $i = \ell$ , the state  $(i, b, c)$  outputs  $(c, b+c)$  w.p.  $1-\eta$  and  $(c, b+c+1)$  w.p.  $\eta$  and transitions to  $(1, 0, 0)$  w.p.  $1/2$  and to  $(1, 0, 1)$  w.p.  $1/2$ .) The entropy of this source is  $(\ell + H(\eta))/(\ell + 1)$ . A compression with  $\varepsilon = (1 - H(\eta))/(2(\ell + 1))$  with  $\text{poly}(\ell/\varepsilon)$  samples from the source would distinguish this source from purely random strings which in turn enables recovery of  $a$ , contradicting the LPN hypothesis.

We thus conclude that compressing an *unknown* Markov source with number of samples that is a polynomial in the mixing time and the inverse of the gap to capacity contradicts the LPN hypothesis.

## Abstract

Key-agreement protocols whose security is proven in the *random oracle model* are an important alternative to protocols based on public-key cryptography. In the random oracle model, the parties and the eavesdropper have access to a shared random function (an “oracle”), but the parties are limited in the number of queries they can make to the oracle. The random oracle serves as an abstraction for black-box access to a symmetric cryptographic primitive, such as a collision resistant hash. Unfortunately, as shown by Impagliazzo and Rudich [STOC '89] and Barak and Mahmoody [Crypto '09], such protocols can only guarantee limited secrecy: the key of any  $\ell$ -query protocol can be revealed by an  $O(\ell^2)$ -query adversary. This quadratic gap between the query complexity of the honest parties and the eavesdropper matches the gap obtained by the *Merkle's Puzzles* protocol of Merkle [CACM '78].

In this work we tackle a new aspect of key-agreement protocols in the random oracle model: their *communication complexity*. In Merkle's Puzzles, to obtain secrecy against an eavesdropper that makes roughly  $\ell^2$  queries, the honest parties need to exchange  $\Omega(\ell)$  bits. We show that for protocols with certain natural properties, ones that Merkle's Puzzle has, such high communication is unavoidable. Specifically, this is the case if the honest parties' queries are uniformly random, or alternatively if the protocol uses non-adaptive queries and has only two rounds. Our proof for the first setting uses a novel reduction from the set-disjointness problem in two-party communication complexity. For the second setting we prove the lower bound directly, using information-theoretic arguments.

Understanding the communication complexity of protocols whose security is proven (in the random-oracle model) is an important question in the study of practical protocols. Our results and proof techniques are a first step in this direction.

## 1 Introduction

In a key-agreement protocol [5], two parties communicating over an insecure channel want to securely agree on a shared secret key, such that an eavesdropper observing their communication cannot find the key. For example, given a hash function  $h : [n] \rightarrow [N]$  that is hard to invert, the players can execute the following protocol, called *Merkle’s puzzles* [13]: we fix an arbitrary parameter  $\ell \approx \sqrt{n}$ , and the parties select uniformly random subsets  $A = \{a_1, \dots, a_\ell\}$ ,  $B = \{b_1, \dots, b_\ell\} \subseteq [n]$  (respectively) of size  $\ell$ . We choose  $\ell, n$  such that with constant probability there is a unique intersection,  $|A \cap B| = 1$ . The first party evaluates  $h$  on every element  $a \in A$ , and sends  $h(a_1), \dots, h(a_\ell)$  to the second party, which then looks for a unique element  $b \in B$  such that  $h(b) = h(a_i)$  for some  $i \in [\ell]$ . If found, the second party sends the index  $i$  to the first party and outputs  $b$  as the secret key; the second party outputs  $a_i$  as the secret key. Because  $h$  is a “good” hash function and  $h(b) = h(a_i)$ , it is likely that  $b = a_i$ , so the players output the same key. Moreover, since  $h$  is hard to invert, an eavesdropper that tries to find the secret key after seeing  $h(a_1), \dots, h(a_\ell), i$  must essentially compute  $h$  on the entire universe in order to invert  $h$  and find  $a_i$ . Thus, we have a quadratic gap between the work performed by the eavesdropper, which must compute  $\Omega(\ell^2)$  hashes, and the work performed by the parties, which compute  $\ell$  hashes each.

Ideally we would strive for an *exponential* gap between the work required to break the security of the protocol and the work of the honest parties. There are numerous candidate constructions of such key-agreement schemes, e.g., [17, 14, 1, 12], based on assumptions implying that *public-key encryption schemes* exist. A fundamental open question is whether we can design key-agreement protocols based on the security of symmetric primitives (e.g., collision resistant hash); the security of such primitives is believed to be more robust than public-key encryption. A very important step in this direction was made by Barak and Mahmoody[2] (following Impagliazzo and Rudich[10]): they showed that as long as the symmetric primitive is used as a black box, the quadratic gap achieved by Merkle’s puzzles is the best possible.

The notion of “black box” is formalized by the *random oracle model*: instead of a concrete hash function  $h$ , we assume that the parties have access to a *random oracle*  $F : [n] \rightarrow [n]$ , a perfectly random function. The random oracle is “the best hash function possible” (w.h.p.), so lower bounds proven in the random oracle model hold for any instantiation where the oracle is replaced by a one-way function. Thus, the lower bound of Barak and Mahmoody rules out any black-box key-agreement scheme from one-way functions that achieves a better than quadratic gap between the eavesdropper’s work and the honest parties.

While a quadratic gap between the  $\ell$ -query honest parties and the  $\ell^2$ -query eavesdropper might not seem like much, and ideally we would wish for an exponential gap, on modern architecture it can yield a good enough advantage, assuming that security is preserved when the random oracle is replaced with a fixed hash function. For example, a consumer-level CPU (Intel Core i5-6600) can compute 5 million SHA-256 hashes per second, and specialized hardware for SHA-256 computation (for example, AntMiner S9) can compute  $14 \times 10^{12}$  hashes per second [3]. It follows that if the honest parties spend one second of computation on standard CPU, an attacker with specialized hardware can violate the security of Merkle's puzzles in less than a second. However, if the parties spend one second on specialized hardware, an attacker with specialized hardware has to spend more than 200,000 years to break the scheme.

So, are Merkle's puzzles a practical and realistic key-agreement scheme? The answer is probably not: even setting aside the question of replacing the random oracle by a concrete hash function, in Merkle's puzzles, the honest parties *send each other*  $\tilde{\Omega}(\ell)$  bits to obtain security against an eavesdropper that makes roughly  $\ell^2$  queries. In our example above, if we instantiate Merkle's puzzles using SHA-256 for one second on specialized hardware, the first party would need to send more than 100 terabytes to the second party. A fundamental question is whether this high communication burden is inherent to secure key-agreement, and more generally, what is the communication cost of cryptographic protocols in the random oracle model and other oracle models. In this paper we initiate the study of the communication complexity of cryptographic protocols in the random-oracle model.

## 1.1 Our Results

We show that for random-oracle protocols with certain natural properties, the high communication incurred by Merkle's puzzles is unavoidable: in order to achieve security against an adversary that can ask  $\Theta(\ell^2)$  queries, the two parties must exchange  $\Omega(\ell)$  bits of communication. Specifically, we show that the bound above holds for protocols where the parties' queries are a uniformly random set, and also for two-round protocols that make non-adaptive (but arbitrary) queries.<sup>6</sup> We stress that a general lower bound for non-adaptive key-agreement protocols would imply a lower bound on the communication complexity of the set-intersection problem. This fact suggests that it is unlikely to find a simple proof for the general case.

To simplify the statements of our results, we focus here on key-agreement protocols whose *agreement* parameter, the probability that the players output the same key, is larger by some constant than their *secrecy* parameter, the probability that an eavesdropper can find the key.

### Uniform-query protocols.

We say that a random-oracle protocol makes *uniform queries* if each party's oracle queries are a uniformly random set. We give the following lower bound on the communication complexity of such protocols.

► **Theorem 1** (lower bound on uniform-queries protocols, informal). *Any  $\ell$ -uniform-query key-agreement protocol achieving non-trivial secrecy against  $o(\ell^2)$ -query adversaries has communication complexity  $\Omega(\ell)$ .*

This theorem is proved by a reduction from *set-disjointness*, a problem in communication complexity that is known to require high communication.

<sup>6</sup> These are both properties of Merkle's puzzles.

**Two-round non-adaptive protocols.**

An oracle protocol is said to make *non-adaptive* queries if the distribution of queries made by the players is fixed in advance, i.e., it is determined before the parties communicate with each other and does not depend on the oracle’s answers. We give the following lower bound on the communication complexity of such protocols.

► **Theorem 2** (lower bound on two-message non-adaptive protocols, informal). *Any two-message  $\ell$ -query non-adaptive key-agreement protocol of non-trivial secrecy against  $q$ -query adversaries has communication complexity  $\Omega(q/\ell)$ .*

Once again this lower bound is nearly-tight with Merkle’s puzzles, where  $q = \Theta(\ell^2)$ , and the communication cost is  $\tilde{\Theta}(\ell)$ .<sup>7</sup>

Following Barak and Mahmoody [2] and Impagliazzo and Rudich [10]), we prove this lower bound by presenting an eavesdropper that makes  $q$  queries and prevents the parties from exploiting the advantage they gain by their joint random oracle calls.

In [2], the communication cost of the protocol is not taken into account: their eavesdropper makes  $O(\ell^2)$  queries and has high probability of finding *all* intersection queries (i.e., all queries that were asked by both players). In our case, if the protocol has communication cost  $C$ , then to prove Theorem 2, our eavesdropper must make only  $O(C \cdot \ell)$  queries (to show the trade-off that  $C = \Omega(q/\ell)$ ). If  $C \ll \ell$ , our eavesdropper makes much fewer queries than the eavesdropper in [2, 10], and in particular it cannot discover all the intersection queries. Instead, our eavesdropper asks only queries that the players *were able to learn* are in their intersection. If a query is in the intersection, but the players have not communicated this fact to each other, then the eavesdropper will not necessarily ask this query (unlike [2, 10]). Finding the correct definition for what it means to “learn” that a given query is in the intersection, and constructing an eavesdropper that makes only  $O(C \cdot \ell)$  queries, are the main difficulty in our proof.

**1.2 Related Work**

Impagliazzo and Rudich [10] showed that the key of any  $\ell$ -query key-agreement protocol in the random-oracle model can be revealed by an  $\tilde{O}(\ell^6)$  query eavesdropper. Barak and Mahmoody [2] improve this bound and present an  $O(\ell^2)$  query eavesdropper for this task, which shows that Merkle puzzles is optimal in this respect. Haitner, Omri, and Zarusim [9] used the machinery of [2] to relate the security of protocols that do not use a random oracle and solve tasks with no input, to the security of no-input protocols in the random-oracle model against an  $O(\ell^2)$ -query adversary. Finding limitations on the usefulness of random oracles for protocols that do take input seems to be a more difficult question. Chor and Kushilevitz [4] and Mahmoody et al. [11] made some progress in this direction. Finally, Haitner, Hoch, Reingold, and Segev [7] gave lower bounds on the communication complexity of statistically hiding commitments and single-server private information retrieval in a weaker oracle model that captures the hardness of one-way functions/permutation more closely than the random-oracle model.

<sup>7</sup> This theorem is also nearly-tight for any  $q$ , with a version of Merkle’s puzzle, in which Alice is sending  $\Theta(q/l)$  answers, from a universe of size  $\Theta(q)$ .

## 1.3 Organization

We begin by giving the formal definitions and notation used throughout the paper in Section 2. High-level overview of our proof techniques is given in Sections 3 and 4. For full proofs, see the full version of this paper in [8].

## 2 Preliminaries

### 2.1 Notations

We use calligraphic letters to denote sets, uppercase for random variables and lowercase for values. For  $m \in \mathbb{N}$ , let  $[m] = \{1, \dots, m\}$ . For a random variable  $X$ , let  $x \stackrel{R}{\leftarrow} X$  to denote that  $x$  is chosen according to  $X$ . Similarly, for a set  $S$  let  $s \stackrel{R}{\leftarrow} S$  to denote that  $s$  is chosen according to the uniform distribution over  $S$ . The support of the distribution  $D$ , denoted  $\text{Supp}(D)$ , is defined as  $\{u \in \mathcal{U} : \Pr_D[u] > 0\}$ . The statistical distance between two distributions  $P$  and  $Q$  over a finite set  $\mathcal{U}$ , denoted  $\text{SD}(P, Q)$ , is defined as  $\frac{1}{2} \sum_{u \in \mathcal{U}} |\Pr_P[u] - \Pr_Q[u]|$ , which is equal to  $\max_{S \subseteq \mathcal{U}} (\Pr_P[S] - \Pr_Q[S])$ .

For a vector  $\vec{X} = X_1, \dots, X_n$  and an index  $i \in [n]$ , let  $X_{<i}$  denote the vector  $X_1, \dots, X_{i-1}$  and  $X_{\leq i}$  denote the vector  $X_1, \dots, X_i$ . For a set of indexes  $T = \{i_1, \dots, i_k\} \subseteq [n]$  such that  $i_1 < i_2 < \dots < i_k$ , let  $X_T$  denote the vector  $X_{i_1}, \dots, X_{i_k}$ . Similarly,  $X_{T, <i}$  denotes the vector  $X_{T \cap \{1, \dots, i-1\}}$ . For a function  $f$ , let  $f(\vec{X}) = (f(X_1), \dots, f(X_n))$ .

For random variables  $A$  and  $B$  we use  $A|_{B=b}$  to denote the distribution of  $A$  condition on the event  $B = b$ , and  $A \times B$  to denote the product between the marginal distributions of  $A$  and  $B$ . When  $A$  is independent from  $B$  we write  $A \perp B$  to emphasize that this is the case.

### 2.2 Interactive Protocols

A two-party protocol  $\Pi = (A, B)$  is a pair of probabilistic interactive Turing machines. The communication between the Turing machines  $A$  and  $B$  is carried out in rounds, where in each round one of the parties is active and the other party is idle. In the  $j$ -th round of the protocol, the currently active party  $P$  acts according to its partial view, writing some value on its output tape, and then sending a message to the other party (i.e., writing the message on the common tape). The communication transcript (henceforth, the transcript) of a given execution of the protocol  $\Pi = (A, B)$ , is the list of messages  $m$  exchanged between the parties in an execution of the protocol, where  $m_{1, \dots, j}$  denotes the first  $j$  messages in  $m$ . A view of a party contains its input, its random tape and the messages exchanged by the parties during the execution. Specifically,  $A$ 's view is a tuple  $v_A = (i_A, r_A, m)$ , where  $i_A$  is  $A$ 's input,  $r_A$  are  $A$ 's random coins, and  $m$  is the transcript of the execution. Let  $\text{out}^A$  denote the output of  $A$  in the end of the protocol, and  $\text{out}^B$   $B$ 's output. Notice that given a protocol, the transcript and the outputs are deterministic function of the joint view  $(i_A, r_A, i_B, r_B)$ . For a joint view  $v$ , let  $\text{trans}(v)$ ,  $\text{out}^A(v)$  and  $\text{out}^B(v)$  be the transcript of the protocol and the parties' outputs determined by  $v$ . For a distribution  $D$  we denote the distribution over the parties' joint view in a random execution of  $\Pi$ , with inputs drawn from  $D$  by  $\Pi(D)$ .

A protocol  $\Pi$  has  $r$  rounds, if for every possible random tapes for the parties, the number of rounds is exactly  $r$ . The Communication Complexity of a protocol  $\Pi$ , denoted as  $\text{CC}(\Pi)$  is the length of the transcript of the protocol in the worst case.

### 2.3 Oracle-Aided Protocols

An oracle-aided two-party protocol  $\Pi = (A, B)$  is a pair of interactive Turing machines, where each party has an additional tape called the oracle tape; the Turing machine can make a query to the oracle by writing a string  $q$  on its tape. It then receives a string *ans* (denoting the answer for this query) on the oracle tape. An oracle-aided protocol is  $\ell$ -queries protocol if each party makes at most  $\ell$  queries during each run of the protocol. In a *non-adaptive* oracle-aided protocol, the parties choose their queries before the protocol starts and before querying the oracle. A *uniform query* oracle-aided protocol, is a non-adaptive protocol in which the parties queries are chosen uniformly from a predetermined set.

### 2.4 Key-Agreement Protocols

Since we are giving lower bounds, we focus on single bit protocols.

► **Definition 3** (key-agreement protocol). Let  $0 \leq \gamma, \alpha \leq 1$  and  $q \in N$ . A two-party boolean output protocol  $\Pi = (A, B)$  is a  $(q, \alpha, \gamma)$ -key-agreement relative to a function family  $\mathcal{F}$ , if the following hold:

**Accuracy:**  $\Pi$  has  $(1 - \alpha)$ -accuracy. For every  $f \in \mathcal{F}$ :

$$\Pr_{v \stackrel{R}{\leftarrow} \Pi^f} [\text{out}^A(v) = \text{out}^B(v)] \geq 1 - \alpha.$$

**Secrecy:**  $\Pi$  has  $(q, \gamma)$ -secrecy. For every  $q$ -query oracle-aided algorithm  $E$ :

$$\Pr_{f \stackrel{R}{\leftarrow} \mathcal{F}, v \stackrel{R}{\leftarrow} \Pi^f} [E^f(\text{trans}(v)) = \text{out}^A(v)] \leq \gamma.$$

If  $\mathcal{F}$  is a trivial function family (e.g.,  $\mathcal{F}$  contains only the identity function), then all correlation between the parties' view is implied by the transcript. Hence, an adversary that on a given transcript  $\tau$  samples a random view for  $A$  that is consistent with  $\tau$ , and outputs whatever  $A$  would upon this view, agrees with  $B$  with the same probability as does  $A$ . This simple argument yields the following fact:

For every  $0 \leq \alpha \leq 1$  and  $0 \leq \gamma < 1 - \alpha$ , there exists no  $(q, \alpha, \gamma)$ -key-agreement protocol relative to the trivial family.

### 2.5 Entropy and Information

In the proof we often need to measure differences between various distributions. For this purpose we use *f-divergences*: given a convex function  $f : \mathbb{R} \rightarrow \mathbb{R}$  with  $f(1) = 0$ , and distributions  $P, Q$ , the *f-divergence of P from Q* is defined as

$$D_f(P \parallel Q) = \sum_{q \in \mathcal{Q}} \Pr[Q = q] f\left(\frac{\Pr[P = q]}{\Pr[Q = q]}\right).$$

Specifically, the two *f-divergences* we use in this paper are the *statistical distance*, obtained by taking  $f(x) = |x - 1|/2$ , and the *KL divergence*, obtained by taking  $f(x) = x \log x$ . Each has its own nice properties and disadvantages: statistical distance is bounded in  $[0, 1]$  but it is not additive, while KL divergence is additive but unbounded.

We frequently need to measure the “amount of dependence” between two random variables. Let  $(X, Y) \sim P_{X,Y}$  be random variables jointly distributed according to  $P_{X,Y}$ , and let  $P_X, P_Y$  be the marginal distribution of  $X$  and  $Y$ , respectively. Also, let  $P_X \times P_Y$  be the product distribution where  $X$  and  $Y$  are sampled independently of each other, each from its marginal

distribution  $P_X, P_Y$  (respectively). To quantify the dependence between  $X$  and  $Y$ , we measure the difference between their joint distribution and the product of the marginals: formally, we define

$$I_f(X; Y) = D_f(P_{X,Y} \parallel P_X \times P_Y).$$

This generalizes the usual notion of mutual information, which is the special case of  $I_f$  where we use KL divergence (i.e., when  $f = x \log x$ ). For clarity, when we use KL divergence we omit the subscript  $f$ , and when using statistical distance, we use the notation  $I_{SD}$  (instead of  $I_{f(x)=|x-1|/2}$ ).

Finally, we also need the notion of *conditional mutual information*, which is simply the average mutual information between two variables  $X, Y$ , where the average is taken over a third random variable  $Z$ . Formally, let  $(X, Y, Z) \sim P_{X,Y,Z}$ . For any value  $z$ , let  $P_{X,Y|Z=z}, P_{X|Z=z}, P_{Y|Z=z}$  be the joint distribution of  $X, Y$  and the marginals of  $X$  and  $Y$ , respectively, all conditioned on the event  $Z = z$ .

Then we define  $I_f(X; Y|Z) = \mathbb{E}_{z \sim P_Z} [D_f(P_{X,Y|Z=z} \parallel P_{X|Z=z} \times P_{Y|Z=z})]$ .

In the next sections we outline the strategy of the proofs.

### 3 Uniform-Query Protocols: Proof Outline

Our lower bound for uniform-query key-agreement protocols is proved via a reduction to *set disjointness*, a classical problem in two-party communication complexity.

In the set disjointness problem, we have two players, Alice and Bob. The players receive inputs  $X, Y \subseteq [n]$ , respectively, of size  $|X| = |Y| = \ell$ , and the players must determine whether  $X \cap Y = \emptyset$ . To do this, the players communicate with each other, and the question is how many bits they must exchange. It is known [16] that for any sufficiently large  $n \in \mathbb{N}$ , if the size of the sets is  $\ell = n/4$ , then the players must exchange  $\Omega(n)$  bits to solve set disjointness, and this holds even for randomized protocols where the players have access to shared randomness and only need to succeed with probability  $2/3$ . Here, we require high success probability *on any input*, not over some specific input distribution. We note that in the 2-party communication complexity model there is no random oracle.

The connection between set disjointness and key agreement comes from the fact that the only *correlation* between the parties' views in a key agreement protocol comes from the *intersection queries*, the queries that both players ask and Eve does not know. Indeed, if Alice asks  $A \subseteq [n]$  and Bob asks  $B \subseteq [n]$ , and the random oracle is  $F : [n] \rightarrow [n]$ , then  $F(A \setminus (A \cap B))$  and  $F(B \setminus (A \cap B))$  are *independent of each other*. In particular, if  $A \cap B = \emptyset$ , then  $F(A)$  and  $F(B)$  are independent, and intuitively, in this case the players cannot securely agree on a secret key, because they have no advantage over the eavesdropper. On the other hand, if  $A \cap B \neq \emptyset$ , then the players can exploit the correlation induced by  $F(A \cap B)$  to securely agree on a secret key. Thus, any secure key agreement protocol “behaves differently” depending on whether  $A \cap B = \emptyset$  or not, and we can use this to solve the set disjointness problem.

Suppose that we are given a secure key-agreement protocol  $\Pi$ , where the players make  $\ell$  uniformly-random queries to an oracle  $F : [n] \rightarrow [n]$ . For simplicity we assume that the protocol has *perfect agreement*, that is, the players always output the same key, and that the security parameter is  $3/4$ , that is, an eavesdropper has probability at most  $3/4$  of outputting the same key as the players. Our full proof does not make these assumptions.

Now, we want to construct from the key-agreement protocol  $\Pi$ , which uses a random oracle, a protocol  $\Pi'$  for set disjointness, *without* a random oracle (as usual in communication complexity). To this end, we consider two possible ways of simulating  $\Pi$  without an oracle:

## 40:8 The Communication Complexity of Key-Agreement

- $\Lambda_{\text{Com}}$ : the players use their shared randomness to simulate the oracle. They interpret the shared randomness as a random function  $F : [n] \rightarrow [n]$ , and whenever  $\Pi$  wants to query some element  $q \in [n]$ , the players use  $F(q)$  as the oracle's answer.
- $\Lambda_{\text{Dist}}$ : the players use their *private* randomness to simulate the oracle. Alice and Bob interpret their private randomness as random functions  $F_A, F_B : [n] \rightarrow [n]$ , respectively. Whenever  $\Pi$  indicates that Alice should query an element  $q \in [n]$ , she uses  $F_A(q)$  as the answer, while Bob uses  $F_B(q)$ .

The first simulation,  $\Lambda_{\text{Com}}$ , is “perfect”: it produces exactly the correct distribution of transcripts and outputs under our key-agreement protocol  $\Pi$ . In particular, the keys produced by the players in  $\Lambda_{\text{Com}}$  always agree, and an eavesdropper that sees the transcript of  $\Lambda_{\text{Com}}$  (but not the shared randomness) can find the key with probability at most  $3/4$ .

On the other hand, the second simulation  $\Lambda_{\text{Dist}}$  is “wrong”, because the players do not use the same random function to simulate the random oracle. In fact, it is known that without shared randomness, secure key agreement is *impossible*, as an eavesdropper that sees the transcript can find the key with the same probability that the players have of agreeing with each other. Therefore there are two possible cases:

**Agreement gap:** The probability that the players agree on the key in  $\Lambda_{\text{Dist}}$  is at most  $7/8$  (compared to one in  $\Lambda_{\text{Com}}$ ), or

**Secrecy gap:** There is an eavesdropper  $E$  that guesses Alice's key in  $\Lambda_{\text{Dist}}$  with probability at least  $7/8$  (compared to  $3/4$  in  $\Lambda_{\text{Com}}$ ).

(Instead of  $7/8$  we could have used here any constant probability in  $(3/4, 1)$ , but in the full proof this choice depends on the agreement and security parameters of  $\Pi$ .)

We divide into cases, depending on which of the two gaps we have.

### Agreement gap

Assume that the players agree with probability at most  $7/8$  in  $\Lambda_{\text{Dist}}$ . For simplicity, let us make the stronger assumption that for any intersection size  $c > 0$ , the probability of agreement between the players is at most  $7/8$ , even *conditioned* on the event that  $|A \cap B| = c$ . A general key-agreement protocol might not satisfy this assumption, which complicates the full proof significantly; see the full version of this paper for the details.

So, we assumed that whenever the intersection is non-empty, the players agree with probability at most  $7/8$ . Observe, however, that when the intersection *is* empty ( $A \cap B = \emptyset$ ), the distribution of transcript and outputs in  $\Lambda_{\text{Dist}}$  is the same as in  $\Pi$ : although each player uses a different random function, they never ask the same query, so there is no inconsistency. Therefore, conditioned on  $A \cap B = \emptyset$ , in  $\Lambda_{\text{Dist}}$  the players have perfect agreement (as in  $\Pi$ ). In other words,  $\Lambda_{\text{Dist}}$  behaves very differently when  $A \cap B = \emptyset$ , in which case the players always agree on the key, compared to the general case, where the players agree with probability at most  $7/8$ . We use this fact to *check* whether  $A \cap B = \emptyset$ . Thus, by checking whether or not they got the same key in  $\Lambda_{\text{Dist}}$ , the players get an indication for whether or not  $A \cap B = \emptyset$ .

Our set disjointness protocol  $\Pi'$  is defined as follows. Given inputs  $X, Y \subseteq [n]$ , respectively, the players simulate  $\Lambda_{\text{Dist}}$  several times. In each simulation, the players agree on a random permutation  $\sigma : [n] \rightarrow [n]$  using their shared randomness, and then the players simulate  $\Lambda_{\text{Dist}}$  using their permuted inputs as the query set; that is, Alice feeds  $A = \sigma(X)$  to  $\Lambda_{\text{Dist}}$  as her query set, and Bob feeds  $B = \sigma(Y)$  to  $\Lambda_{\text{Dist}}$  as his query set. Note that  $A, B$  are uniformly random, *subject to* having an intersection of size  $|X \cap Y|$ .

After each simulation of  $\Lambda_{\text{Dist}}$ , the players send each other the keys output under  $\Lambda_{\text{Dist}}$ , and check if they got the same key. Finally, they output “ $X \cap Y = \emptyset$ ” iff they got the same key in all the simulations of  $\Lambda_{\text{Dist}}$ .

Since  $\Lambda_{\text{Dist}}$  has perfect agreement when there is no intersection, the players always succeed when  $X \cap Y = \emptyset$ . However, by assumption, whenever  $X \cap Y \neq \emptyset$ , the probability of agreement in  $\Lambda_{\text{Dist}}$  is at most  $7/8$ , so if we repeat  $\Lambda_{\text{Dist}}$  sufficiently many times, the probability that all instances output the same key will be at most  $1/3$ .

### Secrecy gap

In this case we convert  $\Lambda_{\text{Com}}$  and  $\Lambda_{\text{Dist}}$  into a pair of protocols with an agreement gap, and then proceed as above.

Consider the protocol  $\Lambda'_{\text{Dist}}$  where the parties acts as in  $\Lambda_{\text{Dist}}$ , but at the end, Bob executes the eavesdropper E on the transcript, and outputs the key that E outputs. Define  $\Lambda'_{\text{Com}}$  analogously.

By assumption, E guesses Alice's output in  $\Lambda_{\text{Dist}}$  with probability at least  $7/8$ , but in  $\Lambda_{\text{Com}}$  it succeeds with probability at most  $3/4$ . Thus, in  $\Lambda'_{\text{Dist}}$  the players agree with probability at least  $7/8$ , but in  $\Lambda'_{\text{Com}}$  they agree with probability at most  $3/4$ ; there is a gap of at least  $1/8$  between the probability of agreement in the two protocols (although they have switched roles and now  $\Lambda'_{\text{Dist}}$  has the higher agreement probability). Note also that  $\Lambda'_{\text{Dist}}$  does not have agreement probability 1, as we assumed for simplicity above, but our full proof can handle this case.

### Formal statement

Here we give the formal statements that we prove for uniform-query protocols. Formally, our reduction is to set-disjointness over the distribution below, which known to be hard for low complexity protocols.

► **Definition 4** (hard distribution for set-disjointness). For  $\ell \in \mathbb{N}$ , let  $\mathcal{Q}_\ell^0 = \{\mathcal{X}, \mathcal{Y} \subset [\ell]: |\mathcal{X}| = |\mathcal{Y}| = \lfloor \ell/4 \rfloor, \mathcal{X} \cap \mathcal{Y} = \emptyset\}$  and let  $\mathcal{Q}_\ell^1 = \{\mathcal{X}, \mathcal{Y} \subset [\ell]: |\mathcal{X}| = |\mathcal{Y}| = \lfloor \ell/4 \rfloor, |\mathcal{X} \cap \mathcal{Y}| = 1\}$ . Let  $D_\ell^0$  and  $D_\ell^1$  be the uniform distribution over  $\mathcal{Q}_\ell^0$  and  $\mathcal{Q}_\ell^1$  respectively, and let  $D_\ell = \frac{3}{4} \cdot D_\ell^0 + \frac{1}{4} \cdot D_\ell^1$ .

Razborov [16] has shown that solving set-disjointness  $D_\ell$  with small error require high communication complexity.

► **Theorem 5** (hardness of  $D_\ell$ , [16]). *Exists  $\epsilon > 0$  such that for every  $\ell \in \mathbb{N}$  and a protocol  $\Pi$  that solves set-disjointness over  $D_\ell$  with error  $\epsilon$ , it holds that  $\text{CC}(\Pi) \geq \Omega(\ell)$ .*

For a finite set  $\mathcal{S}$ , let  $\mathcal{F}_\mathcal{S} = \{f : \mathcal{S} \mapsto \{0, 1\}^*\}$  be the family of all functions from  $\mathcal{S}$  to binary strings. Our reduction is stated in the following theorem.

► **Theorem 6** (from uniform-query key-agreement protocols to set-disjointness). *Assume exists an  $\ell$ -uniform-query  $(0, \alpha, \gamma)$ -key agreement protocol relative to  $\mathcal{F}_\mathcal{S}$ , for some set  $\mathcal{S}$ , of communication complexity  $c$ . Then there exists a protocol for solving set-disjointness over  $D_\ell$  with  $\epsilon$  error and communication complexity  $\frac{2^{15} \cdot \ell^4 \cdot \log 1/\epsilon}{|\mathcal{S}|^2 (1 - \alpha - \gamma)^4} \cdot c$ .*

Note that the above theorem holds also for protocols that are only secure against eavesdropper without access to the oracle. Combining theorems 5 and 6 yields the following bound on the communication complexity of uniform-query key-agreement protocols.

► **Theorem 7** (Main result for uniform-inputs protocols). *For any  $\ell$ -uniform-query  $(q, \alpha, \gamma)$ -key agreement protocol  $\Pi$  relative to  $\mathcal{F}_\mathcal{S}$ , it holds that  $\text{CC}(\Pi) \in \Omega((1 - \alpha - \gamma)^4 q^2 / \ell^3)$ .*

### What about general protocols?

It was important for our reduction to assume that the key-agreement protocol makes uniformly-random queries. Indeed, this reduction fails in the general case: consider the protocol where Alice and Bob always query 1, and output  $F(1)$  as their secret key. This protocol is completely insecure, since the eavesdropper can also query 1 and output  $F(1)$ . But our reduction would not work for it, because the input distribution where both players get the set  $\{1\}$  is not hard for set disjointness (indeed it is trivial). We see that the “hardness” of secure key-agreement is not necessarily that it is hard for the players to find their intersection queries, but that the eavesdropper should not be able to *predict* the intersection queries that the players use. Our second lower bound makes this intuition explicit and uses it to get a lower bound on two-round protocols with arbitrary (but non-adaptive) query distributions.

## 4 Two-Message Non-Adaptive Protocols: Proof Outline

In this section we describe a lower bound on the communication cost of any key-agreement protocol that makes non-adaptive queries and uses two rounds of communication: we show that any such protocol that makes  $\ell$  queries and is secure against an adversary that makes  $q$  queries must send a total of  $\Omega(q/\ell)$  bits. In particular, taking  $q = \Theta(\ell^2)$ , this shows that Merkle’s puzzles is optimal in its communication cost. Formally, we show the following bound, where  $\mathcal{F}_n$  is the family of all functions from  $\{0, 1\}^n$  to  $\{0, 1\}^n$ :

► **Theorem 8** (Main theorem for two-message, non-adaptive protocols). *For any  $n \in \mathbb{N}$ , the communication complexity of a two-message, non-adaptive,  $\ell$ -query  $(q, \alpha, \gamma)$ -key-agreement protocol relative to  $\mathcal{F}_n$  is at least*

$$\frac{(1 - \alpha - \gamma)^2 q}{50^2 \ell} - 6.$$

In this proof, we once again relate the parties’ advantage over the eavesdropper to the information they gained about the intersection of their query sets. We show that to produce a shared key, the parties need to learn a lot of information about this intersection. Moreover, the query sets and their intersection need to be “unpredictable” (have high min-entropy) given the transcript, otherwise an eavesdropper could make the same queries and output the same key.

### 4.1 Some examples

Let us illustrate the ideas behind the lower bound by way of some examples.

#### Example 1

We already discussed the naive example where both players query 1 and output  $F(1)$ , and said that it is insecure because the eavesdropper can *predict* the intersection query. Here is another instantiation of this idea: Alice and Bob view the domain  $\ell^2$  as an  $\ell \times \ell$  matrix, so that the oracle queries are represented by pairs  $(i, j) \in [\ell]^2$ . Alice chooses a row  $a \in [\ell]$ , and queries all the elements of the row (that is, all pairs  $(a, j)$  where  $j \in [\ell]$ ); Bob chooses a column  $b \in [\ell]$  and queries all the elements of the column (all pairs  $(i, b)$  where  $i \in [\ell]$ ). Then, Alice sends  $a$  to Bob, who responds with  $F(a, b)$ . From  $F(a, b)$ , Alice can compute  $b$ , by finding the (w.h.p. unique) index  $j$  such that  $F(a, b) = F(a, j)$ . Both players output the first bit of  $b$  as the key.

This protocol is slightly less naïve than the previous one: now there are no queries that have high prior probability of being asked, and the index  $b$  of the query that determines the key is uniformly random a-priori. However, once Alice sends  $a$  to Bob, the game is up: Eve can also query row  $a$  and find  $b$  the same way Alice does.

We see that in addition to queries that have a high prior probability of being asked, Eve also needs to ask queries that have a high *posterior* probability of being asked, after she sees  $M_1$ . It turns out that this is enough: if we were to continue for more than 2 rounds, then Eve would also need to ask queries that become likely after seeing  $M_2$ , and so on, but to prove a 2-round lower bound, Eve does not need to ask these queries. Intuitively, if a query only becomes likely after  $M_2$  is sent, then this is “too late” for it to be useful to the players, and Eve can ignore it.

## Example 2

First, both players query 1. Then they carry out the protocol from Example 1, but all messages are “encrypted” by XOR-ing them with  $F(1)$ .

From this example we see that Eve needs to be somewhat adaptive: when she decides what queries to ask after seeing  $M_1$ , she must incorporate the queries she asked before the first round (in this case, she would query 1). Essentially, when Eve tries to understand what the players have done in round  $i$ , she should take into account all the queries she made up to round  $i$ .

Should Eve be adaptive *inside* each round? In other words, after seeing  $M_1$ , should she ask all queries  $\mathcal{E}_1$  that became likely, then compute which new queries are now likely given  $M_1, \mathcal{E}_1$ , and so on, until she reaches a fixpoint?

It turns out that for our purposes here, because we consider non-adaptive protocols, Eve does not need to do this.

## Heavy queries

Our attacker Eve tries to break the security of the protocol by asking all queries that are “somewhat likely” to be asked by the players; these queries are called *heavy queries*. Informally, a query  $q \in \{0, 1\}^n$  is *heavy* after round  $i$  if given the transcript up to round  $i$  (inclusive), and given Eve’s queries up to round  $i$ , the probability that  $q$  is asked by one (or both) of the players exceeds some threshold  $\delta$  which is fixed in advance.

More formally, the set  $\mathcal{E}_i$  of heavy queries after round  $i$  is defined by induction on rounds, as follows: the a-priori heavy queries,  $\mathcal{E}_0$ , are given by

$$\mathcal{E}_0 = \{q \in \{0, 1\}^n : \Pr[q \in X \cup Y] \geq \delta\}.$$

These are queries that are “somewhat likely” to be asked before the protocol begins. For  $i > 0$ , we define

$$\mathcal{E}_i = \mathcal{E}_{i-1} \cup \{q \in \{0, 1\}^n : \Pr[q \in X \cup Y \mid M_{\leq i}, F(\mathcal{E}_{i-1})] \geq \delta\}.$$

In other words, after round  $i$ , Eve asks all queries  $q \in \{0, 1\}^n$  that have probability at least  $\delta$  of being queried by the players, given the messages  $M_{\leq i}$  that Eve observed up to round  $i$  and the heavy queries she asked before,  $\mathcal{E}_{i-1}$ .

### A simplified normal form for protocols

To simplify the proof of the lower bound, we first apply an easy transformation to the protocol: given a key agreement protocol  $\Pi$ , we construct a protocol  $\Pi'$ , which has nearly the same communication and query complexity as  $\Pi$ , the same number of rounds, and the same agreement and nearly the same security parameters. But  $\Pi'$  also has the following properties: first,  $\Pi'$  has no a-priori heavy queries, that is,  $\mathcal{E}_0 = \emptyset$ ; and second, the secret key output by Bob in  $\Pi'$  is the first bit of Bob's last query. This easy transformation is omitted in this overview.

### Measuring the Players' Advantage Over Eve

As we saw in the examples above, the players' ability to produce a shared secret key is closely tied to how much information *the players* have that *Eve does not have* about the intersection of the query sets,  $X \cap Y$ .

To quantify this advantage, define the following random variables:

- $S_i = (X \cap Y) \setminus \mathcal{E}_{i-1}$ , the intersection queries that have not been asked by Eve.
- $F(S_i)$ : the answers to the queries in  $S_i$ .
- $V_E^i = (\mathcal{E}'_i, F(\mathcal{E}'_i))$ : a subset of the heavy queries for the previous round, and the answers to them. Here,  $\mathcal{E}'_i \subseteq \mathcal{E}_i$  is a subset that will be defined later (and depends on the round number  $i$ ). For technical reasons, it is convenient to use only some of the heavy queries in some contexts; essentially, in some places in our proof, Eve uses only some of her power. This helps us avoid some unnecessary dependencies.

We measure the advantage gained by the players in round  $i$  by an expression of the form:

$$I_f(S_i, F(S_i); M_i | Z, V_E^{i-1}, M_{<i}), \quad (1)$$

where  $I_f$  is the information with respect to the  $f$ -divergence,  $M_i, M_{<i}$  are the  $i$ -th message and the messages of rounds  $1, \dots, i-1$ ,  $Z$  is the query set of the player that sent  $M_i$  (either  $X$  or  $Y$ , depending on the round number  $i$ ). Note that Eve uses her heavy queries from the previous rounds,  $V_E^{i-1}$ , to “try to understand” what is going on in the current round.

Intuitively, this expression measures how much information the  $i$ -th message conveys about the intersection queries and their answers, which Eve *cannot guess*. For this reason, the random variable  $S_i$  excludes intersection queries that were asked by Eve. Notice that on the right-hand side we condition on Eve's view (or on things Eve can sample): Eve has already seen the messages  $M_{<i}$  and asked the heavy queries  $V_E^{i-1} = (\mathcal{E}'_{i-1}, F(\mathcal{E}'_{i-1}))$ , and she can sample the queries  $Z$ , either  $X$  or  $Y$ , from the correct distribution given the transcript and her queries. Crucially, this does not require her to make any oracle queries: we do not require her to sample the answers  $F(Z)$ , only the queries  $Z$ . In other words, Eve can *pretend* to be whichever player the query set  $Z$  belongs to, and by conditioning on her view, we essentially neutralize all the information that Eve can extract about the intersection. Thus, the expression in (1) measures the information the players gain about the intersection but that is hidden from Eve.<sup>8</sup>

Our proof consists of showing:

<sup>8</sup> As we said above, we use only some of Eve's heavy queries,  $\mathcal{E}'_{i-1} \subseteq \mathcal{E}_i$ , so this intuition is not completely accurate; specifically, when (1) is *large*, it does not mean that Eve cannot guess a lot about the intersection, because she could use the full set  $\mathcal{E}_i$ . However, when (1) is *small*, then indeed Eve knows almost as much about the intersection as the players do, because her view *includes*  $V_E^{i-1}$  (and possibly more).

- Step I:** After the first message  $M_1$  is sent, the advantage gained is small, only  $O(\delta|M_1|)$ . For this part of the proof we use KL-divergence to measure the advantage.
- Step II:** After the second message  $M_2$  is sent, the advantage is still small, only  $O(\sqrt{\delta(|M_1| + |M_2|)})$ . Here we use statistical distance to measure the advantage, for reasons we will explain below.
- Step III:** When the expression in (1) is small (i.e., the players only have a small “advantage”), then indeed, Eve can break the security of the protocol, by pretending to be one of the players and sampling the secret key that this player would output.

Next we explain in more detail how each step is carried out.

## 4.2 Outline of the Proof

### Step III: How Eve breaks security

Let us start from the end: suppose that after the second round, the “advantage” is small:

$$I_f(S_2, F(S_2); M_2 | Y, M_1, V_E^1) \leq \beta,$$

where  $\beta = O(\sqrt{\delta(|M_1| + |M_2|)}) \ll 1$ . Here, the advantage is measured in statistical distance (that is, we take  $f(t) = |t - 1|/2$ ). We want to show that Eve can break the security of the protocol, by guessing the secret key.

As we said, Eve’s strategy is to “pretend” that she is Bob, and sample Bob’s output,  $\text{out}^B$ .

In a general protocol, to do this, Eve needs to sample Bob’s queries  $Y$  and the answers  $F(Y)$ , and then she can compute  $\text{out}^B = \text{out}^B(Y, F(Y), M_1, M_2)$ . However, recall that we transformed the protocol so that  $\text{out}^B$  is a fixed function of  $Y$ ; therefore, Eve in fact needs to do nothing clever, only sample  $Y$  given her view  $M_1, M_2, \mathcal{E}_1, F(\mathcal{E}_1)$  and compute  $\text{out}^B$  from  $Y$ .

We need to show that Eve’s key is close to the correct distribution, the one used by the players. In general, if too much communication is allowed, this is not true, as shown by the following example.

► **Example 9.** In Merkle’s puzzles, Alice’s message is  $F(X)$ , and Bob responds with  $F(s)$ , where  $s \in X \cap Y$  is some intersection query. The original secret key (before our transformation) is the first bit  $s^1$ . After our transformation, the secret key is  $Y_{\ell+1}^1$ , and as part of  $M_2$ , Bob sends Alice the bit  $b = s^1 \oplus Y_{\ell+1}^1$  so that she can extract  $Y_{\ell+1}^1$ .

From Alice’s perspective, given  $X, F(X)$ , Bob’s message  $M_2 = F(s)$ ,  $b$  fixes  $Y_{\ell+1}^1$  to the value  $b \oplus s^1$ . (We ignore here the tiny probability that  $s$  cannot be uniquely computed from  $X, F(X)$  and  $F(s)$ , i.e., the probability of a collision in  $F$ .) However, from Eve’s perspective, because she does not know  $X, F(X)$  and she asks no queries (there are no heavy queries in Merkle’s puzzles), the intersection element  $s$  remains uniformly random. When Eve samples  $Y_{\ell+1}^1$  given  $M_1, M_2$  and her non-existent heavy queries, the result is random, and completely independent from the true secret key.

We need to show that when the players’ advantage is small, then the example above cannot happen, and Eve’s key agrees with the players’ w.h.p. To this end, we are interested in the difference between Eve’s “pretend distribution”, and the true distribution that the players use to produce the key: if the two distributions are close, then Eve’s chances of guessing the right secret key are roughly the same as Bob’s. The *only difference* between these two distributions is that given  $M_1, M_2$  and  $\mathcal{E}_1, F(\mathcal{E}_1)$  (which the players do not use),

## 40:14 The Communication Complexity of Key-Agreement

- The players' keys are produced according to the *joint distribution*  $(\text{out}^A, \text{out}^B)$ , and in particular, both players have the same answers  $F(S_2)$  to the non-heavy intersection queries  $S_2 = (X \cap Y) \setminus \mathcal{E}_1$ .
- Eve's pretense that she is Bob is carried out *independently* from Alice's view: Eve cannot use the true intersection queries (which she does not know), only what she has learned about them from  $M_1, M_2, V_E^i$ . The joint distribution of Alice and Eve's keys is therefore given by the product distribution  $\text{out}^A \times \text{out}^B$ .

So, we would like to bound the difference between the joint distribution and the product distribution, i.e.,

$$I_f(\text{out}^A; \text{out}^B | M_1, M_2, \mathcal{E}_1, F(\mathcal{E}_1)).$$

Given the conditioning, Alice's output  $\text{out}^A$  is a function of her view,  $X, F(X)$ . Also, we assumed that Bob's output is a function of his queries  $Y$ . Therefore,

$$I_f(\text{out}^A; \text{out}^B | M_1, M_2, \mathcal{E}_1, F(\mathcal{E}_1)) \leq I_f(X, F(X); Y | M_1, M_2, \mathcal{E}_1, F(\mathcal{E}_1)). \quad (2)$$

Now we need to show that given Eve's view, the dependence between  $X, F(X)$  and  $Y$  is bounded in terms of the advantage:

$$I_f(X, F(X); Y | M_1, M_2, \mathcal{E}_1, F(\mathcal{E}_1)) \leq I_f(S_2, F(S_2); M_2 | M_1, Y, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)). \quad (3)$$

This proof is somewhat tedious; it relies on the fact that  $M_2$  is a function of  $M_1, Y$  and  $F(Y)$ , and on the fact that  $X, F(X)$  are independent of  $Y, F(Y)$  given the intersection queries and answers,  $S_2, F(S_2)$  and  $\mathcal{E}_1, F(\mathcal{E}_1)$ . Intuitively, all the dependence between  $X, F(X)$  and  $Y$  "flows through" what the players learn about the intersection, and the proof of (3) formalizes this intuition.

### Step I: Bounding the advantage after the first round

For the first round, we analyze the players' advantage in terms of KL-divergence, and bound

$$I(S_1, F(S_1); M_1 | X).$$

Notice that we do not use Eve at this point, because we eliminated any a-priori heavy queries, so there is nothing Eve needs to query in order to "understand"  $M_1$ . For the same reason,  $S_1 = X \cap Y$  (there are no heavy queries to remove from the intersection).

We claim that

$$I(S_1, F(S_1); M_1 | X) \leq \delta |M_1|. \quad (4)$$

This is not hard to see: suppose  $X = x$ . Because we got rid of the a-priori heavy queries, every individual query  $q \in x$  has probability at most  $\delta$  of being asked by Bob (otherwise,  $q$  would be heavy). Therefore, for every  $q \in x$ , we have  $\Pr[q \in S_1 | X = x] \leq \delta$ . Because  $M_1$  is generated by Alice without knowing  $S_1$ , and every query is in  $S_1$  only w.p. at most  $\delta$ , intuitively, the information in  $M_1$  "only applies" to the queries in  $S_1$  with probability  $\delta$ . Therefore the information that  $M_1$  gives about  $S, F(S_1)$  is at most  $\delta |M_1|$ .

The actual proof involves a Shearer-like argument for mutual information, similar to the ones used in [6, 15].

**Step II: Bounding the advantage after the second round**

Now we must bound the advantage the players gain after the second round, and show that

$$I_{SD}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) = O(\sqrt{|\mathcal{M}_1| + |\mathcal{M}_2|}). \quad (5)$$

As we said, we switch here to using statistical distance, and we will see why below.

Following the first round, we know that not much is known about the intersection, because Alice's message  $M_1$  did not convey a lot of information about it. So, our proof here proceeds in two steps: first, we "pretend" that *nothing* is known about the intersection, and consider the distribution  $\mu'$  where given  $M_1$  the distribution of  $Y, F(Y)$  is completely independent from  $X$ . We show that under  $\mu'$ , Bob's message  $M_2$  would only convey  $\delta|\mathcal{M}_2|$  bits of information about the intersection. This is very similar to the analysis of the first round, and it is also carried out using KL-divergence. Formally, we show that for the distribution  $\mu'$  where  $Y, F(Y)$  are drawn independently of  $X$ , we have

$$I^{\mu'}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) \leq \delta|\mathcal{M}_2|. \quad (6)$$

The proof relies on the fact that we excluded heavy queries from  $S_2$  (recall that  $S_2 = (X \cap Y) \setminus \mathcal{E}_1$ ), so given the conditioning, any query in  $Y$  can only belong to  $S_2$  with probability at most  $\delta$ .

However,  $\mu'$  is not the real distribution: given  $M_1$ , we do know a little about the intersection, so  $Y, F(Y)$  are not completely independent from  $X$ . Our next step is to switch to statistical distance, and show that the real distribution  $\mu$  (where  $X, Y$  are not independent) and  $\mu'$  (where they are) are close to each other. Therefore, what we showed for  $\mu'$  is also true for  $\mu$ , with the addition of a small penalty corresponding to the distance between  $\mu$  and  $\mu'$ .

Formally, we prove that

$$\begin{aligned} & I_{SD}^{\mu}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) \\ & \leq O\left(I_{SD}^{\mu'}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) + D_{SD}(\mu' \parallel \mu)\right) \end{aligned} \quad (7)$$

Under  $\mu'$ , by (6) and Pinsker's inequality, we have:

$$I_{SD}^{\mu'}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) \leq \sqrt{\delta|\mathcal{M}_2|}. \quad (8)$$

So, under  $\mu'$  the expected amount of information revealed is small.

Next, we bound the difference between  $\mu$  and  $\mu'$ . We show that:

$$I(Y, F(Y); X|M_1) \leq I(S_1, F(S_1); M_1|X).$$

This is quite similar to the proof of Step III above – here we do use standard mutual information, so the proof uses the chain rule, just as we did above. Since we have shown in Step I that  $I(S_1, F(S_1); M_1|X) \leq \delta|\mathcal{M}_1|$ , we conclude using Pinsker's inequality that

$$D_{SD}(\mu' \parallel \mu) \leq \sqrt{D_{KL}(\mu' \parallel \mu)} \leq \sqrt{\delta|\mathcal{M}_1|}. \quad (9)$$

Together, (8) and (9) are the ingredients we need to apply (7), and obtain:

$$\begin{aligned} & I_{SD}^{\mu}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) \\ & \leq O\left(I_{SD}^{\mu'}(S_2, F(S_2); M_2|Y, M_1, \mathcal{E}_1 \cap Y, F(\mathcal{E}_1 \cap Y)) + D_{SD}(\mu' \parallel \mu)\right) \\ & \leq O(\sqrt{\delta(|\mathcal{M}_1| + |\mathcal{M}_2|)}). \end{aligned}$$

## Abstract

The Paulsen problem is a basic problem in operator theory that was resolved in a recent four-decade work of Kwok, Lau, Lee and Ramachandran. In particular, they showed that every  $\epsilon$ -nearly equal norm Parseval frame in  $d$  dimensions is within squared distance  $O(\epsilon d^{13/2})$  of an equal norm Parseval frame. We give a dramatically simpler proof based on the notion of radial isotropic position, and along the way show an improved bound of  $O(\epsilon d^2)$ .

## 1 Introduction

The Paulsen problem is a basic problem in operator theory that was resolved in a recent work of Kwok, Lau, Lee and Ramachandran [12]. To state the problem, we need the following definition:

► **Definition 1.** We say that a set of vectors  $v_1, v_2, \dots, v_n \in \mathbb{R}^d$  is an *equal norm Parseval frame* if

$$\sum_{i=1}^n v_i v_i^T = I \text{ and } \|v_i\|_2^2 = \frac{d}{n} \text{ for each } i.$$

Alternatively, we say that it is an  $\epsilon$ -nearly equal norm Parseval frame if

$$(1 - \epsilon)I \preceq \sum_{i=1}^n v_i v_i^T \preceq (1 + \epsilon)I \text{ and } (1 - \epsilon)\frac{d}{n} \leq \|v_i\|_2^2 \leq (1 + \epsilon)\frac{d}{n} \text{ for each } i.$$

When we drop the condition on the norm of each vector, we refer to the set of vectors as a *Parseval frame* or an  $\epsilon$ -nearly Parseval frame respectively. Let  $\mathcal{F}$  denote the set of

## 41:2 The Paulsen Problem Made Simple

all equal norm Parseval frames. Lastly for two sequences of vectors  $V = v_1, v_2, \dots, v_n$  and  $W = w_1, w_2, \dots, w_n$  of the same length, we let

$$\text{dist}^2(V, W) = \sum_{i=1}^n \|v_i - w_i\|^2.$$

With this terminology in hand, the Paulsen problem asks:

► **Conjecture 2.** *For every  $\epsilon$ -nearly equal norm Parseval frame  $V$ , is*

$$\inf_{W \in \mathcal{F}} \text{dist}^2(V, W)$$

*bounded by a fixed polynomial in  $\epsilon$  and  $d$ ?*

See [12] and references therein for a detailed account of the history of the Paulsen problem along with earlier bounds on the squared distance that were polynomial in  $\epsilon$ ,  $d$  and  $n$ . Through a tour-de-force utilizing operator scaling, connections to dynamical systems and ideas from smoothed analysis, Kwok, Lau, Lee and Ramachandran [12] proved that the squared distance is at most  $O(\epsilon d^{13/2})$ . The paper was 104 pages long and highly complex. Our main result is a dramatically simpler proof of the Paulsen conjecture, that also yields a much better bound:

► **Theorem 3 (Main).** *For any  $\epsilon$ -nearly equal norm Parseval frame  $V$ , there is an equal norm Parseval frame  $W$  with*

$$\text{dist}^2(V, W) \leq 20\epsilon d^2.$$

In terms of lower bounds, Cahill and Casazza [4] gave a family of examples of  $\epsilon$ -nearly equal norm Parseval frames where the squared distance to the closest equal norm Parseval frame is at least  $\Omega(\epsilon d)$ . It is an interesting open question to close this gap.

Our main idea is to make use of the notion of *radial isotropic position*<sup>3</sup>. In the next section, we define it formally. But to understand it informally, it is useful to compare it to the more familiar notion of placing a set of vectors in isotropic position: Given a set of vectors  $V = v_1, v_2, \dots, v_n \in \mathbb{R}^d$ , is there an invertible affine transformation that generates a new set of vectors  $Y = Av_1 + b, Av_2 + b, \dots, Av_n + b$  that has mean zero and identity covariance? It is well known that there is such a transformation if and only if  $\sum_i v_i v_i^T$  has full rank.

However such a transformation can also stretch out some directions much more than others – e.g. if all but one of the vectors in  $V$  are contained in a  $d - 1$ -dimensional subspace. In this case, the set of vectors after applying the transformation would be quite far from where it started out, in total squared distance. Informally, radial isotropic position asks for a linear transformation  $A$  so that the *renormalized* vectors  $w_i = Av_i / \|Av_i\|$  have the property that  $\sum_i w_i w_i^T$  is a scalar multiple of the identity. The transformation is now nonlinear but is particularly well suited for constructing a close by equal norm Parseval frame.

One can now ask the same sort of question as before: When can a set of vectors be placed in radial isotropic position? Barthe [2] gave a complete characterization of when this is and is not possible which in turn plays a key role in our proof. It turns out that a sufficient condition is that every  $d$  vectors are linearly independent. Now we construct an equal norm Parseval frame as follows: First we renormalize the vectors in  $V$  and then we perturb them.

---

<sup>3</sup> This concept goes by many other names in the literature, such as *well-spread vectors* [5] or *geometric scaling for rank one Brascamp-Lieb datum* [9]. The name we use here originated in [11].

Perturbations play a delicate role in [12]. They give a dynamical system which constructs an equal norm Parseval frame from an  $\epsilon$ -nearly equal norm Parseval frame as its input. In order to bound the total squared distance between the input and output, they need to lower bound the convergence rate. They do this through a certain pseudorandom property (Definition 4.3.2) which they show holds when the input is appropriately perturbed. In our proof, all we need is that the perturbations do not move the set of points by too much in squared distance and that afterwards every  $d$  of them are linearly independent<sup>4</sup>. The latter condition guarantees that there is a linear transformation that places them in radial isotropic position. Let  $W$  be the set of vectors, after applying the linear transformation and renormalizing. By definition, it is an equal norm Parseval frame. Our main technical contribution is in bounding the squared distance between  $V$  and  $W$ , which we do through some elementary but subtle algebraic manipulations.

Taking a step back, the notion of radial isotropic position seems quite powerful and mysterious but has thus far only found a handful of applications. Forster [7] used it to prove a remarkable lower bound in communication complexity (by lower bounding the sign rank of the Hadamard matrix). Hardt and Moitra [11] gave the first algorithm for computing the transformation that places a set of vectors in radial isotropic position (under a slight strengthening of Barthe's conditions). They also gave applications to linear regression in the presence of outliers. Dvir, Saraf and Wigderson [5] used it to prove superquadratic lower bounds for 3-query locally correctable codes over the reals. Here we use it to give a simple proof of the Paulsen conjecture. Are there other exciting applications waiting to be discovered?

## Connections to Operator Scaling and the Brascamp-Lieb Inequality

Radial isotropic position is itself a special case of the more general notion of *geometric position* [1, 2] where we are given an  $n$  tuple of linear transformations  $B_1, B_2, \dots, B_n$  of dimensions  $d_1 \times d, d_2 \times d, \dots, d_n \times d$  and a nonnegative vector  $c$  of dimension  $n$  with  $\sum_{i=1}^n c_i d_i = d$  and the goal is to find square, invertible matrices  $A_1, A_2, \dots, A_n$  and  $A$  so that

$$\sum_{i=1}^n c_i (A_i^{-1} B_i A)^T (A_i^{-1} B_i A) = I \text{ and } (A_i^{-1} B_i A) (A_i^{-1} B_i A)^T = I \text{ for each } i.$$

If we set  $d_i = 1$  for all  $i$ , then each linear transformation  $B_i$  can be written as the inner-product with some vector  $v_i$ . Now if we also set  $c_i = \frac{d}{n}$  for all  $i$ , it is easy to check that  $A$  places the set of vectors  $v_1, v_2, \dots, v_n$  in radial isotropic position.

It turns out that having  $A_1, A_2, \dots, A_n$  and  $A$  that place  $B_1, B_2, \dots, B_n$  in geometric position with respect to the vector  $c$  yields an explicit expression for the best constant  $C$  for which the inequality

$$\int_{x \in \mathbb{R}^d} \prod_{i=1}^n (f_i(B_i x))^{c_i} dx \leq C \prod_{i=1}^n \left( \int_{x_i \in \mathbb{R}^{d_i}} f_i(x_i) dx_i \right)^{c_i}$$

holds over all  $m$  tuples of nonnegative functions  $f_1, f_2, \dots, f_m$  [3]. This is called the Brascamp-Lieb inequality.

<sup>4</sup> In particular, essentially all sufficiently small perturbations would work for us. It could even be an infinitesimal perturbation because we do not need any quantitative bounds on how far they are from having a non-trivial linear dependence.

Finally, in terms of how to compute  $A_1, A_2, \dots, A_n$  and  $A$ , a popular approach is *operator scaling* [10] and there has been considerable recent progress in bounding the number of iterations it needs [8, 9]. As we mentioned, Kwok, Lau, Lee and Ramachandran [12] used operator scaling to solve the Paulsen conjecture. In this sense, our approach and theirs are closely related in that they both revolve around algorithms (in our case the ellipsoid algorithm) for computing radial isotropic position. Perhaps the main technical divergence is that they track how the squared distance changes after each iteration of operator scaling, while we are able to bound the squared distance just based on transformation that places  $v_1, v_2, \dots, v_n$  into radial isotropic position. It is also worth mentioning that if instead of proving existence of a nearby equal norm Parseval frame, we want to find it up to some target precision  $\delta$ , the approaches based on operator scaling typically require the number of iterations to be polynomial in  $1/\delta$ . In contrast, we will give algorithms whose running time is polynomial in  $\log 1/\delta$ .

## 2 Radial Isotropic Position and the Proof

First we introduce some of the basic concepts and results about radial isotropic position. We will do so in slightly more generality than we will ultimately need.

► **Definition 4.** We say that a set of vectors  $u_1, u_2, \dots, u_n \in \mathbb{R}^d$  is in *radial isotropic position* with respect to a coefficient vector  $c \in \mathbb{R}^n$  if

$$\sum_{i=1}^n c_i \left( \frac{u_i}{\|u_i\|} \right) \left( \frac{u_i}{\|u_i\|} \right)^T = I.$$

Note that if we take the trace of both sides in the expression, we get the necessary condition that  $\sum_{i=1}^n c_i = d$ . In fact we will only ever consider the case when each  $c_i = \frac{d}{n}$ . We will also need the following key definition:

► **Definition 5** ([6]). For a set  $U$  of vectors  $u_1, u_2, \dots, u_n \in \mathbb{R}^d$ , its *basis polytope* is defined as

$$\mathcal{B}(U) = \left\{ c \in \mathbb{R}^n \text{ s.t. } \sum_{i=1}^n c_i = d \text{ and for all } A \subseteq [n], \dim(\text{span}\{u_i\}_{i \in A}) \geq \sum_{i \in A} c_i \right\}.$$

Now we are ready to state Barthe's theorem:

► **Theorem 6** ([2]). *A set of vectors  $U = u_1, u_2, \dots, u_n \in \mathbb{R}^d$  can be put into radial isotropic position with respect to  $c$  by a linear transformation if and only if  $c \in \mathcal{B}(U)$ .*

Some further remarks: (1) The usual definition of the basis polytope is based on taking the convex hull of the indicators of subsets of vectors in  $U$  that form a basis. (2) The alternative definition we gave in Definition 5 will be more directly useful for our purposes, and was proven to be equivalent by Edmonds [6]. He used this equivalence to give a separation oracle for the basis polytope, which in turn plays a key role in the algorithm of Hardt and Moitra [11] for computing the linear transformation that puts a set of vectors into radial isotropic position.

See <https://arxiv.org/abs/1809.04726> for the proof of the main theorem. The main idea is to renormalize and then perturb the vectors in  $V$ . After the perturbation, we can invoke Theorem 6 to find a transformation  $A$  that places the vectors in radial isotropic position. We show that we can assume without loss of generality that  $A$  is a nonnegative diagonal matrix whose entries are sorted in non-increasing order along the diagonal. Our main technical lemma gives a bound on the squared distance:

► **Lemma 7.** *Suppose  $U$  is a  $4\epsilon$ -nearly Parseval frame and  $A$  is an entrywise diagonal matrix that puts  $U$  in radial isotropic position. Also suppose that for each  $i$*

$$(1 - \gamma') \frac{d}{n} \leq \|u_i\|_2^2 \leq (1 + \gamma') \frac{d}{n}.$$

Now set

$$W = w_1, w_2, \dots, w_n \text{ with } w_i \triangleq \sqrt{\frac{d}{n}} \left( \frac{Au_i}{\|Au_i\|} \right).$$

Then we have that  $\text{dist}^2(U, W) \leq 8\epsilon d^2 + 4\gamma' d^2$ .

See <https://arxiv.org/abs/1809.04726> for the proof of the main technical lemma.

### 3 An Algorithm for the Paulsen Problem

Every step of the proof of Theorem 3 is straightforward to implement algorithmically, except for the step where we compute the transformation  $A$  that places the set of vectors  $U$  in radial isotropic position. Fortunately, Hardt and Moitra [11] gave an algorithm for computing  $A$  under a slight strengthening of Barthe's conditions which holds in our setting. Informally, they require the vector  $c$  to be strictly inside the basis polytope according to the following notion of scaling:

► **Definition 8.** Let  $(1 - \alpha)\mathcal{B}(U)$  denote the set of vectors  $c$  with the following properties: (1)  $\sum_{i=1}^n c_i = d$ , (2)  $0 \leq c_i \leq 1$  for all  $i$  and (3) for all nonnegative directions  $u$  with  $u_{\min} = 0$ ,

$$(1 - \alpha) \max_{v \in \mathcal{B}(U)} u^T v \geq u^T c.$$

We will state a special case of their main theorem, which is sufficient for our purposes.

► **Theorem 9** ([11]). *Let  $\delta > 0$  and  $\alpha > 0$ . Suppose  $U = u_1, u_2, \dots, u_n \in \mathbb{R}^d$  has the property that every set of  $d$  vectors are linearly independent. Then given  $c \in (1 - \alpha)\mathcal{B}(U)$ , there is an algorithm to find a linear transformation  $A$  so that*

$$\sum_{i=1}^n c_i \left( \frac{Au_i}{\|Au_i\|} \right) \left( \frac{Au_i}{\|Au_i\|} \right)^T = I + J$$

where  $\|J\|_\infty \leq \delta$  – i.e. the largest entry of  $J$  in absolute value is at most  $\delta$ . The running time is polynomial in  $1/\alpha$ ,  $\log 1/\delta$  and  $L$  where  $L$  is an upper bound on the bit complexity of  $U$  and  $c$ .

By combining their algorithm with our proof of Theorem 3 we get:

► **Corollary 10.** *Suppose  $V = v_1, v_2, \dots, v_n \in \mathbb{R}^d$  is an  $\epsilon$ -nearly equal norm Parseval frame. Furthermore suppose  $n > d$ . Then given  $\delta > 0$ , there is an algorithm to compute a  $\delta$ -nearly equal norm Parseval frame  $W$  with*

$$\text{dist}^2(V, W) \leq 20\epsilon d^2$$

whose running time is polynomial in  $\log 1/\delta$  and  $L$  where  $L$  is an upper bound on the bit complexity of  $V$ .

See <https://arxiv.org/abs/1809.04726> for the proof of the corollary. This answers an open question of [12], where they ask whether there is an algorithm for finding an equal norm Parseval frame up to some precision  $\delta$  whose running time is polynomial in  $\log 1/\delta$ .

## Abstract

In this work, we examine the feasibility of secure and undetectable point-to-point communication when an adversary (e.g., a government) can read all encrypted communications of surveillance targets. We consider a model where the only permitted method of communication is via a government-mandated encryption scheme, instantiated with government-mandated keys. Parties cannot simply encrypt ciphertexts of some other encryption scheme, because citizens caught trying to communicate outside the government's knowledge (e.g., by encrypting strings which do not appear to be natural language plaintexts) will be arrested. The one guarantee we suppose is that the government mandates an encryption scheme which *is* semantically secure against outsiders: a perhaps reasonable supposition when a government might consider it advantageous to secure its people's communication against foreign entities. But then, what good is semantic security against an adversary that holds all the keys and has the power to decrypt?

We show that even in the pessimistic scenario described, citizens *can* communicate securely and undetectably. In our terminology, this translates to a positive statement: all semantically secure encryption schemes support *subliminal communication*. Informally, this means that there is a two-party protocol between Alice and Bob where the parties exchange ciphertexts of what appears to be a normal conversation even to someone who knows the secret keys and thus can read the corresponding plaintexts. And yet, at the end of the protocol, Alice will have transmitted her secret message to Bob. Our security definition requires that the adversary not be able to tell whether Alice and Bob are just having a normal conversation using the mandated encryption scheme, or they are using the mandated encryption scheme for subliminal communication.

Our topics may be thought to fall broadly within the realm of *steganography*. However, we deal with the non-standard setting of an adversarially chosen distribution of cover objects (i.e., a stronger-than-usual adversary), and we take advantage of the fact that our cover objects are ciphertexts of a semantically secure encryption scheme to bypass impossibility results which we show for broader classes of steganographic schemes. We give several constructions of subliminal communication schemes under the assumption that key exchange protocols with pseudorandom messages exist (such as Diffie-Hellman, which in fact has truly random messages).

### 1 Introduction

Suppose that we lived in a world where the government wished to read all the communications of its citizens, and thus decreed that citizens must not communicate in any way other than by using a specific, government-mandated encryption scheme with government-mandated keys. Even face-to-face communication is not allowed: in this Orwellian world, anyone who is caught speaking to another person will be arrested for treason. Similarly, anyone whose communications appear to be hiding information will be arrested: e.g., if the plaintexts encrypted using the government-mandated scheme are themselves ciphertexts of a different encryption scheme. However, the one assumption that we entertain in this paper, is that the government-mandated encryption scheme is, in fact, semantically secure: this is a tenable supposition with respect to a government that considers secure encryption to be in its interest, in order to prevent foreign powers from spying on its citizens' communications.

A natural question then arises: is there any way that the citizens would be able to communicate in a fashion undetectable to the government, based only on the semantic security of the government-mandated encryption scheme, and *despite the fact that the government knows the keys and has the ability to decrypt all ciphertexts*?<sup>4</sup> What can semantic security possibly guarantee in a setting where the adversary has the private keys?

This question may appear to fall broadly within the realm of *steganography*: the science of hiding secret communications within other innocent-looking communications (called “cover objects”), in an undetectable way. Indeed, it can be shown that if two parties have a shared secret, then based on slight variants of existing techniques for *secret-key steganography*, they can conduct communications hidden from the government.<sup>5</sup>

However, the question of whether two parties who have never met before can conduct hidden communications is more interesting. This is related to the questions of *public-key steganography* and *steganographic key exchange* which were both first formalized by von Ahn and Hopper [23]. Public-key steganography is inadequate in our setting since exchanging or publishing public keys is potentially conspicuous and thus is not an option in our setting. All prior constructions of steganographic key exchange require the initial sampling of a public random string that serves as a public parameter of the steganographic scheme. Intuitively, in these constructions, the public random string can be thought to serve the purpose of

---

<sup>4</sup> We note that one could, alternatively, consider an adversary with decryption capabilities arising from possession of some sort of “backdoor.” For the purposes of this paper, we opted for the simpler and still sufficiently expressive model where the adversary’s decryption power comes from knowledge of all the decryption keys.

<sup>5</sup> We refer the reader to Section 1.4 for more details.

selecting a specific steganographic scheme from a family of schemes *after* the adversary has chosen a strategy. That is, the schemes crucially assume that the adversary (the dystopian government, in our story above) cannot choose its covert distribution as a function of the public parameter.

It is conservative and realistic to expect a malicious adversary to choose the covert distribution *after* the honest parties have decided on their communication protocol (including the public parameters). After all, malice never sleeps [18]. Alas, we show that if the covert distribution is allowed to depend on the communication protocol, steganographic communication is impossible. In other words, for every purported steganographic communication protocol, there is a covert distribution (even one with high min-entropy) relative to which the communication protocol fails to embed subliminal messages. The relatively simple counterexample we construct is inspired by the impossibility of deterministic extraction.

**Semantic Security to the Rescue?** However, this impossibility result does not directly apply to our setting, as our covert distribution is restricted to be a sequence of ciphertexts (that may encrypt arbitrary messages). Moreover, the ciphertexts are semantically secure against entities that are not privy to the private keys. We define the notion of a *subliminal communication scheme* (Definition 7) as a steganographic communication scheme where security holds relative to covert distributions that are guaranteed to be ciphertexts of some semantically secure encryption scheme. Is there a way to use semantic security to enable subliminal communication?

Our first answer to this question is negative. In particular, consider the following natural construction: first, design an extractor function  $f$ ; then, to subliminally transmit a message bit  $b$ , sample encryptions  $c$  of a (even adversarially prescribed) plaintext  $m$  using independent randomness every time, until  $f(c) = b$ . There are two reasons this idea does not work. First, if the plaintext bit  $b$  is not random, the adversary can detect this by applying the extractor function  $f$  to the transmitted covert. Second, the government can pick an adversarial (semantically secure) encryption scheme where the extractor function  $f$  is constant on all ciphertexts; this is again similar to the impossibility of deterministic extraction.

Nevertheless, we show how to circumvent these difficulties and use the semantic security of the underlying (adversarial) encryption scheme to construct subliminal communication.

► **Theorem 1** (Informal version of Theorem 11). *Under the decisional Diffie-Hellman (DDH) assumption – or any other assumption that gives rise to a key exchange protocol with messages indistinguishable from random – there is a subliminal communication scheme which allows the transmission of  $O(\log \kappa)$  many bits per ciphertext after a setup phase of  $\tilde{O}(\log \kappa)$  ciphertexts ( $\kappa$  is the security parameter).*

We then show how to improve our first construction to reduce the length of the setup phase under additional assumptions.

## 1.1 Overview of Our Construction

The first idea in our construction is implicit in essentially all the works in steganography starting from [20]: namely, to achieve subliminal communication of arbitrary messages, it is sufficient to be able to undetectably communicate *uniformly randomly distributed strings of one's choice*. In other words, Alice samples a string  $r$  which is randomly distributed, produces some ciphertext(s) to be sent to Bob, such that Bob is able to learn  $r$  from them, and yet a PPT eavesdropper Eve who sees the entire communication transcript cannot distinguish between the following two cases:

1. Alice is indeed sending (hereafter, “embedding”) random strings to Bob, or
2. Alice is producing ciphertexts using the unmodified government-mandated encryption algorithm, without embedding such random strings.

To be more precise, the indistinguishability requirement holds for any given (adversarially specified) distribution  $\mathcal{M}$  of message sequences that Alice may choose to encrypt using the government-mandated encryption scheme. Notice that this does not preclude that Eve may be able to learn  $r$  and indeed, our constructions do allow an eavesdropper to learn the embedded strings. Given the ability to undetectably communicate randomly distributed strings, Alice and Bob can then embed to each other the messages of a key-exchange protocol with randomly distributed messages (such as Diffie-Hellman) to establish a shared secret, and then embed to each other ciphertexts of a secret-key encryption scheme with pseudorandom ciphertexts, using the established secret as the key.

All known constructions of such *undetectable random string embedding* rely on the sampling of a public random seed after the adversarial strategy is fixed. In this paper, however, we are interested in bootstrapping hidden communications from the very ground up: we are not willing to assume that the parties start from a state where a seed is already present.

We observe that the ability to embed randomly distributed strings *of one’s choice* – rather than, e.g., to apply a deterministic function to ciphertexts of the government-mandated encryption scheme, and thereby obtain randomly distributed strings which the creator of the ciphertexts did not choose – is crucial to the above-outlined scheme. The notion of undetectably embedding *exogenous* random strings – i.e., strings that are randomly distributed outside of Alice’s control, but both Alice and Bob can read them – is seemingly much weaker, and certainly cannot be used to embed key exchange messages or secret-key ciphertexts. However, we observe that this weaker primitive turns out to be achievable, for our specific setting, without the troublesome starting assumption of a public random seed. We identify a method for embedding *exogenous* random strings into ciphertexts of an adversarially chosen encryption scheme (interestingly, our method does not generalize to embedding into arbitrary min-entropy distributions). We then exploit this method to allow the communicating parties to establish a random seed – from which point they can proceed to embed random strings *of their choice*, as described above.

In building this weaker primitive, in order to bypass our earlier-described impossibility result, we extract from two ciphertexts at a time, instead of one. We begin with the following simple idea: for each consecutive pair of ciphertexts  $c$  and  $c'$ , a single hidden (random) bit  $b$  is defined by  $b = f(c, c')$  where  $f$  is some two-source extractor. It is initially unclear why this should work because (1)  $c$  and  $c'$  are encryptions of messages  $m$  and  $m'$  which are potentially dependent, and two-source extractors are not guaranteed to work without independence; and (2) even if this difficulty could be overcome, ciphertexts of semantically secure encryption scheme can have min-entropy as small as  $\omega(\log \kappa)$  (where  $\kappa$  is the security parameter) and no known two-source extractor known can extract from such a small min-entropy.

We overcome difficulty (1) by relying on the semantic security of the ciphertexts of the adversarially chosen encryption scheme. Paradoxically, even though the adversary knows the decryption key, we exploit the fact that semantic security still holds against the *extractor*, which does not have the decryption key. The inputs in our case are ciphertexts which are not necessarily independent, but semantic security implies that they are computationally indistinguishable from being independent. Thus, the output of  $f(c, c')$  is pseudorandom. Indeed, when  $f$  outputs a single bit (as in our construction), the output is also statistically close to random. The crucial point here is that the semantic security of the encryption scheme is used not against the government, but rather against the extraction function  $f$ .

Our next observation, to address difficulty (2), is that the ciphertexts are not only computationally independent, but they are also computationally indistinguishable from i.i.d. In particular, each pair of ciphertexts is indistinguishable from a pair of encryptions of 0, by semantic security. Based on this observation, we can use a very simple “extractor”, namely, the greater-than function GT. In fact, GT is an extractor with two input sources, whose output bit has negligible bias when the sources have  $\omega(\log \kappa)$  min-entropy and are *independently and identically distributed* (this appears to be a folklore observation; see, e.g., [3]). Because of the last condition, GT is not a true two-source extractor according to standard definitions, but is still suitable for our setting.

By repeatedly extracting random bits from pairs of consecutive ciphertexts using GT, Alice and Bob can construct a shared random string  $s$ . Note that in this process, Alice and Bob generate ciphertexts using the unmodified government-mandated encryption scheme, so the indistinguishability requirement clearly holds. We stress again that  $s$  is also known to a passive eavesdropper of the communication. This part of our construction, up to the construction of the string  $s$ , is presented in details in Section 5.1. From there, constructing a subliminal communication scheme is not hard: Alice and Bob use  $s$  as the seed of a strong seeded extractor to subliminally communicate random strings *of their choice* as explained in Section 5.2. The complete description of our protocol is given in Section 5.3.

## 1.2 Improved Constructions for Specific Cases

While our first construction has the advantage of simplicity, the initial phase to agree on shared random string (using the GT function) transmits only one hidden bit per ciphertext of the government-mandated encryption scheme. A natural question is whether this rate of transmission can be improved. We show that if the government-mandated encryption scheme is *succinct* in the sense that the ciphertext expansion factor is at most 2, then it is possible to improve the rate of transmission in this phase to  $O(\log \kappa)$  hidden bits per ciphertext using an alternative construction based on the extractor from [12]. In other words, our first result showed that if the government-mandated encryption scheme is semantically secure, we can use it to communicate subliminally; the second result shows that if the government-mandated encryption scheme is efficient, that is even better for us, in the sense that it can be used for more efficient subliminal communication.

► **Theorem 2 (Informal).** *If there is a secure key exchange protocol whose message distribution is pseudorandom, then there is a subliminal communication scheme in which a shared seed is established in two exchanges of ciphertexts of a succinct encryption scheme.*

Theorem 1 exploited the specific nature of the cover object distribution in our setting (specifically, that a sequence of encryptions of arbitrary messages is indistinguishable from an i.i.d. sequence of encryptions of zero). Theorem 2 exploits an additional consequence of the semantic security of the government-mandated encryption scheme: if it is succinct, then ciphertexts are computationally indistinguishable from sources of high min-entropy (i.e., they have large HILL-entropy).

It may be possible to use more advanced two-source extractors to work with a larger class of encryption schemes (with larger expansion factors); however, the best known such extractors have an inverse polynomial error rate [8] (whereas our construction’s extractor has negligible error). Consequently, designing a subliminal communication protocol using these extractors seems to require additional ideas, and we leave this as an open problem.

Finally, we show yet another approach in cases where the distribution of “innocent” messages to be encrypted under the government-mandated encryption scheme has a certain amount of conditional min-entropy. For such cases, we construct an alternative scheme

that leverages the semantic security of the encryption scheme in a rather different way: namely, the key fact for this alternative construction is that (in the absence of a decryption key) a ciphertext appears independent of the message it encrypts. In this case, running a two-source extractor on the message and the ciphertext works. The resulting improvement in the efficiency of the scheme is comparable to that of Theorem 2.

► **Theorem 3 (Informal).** *If there is a secure key-exchange protocol whose message distribution is pseudorandom, then there is a subliminal communication scheme for any cover distribution that either*

- *consists of ciphertexts of a semantically secure encryption scheme, if the innocent message distribution  $\mathcal{M}$  has conditional min-entropy rate  $1/2$ , or*
- *consists of ciphertexts of a semantically secure and succinct encryption scheme, if the innocent message distribution  $\mathcal{M}$  has conditional min-entropy  $\omega(\log \kappa)$ .*

*In both cases, the shared seed is established during the setup phase in only two exchanges of ciphertexts.*

Due to space constraints, the results described in this subsection (1.2) are not discussed further herein. They are presented in detail in the full version of this paper [17].

### 1.3 Final Introductory Remarks

**On Our Modeling Assumptions.** Our model considers a relatively powerful adversary that, for example, has the ability to choose the encryption scheme using which all parties must communicate, and to decrypt all such communications. We believe that this can be very realistic in certain scenarios, but it is also important to note the limitations that our model places on the adversary.

The most obvious limitation is that the encryption scheme chosen by the adversary must be semantically secure (against third parties that do not have the ability to decrypt). Another assumption is that citizens are able to run algorithms of their choice on their own computers without, for instance, having every computational step monitored by the government. Moreover, citizens may use encryption randomness of their choice when producing ciphertexts of the government-mandated encryption scheme: in fact, this is a key fact that our construction exploits. Interestingly, secrecy of the encryption randomness from the adversary is irrelevant: after all, the adversary can always choose an encryption scheme where the encryption randomness is recoverable given the decryption key. Despite this, the ability of the encryptor to choose the randomness to input to the encryption algorithm can be exploited – as by our construction – to allow for subliminal communication.

**The Meaning of Semantic Security when the Adversary Can Decrypt.** In an alternate light, our work may be viewed as asking the question: *what guarantee, if any, does semantic security provide against adversary in possession of the decryption key?* Our results find, perhaps surprisingly, that some meaningful guarantee is still provided by semantic security even against an adversary is able to decrypt: more specifically, that *any* communication channel allowing transmission of ciphertexts can be leveraged to allow for undetectable communications between two parties that have never met. From this perspective, our work may be viewed as the latest in a scattered series of recent works that consider what guarantees can be provided by cryptographic primitives that are somehow “compromised” – examples of recent works in this general flavor are cited in Section 1.4 below.

**Concrete Security Parameters.** From a more practical perspective, it may be relevant to consider that the government in our hypothetical Orwellian scenario would be incentivized to opt for an encryption scheme with the least possible security level so as to ensure security against foreign powers. In cases where the government considers itself to have more computational power than foreign adversaries (perhaps by a constant factor), this could create an interesting situation where the security parameter with which the government-mandated scheme must be instantiated is *below* what is necessary to ensure security against the government’s own computational power.

Such a situation could be risky for citizens’ hidden communications: intuitively, our constructions guarantee indistinguishability *against the citizens’ own government* between an “innocent” encrypted conversation and one which is carrying hidden subliminal messages. However, the distinguishing advantage in this indistinguishability game *depends on the security parameter* of the government-mandated encryption scheme. Thus, it could be that the two distributions are far enough apart for the citizens’ own government to distinguish (though not for foreign governments to distinguish). We observe that citizens cognizant of this situation can further reduce the distinguishing advantage beyond that provided by our basic construction, using the standard technique of amplifying the proximity of a distribution (which is far from random) to uniformly random, by taking the XOR of several samples from the far-from-random distribution.

Having outlined this potential concern and solution, the rest of the paper will disregard these issues in the interest of clarity of exposition, and present a purely asymptotic analysis.

**Open Problems.** Our work suggests a number of open problems. A natural one is the extent to which the modeling assumptions that this work makes – such as the ability of honest encryptors to use true randomness for encryption – can be relaxed or removed, while preserving the ability to communicate subliminally. For example, one could imagine yet another alternate universe, in which the hypothetical Orwellian government not only mandates that citizens use the prescribed encryption scheme, but also that their encryption randomness must be derived from a specific government-mandated pseudorandom generator.

The other open problems raised by our work are of a more technical nature and better understood in the context of the specific details of our constructions; for this reason we defer their discussion to Section 6.

## 1.4 Other Related Work

The scientific study of steganography was initiated by Simmons more than thirty years ago [20], and is the earliest mention of the term “subliminal channel” referring to the conveyance of information in a cryptosystem’s output in a way that is different from the intended output,<sup>6</sup> of which we are aware. Subsequent works such as [7, 19, 27] initially explored information-theoretic treatments of steganography, and then Hopper, Langford, and von Ahn [16] gave the first complexity-theoretic (secret-key) treatment almost two decades later. Public-key variants of steganographic notions – namely, public-key steganography and steganographic key exchange – were first defined by [23]. There is very little subsequent literature on public-key steganographic primitives; one notable example is by Backes and Cachin [2], which considers public-key steganography against active attacks (their attack model, which is stronger than that of [23], was also considered in [16] but had never been applied to the public-key setting).

---

<sup>6</sup> This phrasing is loosely borrowed from [26].

The alternative perspective of our work as addressing the question of whether any sort of secret communication can be achieved via transmission of ciphertexts of an adversarially designed cryptosystem alone fits into a scattered series of recent works that consider what guarantees can or cannot be provided by compromised cryptographic primitives. For example, Goldreich [14], and later, Cohen and Klein [10], consider what unpredictability guarantee is achieved by the classic GGM construction [15] when the traditionally secret seed is known; Austrin et al. [1] study whether certain cryptographic primitives can be secure even in the presence of an adversary that has limited ability to tamper with honest parties' randomness; Dodis et al. [13] consider what cryptographic primitives can be built based on backdoored pseudorandom generators; and Bellare, Jaeger, and Kane [4] present attacks that work against any symmetric-key encryption scheme, that completely compromise security by undetectably corrupting the algorithms of the encryption scheme (such attacks might, for example, be feasible if an adversary could generate a bad version of a widely used cryptographic library and install it on his target's computer).

The last work mentioned above, [4], is actually part of the broader field of kleptography, originally introduced by Young and Yung [26, 25, 24]. Broadly speaking, a *kleptographic attack* “uses cryptography against cryptography” [26] – i.e., changes the behavior of a cryptographic system in a fashion undetectable to an honest user with black-box access to the cryptosystem, such that the use of the modified system leaks some secret information (e.g., plaintexts or key material) to the attacker who performed the modification. An example of such an attack might be to modify the key generation algorithm of an encryption scheme such that an adversary in possession of a “back door” can derive the private key from the public key, yet an honest user finds the generated key pairs to be indistinguishable from correctly produced ones. Kleptography has enjoyed renewed research activity since [5] introduced a formal model of a specific type of kleptographic attack called *algorithm substitution attacks* (ASAs), motivated by recent revelations suggesting that intelligence agencies have successfully implemented attacks of this nature at scale. Recently, [6] formalized an equivalence between certain variants of ASA and steganography.

Our setting differs significantly from kleptography in that the encryption algorithms are public and not tampered with (i.e., adhere to a purported specification), and in fact may be *known* to be designed by an adversarial party.

## 2 Preliminaries

Proofs of all propositions, lemmata, and theorems are in the full version of this paper [17] due to space constraints.

**Notation.**  $\kappa$  is the security parameter throughout. PPT means “probabilistic polynomial time.”  $[n]$  denotes the set  $\{1, \dots, n\}$ .  $U_n$  is a uniform variable over  $\{0, 1\}^n$ , independent of every other variable in this paper. We write  $X \sim Y$  to express that  $X$  and  $Y$  are identically distributed. Given two variables  $X$  and  $Y$  over  $\{0, 1\}^k$ , we denote by  $\|X - Y\|_s$  the statistical distance defined by:

$$\|X - Y\|_s = \frac{1}{2} \sum_{x \in \{0, 1\}^k} |\Pr[X = x] - \Pr[Y = x]| .$$

For a random variable  $X$ , we define the min-entropy of  $X$  by  $H_\infty(X) = -\log \max_x \Pr[X = x]$ . The collision probability is  $\text{CP}(X) = \sum_x \Pr[X = x]^2$ .

## 2.1 Encryption and Key Exchange

We assume familiarity with the standard notions of semantically secure public-key and private-key encryption, and key exchange. This subsection defines notation and terminology.

**Public-Key Encryption.** We use the notation  $E = (E.Gen, E.Enc, E.Dec)$  for the public-key encryption scheme mandated by the adversary.

**Secret-key Encryption.** We write  $SKE = (SKE.Gen, SKE.Enc, SKE.Dec)$  to denote a secret-key encryption scheme. We define a *pseudorandom secret-key encryption scheme* to be a secret-key encryption scheme whose ciphertexts are indistinguishable from random. It is a standard result that pseudorandom secret-key encryption schemes can be built from one-way functions.

**Key Exchange.** A *key-exchange protocol*  $\Lambda$  is a two-party protocol executed between two parties  $P_0$  and  $P_1$ , where each party outputs a key at the end of the protocol. The *correctness* guarantee for key-exchange Protocols requires that the two outputted keys be equal with overwhelming probability. The security guarantee for key-exchange protocols requires that  $(T, K) \stackrel{c}{\approx} (T, K_{\S})$ , where  $T$  is a key-exchange protocol transcript,  $K$  is the shared key established in  $T$ , and  $K_{\S}$  is a random unrelated key.

We define a *pseudorandom key-exchange protocol* to be a key-exchange protocol whose transcripts are distributed indistinguishably from random. That is, a pseudorandom key-exchange protocol has the stronger guarantee that  $(T, K) \stackrel{c}{\approx} (U, K_{\S})$  where  $U$  is the uniform distribution over message sequences of the appropriate length, where messages are drawn randomly from the message space of  $\Lambda$ .

The classical protocol of Diffie and Hellman [11] is pseudorandom; in fact, its messages are uniformly random over a cyclic group  $G$ . However, the constructions in this paper assume a key-exchange protocol whose messages are pseudorandom *over bit strings*. In fact, it is possible to transform a key-exchange protocol whose messages are pseudorandom over an arbitrary domain  $G \subseteq \{0, 1\}^{\ell}$  into a key-exchange protocol whose messages are pseudorandom over bit strings. Proposition 4, below, gives an encoding and decoding algorithm to transform uniformly random messages in  $G$  into a sequence of uniformly random messages in  $\{0, 1\}^{\ell}$ . The encoding and decoding algorithms run in polynomial time as long as the density of messages  $\frac{|G|}{2^{\ell}}$  is noticeable (i.e., at least  $\frac{1}{\kappa^c}$  for some  $c \geq 1$ ). This is the case, for example, when the Diffie-Hellman protocol is instantiated with the group of quadratic residues modulo a safe prime (in which case the density of message is constant close to  $\frac{1}{2}$ ).

► **Proposition 4.** *Let  $G$  be a subset of  $\{0, 1\}^{\ell}$  and define  $p = \frac{\kappa 2^{\ell}}{|G|}$ . There is an encoding algorithm  $E : G \rightarrow (\{0, 1\}^{\ell})^p$  and a decoding algorithm  $D : (\{0, 1\}^{\ell})^p \rightarrow G \cup \{\perp\}$  that satisfy the following properties:*

1. Correctness: *for all  $g \in G$ ,  $\Pr [D(E(g)) \neq g]$  is negligible in  $\kappa$ .*
  2. Randomness: *for uniformly random  $g \leftarrow G$ ,  $E(g)$  is uniformly random over  $(\{0, 1\}^{\ell})^p$ .*
- Explicit descriptions of algorithms  $E, D$  are given in the full version of this paper.*

## 2.2 Extractors

Next, we give standard definitions of two-source and seeded extractors.

► **Definition 5.** The family  $2\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{n'} \rightarrow \{0, 1\}^{\ell}$  is a  $(k_1, k_2, \varepsilon)$  *two-source extractor* if for all  $\kappa \in \mathbb{N}$  and for all pairs  $(X, Y)$  of independent random variables over  $\{0, 1\}^{n(\kappa)} \times \{0, 1\}^{n'(\kappa)}$  such that  $H_{\infty}(X) \geq k_1(\kappa)$  and  $H_{\infty}(Y) \geq k_2(\kappa)$ , it holds that

$\|2\text{Ext}_\kappa(X, Y) - U_{\ell(\kappa)}\|_{\mathfrak{s}} \leq \varepsilon(\kappa)$ . We say that  $2\text{Ext}$  is *strong w.r.t. the first input* if it satisfies the stronger property that  $\|(X, 2\text{Ext}_\kappa(X, Y)) - (X, U_{\ell(\kappa)})\|_{\mathfrak{s}} \leq \varepsilon(\kappa)$ . A strong two-source extractor w.r.t. the second input is defined analogously. Finally, we say that  $2\text{Ext}$  is a  $(k, \varepsilon)$  *same-source* extractor if  $n = n'$  and the extractor output is only required to be statistically close to uniform when  $(X, Y)$  is a pair of i.i.d. random variables with  $H_\infty(X) = H_\infty(Y) \geq k(\kappa)$ .

► **Definition 6.** The family  $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^{n'} \rightarrow \{0, 1\}^\ell$  is a  $(k, \varepsilon)$  *seeded extractor* if for all  $\kappa \in \mathbb{N}$  and any random variable  $X$  over  $\{0, 1\}^{n'(\kappa)}$  such that  $H_\infty(X) \geq k(\kappa)$ , it holds that  $\|\text{Ext}_\kappa(U_{n(\kappa)}, X) - U_{\ell(\kappa)}\|_{\mathfrak{s}} \leq \varepsilon(\kappa)$ . We say moreover that  $\text{Ext}$  is *strong* if it satisfies the stronger property that  $\|(U_{n(\kappa)}, \text{Ext}_\kappa(U_{n(\kappa)}, X)) - (U_{n(\kappa)}, U_{\ell(\kappa)})\|_{\mathfrak{s}} \leq \varepsilon(\kappa)$ .

### 3 Subliminal Communication

**Conversation Model.** The protocols we will construct take place over a communication between two parties  $P_0$  and  $P_1$  alternately sending each other ciphertexts of a public-key encryption scheme. *W.l.o.g.*, we assume that  $P_0$  initiates the communication, and that communication occurs over a sequence of *exchange-rounds* each of which comprises two sequential messages: in each exchange-round, one party  $P_b$  sends a message to  $P_{1-b}$  and then  $P_{1-b}$  sends a message to  $P_b$ . Let  $m_{b,i}$  denote the plaintext message sent by  $P_b$  to  $P_{1-b}$  in exchange-round  $i$ , and let  $\mathbf{m}_i = (m_{0,i}, m_{1,i})$  denote the pair of messages exchanged. For  $i \geq 1$ , let us denote by  $\tau_{0,i} = (\mathbf{m}_1, \dots, \mathbf{m}_{i-1})$  and  $\tau_{1,i} = (\mathbf{m}_1, \dots, \mathbf{m}_{i-1}, m_{0,i})$  the plaintext transcripts available to  $P_0$  and  $P_1$  respectively during exchange-round  $i$ , in the case when  $P_0$  sends the first message in exchange-round  $i$ .<sup>7</sup> We define  $\tau_{0,0}$  and  $\tau_{1,0}$  to be empty lists (i.e., empty starting transcripts). (Note that when a notation contains both types of subscripts, we write the subscripts denoting the party and round in **blue** and **red** respectively, to improve readability.)

Recall that our adversary has the power to decrypt all ciphertexts under its chosen public-key encryption scheme  $\mathbb{E}$ . Intuitively, it is therefore important that the plaintext conversation between  $P_0$  and  $P_1$  appears innocuous (and does not, for example, consist of ciphertexts of another encryption scheme). To model this, we assume the existence of a next-message distribution  $\mathcal{M}$ , which outputs a next innocuous message given the transcript of the plaintext conversation so far. This is denoted by  $m_{b,i} \leftarrow \mathcal{M}(\tau_{b,i})$ .

In all the protocols we consider, the symbol  $\mathfrak{s}$  is used to denote internal state kept locally by  $P_0$  and  $P_1$ . It is implicitly assumed that each party's state contains an up-to-date transcript of all messages received during the protocol. Parties may additionally keep other information in their internal state, as a function of the local computations they perform. For  $i \geq 1$ ,  $\mathfrak{s}_{b,i}$  denotes the state of  $P_b$  at the conclusion of exchange-round  $i$ . Initial states  $\mathfrak{s}_{b,0} = \emptyset$  are empty.

We begin with a simpler definition that only syntactically allows for the transmission of a single message (Definition 7). This both serves as a warm-up to the multi-message definition presented next (Definition 8), and will be used in its own right to prove impossibility results.

► **Definition 7.** A *subliminal communication scheme* is a two-party protocol:

$$\Pi^{\mathbb{E}} = (\Pi_{0,1}^{\mathbb{E}}, \Pi_{1,1}^{\mathbb{E}}, \Pi_{0,2}^{\mathbb{E}}, \Pi_{1,2}^{\mathbb{E}}, \dots, \Pi_{0,r}^{\mathbb{E}}, \Pi_{1,r}^{\mathbb{E}}; \Pi_{1,\text{out}}^{\mathbb{E}})$$

<sup>7</sup> If instead  $P_1$  spoke first in round  $i$ , then  $\tau_{0,i}$  would contain  $m_{1,i}$ , and  $\tau_{1,i}$  would not contain  $m_{0,i}$ .

where  $r \in \text{poly}$  is the number of exchange-rounds and each  $\Pi_{b,i}^E$  is a PPT algorithm with oracle access to the algorithms of a public-key encryption scheme  $E$ . Party  $P_0$  is assumed to receive as input a message  $\text{msg}$  (of at least one bit) that is to be conveyed to  $P_1$  in an undetectable fashion. The algorithms  $\Pi_{b,i}^E$  are used by  $P_b$  in round  $i$ , respectively, and  $\Pi_{1,\text{out}}^E$  denotes the algorithm run by  $P_1$  to produce an output  $\text{msg}'$  at the end of the protocol.

A subliminal communication scheme must satisfy the following syntax, correctness and security guarantees.

- **Syntax.** In each exchange-round  $i = 1, \dots, r$ :
  1.  $P_0$  performs the following steps:
    - a. Sample “innocuous message”  $m_{0,i} \leftarrow \mathcal{M}(\tau_{0,i-1})$ .
    - b. Generate ciphertext and state  $(c_{0,i}, \mathfrak{s}_{0,i}) \leftarrow \Pi_{0,i}^E(\text{msg}, m_{0,i}, \text{pk}_1, \mathfrak{s}_{0,i-1})$ .
    - c. Locally store  $\mathfrak{s}_{0,i}$  and send  $c_{0,i}$  to  $P_1$ .
  2. Then,  $P_1$  performs the following steps:<sup>8</sup>
    - a. Sample “innocuous message”  $m_{1,i} \leftarrow \mathcal{M}(\tau_{1,i-1})$ .
    - b. Generate ciphertext and state  $(c_{1,i}, \mathfrak{s}_{1,i}) \leftarrow \Pi_{1,i}^E(m_{1,i}, \text{pk}_0, \mathfrak{s}_{1,i-1})$ .
    - c. Locally store  $\mathfrak{s}_{1,i}$  and send  $c_{1,i}$  to  $P_0$ .

After  $r$  rounds,  $P_1$  computes  $\text{msg}' = \Pi_{1,\text{out}}^E(\text{sk}_1, \mathfrak{s}_{1,r})$  and halts.
- **Correctness.** For any  $\text{msg} \in \{0, 1\}^\kappa$ , if  $P_0$  and  $P_1$  play  $\Pi^E$  honestly, then  $\text{msg}' = \text{msg}$  with probability  $1 - \text{negl}(\kappa)$ . The probability is taken over the key generation  $(\text{pk}_0, \text{sk}_0), (\text{pk}_1, \text{sk}_1) \leftarrow E.\text{Gen}$  and the randomness of the protocol algorithms, as well as the message distribution  $\mathcal{M}$ .
- **Subliminal Indistinguishability.** For any semantically secure public-key encryption scheme  $E$ , any  $\text{msg} \in \{0, 1\}^\kappa$  and any next-message distribution  $\mathcal{M}$ , for  $(\text{pk}_i, \text{sk}_i) \leftarrow E.\text{Gen}$ ,  $i \in \{0, 1\}$ , the following distributions are computationally indistinguishable:

<u>Ideal</u> ( $\text{pk}_0, \text{sk}_0, \text{pk}_1, \text{sk}_1, \mathcal{M}$ ):	<u>Subliminal<math>_{\Pi}</math></u> ( $\text{msg}, \text{pk}_0, \text{sk}_0, \text{pk}_1, \text{sk}_1, \mathcal{M}$ ):
for $i = 1, \dots, r$ :	for $i = 1, \dots, r$ :
$m_{0,i} \leftarrow \mathcal{M}(\tau_{0,i})$	$m_{0,i} \leftarrow \mathcal{M}(\tau_{0,i})$
$m_{1,i} \leftarrow \mathcal{M}(\tau_{1,i})$	$m_{1,i} \leftarrow \mathcal{M}(\tau_{1,i})$
$c_{0,i} \leftarrow E.\text{Enc}(\text{pk}_1, m_{0,i})$	$(c_{0,i}, \mathfrak{s}_{0,i}) \leftarrow \Pi_{0,i}^E(\text{msg}, m_{0,i}, \text{pk}_1, \mathfrak{s}_{0,i-1})$
$c_{1,i} \leftarrow E.\text{Enc}(\text{pk}_0, m_{1,i})$	$(c_{1,i}, \mathfrak{s}_{1,i}) \leftarrow \Pi_{1,i}^E(m_{1,i}, \text{pk}_0, \mathfrak{s}_{1,i-1})$
output $(\text{pk}_0, \text{sk}_0, \text{pk}_1, \text{sk}_1; (c_{b,i})_{b \in \{0,1\}, i \in [r]})$	output $(\text{pk}_0, \text{sk}_0, \text{pk}_1, \text{sk}_1; (c_{b,i})_{b \in \{0,1\}, i \in [r]})$

If the *subliminal indistinguishability* requirement is satisfied only for next-message distributions  $\mathcal{M}$  in a restricted set  $\mathbb{M}$ , rather than for any  $\mathcal{M}$ , then  $\Pi$  is said to be a *subliminal communication scheme for  $\mathbb{M}$* .

For simplicity, Definition 7 presents a communication scheme in which only a single hidden message  $\text{msg}$  is transmitted. More generally, it is desirable to transmit multiple messages, and bidirectionally, and perhaps in an adaptive manner.<sup>9</sup> In multi-message schemes, it may be beneficial for efficiency that the protocol have a two-phase structure where some initial

<sup>8</sup> Note that the steps executed by  $P_0$  and  $P_1$  are entirely symmetric except in the following two aspects: first,  $P_0$ 's input  $\text{msg}$  is present in step 1b but not in step 2b; and secondly, the state  $\mathfrak{s}_{1,i-1}$  used in step 2b contains the round- $i$  message  $c_{0,i}$ , whereas the state  $\mathfrak{s}_{0,i-1}$  used in step 1b depends only on the transcript until round  $i - 1$ .

<sup>9</sup> That is, the messages to be transmitted may become known as the protocol progresses, rather than all being known at the outset. This is the case, for example, if future messages depend on responses to previous ones.

preprocessing is done in the first phase, and then the second phase can thereafter be invoked many times to transmit different hidden messages.<sup>10</sup> This is a useful notion later in the paper, for our constructions, so we give the definition of a multi-message scheme here.

► **Definition 8.** A *multi-message subliminal communication scheme* is a two-party protocol defined by a pair  $(\Phi, \Xi)$  where  $\Phi$  (“Setup Phase”) and  $\Xi$  (“Communication Phase”) each define a two-party protocol. Each party outputs a state at the end of  $\Phi$ , which it uses as an input in each subsequent invocation of  $\Xi$ . An execution of a multi-message subliminal communication scheme consists of an execution of  $\Phi$  followed by one or more executions of  $\Xi$ . More formally:

$$\begin{aligned}\Phi^E &= (\Phi_{0,1}^E, \Phi_{1,1}^E, \Phi_{0,2}^E, \Phi_{1,2}^E, \dots, \Phi_{0,r}^E, \Phi_{1,r}^E) \\ \Xi^E &= (\Xi_{0,1}^E, \Xi_{1,1}^E, \Xi_{0,2}^E, \Xi_{1,2}^E, \dots, \Xi_{0,r'}^E, \Xi_{1,r'}^E, \Xi_{1,\text{out}}^E)\end{aligned}$$

where  $r, r' \in \text{poly}$  are the number of exchange-rounds in  $\Phi$  and  $\Xi$  respectively. and where each  $\Phi_{b,i}^E, \Xi_{b,i}^E$  is a PPT algorithm with oracle access to the algorithms of a public-key encryption scheme  $E$ . The protocol must satisfy the following syntax, correctness and security guarantees.

■ **Syntax.** In each exchange-round  $i = 1, \dots, r$  of  $\Phi$ :  $P_0$  executes the following steps for  $b = 0$ , and then  $P_1$  executes the same steps for  $b = 1$ .

1. Sample “innocuous message”  $m_{b,i} \leftarrow \mathcal{M}(\tau_{b,i-1})$ .
2. Generate ciphertext and state  $(c_{b,i}, \mathfrak{s}_{b,i}) \leftarrow \Phi_{b,i}^E(m_{b,i}, \text{pk}_{1-b}, \mathfrak{s}_{b,i-1})$ .
3. Locally store  $\mathfrak{s}_{b,i}$  and send  $c_{b,i}$  to  $P_{1-b}$ .

After the completion of  $\Phi$ , either party may initiate  $\Xi$  by sending a first message of the  $\Xi$  protocol (with respect to a message  $\text{msg}$  to be steganographically hidden, known to the initiating party). Let  $P_S$  and  $P_R$  denote the initiating and non-initiating parties in an execution of  $\Xi$ , respectively.<sup>11</sup> Let  $\text{msg} \in \{0, 1\}^\kappa$  be the hidden message that  $P_S$  is to transmit to  $P_R$  in an undetectable fashion during an execution of  $\Xi$ .

The execution of  $\Xi$  proceeds as follows over exchange-rounds  $i' = 1, \dots, r'$ :

- $P_S$  acts as follows:
  1. Sample  $m_{S,r+i'} \leftarrow \mathcal{M}(\tau_{S,r+i'-1})$ .
  2. Generate  $(c_{S,r+i'}, \mathfrak{s}_{S,r+i'}) \leftarrow \Xi_{0,i'}^E(\text{msg}, m_{S,r+i'}, \text{pk}_R, \mathfrak{s}_{S,r+i'-1})$ .
  3. Locally store  $\mathfrak{s}_{S,r+i'}$  and send  $c_{S,r+i'}$  to  $P_R$ .
- $P_R$  acts as follows:
  1. Sample  $m_{R,r+i'} \leftarrow \mathcal{M}(\tau'_{R,r+i'-1})$ .
  2. Generate  $(c_{R,r+i'}, \mathfrak{s}_{R,r+i'}) \leftarrow \Xi_{1,i'}^E(m_{R,r+i'}, \text{pk}_S, \mathfrak{s}_{R,r+i'-1})$ .
  3. Locally store  $\mathfrak{s}_{R,r+i'}$  and send  $c_{R,r+i'}$  to  $P_S$ .

At the end of an execution of  $\Xi$ ,  $P_R$  computes  $\text{msg}' = \Xi_{1,\text{out}}^E(\text{sk}_1, \mathfrak{s}_{1,r+r'})$ .

■ **Correctness.** For any  $\text{msg} \in \{0, 1\}^\kappa$ , if  $P_0$  and  $P_1$  execute  $(\Phi, \Xi)$  honestly, then for every execution of  $\Xi$ , the transmitted and received messages  $\text{msg}$  and  $\text{msg}'$  are equal with overwhelming probability. The probability is taken over the key generation  $(\text{pk}_0, \text{sk}_0), (\text{pk}_1, \text{sk}_1) \leftarrow E.\text{Gen}$  and the randomness of the protocol algorithms, as well as the message distribution  $\mathcal{M}$ .

<sup>10</sup> As a concrete example: consider a protocol for transmitting multiple encrypted messages with a one-time “phase 1” consisting of key exchange, and a “phase 2” encompassing the ciphertext transmission which can be invoked many times.

<sup>11</sup> Subscripts  $S, R \in \{0, 1\}$  stand for “sender” and “receiver,” respectively.

- Subliminal Indistinguishability.** For any semantically secure public-key encryption scheme  $E$ , any polynomial  $p = p(\kappa)$ , any sequence of hidden messages  $\vec{msg} = (msg_i)_{i \in [p]} \in (\{0, 1\}^\kappa)^p$ , any sequence of bits  $\vec{b} = (b_1, \dots, b_p) \in \{0, 1\}^p$  and any next-message distribution  $\mathcal{M}$ , for  $(pk_b, sk_b) \leftarrow E.Gen$ ,  $b \in \{0, 1\}$  the following distributions are computationally indistinguishable:

<p><b>Ideal</b><math>(pk_0, sk_0, pk_1, sk_1, \mathcal{M})</math>:</p> <p>for <math>i = 1, \dots, r + pr'</math>:</p> <p style="padding-left: 20px;"><math>m_{0,i} \leftarrow \mathcal{M}(\tau_{0,i})</math></p> <p style="padding-left: 20px;"><math>m_{1,i} \leftarrow \mathcal{M}(\tau_{1,i})</math></p> <p style="padding-left: 20px;"><math>c_{0,i} \leftarrow E.Enc(pk_1, m_{0,i})</math></p> <p style="padding-left: 20px;"><math>c_{1,i} \leftarrow E.Enc(pk_0, m_{1,i})</math></p> <p>output:</p> <p style="padding-left: 20px;"><math>(pk_0, sk_0, pk_1, sk_1; (c_{b,i})_{b \in \{0,1\}, i \in [r+pr']})</math></p>	<p><b>Subliminal</b><math>_{\Phi, \Xi}(\vec{msg}, \vec{b}, pk_0, sk_0, pk_1, sk_1, \mathcal{M})</math>:</p> <p>for <math>i = 1, \dots, r</math>:</p> <p style="padding-left: 20px;"><math>m_{0,i} \leftarrow \mathcal{M}(\tau_{0,i})</math></p> <p style="padding-left: 20px;"><math>m_{1,i} \leftarrow \mathcal{M}(\tau_{1,i})</math></p> <p style="padding-left: 20px;"><math>(c_{0,i}, s_{0,i}) \leftarrow \Phi_{0,i}^E(msg, m_{0,i}, pk_1, s_{0,i-1})</math></p> <p style="padding-left: 20px;"><math>(c_{1,i}, s_{1,i}) \leftarrow \Phi_{1,i}^E(m_{1,i}, pk_0, s_{1,i-1})</math></p> <p>for <math>j = 1, \dots, p</math>:</p> <p style="padding-left: 20px;">let <math>\beta = b_j</math> and <math>\bar{\beta} = 1 - b_j</math></p> <p style="padding-left: 20px;">for <math>i' = 1, \dots, r'</math>:</p> <p style="padding-left: 40px;">let <math>\iota = r + (j - 1)r' + i'</math></p> <p style="padding-left: 40px;"><math>m_{\beta,\iota} \leftarrow \mathcal{M}(\tau_{\beta,\iota})</math></p> <p style="padding-left: 40px;"><math>m_{\bar{\beta},\iota} \leftarrow \mathcal{M}(\tau_{\bar{\beta},\iota})</math></p> <p style="padding-left: 40px;"><math>(c_{\beta,\iota}, s_{\beta,\iota}) \leftarrow \Xi_{\beta,i'}^E(msg, m_{\beta,\iota}, pk_{\bar{\beta}}, s_{\beta,\iota-1})</math></p> <p style="padding-left: 40px;"><math>(c_{\bar{\beta},\iota}, s_{\bar{\beta},\iota}) \leftarrow \Xi_{\bar{\beta},i'}^E(m_{\bar{\beta},\iota}, pk_{\beta}, s_{\bar{\beta},\iota-1})</math></p> <p>output:</p> <p style="padding-left: 20px;"><math>(pk_0, sk_0, pk_1, sk_1; (c_{b,i})_{b \in \{0,1\}, i \in [r+pr']})</math></p>
---	--

If the *subliminal indistinguishability* requirement is satisfied only for  $M$  in a restricted set  $\mathbb{M}$ , rather than for any  $\mathcal{M}$ , then  $(\Phi, \Xi)$  is said to be a *multi-message subliminal communication scheme* for  $\mathbb{M}$ .

## 4 Impossibility Results

### 4.1 Locally Decodable Subliminal Communication Schemes

A first attempt at achieving subliminal communication might consider schemes with the following natural property: the receiving party  $P_1$  extracts hidden bits *one ciphertext at a time*, by the application of a single decoding function. We refer to such schemes as *locally decodable* and our next impossibility theorem shows that non-trivial locally decodable schemes do not exist if the encryption scheme  $E$  is chosen adversarially.

► **Theorem 9.** *For any locally decodable protocol  $\Pi$  satisfying the syntax of a single-message subliminal communication scheme (Definition 7), there exists a semantically secure public-key encryption scheme  $E$  such that  $E$  violates the correctness condition of Definition 7. Therefore, no locally decodable protocol  $\Pi$  is a subliminal communication scheme.*

► **Remark.** The essence of the above theorem is the impossibility of deterministic extraction: no single deterministic function can deterministically extract from ciphertexts of arbitrary encryption schemes. The way to bypass this impossibility is to have the extractor depend on the encryption scheme. Note that multiple-source extraction, which is used in our constructions in the subsequent sections, implicitly do depend on the underlying encryption scheme, since the additional sources of input depend on the encryption scheme and thus can be thought of as “auxiliary input” that is specific to the encryption scheme at hand.

## 4.2 Steganography for Adversarial Cover Distributions

Our second impossibility result concerns a much more general class of communication schemes, which we call *steganographic communication schemes*. Subliminal communication schemes, as well as the existing notions of public-key steganography and steganographic key exchange from the steganography literature, are instantiations of the more general definition of a (multi-message) steganographic communication scheme. To our knowledge, the general notion of a steganographic communication scheme has not been formalized in this way in prior work. In the context of this work, the general definition is helpful for proving broad impossibilities across multiple types of steganographic schemes.

As mentioned in the introduction, a limitation of all existing results in the steganographic literature, to our knowledge, is that they assume that the *cover distribution* – i.e., the distribution of innocuous objects in which steganographic communication is to be embedded – is fixed *a priori*. In particular, the cover distribution is assumed not to depend on the description of the steganographic communication scheme. The impossibility result given in Section 4.1 is an example illustrative of the power of adversarially choosing the cover distribution: Theorem 9 says that by choosing the encryption scheme  $E$  to depend on a given subliminal communication scheme, an adversary can rule out the possibility of any hidden communication at all.

Our next impossibility result (Theorem 10) shows that if the cover distribution is chosen adversarially, then non-trivial steganographic communication is impossible.

► **Theorem 10.** *Let  $\Pi$  be a protocol with the syntax of a steganographic communication scheme. Then for any  $k \in \mathbb{N}$ , there exists a cover distribution  $\mathcal{C}$  of conditional min-entropy  $k$  such that steganographic indistinguishability of  $\Pi$  does not hold.*

We have elected to present the definition of a *steganographic communication scheme* as well as the proof of Theorem 10 in the full version of this paper [17] since the definition introduces a set of new notation only used for the corresponding impossibility result, and both the definition and the impossibility result are somewhat tangential to the main results of this work, whose focus is on subliminal communication schemes.

## 5 Construction of the Subliminal Scheme

The goal of this section is to establish the following theorem, which states that our construction  $(\Phi^*, \Xi^*)$  is a subliminal communication scheme when instantiated with a pseudorandom key-exchange protocol (such as Diffie-Hellman).

► **Theorem 11.** *The protocol  $(\Phi^*, \Xi^*)$  given in Definition 17, when instantiated with a pseudorandom key-exchange protocol  $\Lambda$ , is a multi-message subliminal communication scheme.*

The description of our scheme can be found in the following subsections. Our construction makes no assumption on the message distribution  $\mathcal{M}$  and in particular holds when the exchanged plaintexts (of the adversarial encryption scheme  $E$ ) are a fixed, adversarially chosen sequence of messages. An informal outline of the construction is given next.

► **Definition 12.** Outline of the construction.

### 1. Setup Phase $\Phi^*$

- a. A  $\tilde{O}(\log \kappa)$ -bit string  $S$  is established between  $P_0$  and  $P_1$  by extracting randomness from pairs of consecutive ciphertexts. (*Protocol overview in Section 5.1.*)

- b. Let  $\text{Ext}$  be a strong seeded extractor, and let  $S$  serve as its seed. By rejection-sampling ciphertexts  $c$  until  $\text{Ext}_S(c) = \text{str}$ , either party can embed a random string  $\text{str}$  of their choice in the conversation. (*Protocol overview in Section 5.2.*) By embedding in this manner the messages of a pseudorandom key-exchange protocol, both parties establish a shared secret  $\text{sk}^*$ .<sup>12</sup>

## 2. Communication Phase $\Xi^*$

Both parties can now communicate arbitrary messages of their choice by (1) encrypting them using a pseudorandom secret-key encryption scheme  $\text{SKE}$  using  $\text{sk}^*$  as the secret key, and (2) embedding the ciphertexts of  $\text{SKE}$  using the rejection-sampling technique described in Step 1b.<sup>13</sup> (*Detailed protocol in Section 5.3.*)

The full protocol is given in Section 5.3.

## 5.1 Establishing a Shared Seed

In this section, we give a protocol which allows  $P_0$  and  $P_1$  to establish a random public parameter which will be used in subsequent phases of our subliminal scheme. This can be thought of as drawing a subliminal scheme at random from a family of subliminal schemes. The parameter is public in the sense that any eavesdropper gains knowledge of it. A crucial point is that the random draw occurs *after* the adversarial encryption scheme  $\text{E}$  is fixed, thus bypassing the impossibility results of Section 4.

Our strategy is simple: extract randomness from pairs of ciphertexts. Since the extractor does not receive the key, semantic security holds with respect to the extractor: a pair of ciphertexts for two arbitrary messages is indistinguishable from two encryptions of a fixed message; thus, a same-source extractor suffices for our purposes. Even though semantic security guarantees only  $\omega(\log \kappa)$  min-entropy of ciphertexts, we can use the “greater-than” extractor (Definition 13) applied to pairs of ciphertexts, and obtain Theorem 14.

► **Definition 13.** The *greater-than extractor*  $\text{GT}$  is defined by  $\text{GT}(x, y) = \mathbf{1}[x \geq y]$ .

► **Theorem 14.** Let  $\text{E}$  be a semantically secure public-key encryption scheme and let  $\rho \in \text{poly}$ . Define random variables as follows.

- For  $b \in \{0, 1\}$ , let  $K_b = (PK_b, SK_b) = \text{E.Gen}(1^\kappa)$ .
- For  $b \in \{0, 1\}$  and  $i \in [2\rho]$ , let  $C_{b,i} = \text{E.Enc}(PK_{1-b}, m_{b,i})$  representing the ciphertexts exchanged between  $P_0$  and  $P_1$  during  $2\rho$  exchange-rounds.
- Let  $S = (\text{GT}(C_{0,1}, C_{0,2}), \text{GT}(C_{1,1}, C_{1,2}), \dots, \text{GT}(C_{1,2\rho-1}, C_{1,2\rho}))$ .

There exists a negligible function  $\varepsilon$  such that  $\|(K_0, K_1, S) - (K_0, K_1, U_{2\rho})\|_s \leq \varepsilon$ .

## 5.2 Embedding Random Strings

In this section, we assume that both parties have access to a public parameter  $S$  and construct a protocol which allows for embedding of uniformly random strings into ciphertexts of an adversarially chosen encryption scheme  $\text{E}$ , as required by Steps 1b and 2 of the construction outline (Definition 12). The security guarantee is that for a uniformly random parameter  $S$  and uniformly random strings to be embedded, the ciphertexts of  $\text{E}$  with embedded random

<sup>12</sup> An eavesdropper who knows  $S$  can compute  $\text{str}$ . Nonetheless, (1)  $\text{sk}^*$  is unknown to the eavesdropper by the security of the key-exchange protocol and (2) the transcript is indistinguishable from one in which no key exchange occurred at all, due to the pseudorandomness of the key-exchange messages.

<sup>13</sup> Again, an eavesdropper could know the  $\text{SKE}$  ciphertexts exchanged, if he knew the seed  $S$ , but could not distinguish the  $\text{SKE}$  ciphertexts from truly random strings, and thus could not tell whether any subliminal communication was occurring at all. See also footnote 12.

**Algorithm 1** Rejection sampler  $\Sigma^{E,S}$ .PUBLIC PARAMETER:  $S$  (a  $d$ -bit seed).INPUT:  $(\text{str}, m, \text{pk})$  where  $\text{str}$  is the string to be embedded.

1. Generate encryption  $c \leftarrow \text{E.Enc}(\text{pk}, m)$ .
2. If  $\text{Ext}(S, c) = \text{str}$ , then output  $c$ . Else, go back to step 1.

strings are indistinguishable from ciphertexts of  $\text{E}$  produced by direct application of  $\text{E.Enc}$ , even to an adversary who knows the decryption keys of  $\text{E}$ . This can be thought of as a relaxation of subliminal indistinguishability (Definition 7) where the two main differences are that (1) the parties have shared knowledge of a random seed, and (2) indistinguishability only holds when embedding a *random* string, rather than for arbitrary strings. Our construction (Theorem 15) relies on a strong seeded extractor that can extract logarithmically many bits from sources of super-logarithmic min-entropy, we note that almost universal hashing is a simple such extractor.

► **Theorem 15.** *Let  $\text{Ext} : \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^v$  be a strong seeded extractor for super-logarithmic min-entropy with  $v = O(\log \kappa)$ , and let  $\text{E}$  be a semantically secure encryption scheme with ciphertext space  $\mathcal{C} = \{0, 1\}^n$ . Let  $\Sigma^{E,S}$  be defined as in Algorithm 1. Then the following guarantees hold:*

1. Correctness: for any  $S \in \{0, 1\}^d$  and  $\text{str} \in \{0, 1\}^v$ , if  $c = \Sigma^{E,S}(\text{str}, m, \text{pk})$ , and  $\text{str}' = \text{Ext}(S, c)$ , then  $\text{str}' = \text{str}$ .
2. Security: let  $(PK, SK) = \text{E.Gen}(1^\kappa)$ ,  $C = \text{E.Enc}(PK, m)$  and  $C' = \Sigma^{E,U_d}(U_v, m, PK)$ ; then  $\|(PK, SK, U_d, C) - (PK, SK, U_d, C')\|_s \leq \varepsilon(\kappa)$  for some negligible function  $\varepsilon$ .

► **Remark.** Rejection sampling is a simple and natural approach that has been used by prior work in the steganographic literature, such as [2]. Despite the shared use of this common technique, our construction is more different from prior art than it might seem at first glance. The novelty of our construction arises from the challenges of working in a model with a stronger adversary who can choose the distribution of ciphertexts (i.e., the adversary gets to choose the public-key encryption scheme  $\text{E}$ ). We manage to bypass the impossibilities outlined in Section 4 notwithstanding this stronger adversarial model, and in contrast to prior work, construct a protocol to established a shared seed from scratch, rather than simply assuming that one has been established in advance.

### 5.3 Full Protocol $(\Phi^*, \Xi^*)$

► **Definition 16** (Key-exchange protocol syntax). A key-exchange protocol is a two-party protocol defined by  $\Lambda = (\Lambda_{0,1}, \Lambda_{1,1}, \Lambda_{0,2}, \Lambda_{1,2}, \dots, \Lambda_{0,k}, \Lambda_{1,k}, \Lambda_{0,\text{out}}, \Lambda_{1,\text{out}})$ . We assume  $k$  simultaneous communication rounds, where  $\Lambda_{b,i}$  represents the computation performed by  $P_b$  in the  $i$ th round. The parties are stateful and their state is implicitly updated at each round to contain the transcript so far and any local randomness generated so far. Each  $\Lambda_{b,i}$  takes as input the transcript up to round  $i - 1$  and the state of  $P_b$ , and outputs a message  $\lambda_{b,i}$  to be sent in the  $i$ th round. For notational simplicity, we write explicitly only the first input to  $\Lambda_{b,i}$ , and leave the second input (i.e., the state) implicit.  $\Lambda_{0,\text{out}}, \Lambda_{1,\text{out}}$  are run by  $P_0, P_1$  respectively to compute the shared secret at the conclusion of the protocol.

Next, we give the full construction of  $(\Phi^*, \Xi^*)$  following the outline in Definition 12.

► **Definition 17.**  $(\Phi^*, \Xi^*)$  is parametrized by the following.

- $\text{Ext} : \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^v$ , a strong seeded extractor.
  - $\Lambda$ , a pseudorandom key-exchange protocol with  $\ell$ -bit messages.<sup>14</sup>
  - SKE, a pseudorandom secret key encryption scheme with  $\xi$ -bit ciphertexts.
- We define each phase of our construction in turn.

## 1. Setup Phase $\Phi^*$

### a. Establishing a $d$ -bit shared seed

- For  $b \in \{0, 1\}$  and  $i \in \{1, \dots, d\}$ ,  $\Phi_{b,i}^*(m_{b,i}, \text{pk}_{1-b}, \mathfrak{s}_{b,i-1})$  outputs a ciphertext  $c_{b,i} = \text{E.Enc}(\text{pk}_{1-b}, m_{b,i})$  and sets the updated state  $\mathfrak{s}_{b,i}$  to be the transcript of all protocol messages sent and received so far.
- At the conclusion of the  $d$  exchange-rounds, each party updates his state to contain the seed  $S$  which is defined by

$$S = (\text{GT}(c_{0,1}, c_{0,2}), \text{GT}(c_{1,1}, c_{1,2}), \dots, \text{GT}(c_{1,d-1}, c_{1,d})) .$$

This seed  $S$  is assumed to be accessible in all future states throughout both phases during the remainder of the protocol.

### b. Subliminal key exchange

Let  $\nu = \frac{\ell}{v}$ . Subliminal key exchange occurs over  $k \cdot \nu$  exchange-rounds.

- For  $j \in \{1, \dots, k\}$  and  $b \in \{0, 1\}$ :
  - $P_b$  retrieves from his state the key-exchange transcript so far  $(\lambda_{b,j'})_{b \in \{0,1\}, j' < j}$ .
  - $P_b$  computes the next key-exchange message  $\lambda_{b,j} \leftarrow \Lambda_{b,j}((\lambda_{b,j'})_{b \in \{0,1\}, j' < j})$ .
  - $P_b$  breaks  $\lambda_{b,j}$  into  $v$ -bit blocks  $\lambda_{b,j} = \lambda_{b,j}^1 || \dots || \lambda_{b,j}^\nu$ .
  - The  $\nu$  blocks are transmitted sequentially as follows. For  $\iota \in \{1, \dots, \nu\}$ :
    - Let  $i = d + (j - 1)\nu + \iota$ .
    - $\Phi_{b,i}^*(m_{b,i}, \text{pk}_{1-b}, \mathfrak{s}_{b,i-1})$  outputs  $c_{b,i} \leftarrow \Sigma^{\text{E},S}(\lambda_{b,j}^\iota, m_{b,i}, \text{pk}_{1-b})$  and sets the updated state  $\mathfrak{s}_{b,i}$  to contain the transcript of all protocol messages sent and received so far.
- At the conclusion of the  $\iota$  exchange-rounds, each party  $b \in \{0, 1\}$  updates his state to contain the  $j$ th key-exchange message  $\lambda_{1-b,j}$  computed as follows:

$$\lambda_{1-b,j} = \text{Ext}(S, c_{b,d+(j-1)\nu+1}) || \dots || \text{Ext}(S, c_{b,d+j\nu})$$

- At the conclusion of the  $k \cdot \nu$  exchange rounds, each party updates his state to contain the secret key  $\text{sk}^*$  computed as:  $\text{sk}^* = \text{SKE.Gen}(1^\kappa; \Lambda_{\text{out}}((\lambda_{b,j})_{b \in \{0,1\}, j \in [k]}))$ .

## 2. Communication Phase $\Xi^*$

Each communication phase occurs over  $r' = \xi/v$  exchange-rounds.

Let  $\beta \in \{0, 1\}$  be the initiating party and let  $\bar{\beta} = 1 - \beta$ .

$P_\beta$  performs the following steps.

- Generate  $c^* \leftarrow \text{SKE.Enc}(\text{sk}^*, \text{msg})$ .
  - Break  $c^*$  into  $v$ -bit blocks  $c^* = c_1^* || \dots || c_{r'}^*$ .
- For  $i' \in \{1, \dots, r'\}$ :
- Let  $i'' = r + i'$ .
  - $\Xi_{0,i'}^*(\text{msg}, m_{0,i''}, \text{pk}_{\bar{\beta}}, \mathfrak{s}_{\beta,i''-1})$  outputs  $c_{\beta,i''} \leftarrow \Sigma^{\text{E},S}(c_{i'}^*, m_{\beta,i''}, \text{pk}_{\bar{\beta}})$ .
  - $\Xi_{1,i'}^*(m_{\bar{\beta},i''}, \text{pk}_{\beta}, \mathfrak{s}_{\bar{\beta},i''-1})$  outputs  $c_{\bar{\beta},i''} \leftarrow \text{E.Enc}(\text{pk}_{\beta}, m_{\bar{\beta},i''})$ .

<sup>14</sup>In presenting our construction  $(\Phi^*, \Xi^*)$ , we do not denote the state of parties w.r.t. the key-exchange protocol  $\Lambda$  by a separate variable, but assume that it is part of the state  $\mathfrak{s}_{b,i}$  of the overall protocol.

- 37     ■ Both parties update their state to contain the transcript of all protocol messages  
38         exchanged so far.

39     After the  $r'$  exchange-rounds,  $P_{\tilde{\beta}}$  computes  $c^{**} = \text{Ext}(S, c_{\beta, r+1}) \parallel \dots \parallel \text{Ext}(S, c_{\beta, r+r'})$ .  
40     Then,  $P_{\tilde{\beta}}$  outputs  $\text{msg}' \leftarrow \text{SKE.Dec}(\text{sk}^*, c^{**})$ . (That is,  $\Xi_{1, \text{out}}^*(\mathfrak{s}_{\tilde{\beta}, r'}) = \text{msg}'$ .)

## 6 Open problems

**Deterministic Extraction.** Our impossibility result in Theorem 9 holds because the adversary can choose the encryption scheme  $\mathbf{E}$  as a function of a given candidate subliminal scheme. However, note that under the additional assumption that  $\mathbf{E}$  is restricted to a predefined class  $E$  of encryption schemes, we could bypass this impossibility as long as a deterministic extractor that can extract randomness from ciphertexts of any encryption scheme in  $E$  exists. We are only aware of two deterministic extractors leading to a positive result for restricted classes of encryption schemes:

- if an upper bound on the circuit size of  $\mathbf{E}$  is known, then we can use the deterministic extractor from [21]. This extractor relies on strong complexity-theoretic assumptions and requires the sources to have min-entropy  $(1 - \gamma)n$  for some unspecified constant  $\gamma$ .
- if  $\mathbf{E}$  is computed by a circuit of constant depth ( $\mathbf{AC}^0$ ), then the deterministic extractor of [22] can be used and requires  $\sqrt{n}$  min-entropy.

Both these extractors have a min-entropy requirement which is not satisfied by ciphertexts of arbitrary encryption schemes. However, it would be interesting to consider improved constructions for the case of specific encryption schemes, or to consider extractors specifically for encryption circuits as opposed to arbitrary circuits satisfying a min-entropy requirement. This would also have direct implications for the efficiency of the subliminal scheme of Section 5.2: indeed, one could then skip Step 1a and use a deterministic extractor directly in Steps 1b and 2, thus saving  $\tilde{O}(\log \kappa)$  exchange-rounds in the setup phase.

**Multi-Source Extraction.** Another interesting question is whether multi-source extractors for the specific case when the sources are independent and identically distributed can achieve better parameters than extractors for general independent sources. We already saw that a very simple extractor (namely, the “greater-than” function) works for i.i.d. sources and extracts one bit with negligible bias, even when the sources only have  $\omega(\log \kappa)$  min-entropy. The non-constructive result of [9] guarantees the existence of a two-source extractor of negligible bias and output length  $\omega(\log \kappa)$  for sources of min-entropy  $\omega(\log \kappa)$ . However, known *explicit* constructions are far from achieving the same parameters, and improving them in the specific case of identically distributed sources is an interesting open problem which was also mentioned in [3].

---

## Abstract

Integer programs with a constant number of constraints are solvable in pseudo-polynomial time. We give a new algorithm with a better pseudo-polynomial running time than previous results. Moreover, we establish a strong connection to the problem  $(\min, +)$ -convolution.  $(\min, +)$ -convolution has a trivial quadratic time algorithm and it has been conjectured that this cannot be improved significantly. We show that further improvements to our pseudo-polynomial algorithm for any fixed number of constraints are equivalent to improvements for  $(\min, +)$ -convolution. This is a strong evidence that our algorithm's running time is the best possible. We also present a faster specialized algorithm for testing feasibility of an integer program with few constraints and for this we also give a tight lower bound, which is based on the SETH.

## 1 Introduction

Vectors  $v^{(1)}, \dots, v^{(n)} \in \mathbb{R}^m$  that sum up to 0 can be seen as a circle in  $\mathbb{R}^m$  that walks from 0 to  $v^{(1)}$  to  $v^{(1)} + v^{(2)}$ , etc. until it reaches  $v^{(1)} + \dots + v^{(n)} = 0$  again. The Steinitz Lemma [17] says that if each of the vectors is small with respect to some norm, we can reorder them in a way that each point in the circle is not far away from 0 w.r.t. the same norm.

Recently Eisenbrand and Weismantel found a beautiful application of this lemma in the area of integer programming [8]. They looked at ILPs of the form  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$ , where  $A \in \mathbb{Z}^{m \times n}$ ,  $b \in \mathbb{Z}^m$  and  $c \in \mathbb{Z}^n$  and obtained a pseudo-polynomial algorithm in  $\Delta$ , the biggest absolute value of an entry in  $A$ , when  $m$  is treated as a constant. The running time they achieve is  $n \cdot O(m\Delta)^{2m} \cdot \|b\|_1^2$  for finding the optimal solution and  $n \cdot O(m\Delta)^m \cdot \|b\|_1$  for finding only a feasible solution. This improves on a classic algorithm by Papadimitriou, which has a running time of  $O(n^{2m+2} \cdot (m\Delta + m\|b\|_\infty)^{(m+1)(2m+1)})$  [15]. The basic idea in [8] is that a solution  $x^*$  for the ILP above can be viewed as a walk in  $\mathbb{Z}^m$  starting at 0 and ending at  $b$ . Every step is a column of the matrix  $A$ : For every  $i \in \{1, \dots, n\}$  we step  $x_i^*$  times in the direction of  $A_i$  (see left picture in Figure 1). By applying the Steinitz Lemma they show that there is an ordering of these steps such that the walk never strays off far from the direct line between 0 and  $b$  (see right picture in Figure 1). They construct a directed graph with one vertex for every integer point near the line between 0 and  $b$  and create an

■ **Figure 1** Steinitz Lemma in Integer Programming.

edge from  $u$  to  $v$ , if  $v - u$  is a column in  $A$ . The weight of the edge is the same as the  $c$ -value of the column. An optimal solution to the ILP can now be obtained by finding a longest path from  $0$  to  $b$ . This can be done in the mentioned time, if one is careful with circles.

In this paper, we present an alternative way to apply the Steinitz Lemma to the same problem. Our approach does not reduce to a longest path problem, but rather solves the ILP in a divide and conquer fashion. Using the Steinitz Lemma and the intuition of a walk from  $0$  to  $b$ , we notice that this walk has to visit a vector  $b'$  near  $b/2$  at some point. We guess this vector and solve the problem with  $Ax = b'$  and  $Ax = b - b'$  independently. Both results can be merged to a solution for  $Ax = b$ . In the sub-problems the norm of  $b$  and the norm of the solution are roughly divided in half. We use this idea in a dynamic program and speed up the process of merging solutions using algorithms for convolution problems. This approach gives us better running times for both the problem of finding optimal solutions and for testing feasibility only. We complete our study by giving (almost) tight conditional lower bounds on the running time in which such ILPs can be solved.

## 1.1 Detailed description of results

In the running times we give, we frequently use logarithmic factors like  $\log(k)$  for some parameter  $k$ . To handle the values  $k \in \{0, 1\}$  formally correct, we would need to write  $\log(k + 1) + 1$  instead of  $\log(k)$  everywhere. This is ignored for simplicity of notation. We are assuming the word RAM model with word size  $O(m \log(m\Delta) + \log(\|b\|_\infty) + \log(\|c\|_\infty))$  (see Preliminaries for details).

### Optimal solutions for ILPs

We show that a solution to  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  can be found in time  $O(m\Delta)^{2m} \cdot \log(\|b\|_\infty) + O(nm)$ . If given a vertex solution to the fractional relaxation, we can even get to  $O(m\Delta)^{2m} + O(nm)$ . The running time can be improved if there exists a truly sub-quadratic algorithm for (min, +)-convolution (see Section 4.1 for details on the problem). However, it has been conjectured that no such algorithm exists and this conjecture is the base of several lower bounds in fine-grained complexity [7, 14, 3]. We show that for every  $m$  the running time above is essentially the best possible unless the (min, +)-convolution conjecture is false. More formally, for every  $m$  there exists no algorithm that solves ILP in time  $f(m) \cdot (n^{2-\delta} + (\Delta + \|b\|_\infty)^{2m-\delta})$  for some  $\delta > 0$  and an arbitrary computable function  $f$ ,

unless there exists a truly sub-quadratic algorithm for  $(\min, +)$ -convolution. Indeed, this means there is an equivalence between improving algorithms for  $(\min, +)$ -convolution and for ILPs of fixed number of constraints. It is notable that this also rules out improvements when both  $\Delta$  and  $\|b\|_\infty$  are small. Our lower bound does leave open some trade-off between  $n$  and  $O(m\Delta)^m$  like for example  $n \cdot O(m\Delta)^m \cdot \log(\|b\|_\infty)$ , which would be an interesting improvement for sparse instances, i.e., when  $n \ll (2\Delta + 1)^m$ . A running time of  $n^{f(m)} \cdot (m\Delta + m\|b\|_\infty)^{m-\delta}$ , however, is not possible (see feasibility below).

### Feasibility of ILPs

Testing only the feasibility of an ILP is easier than finding an optimal solution. It can be done in time  $O(m\Delta)^m \cdot \log(\Delta) \cdot \log(\Delta + \|b\|_\infty) + O(nm)$  by solving a Boolean convolution problem that has a more efficient algorithm than the  $(\min, +)$ -convolution problem that arises in the optimization version. Under the STRONG EXPONENTIAL TIME HYPOTHESIS (SETH) this running time is tight except for logarithmic factors. If this conjecture holds, there is no  $n^{f(m)} \cdot (m\Delta + m\|b\|_\infty)^{m-\delta}$  time algorithm for any  $\delta > 0$  and any computable function  $f$ .

## 1.2 Other related work

The case where the number of variables  $n$  is fixed and not  $m$  as in this paper behaves somewhat differently. There is a  $2^{O(n \log(n))} \cdot |I|^{O(1)}$  time algorithm ( $|I|$  being the encoding length of the input), whereas an algorithm of the kind  $f(m) \cdot |I|^{O(1)}$  (or even  $|I|^{f(m)}$ ) is impossible for any computable function  $f$ , unless  $P = NP$ . This can be seen with a trivial reduction from UNBOUNDED KNAPSACK (where  $m = 1$ ). The  $2^{O(n \log(n))} \cdot |I|^{O(1)}$  time algorithm is due to Kannan [12] improving over a  $2^{O(n^2)} \cdot |I|^{O(1)}$  time algorithm by Lenstra [11]. It is a long open question whether  $2^{O(n)} \cdot |I|^{O(1)}$  is possible instead [8].

Another intriguing question is whether a running time like  $(m\Delta + m\|b\|_\infty)^{O(m)} \cdot n^{O(1)}$  is still possible when upper bounds on variables are added to the ILP. In [8] an algorithm for this extension is given, but the exponent of  $\Delta$  is  $O(m^2)$ .

As for other lower bounds on pseudo-polynomial algorithms for integer programming, the only result we are aware of is a bound of  $n^{o(m/\log(m))} \cdot \|b\|_\infty^{o(m)}$  due to Fomin et al. [9], which is based on the ETH (a weaker conjecture than the SETH). Their reduction implies that there is no algorithm with running time  $n^{o(m/\log(m))} \cdot (\Delta + \|b\|_\infty)^{o(m)}$ , since in their construction the matrix  $A$  is non-negative and therefore columns with entries larger than  $\|b\|_\infty$  can be discarded; thus leading to  $\Delta \leq \|b\|_\infty$ . As opposed to our bounds, theirs does not give a precise value for the constant in the exponent.

## 2 Preliminaries

In this paper we are assuming a word size of  $O(m \log(m\Delta) + \log(\|b\|_\infty) + \log(\|c\|_\infty))$  in the word RAM model, that is to say, arithmetic operations on numbers of this encoding size take constant time. When considering  $m$  to be a constant, this makes perfect sense. Also, since we are going to use algorithms with space roughly  $O(m\Delta)^m$ , it is only natural to assume that a single pointer fits into a word.

In the remainder of the paper we will assume that  $A$  has no duplicate columns. Note that we can completely ignore a column  $i$ , if there is another identical column  $i'$  with  $c_{i'} \geq c_i$ . This implies that in time  $O(nm) + O(\Delta)^m$  we can reduce to an instance without duplicate columns and, in particular, with  $n \leq (2\Delta + 1)^m$ . The running time can be achieved as follows.

## 43:4 On Integer Programming and Convolution

We create a new matrix for the ILP with all  $(2\Delta + 1)^m$  possible columns (in lexicographic order) and objective value  $c_i = -\infty$  for all columns  $i$ . Now we iterate over all  $n$  old columns and compute in time  $O(m)$  the index of the new column corresponding to the same entries. We then replace its objective value with the current one if this is bigger. In the upcoming running times we will omit the additive term  $O(nm)$  and assume the duplicates are already eliminated ( $O(\Delta)^m$  is always dominated by actual algorithms running time).

► **Theorem 1 (Steinitz Lemma).** *Let  $\|\cdot\|$  be a norm in  $\mathbb{R}^m$  and let  $v^{(1)}, \dots, v^{(t)} \in \mathbb{R}^m$  such that  $\|v^{(i)}\| \leq 1$  for all  $i$  and  $v^{(1)} + \dots + v^{(t)} = 0$ . Then there exists a permutation  $\pi \in S_t$  such that for all  $j \in \{1, \dots, t\}$*

$$\left\| \sum_{i=1}^j v^{(\pi(i))} \right\| \leq m.$$

The proof for bound  $m$  is due to Sevast'janov [16] (see also [8] for a good overview). Eisenbrand and Weismantel observed that the Steinitz Lemma implies the following.

► **Corollary 2 ([8]).** *Let  $v^{(1)}, \dots, v^{(t)}$  denote columns of  $A$  with  $\sum_{i=1}^t v^{(i)} = b$ . Then there exists a permutation  $\pi \in S_t$  such that for all  $j \in \{1, \dots, t\}$*

$$\left\| \sum_{i=1}^j v^{(\pi(i))} - \frac{j}{t} \cdot b \right\|_{\infty} \leq 2m\Delta.$$

This can be obtained by inserting  $(v^{(i)} - b/t)/(2\Delta)$ ,  $i \in \{1, \dots, t\}$ , in the Steinitz Lemma. Note that  $\|v^{(i)} - b/t\|_{\infty} \leq 2\Delta$ .

► **Lemma 3.** *Let  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  be bounded and feasible. Then there exists an optimal solution  $x^*$  with  $\|x^*\|_1 \leq O(m\Delta)^m (\|b\|_{\infty} + 1)$ .*

A similar bound is proved for example in [15]. However, we can also give a proof via the Steinitz Lemma.

**Proof.** Let  $x^*$  be an optimal solution of minimal 1-norm. Let  $v^{(1)}, \dots, v^{(t)}$  denote the multiset of columns of  $A$  that represent  $x^*$ . Assume w.l.o.g. these vectors are ordered as in the previous corollary. There cannot be a circle of positive value in  $v^{(1)}, \dots, v^{(t)}$  or else the ILP would be unbounded. By circle we mean a non-empty subset that sums up to 0 and we consider the value of the columns with regard to  $c$ . In fact, there cannot be a circle of nonpositive value either, since the 1-norm of the solution is minimal. Hence, each vector in  $\mathbb{Z}^m$  is visited at most once by the walk  $v^{(1)}, v^{(1)} + v^{(2)}, \dots, v^{(1)} + \dots + v^{(t)} = b$ . The number of integer points  $a$  with

$$\|a - \gamma b\|_{\infty} \leq 2m\Delta \tag{1}$$

for some  $\gamma \in [0, 1]$  is at most  $O(m\Delta)^m \cdot (\|b\|_{\infty} + 1)$  and this upper bounds the 1-norm of  $x^*$ : Assume w.l.o.g.  $\|b\|_{\infty} > 0$  as the case  $b = 0$  is trivial. Take  $\|b\|_{\infty} + 1$  many points evenly distributed along the line from 0 to  $b$ , i.e.,  $b \cdot 0/\|b\|_{\infty}$ ,  $b \cdot 1/\|b\|_{\infty}, \dots, b \cdot \|b\|_{\infty}/\|b\|_{\infty}$ . Then the distance between two consecutive points is small:

$$\left\| b \cdot \frac{j+1}{\|b\|_{\infty}} - b \cdot \frac{j}{\|b\|_{\infty}} \right\|_{\infty} = \left\| \frac{b}{\|b\|_{\infty}} \right\|_{\infty} = 1.$$

In particular, for every vector of the form  $\gamma b$ ,  $\gamma \in [0, 1]$ , there is a point  $b \cdot j/\|b\|_\infty$  that is not further away than  $1/2$ . Thus, for every  $a$  that satisfies (1), we have a point  $b \cdot j/\|b\|_\infty$  with

$$\left\| a - b \cdot \frac{j}{\|b\|_\infty} \right\|_\infty \leq \|a - \gamma b\|_\infty + \left\| \gamma b - b \cdot \frac{j}{\|b\|_\infty} \right\|_\infty \leq 2m\Delta + 1/2.$$

To upper bound the number of vectors of type (1), we count the number of vectors within distance at most  $2m\Delta + 1/2$  to each of the  $\|b\|_\infty + 1$  points. This number is at most  $(\|b\|_\infty + 1) \cdot (4m\Delta + 2)^m$ . This concludes the proof.  $\blacktriangleleft$

**► Corollary 4.** *By adding a zero column we can assume w.l.o.g., if the ILP is feasible and bounded, then there exists an optimal solution  $x^*$  with  $\|x^*\|_1 = U$  where  $U$  is the upper bound for  $\|x^*\|_1$ . By scaling the bound of Lemma 3 to the next power of 2, we can assume that  $\|x^*\|_1 = 2^K$  where  $K \in \mathbb{N}$  and  $K \leq O(m \log(m\Delta) + \log(\|b\|_\infty))$ .*

### 3 Dynamic Program

In this section we will show how to compute the best solution  $x^*$  to an ILP with the additional constraint  $\|x^*\|_1 = 2^K$ . If the ILP is bounded, then with  $K = O(m \log(m\Delta) + \log(\|b\|_\infty))$  and an extra zero column this is the optimum to the ILP (Corollary 4). In Section 3.2 we discuss how to cope with unbounded ILPs. For every  $i = K, K-1, \dots, 0$  and every  $b'$  with

$$\|b' - 2^{-i} \cdot b\|_\infty \leq 4m\Delta$$

we solve  $\max\{c^T x : Ax = b', \|x\|_1 = 2^{K-i}, x \in \mathbb{Z}_{\geq 0}^n\}$ . We start by computing these for  $i = K$  and then iteratively derive solutions for smaller values of  $i$  using only the bigger ones. Ultimately, we will compute a solution for  $i = 0$  and  $b' = b$ .

If  $i = K$ , then every solution must consist of exactly one column ( $\|x\|_1 = 1$ ). We can compute this solution by finding the column that equals  $b'$  should there exist one and set  $-\infty$  otherwise.

Fix some  $i < K$  and  $b'$  and let  $v^{(1)}, \dots, v^{(t)}$  be columns of  $A$  that correspond to an optimal solution to  $\max\{c^T x : Ax = b', \|x\|_1 = 2^{K-i}, x \in \mathbb{Z}_{\geq 0}^n\}$ . In particular,  $v^{(1)} + \dots + v^{(t)} = b'$  and  $t = 2^{K-i}$ . Assume w.l.o.g. that the  $v^{(i)}$  are ordered such that for all  $j \in \{0, \dots, t\}$

$$\left\| \sum_{i=1}^j v^{(i)} - \frac{j}{t} \cdot b' \right\|_\infty \leq 2m\Delta.$$

Note that  $v^{(1)}, \dots, v^{(t/2)}$  is an optimal solution to  $\max\{c^T x : Ax = b'', \|x\|_1 = 2^{K-(i+1)}, x \in \mathbb{Z}_{\geq 0}^n\}$  where  $b'' = v^{(1)} + \dots + v^{(t/2)}$ . Likewise,  $v^{(t/2+1)}, \dots, v^{(t)}$  is an optimal solution to  $\max\{c^T x : Ax = b' - b'', \|x\|_1 = 2^{K-(i+1)}, x \in \mathbb{Z}_{\geq 0}^n\}$ . We claim that  $\|b'' - 2^{-(i+1)} \cdot b\|_\infty \leq 4m\Delta$  and  $\|(b' - b'') - 2^{-(i+1)} \cdot b\|_\infty \leq 4m\Delta$ . This implies that we can look up solutions for  $b''$  and  $b' - b''$  in the dynamic table and their union is a solution for  $b'$ . Clearly it is also optimal. We do not know  $b''$ , but we can guess it: There are only  $(8m\Delta + 1)^m$  candidates. To compute an entry, we therefore enumerate all possible  $b''$  and take the two partial solutions (for  $b''$  and  $b' - b''$ ), where the sum of both values is maximized.

**Proof of claim**

We have that,

$$\begin{aligned} \left\| \sum_{i=1}^{t/2} v^{(i)} - 2^{-(i+1)} \cdot b \right\|_{\infty} &= \left\| \sum_{i=1}^{t/2} v^{(i)} - \frac{1}{2} \cdot b' + \frac{1}{2} \cdot b' - 2^{-(i+1)} \cdot b \right\|_{\infty} \\ &\leq \left\| \sum_{i=1}^{t/2} v^{(i)} - \frac{1}{2} \cdot b' \right\|_{\infty} + \left\| \frac{1}{2} \cdot b' - 2^{-(i+1)} \cdot b \right\|_{\infty} \leq 2m\Delta + \frac{1}{2} \|b' - 2^{-i} \cdot b\|_{\infty} \leq 4 \cdot m\Delta. \end{aligned}$$

In a similar way, we can show that

$$\begin{aligned} \left\| \sum_{i=t/2+1}^t v^{(i)} - 2^{-(i+1)} \cdot b \right\|_{\infty} &= \left\| \sum_{i=t/2+1}^t v^{(i)} - \sum_{i=1}^t v^{(i)} + b' - 2^{-(i+1)} \cdot b \right\|_{\infty} \\ &= \left\| \frac{1}{2} \cdot b' - \sum_{i=1}^{t/2} v^{(i)} + \frac{1}{2} \cdot b' - 2^{-(i+1)} \cdot b \right\|_{\infty} \\ &\leq \left\| \sum_{i=1}^{t/2} v^{(i)} - \frac{1}{2} \cdot b' \right\|_{\infty} + \left\| \frac{1}{2} \cdot b' - 2^{-(i+1)} \cdot b \right\|_{\infty} \leq 4 \cdot m\Delta. \end{aligned}$$

**3.1 Naive running time**

The dynamic table has  $(K+1) \cdot O(m\Delta)^m$  entries. To compute an entry,  $O(n \cdot m) \leq O(m\Delta)^m$  operations are necessary during initialization and  $O(m\Delta)^m$  in the iterative calculations. This gives a total running time of

$$O(m\Delta)^{2m} \cdot (K+1) = O(m\Delta)^{2m} \cdot (m \log(m\Delta) + \log(\|b\|_{\infty})) = O(m\Delta)^{2m} \cdot (\log(\Delta) + \log(\|b\|_{\infty})).$$

Note that  $O(m\Delta)^{2m} = O(m\Delta)^{2m} \cdot 2^m$  hides factors polynomial in  $m$ .

**3.2 Unbounded solutions**

In the previous dynamic program there is no mechanism for detecting when the ILP is unbounded. We follow the approach from [8] to handle unbounded ILPs. The ILP  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  is unbounded, if and only if  $\{x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  has a solution and  $\max\{c^T x : Ax = 0, x \in \mathbb{Z}_{\geq 0}^n\}$  has any solution with positive objective value. After running the dynamic program - thereby verifying that there exists any solution - we have to check if the latter condition holds. We can simply run the algorithm again on  $\max\{c^T x : Ax = 0, x \in \mathbb{Z}_{\geq 0}^n\}$  with  $K = m \cdot \lceil \log(2m\Delta + 1) \rceil$ . If it returns a positive value, the ILP is unbounded. Let us argue why this is enough. We need to understand that when there is a positive solution to  $\max\{c^T x : Ax = 0, x \in \mathbb{Z}_{\geq 0}^n\}$ , then there is also a positive solution with 1-norm at most  $(2m\Delta + 1)^m \leq 2^K$ . Let  $x^*$  be a positive solution to the former ILP with minimal 1-norm, i.e.,  $c^T x^* > 0$  and  $\|x^*\|_1$  minimal. Let  $v^{(1)}, \dots, v^{(t)}$  be the multiset of columns representing  $x^*$ . We assume that they are ordered as in Corollary 2. If  $t > (2m\Delta + 1)^m$ , then there must be two identical partial sums  $\sum_{i=1}^j v^{(i)} = \sum_{i=1}^k v^{(i)}$  with  $j < k$ . In other words, the circle can be decomposed into two circles  $v^{(1)}, \dots, v^{(j)}, v^{(k+1)}, \dots, v^{(t)}$  and  $v^{(j+1)}, \dots, v^{(k)}$ . One of these must be a positive solution or else their sum would be negative. This means the 1-norm of  $x^*$  is not minimal. We conclude that  $t \leq (2m\Delta + 1)^m$ .

## 4 Improvements to the running time

### 4.1 Applying convolution

Can we speed up the computation of entries in the dynamic table? Let  $D_i$  be the set of vectors  $b'$  with  $\|b' - 2^{-i} \cdot b\|_\infty \leq 4m\Delta$ . Recall, the dynamic programs computes values for each element in  $D_K, D_{K-1}, \dots, D_1$ . More precisely for the value of  $b' \in D_i$  we consider vectors  $b''$  such that  $b'', b' - b'' \in D_{i+1}$  and take the maximum sum of the values for  $b'', b' - b''$  among all. First consider only the case of  $m = 1$ . Here we have that  $b' \in D_i$  is equivalent to  $-4\Delta \leq b' - 2^{-i} \cdot b \leq 4\Delta$ . This problem is well studied. It is a variant of (min, +)-convolution.

(MIN, +)-CONVOLUTION

**Input:**  $r_1, \dots, r_n$  and  $s_1, \dots, s_n$ .

**Output:**  $t_1, \dots, t_n$ , where  $t_k = \min_{i+j=k} r_i + s_j$ .

(max, +)-convolution is the counterpart where the maximum is taken instead of the minimum. The two problems are equivalent. Each of them can be transformed to the other by negating the elements. We construct an instance of (max, +)-convolution of size  $12\Delta + 2$ . We set  $r_j$  and  $s_j$ ,  $j \in \{1, \dots, 8\Delta + 1\}$  both to the value for  $b/2^{i+1} - (4\Delta + 1) + j \in D_{i+1}$  in the dynamic table. Set the remaining values of  $r$  and  $s$  to  $-\infty$ . Then for  $b' = b/2^i - (4\Delta + 1) + k \in D_i$ , the correct result will be at  $t_{4\Delta+1+k}$ .

(min, +)-convolution admits a trivial  $O(n^2)$  time algorithm and it has been conjectured that there exists no truly sub-quadratic algorithm [7]. There does, however, exist an  $O(n^2 / \log(n))$  time algorithm [4], which we are going to use. In fact, there is a slightly faster algorithm with running time  $n^2 / 2^{\Omega(\sqrt{\log(n)})}$  [6].

We can reduce the problem for arbitrary  $m$  to a (max, +)-convolution instance of size  $O(m\Delta)^m$ . To do so, project a vector  $b' \in D_i$  to

$$f_i(b') = \sum_{j=1}^m (16m\Delta + 3)^{j-1} \underbrace{(4m\Delta + 1 + b'_j - b_j/2^i)}_{\in [1, 8m\Delta+1]}. \quad (2)$$

The value  $16m\Delta + 3$  is chosen because it is always greater than the sum of two values of the form  $4m\Delta + 1 + b'_j - b_j/2^i$ . For all  $a, a' \in D_{i+1}, b' \in D_i$ , it holds that  $f_{i+1}(a) + f_{i+1}(a') = f_i(b')$ , if and only if  $a + a' = b' - (4m\Delta + 1, \dots, 4m\Delta + 1)^T$ :

**Proof**  $\Rightarrow$ . Let  $f_{i+1}(a) + f_{i+1}(a') = f_i(b')$ . Then in particular,

$$f_{i+1}(a) + f_{i+1}(a') \equiv f_i(b') \pmod{16m\Delta + 3}$$

Since all but the first element of the sum (2) are multiples of  $16m\Delta + 3$ , i.e., they are equal 0 modulo  $16m\Delta + 3$ , we can omit them in the equation. Hence,

$$(4m\Delta + 1 + a_1 - b_1/2^{i+1}) + (4m\Delta + 1 + a'_1 - b_1/2^{i+1}) \equiv (4m\Delta + 1 + b'_1 - b_1/2^i) \pmod{16m\Delta + 3}.$$

We even have equality (without modulo) here, because both sides are smaller than  $16m\Delta + 3$ . Simplifying the equation gives  $a_1 + a'_1 = b'_1 - (4m\Delta + 1)$ . Now consider again the equation  $f_{i+1}(a) + f_{i+1}(a') = f_i(b')$ . In the sums leave out the first element. The equation still holds, since by the elaboration above this changes the left and right hand-side by the same value. We can now repeat the same argument to obtain  $a_2 + a'_2 = b'_2 - (4m\Delta + 1)$  and the same for all other dimensions.  $\blacktriangleleft$

**Proof**  $\Leftarrow$ . Let  $a + a' = b' - (4m\Delta + 1, \dots, 4m\Delta + 1)^T$ . Then for every  $j$ ,

$$(4m\Delta + 1 + a_j - b_j/2^{i+1}) + (4m\Delta + 1 + a'_j - b_j/2^{i+1}) = 4m\Delta + 1 + b'_j - b_j/2^i.$$

It directly follows that  $f_{i+1}(a) + f_{i+1}(a') = f_i(b')$ .  $\blacktriangleleft$

This means when we write the value of each  $b'' \in D_{i+1}$  to  $r_j$  and  $s_j$ , where  $j = f_{i+1}(b'')$ , the correct solutions will be in  $t$ . More precisely, we can read the result for some  $b' \in D_i$  at  $t_k$  where  $k = f_i(b' + (4m\Delta + 1, \dots, 4m\Delta + 1)^T)$ .

With an algorithm for  $(\min, +)$ -convolution with running time  $T(n)$  we get an algorithm with running time  $T(O(m\Delta)^m) \cdot (m \log(m\Delta) + \log(\|b\|_\infty))$ . Inserting  $T(n) = n^2/\log(n)$  we get:

**► Theorem 5.** *There exists an algorithm that finds the optimum of  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$ , in time  $O(m\Delta)^{2m} \cdot (1 + \log(\|b\|_\infty)/\log(\Delta))$ .*

Clearly, a sub-quadratic algorithm, where  $T(n) = n^{2-\delta}$  for some  $\delta > 0$ , would directly improve the exponent. Next, we will consider the problem of only testing feasibility of an ILP. Since we only record whether or not there exists a solution for a particular right-hand side, the convolution problem reduces to the following.

**BOOLEAN CONVOLUTION**  
**Input:**  $r_1, \dots, r_n \in \{0, 1\}$  and  $s_1, \dots, s_n \in \{0, 1\}$ .  
**Output:**  $t_1, \dots, t_n \in \{0, 1\}$ , where  $t_k = \bigvee_{i+j=k} r_i \wedge s_j$ .

This problem can be solved very efficiently via fast Fourier transform. We compute the  $(+, \cdot)$ -convolution of the input. It is well known that this can be done using FFT in time  $O(n \log(n))$ . The  $(+, \cdot)$ -convolution of  $r$  and  $s$  is the vector  $t$ , where  $t_k = \sum_{i+j=k} r_i \cdot s_j$ . To get the Boolean convolution instead, we simply replace each  $t_k > 0$  by 1. Using  $T(n) = O(n \log(n))$  for the convolution algorithm we obtain the following.

**► Theorem 6.** *There exists an algorithm that finds an element in  $\{x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$ , if there is one, in time  $O(m\Delta)^m \cdot \log(\Delta) \cdot \log(\Delta + \|b\|_\infty)$ .*

This can be seen from the calculation below. First we scrape off factors polynomial in  $m$ :

$$O(m\Delta)^m \cdot m \log(m\Delta) \cdot (m \log(m\Delta) + \log(\|b\|_\infty)) \leq O(m\Delta)^m \cdot \log(\Delta) \cdot (\log(\Delta) + \log(\|b\|_\infty))$$

Next, we use that  $\log(\Delta) + \log(\|b\|_\infty) = \log(\Delta \cdot \|b\|_\infty) \leq \log((\Delta + \|b\|_\infty)^2) = O(\log(\Delta + \|b\|_\infty))$ .

## 4.2 Use of proximity

Eisenbrand and Weismantel gave the following bound on the proximity between continuous and integral solutions.

**► Theorem 7 ([8]).** *Let  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  be feasible and bounded. Let  $x^*$  be an optimal vertex solution of the fractional relaxation. Then there exists an optimal solution  $z^*$  with*

$$\|z^* - x^*\|_1 \leq m(2m\Delta + 1)^m.$$

We briefly explain, how they use this theorem to reduce the right-hand side  $b$  at the expense of computing the optimum of the fractional relaxation: Note that  $z_i^* \geq \ell_i := \max\{0, \lceil x_i^* \rceil - m(2m\Delta + 1)^m\}$ . Since  $x^*$  is a vertex solution, it has at most  $m$  non-zero components. By

setting  $y = x - \ell$  we obtain the equivalent ILP  $\max\{c^T y : Ay = b - A\ell, y \in \mathbb{Z}_{\geq 0}^n\}$ . Indeed, this ILP has a bounded right-hand side:

$$\|b - A\ell\|_{\infty} = \|A(x^* - \ell)\|_{\infty} \leq \Delta m^2 (2m\Delta + 1)^m = O(m\Delta)^{m+1}.$$

Here, we use that  $x^*$  and  $\ell$  differ only in non-zero components of  $x^*$  and in those by at most  $m(2m\Delta + 1)^m$ . Like in earlier bounds, the O-notation hides polynomial terms in  $m$ . Using the  $n \cdot O(m\Delta)^{2m} \cdot \|b\|_1^2$  time algorithm from [8], this gives a running time of  $n \cdot O(m\Delta)^{4m+2} + \text{LP}$ , where LP is the time to solve the relaxation. The logarithmic dependence on  $\|b\|_{\infty}$  in our new algorithm leads to a much smaller exponent: Using Theorem 5 and the construction above, the ILP can be solved in time  $O(m\Delta)^{2m} + \text{LP}$ . Feasibility can be tested in time  $O(m\Delta)^m \cdot \log^2(\Delta) + \text{LP}$  using Theorem 6.

### 4.3 Heterogeneous matrices

Let  $\Delta_1, \dots, \Delta_m \leq \Delta$  denote the largest absolute values of each row in  $A$ . When some of these values are much smaller than  $\Delta$ , the maximum among all, we can do better than  $O(m\Delta)^{2m} \cdot \log(\|b\|_{\infty})$ . An example for a highly heterogeneous matrix is UNBOUNDED KNAPSACK with cardinality constraints. Consider the norm  $\|v\| = 1/2 \cdot \max_k |v_k/\Delta_k|$  and let  $v^{(1)}, \dots, v^{(t)} \in \mathbb{Z}^m$  be the multiset of columns corresponding to an optimal solution of the ILP. Using the Steinitz Lemma on this norm, it follows that there exists a permutation  $\pi$  such that for all  $j \in \{1, \dots, t\}$  and  $k \in \{1, \dots, k\}$

$$\left| \sum_{i=1}^j v_k^{(\pi(i))} - \frac{j}{t} \cdot b_k \right| \leq 2m\Delta_k.$$

This means the number of states we have to consider reduces from  $O(m\Delta)^m$  to  $\prod_{k=1}^m O(m\Delta_k)$  at each level of the dynamic program. Hence, we obtain the running time  $\prod_{k=1}^m O(m\Delta_k)^2 \cdot \log(\|b\|_{\infty})$ . When the objective function has small coefficients, it is more efficient to perform a binary search for the optimum and encode the objective function as an additional constraint. We can bound the optimum by  $O(m\Delta)^m \cdot (\|b\|_{\infty} + 1) \cdot \|c\|_{\infty}$  using the bound on the 1-norm of the solution. Hence, the binary search takes at most  $O(m \log(m\Delta \cdot \|c\|_{\infty} \cdot \|b\|_{\infty})) = O(m \log(m\Delta + \|c\|_{\infty} + \|b\|_{\infty}))$  iterations. For a guess  $\tau$  the following feasibility ILP tests if there is a solution of value at least  $\tau$ .

$$\begin{pmatrix} c_1 & \dots & c_n & -1 \\ & & & 0 \\ & A & & \vdots \\ & & & 0 \end{pmatrix} x = \begin{pmatrix} \tau \\ b_1 \\ \vdots \\ b_n \end{pmatrix}$$

$$x \in \mathbb{Z}_{\geq 0}^{n+1}$$

We can solve the ILP above in time

$$T(\|c\|_{\infty} \cdot \prod_{k=1}^m O((m+1)\Delta_k)) \cdot \log(\|b\|_{\infty} + \tau) \leq T(\|c\|_{\infty} \cdot \prod_{k=1}^m O(m\Delta_k)) \cdot m \log(m\Delta + \|c\|_{\infty} + \|b\|_{\infty}),$$

where  $T(n) = O(n \log(n))$  is the running time of Boolean convolution. By adding the time for the binary search and by hiding polynomials in  $m$ , we get the total running time of

$$\|c\|_{\infty} \cdot \prod_{k=1}^m [O(m\Delta_k)] \cdot \log(\Delta + \|c\|_{\infty}) \cdot \log^2(\Delta + \|c\|_{\infty} + \|b\|_{\infty}).$$

**5 Lower bounds**

**5.1 Optimization problem**

We use an equivalence between UNBOUNDED KNAPSACK and (min, +)-convolution regarding sub-quadratic algorithms.

UNBOUNDED KNAPSACK  
**Input:**  $C \in \mathbb{N}$ ,  $w_1, \dots, w_n \in \mathbb{N}$ , and  $p_1, \dots, p_n \in \mathbb{N}$ .  
**Output:** Multiplicities  $x_1, \dots, x_n$ , such that  $\sum_{i=1}^n x_i \cdot w_i \leq C$  and  $\sum_{i=1}^n x_i \cdot p_i$  is maximized.

Note that when we instead require  $\sum_{i=1}^n x_i \cdot w_i = C$  in the problem above, we can transform it to this form by adding an item of profit zero and weight 1.

► **Theorem 8** ([7]). *For any  $\delta > 0$  there exists no  $O((n + C)^{2-\delta})$  time algorithm for UNBOUNDED KNAPSACK unless there exists a truly sub-quadratic algorithm for (min, +)-convolution.*

When using this theorem, we assume that the input already consists of the at most  $C$  relevant items only,  $n \leq C$ , and  $w_i \leq C$  for all  $i$ . This preprocessing can be done in time  $O(n + C)$ .

► **Theorem 9.** *For every fixed  $m$  there does not exist an algorithm that solves ILPs with  $m$  constraints in time  $f(m) \cdot (n^{2-\delta} + (\Delta + \|b\|_\infty)^{2m-\delta})$  for some  $\delta > 0$  and a computable function  $f$ , unless there exists a truly sub-quadratic algorithm for (min, +)-convolution.*

**Proof.** Let  $\delta > 0$  and  $m \in \mathbb{N}$ . Assume that there exists an algorithm that solves ILPs of the form  $\max\{c^T x : Ax = b, x \in \mathbb{Z}_{\geq 0}^n\}$  where  $A \in \mathbb{Z}^{m \times n}$ ,  $b \in \mathbb{Z}^m$ , and  $c \in \mathbb{Z}^n$  in time  $f(m) \cdot (n^{2-\delta} + (\Delta + \|b\|_\infty)^{2m-\delta})$ , where  $\Delta$  is the greatest absolute value in  $A$ . We will show that this implies an  $O((n + C)^{2-\delta'})$  time algorithm for the UNBOUNDED KNAPSACK PROBLEM for some  $\delta' > 0$ . Let  $(C, (w_i)_{i=1}^n, (p_i)_{i=1}^n)$  be an instance of this problem. Let us first observe that the claim holds for  $m = 1$ . Clearly the UNBOUNDED KNAPSACK PROBLEM (with equality) can be written as the following ILP (UKS1).

$$\begin{aligned} & \max \sum_{i=1}^n p_i \cdot x_i \\ & \sum_{i=1}^n w_i \cdot x_i = C \\ & x \in \mathbb{Z}_{\geq 0}^n \end{aligned}$$

Since  $w_i \leq C$  for all  $i$  (otherwise the item can be discarded), we can solve this ILP by assumption in time  $f(1) \cdot (n^{2-\delta} + (2C)^{2-\delta}) \leq O((n + C)^{2-\delta})$ . Now consider the case where  $m > 1$ . We want to reduce  $\Delta$  by exploiting the additional rows. Let  $\Delta = \lfloor C^{1/m} \rfloor + 1 > C^{1/m}$ . We write  $C$  in base- $\Delta$  notation, i.e.,

$$C = C^{(0)} + \Delta C^{(1)} + \dots + \Delta^{m-1} C^{(m-1)},$$

where  $0 \leq C^{(k)} < \Delta$  for all  $k$ . Likewise, write  $w_i = w_i^{(0)} + \Delta w_i^{(1)} + \dots + \Delta^{m-1} w_i^{(m-1)}$  with

$0 \leq w_i^{(k)} < \Delta$  for all  $k$ . We claim that (UKS1) is equivalent to the following ILP (UKSm).

$$\begin{aligned} \max \sum_{i=1}^n p_i \cdot x_i \\ \sum_{i=1}^n [w_i^{(0)} \cdot x_i] - \Delta \cdot y_1 = C^{(0)} \end{aligned} \quad (3)$$

$$\sum_{i=1}^n [w_i^{(1)} \cdot x_i] + y_1 - \Delta \cdot y_2 = C^{(1)} \quad (4)$$

$\vdots$

$$\sum_{i=1}^n [w_i^{(m-2)} \cdot x_i] + y_{m-2} - \Delta \cdot y_{m-1} = C^{(m-2)} \quad (5)$$

$$\sum_{i=1}^n [w_i^{(m-1)} \cdot x_i] + y_{m-1} = C^{(m-1)} \quad (6)$$

$$\begin{aligned} x &\in \mathbb{Z}_{\geq 0}^n \\ y &\in \mathbb{Z}_{\geq 0}^m \end{aligned}$$

**Claim**  $x \in (\text{USK1}) \Rightarrow x \in (\text{USKm})$

Let  $x$  be a solution to (UKS1). Then for all  $1 \leq \ell \leq m$ ,

$$\sum_{i=1}^n \sum_{k=0}^{\ell-1} \Delta^k w_i^{(k)} \cdot x_i \equiv \sum_{i=1}^n w_i \cdot x_i \equiv C \equiv \sum_{k=0}^{\ell-1} \Delta^k C^{(k)} \pmod{\Delta^\ell}.$$

This is because all  $\Delta^\ell w_i^{(\ell)}, \dots, \Delta^{m-1} w_i^{(m-1)}$  and  $\Delta^\ell C^{(\ell)}, \dots, \Delta^{m-1} C^{(m-1)}$  are multiples of  $\Delta^\ell$ . It follows that there exists an  $y_\ell \in \mathbb{Z}$  such that

$$\sum_{i=1}^n \sum_{k=0}^{\ell-1} [\Delta^k w_i^{(k)} \cdot x_i] - \Delta^\ell \cdot y_\ell = \sum_{k=0}^{\ell-1} \Delta^k C^{(k)}.$$

Furthermore,  $y_\ell$  is non-negative, because otherwise

$$\begin{aligned} \sum_{k=0}^{\ell-1} \Delta^k C^{(k)} &\leq \sum_{k=0}^{\ell-1} \Delta^k (\Delta - 1) < \Delta^{\ell-1} (\Delta - 1) \sum_{k=0}^{\infty} \Delta^{-k} \\ &= \Delta^{\ell-1} \frac{\Delta - 1}{1 - \frac{1}{\Delta}} = \Delta^\ell \leq -\Delta^\ell y_\ell \leq \sum_{i=1}^n \sum_{k=0}^{\ell-1} [\Delta^k w_i^{(k)} \cdot x_i] - \Delta^\ell y_\ell. \end{aligned}$$

We choose  $y_1, \dots, y_m$  exactly like this. The first constraint (3) follows directly. Now let  $\ell \in \{2, \dots, m\}$ . By choice of  $y_{\ell-1}$  and  $y_\ell$  we have that

$$\sum_{i=1}^n \left[ \underbrace{\left( \sum_{k=0}^{\ell-1} \Delta^k w_i^{(k)} - \sum_{k=0}^{\ell-2} \Delta^k w_i^{(k)} \right)}_{=\Delta^{\ell-1} w_i^{(\ell-1)}} \cdot x_i \right] + \Delta^{\ell-1} \cdot y_{\ell-1} - \Delta^\ell \cdot y_\ell = \underbrace{\sum_{k=0}^{\ell-1} \Delta^k C^{(k)} - \sum_{k=0}^{\ell-2} \Delta^k C^{(k)}}_{=\Delta^{\ell-1} C^{(\ell-1)}}. \quad (7)$$

## 43:12 On Integer Programming and Convolution

Dividing both sides by  $\Delta^{\ell-1}$  we get every constraint (4) - (5) for the correct choice of  $\ell$ . Finally, consider the special case of the last constraint (6). By choice of  $y_m$  we have that

$$\sum_{i=1}^n \underbrace{\sum_{k=0}^{m-1} \Delta^k w_i^{(k)}}_{=w_i} \cdot x_i - \Delta^m \cdot y_m = \underbrace{\sum_{k=0}^{m-1} \Delta^k C^{(k)}}_{=C}.$$

Thus,  $y_m = 0$  and (7) implies the last constraint (with  $\ell = m$ ).

**Claim**  $x \in (\text{USK}m) \Rightarrow x \in (\text{USK}1)$

Let  $x_1, \dots, x_n, y_1, \dots, y_{m-1}$  be a solution to (UKSm) and set  $y_m = 0$ . We show by induction that for all  $\ell \in \{1, \dots, m\}$

$$\sum_{i=1}^n \sum_{k=0}^{\ell-1} \Delta^k w_i^{(k)} \cdot x_i - \Delta^\ell y_\ell = \sum_{k=0}^{\ell-1} \Delta^k C^{(k)}.$$

With  $\ell = m$  this implies the claim as  $y_m = 0$  by definition. For  $\ell = 1$  the equation is exactly the first constraint (3). Now let  $\ell > 1$  and assume that the equation above holds. We will show that it also holds for  $\ell + 1$ . From (USK $m$ ) we have

$$\sum_{i=1}^n [w_i^{(\ell)} \cdot x_i] + y_\ell - \Delta \cdot y_{\ell+1} = C^{(\ell)}.$$

Multiplying each side by  $\Delta^\ell$  we get

$$\sum_{i=1}^n [\Delta^\ell w_i^{(\ell)} \cdot x_i] + \Delta^\ell y_\ell - \Delta^{\ell+1} \cdot y_{\ell+1} = \Delta^\ell C^{(\ell)}.$$

By adding and subtracting the same elements, it follows that

$$\sum_{i=1}^n \left[ \left( \sum_{k=0}^{\ell} \Delta^k w_i^{(k)} - \sum_{k=0}^{\ell-1} \Delta^k w_i^{(k)} \right) \cdot x_i \right] + \Delta^\ell \cdot y_\ell - \Delta^{\ell+1} \cdot y_{\ell+1} = \sum_{k=0}^{\ell} \Delta^k C^{(k)} - \sum_{k=0}^{\ell-1} \Delta^k C^{(k)}.$$

By inserting the induction hypothesis we conclude

$$\sum_{i=1}^n \sum_{k=0}^{\ell} [\Delta^k w_i^{(k)} \cdot x_i] - \Delta^{\ell+1} y_{\ell+1} = \sum_{k=0}^{\ell} \Delta^k C^{(k)}.$$

### Constructing and solving the ILP

The ILP (UKSm) can be constructed easily in  $O(Cm + nm) \leq O((n + C)^{2-\delta/m})$  operations (recall that  $m$  is a constant). We obtain  $\Delta = \lfloor C^{1/m} \rfloor + 1$  by guessing: More precisely, we iterate over all numbers  $\Delta_0 \leq C$  and find the one where  $(\Delta_0 - 1)^m < C \leq \Delta_0^m$ . There are of course more efficient, non-trivial ways to compute the rounded  $m$ -th root. The base- $\Delta$  representation for  $w_1, \dots, w_n$  and  $C$  can be computed with  $O(m)$  operations for each of these numbers.

All entries of the matrix in (UKSm) and the right-hand side are bounded by  $\Delta = O(C^{1/m})$ . Therefore, by assumption this ILP can be solved in time

$$f(m) \cdot (n^{2-\delta} + O(C^{1/m})^{2m-\delta}) \leq f(m) \cdot O(1)^{2m-\delta} \cdot (n + C)^{2-\delta/m} = O((n + C)^{2-\delta/m})$$

This would therefore yield a truly sub-quadratic algorithm for the UNBOUNDED KNAPSACK PROBLEM.  $\blacktriangleleft$

## 5.2 Feasibility problem

We will show that our algorithm for solving feasibility of ILPs is optimal (except for log factors). We use a recently discovered lower bound for k-SUM based on the SETH.

k-SUM

**Input:**  $T \in \mathbb{N}_0$  and  $Z_1, \dots, Z_k \subset \mathbb{N}_0$  where  $|Z_1| + |Z_2| + \dots + |Z_k| = n \in \mathbb{N}$ .

**Output:**  $z_1 \in Z_1, z_2 \in Z_2, \dots, z_k \in Z_k$  such that  $z_1 + z_2 + \dots + z_k = T$ .

► **Theorem 10** ([1]). *If the SETH holds, then for every  $\delta > 0$  there exists a value  $\gamma > 0$  such that k-SUM cannot be solved in time  $O(T^{1-\delta} \cdot n^{\gamma k})$ .*

This implies that for every  $p \in \mathbb{N}$  there is no  $O(T^{1-\delta} \cdot n^p)$  time algorithm for k-SUM if  $k \geq p/\gamma$ .

► **Theorem 11.** *If the SETH holds, for every fixed  $m$  there does not exist an algorithm that solves feasibility of ILPs with  $m$  constraints in time  $n^{f(m)} \cdot (\Delta + \|b\|_\infty)^{m-\delta}$ .*

**Proof.** Like in the previous reduction we start with the case of  $m = 1$ . For higher values of  $m$  the result can be shown in the same way as before.

Suppose there exists an algorithm for solving feasibility of ILPs with one constraint in time  $n^{f(1)} \cdot (\Delta + \|b\|_\infty)^{1-\delta}$  for some  $\delta > 0$  and  $f(1) \in \mathbb{N}$ . Set  $k = \lceil f(1)/\gamma \rceil$  with  $\gamma$  as in in Theorem 10 and consider an instance  $(T, Z_1, \dots, Z_k)$  of k-SUM. We will show that this can be solved in time  $O(T^{1-\delta} \cdot n^{f(1)})$ , which contradicts the SETH. For every  $i \leq k$  and every  $z \in Z_i$  we use a binary variable  $x_{i,z}$  that describes whether  $z$  is used. We can easily model k-SUM as the following ILP:

$$\begin{aligned} \sum_{i=1}^k \sum_{z \in Z_i} z \cdot x_{i,z} &= T \\ \sum_{z \in Z_i} x_{i,z} &= 1 && \forall i \in \{1, \dots, k\} \\ x_{i,z} &\in \mathbb{Z}_{\geq 0} && \forall i \in \{1, \dots, k\}, z \in Z_i \end{aligned}$$

However, since we want to reduce to an ILP with one constraint, we need a slightly more sophisticated construction. We will show that the cardinality constraints can be encoded into the k-SUM instance by increasing the numbers by a factor of  $2^{O(k)}$ , which is in  $O(1)$  since  $k$  is some constant depending on  $f(1)$  and  $\gamma$  only. We will use this to obtain an ILP with only one constraint and values of size at most  $O(T)$ . A similar construction is also used in [1].

Our goal is to construct an instance  $(T', Z'_1, \dots, Z'_k)$  such that for every  $x^*$  it holds that  $x^*$  is a solution to the first ILP if and only if  $x^* \in \{x : \sum_{i=1}^k \sum_{z \in Z'_i} z \cdot x_{i,z} = T', x \in \mathbb{Z}_{\geq 0}^n\}$  (\*). We will use one element to represent each element in the original instance. Consider the binary representation of numbers in  $Z'_1 \cup \dots \cup Z'_k$  and of  $T'$ . The numbers in the new instance will consist of three parts and  $\lceil \log(k) \rceil$  many 0s between them to prevent interference. For an illustration of the construction see Figure 2. The  $\lceil \log(k) \rceil$  most significant bits ensure that exactly  $k$  elements are selected; the middle part are  $k$  bits that ensure of every set  $Z'_i$  exactly one element is selected; the least significant  $\lceil \log(T) \rceil$  bits represent the original values of the elements. Set the values in the first part of the numbers to 1 for all elements  $Z'_1 \cup \dots \cup Z'_k$  and to  $k$  in  $T'$ . Clearly this ensures that at most  $k$  elements are chosen. The sum of at most  $k$  elements cannot be larger than  $k \leq 2^{\lceil \log(k) \rceil}$  times the biggest element. This implies that the buffers of  $\lceil \log(k) \rceil$  zeroes cannot overflow and we can consider each of the three parts independently. It follows that exactly  $k$  elements must be chosen by any

$$\begin{aligned}
 Z'_i \ni z' &= \overbrace{0 \dots 0001}^{\text{bin}(1)} \mid \overbrace{0 \dots 0}^{\lceil \log(k) \rceil} \mid \overbrace{0 \dots 010 \dots 0}^{\text{bin}(2^i)} \mid \overbrace{0 \dots 0}^{\lceil \log(k) \rceil} \mid \overbrace{0110 \dots}^{\text{bin}(z)} \\
 T' &= \overbrace{0 \dots 1011}^{\text{bin}(k)} \mid \overbrace{0 \dots 0}^{\lceil \log(k) \rceil} \mid \overbrace{1111 \dots 1111}^{\text{bin}(2^{k+1}-1)} \mid \overbrace{0 \dots 0}^{\lceil \log(k) \rceil} \mid \overbrace{1011 \dots}^{\text{bin}(T)}
 \end{aligned}$$

■ **Figure 2** Construction of  $Z'_i$  and  $T'$ .

feasible solution. The system  $\{x : \sum_{i=1}^k 2^i x_i = 2^{k+1} - 1, \|x\|_1 = k, \mathbb{Z}_{\geq 0}^k\}$  has exactly one solution and this solution is  $(1, 1, \dots, 1)$ : Consider summing up  $k$  powers of 2 and envision the binary representation of the partial sums. When we add some  $2^i$  to the partial sum, the number of ones in the binary representation increases by one, if the  $i$ 'th bit of the current sum is zero. Otherwise, it does not increase. However, since in the binary representation of the final sum there are  $k$  ones, it has to increase in each addition. This means no power of two can be added twice and therefore each has to be added exactly once.

It follows that the second part of the numbers enforces that of every  $Z'_i$  exactly one element is chosen. We conclude that  $(*)$  solves the initial  $k$ -SUM instance. By assumption this can be done in time  $n^{f(1)} \cdot (\Delta + \|b\|_\infty)^{1-\delta} = n^{f(1)} \cdot O(T')^{1-\delta} = O(n^{f(1)} \cdot T^{1-\delta})$ . Here we use that  $T' \leq 2^{3 \log(k) + k + \log(T) + 4} = O(k^3 2^k T) = O(T)$ , since  $k$  is a constant.

For  $m > 1$  we can use the same construction as in the reduction for the optimization problem: Suppose there is an algorithm that finds feasible solutions to ILPs with  $m$  constraints in time  $n^{f(m)} \cdot (\Delta + \|b\|_\infty)^{m-\delta}$ . Choose  $\gamma$  such that there is no algorithm for  $k$ -SUM with running time  $O(T^{1-\delta/m} \cdot n^{\gamma k})$  (under SETH). We set  $k = \lceil f(m)/\gamma \rceil$ . By splitting the one constraint of  $(*)$  into  $m$  constraints we can reduce the upper bound on elements from  $O(T)$  to  $O(T^{1/m})$ . This means the assumed running time for solving ILPs can be used to solve  $k$ -SUM in time

$$n^{f(m)} \cdot O(T^{1/m})^{m-\delta} \leq n^{\gamma k} \cdot O(1)^{m-\delta} \cdot T^{1-\delta/m} = O(n^{\gamma k} \cdot T^{1-\delta/m}). \quad \blacktriangleleft$$

## 6 Applications

We describe the implications of our results on a couple of well-known problems, which can be formulated using ILPs with few constraints and small entries. In particular, we give an example, where the reduction of the running time by a factor  $n$  improves on the state-of-the-art and one where the logarithmic dependence on  $\|b\|_\infty$  proves useful.

### 6.1 Unbounded Knapsack and Unbounded Subset-Sum

UNBOUNDED KNAPSACK with equality constraint is simply an ILP with  $m = 1$  and positive entries and objective function:

$$\max \left\{ \sum_{i=1}^n p_i \cdot x_i : \sum_{i=1}^n w_i \cdot x_i = C, x \in \mathbb{Z}_{\geq 0}^n \right\}$$

where  $p_i \geq 0$  are called the profits and  $w_i \geq 0$  the weights of the items  $1, \dots, n$ . More common is to let  $C$  be only an upper bound on  $\sum_{i=1}^n w_i \cdot x_i$ , but that variant easily reduces to the problem above by adding a slack variable. UNBOUNDED SUBSET-SUM is the same problem

without an objective function, i.e., the problem of finding a multiset of items whose weights sum up to exactly  $C$ . We assume that no two items have the same weight. Otherwise in time  $O(n + \Delta)$  we can remove all duplicates by keeping only the most valuable ones. The fractional solutions to both problems are of a very simple structure: For UNBOUNDED KNAPSACK choose only the item  $i$  of maximal efficiency, that is  $p_i/w_i$ , and select it  $C/w_i$  times. For UNBOUNDED SUBSET-SUM choose an arbitrary item. This gives algorithms with running time  $O(\Delta^2)$  and  $O(\Delta \log^2(\Delta))$  for UNBOUNDED KNAPSACK and UNBOUNDED SUBSET-SUM, respectively, where  $\Delta$  is the maximum weight among all items (using the results from Section 4.2). The previously best pseudo-polynomial algorithms for UNBOUNDED KNAPSACK, have running times  $O(nC)$  (standard dynamic programming; see e.g. [13]),  $O(n\Delta^2)$  [8], or very recently  $O(\Delta^2 \log(C))$  [2]. We note that the algorithm from the last paper, which was discovered independently and concurrently to our results, also uses (min, +)-convolution. It could probably be improved to the same running time as our general algorithm using the proximity ideas. For UNBOUNDED SUBSET-SUM the state-of-the-art algorithm has a running time  $O(C \log(C))$  [5]. Hence, our algorithm is preferable when  $\Delta \ll C$ .

## 6.2 Scheduling on Identical Machines

The problem SCHEDULING ON IDENTICAL MACHINES asks for the distribution of  $N$  jobs onto  $M \leq N$  machines. Each job  $j$  has a processing time  $p_j$  and the objective is to minimize the makespan, i.e., the maximum sum of processing times on a single machine. Since an exact solution cannot be computed unless  $P = NP$ , we are satisfied with a  $(1 + \epsilon)$ -approximation, where  $\epsilon > 0$  is part of the input. We will outline how this problem can be solved using our algorithm. More details on many of the techniques involved can be found in [10].

We consider here the variant, in which a makespan  $\tau$  is given and we have to find a schedule with makespan at most  $(1 + \epsilon)\tau$  or prove that there exists no schedule with makespan at most  $\tau$ . This suffices by using a standard dual approximation framework. It is easy to see that one can discard all jobs of size at most  $\epsilon \cdot \tau$  and add them greedily after a solution for the other jobs is found. The big jobs can each be rounded to the next value of the form  $\epsilon \cdot \tau \cdot (1 + \epsilon)^i$  for some  $i$ . This reduces the number of different processing times to  $O(1/\epsilon \log(1/\epsilon))$  many and increases the makespan by at most a factor of  $1 + \epsilon$ . We are now ready to write this problem as an ILP. A configuration is a way to use a machine. It describes how many jobs of each size are assigned to this machine. Since we aim for a makespan of  $(1 + \epsilon) \cdot \tau$ , the sum of these sizes must not exceed this value. The configuration ILP has a variable for every valid configuration and it describes how many machines use this configuration. Let  $\mathcal{C}$  be the set of valid configurations and  $C_k$  the multiplicity of size  $k$  in a configuration  $C \in \mathcal{C}$ . The following ILP solves the rounded instance. We note that there is no objective function in it.

$$\begin{aligned} \sum_{C \in \mathcal{C}} x_C &= M \\ \sum_{C \in \mathcal{C}} C_k \cdot x_C &= N_k & \forall k \in \mathcal{K} \\ x_C &\in \mathbb{Z}_{\geq 0} & \forall C \in \mathcal{C} \end{aligned}$$

Here  $\mathcal{K}$  are the rounded sizes and  $N_k$  the number of jobs with rounded size  $k \in \mathcal{K}$ . The first constraint enforces that the correct number of machines is used, the next  $|\mathcal{K}|$  many enforce that for each size the correct number of jobs is scheduled.

It is notable that this ILP has only few constraints (a constant for a fixed choice of  $\epsilon$ ) and also the entries of the matrix are small. More precisely, they are at most  $1/\epsilon$ , since every size is at least  $\epsilon \cdot \tau$  and therefore no more than  $1/\epsilon$  jobs fit in one configuration. The ILP

can be solved with our algorithm. Note that  $\Delta \leq 1/\epsilon$ ,  $m = O(1/\epsilon \log(1/\epsilon))$ ,  $\|b\|_\infty \leq N$ , and  $n \leq (1/\epsilon)^{O(1/\epsilon \log(1/\epsilon))}$ . Including the rounding in time  $O(N + 1/\epsilon \log(1/\epsilon))$  the running time for the ILP is

$$\begin{aligned} O(m\Delta)^m \cdot \log(\Delta) \cdot \log(\Delta + \|b\|_\infty) + O(nm) + O(N + 1/\epsilon \log(1/\epsilon)) \\ \leq 2^{O(1/\epsilon \log^2(1/\epsilon))} \log(N) + O(N + 1/\epsilon \log(1/\epsilon)) \leq 2^{O(1/\epsilon \log^2(1/\epsilon))} + O(N). \end{aligned}$$

The trick in the bound above is to distinguish between the cases  $2^{O(1/\epsilon \log^2(1/\epsilon))} \leq \log(N)$  and  $2^{O(1/\epsilon \log^2(1/\epsilon))} > \log(N)$ . The same running time (except for a higher constant in the exponent) could be obtained with [8]. However, in order to avoid a multiplicative factor of  $N$ , one would have to solve the LP relaxation first and then use proximity. Our approach gives an easier, purely combinatorial algorithm. The crucial feature of our algorithm is the lower dependence on  $\|b\|_\infty$ .

## Abstract

Integer linear programs of configurations, or configuration IPs, are a classical tool in the design of algorithms for scheduling and packing problems, where a set of items has to be placed in multiple target locations. Herein a configuration describes a possible placement on one of the target locations, and the IP is used to choose suitable configurations covering the items. We give an augmented IP formulation, which we call the module configuration IP. It can be described within the framework of  $n$ -fold integer programming and therefore be solved efficiently. As an application, we consider scheduling problems with setup times, in which a set of jobs has to be scheduled on a set of identical machines, with the objective of minimizing the makespan. For instance, we investigate the case that jobs can be split and scheduled on multiple machines. However, before a part of a job can be processed an uninterrupted setup depending on the job has to be paid. For both of the variants that jobs can be executed in parallel or not, we obtain an efficient polynomial time approximation scheme (EPTAS) of running time  $f(1/\varepsilon) \times \text{poly}(|I|)$  with a single exponential term in  $f$  for the first and a double exponential one for the second case. Previously, only constant factor approximations of  $5/3$  and  $4/3 + \varepsilon$  respectively were known. Furthermore, we present an EPTAS for a problem where classes of (non-splittable) jobs are given, and a setup has to be paid for each class of jobs being executed on one machine.

## 1 Introduction

In this paper, we present an augmented formulation of the classical integer linear program of configurations (configuration IP) and demonstrate its use in the design of efficient polynomial time approximation schemes for scheduling problems with setup times. Configuration IPs are widely used in the context of scheduling or packing problems, in which items have to be distributed to multiple target locations. The configurations describe possible placements on a single location, and the integer linear program (IP) is used to choose a proper selection covering all items. Two fundamental problems, for which configuration IPs have prominently been used, are bin packing and minimum makespan scheduling on identical parallel machines, or machine scheduling for short. For bin packing, the configuration IP was introduced as early as 1961 by Gilmore and Gomory [10], and the recent results for both problems typically use configuration IPs as a core technique, see, e.g., [11, 15]. In the present work, we consider scheduling problems and therefore introduce the configuration IP in more detail using the example of machine scheduling.

**Configuration IP for Machine Scheduling.** In the problem of machine scheduling, a set  $\mathcal{J}$  of  $n$  jobs is given together with processing times  $p_j$  for each job  $j$  and a number  $m$  of identical machines. The objective is to find a schedule  $\sigma : \mathcal{J} \rightarrow [m]$ , such that the makespan is minimized, that is, the latest finishing time of any job  $C_{\max}(\sigma) = \max_{i \in [m]} \sum_{j \in \sigma^{-1}(i)} p_j$ . For a given makespan bound, the configurations may be defined as multiplicity vectors indexed by the occurring processing times, where the overall length of the chosen processing times does not violate the bound. The configuration IP is then given by variables  $x_C$  for each configuration  $C$ ; constraints ensuring that there is a machine for each configuration, i.e.,  $\sum_C x_C = m$ ; and further constraints due to which the jobs are covered, i.e.,  $\sum_C C_p x_C = |\{j \in \mathcal{J} \mid p_j = p\}|$  for each processing time  $p$ . In combination with certain simplification techniques, this type of IP is often used in the design of *polynomial time approximation schemes* (PTAS). A PTAS is a procedure that, for any fixed accuracy parameter  $\varepsilon > 0$ , returns a solution with approximation guarantee  $(1 + \varepsilon)$  that is, a solution, whose objective value lies within a factor of  $(1 + \varepsilon)$  of the optimum. In the context of machine scheduling, the aforementioned simplification techniques can be used to guess the target makespan  $T$  of the given instance; to upper bound the cardinality of the set of processing times  $P$  by a constant (depending in  $1/\varepsilon$ ); and to lower bound the processing times in size, such that they are within a constant factor of the makespan  $T$  (see, e.g., [3, 15]). Hence, only a constant number of configurations is needed, yielding an integer program with a constant number of variables. Integer programs of that kind can be efficiently solved using the classical algorithm by Lenstra and Kannan [21, 17], yielding a PTAS for machine scheduling. Here, the error of  $(1 + \varepsilon)$  in the quality of the solution is due to the simplification steps, and the scheme has a running time of the form  $f(1/\varepsilon) \times \text{poly}(|I|)$ , where  $|I|$  denotes the input size, and  $f$  some computable function. A PTAS with this property is called *efficient* (EPTAS). Note that for a regular PTAS a running time of the form  $|I|^{f(1/\varepsilon)}$  is allowed. It is well known, that machine scheduling is strongly NP-hard, and therefore there is no optimal polynomial time algorithm, unless  $P=NP$ , and also a so-called *fully polynomial* PTAS (FPTAS) – which is an EPTAS with a polynomial function  $f$  – cannot be hoped for.

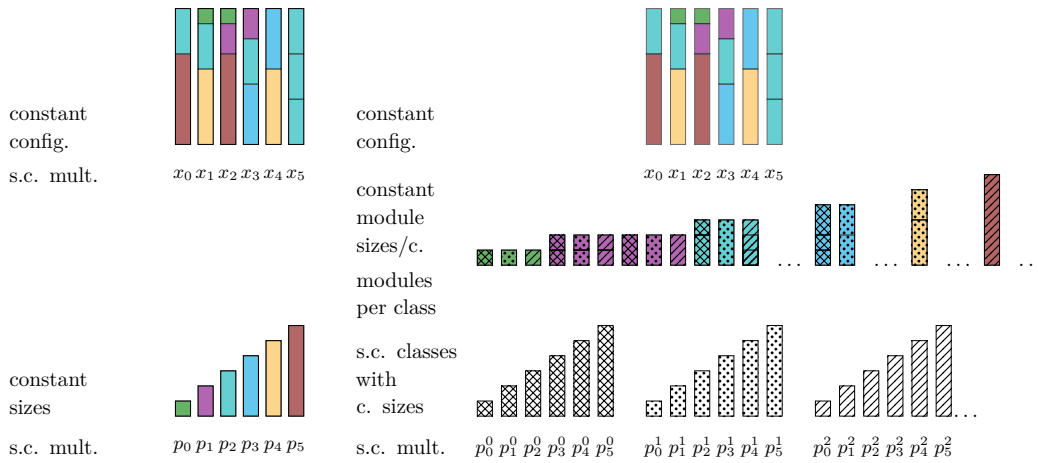

**Machine Scheduling with Classes.** The configuration IP is used in a wide variety of approximation schemes for machine scheduling problems [3, 15]. However, the approach often ceases to work for scheduling problems in which the jobs have to fulfill some additional

requirements, like, for instance, class dependencies. A problem emerging, in this case, is that the additional requirements have to be represented in the configurations, resulting in a super-constant number of variables in the IP. We elaborate on this using a concrete example: Consider the variant of machine scheduling in which the jobs are partitioned into  $K$  setup classes. For each job  $j$  a class  $k_j$  is given and for each class  $k$  a setup time  $s_k$  has to be paid on a machine, if a job belonging to that class is scheduled on it, i.e.,  $C_{\max}(\sigma) = \max_{i \in [m]} \left( \sum_{j \in \sigma^{-1}(i)} p_j + \sum_{k \in \{k_j \mid j \in \sigma^{-1}(i)\}} s_k \right)$ . With some effort, simplification steps similar to the ones for machine scheduling can be applied. In the course of this, the setup times as well can be bounded in number and guaranteed to be sufficiently big [16]. However, it is not hard to see that the configuration IP still cannot be trivially extended, while preserving its solvability. For instance, extending the configurations with multiplicities of setup times will not work, because then we have to make sure that a configuration is used for a fitting subset of classes, creating the need to encode class information into the configurations or introduce other class dependent variables.

**Module Configuration IP.** Our approach to deal with the class dependencies of the jobs is to cover the job classes with so-called modules and cover the modules in turn with configurations in an augmented IP called the module configuration IP (MCIP). In the setup class model, for instance, the modules may be defined as combinations of setup times and configurations of processing times, and the actual configurations as multiplicity vectors of module sizes. The number of both the modules and the configurations will typically be bounded by a constant. To cover the classes by modules each class is provided with its own set of modules, that is, there are variables for each pair of class and module. Since the number of classes is part of the input, the number of variables in the resulting MCIP is super-constant, and therefore the algorithm by Lenstra and Kannan [21, 17] is not the proper tool for the solving of the MCIP. However, the MCIP has a certain simple structure: The mentioned variables are partitioned into uniform classes each corresponding to the set of modules, and for each class, the modules have to do essentially the same – cover the jobs of the class. Utilizing these properties, we can formulate the MCIP in the framework of  $n$ -fold integer programs – a class of IPs whose variables and constraints fulfill certain uniformity requirements. In 2013 Hemmecke, Onn, and Romanchuk [12] showed that  $n$ -fold IPs can be efficiently solved, and very recently both Eisenbrand, Hunkenschroder and Klein [9] and independently Koucký, Levin and Onn [20] developed algorithms with greatly improved running times for the problem. For a detailed description of the MCIP, the reader is referred to Section 3. In Figure 1 the basic idea of the MCIP is visualized.

Using the MCIP, we are able to formulate an EPTAS for machine scheduling in the setup class model described above. Before, only a regular PTAS with running time  $nm^{\mathcal{O}(1/\varepsilon^5)}$  was known [16]. To the best of our knowledge, this is the first use of  $n$ -fold integer programming in the context of approximation algorithms.

**Results and Methodology.** To show the conceptual power of the MCIP, we utilize it for two more problems: The *splittable* and the *preemptive* setup model of machine scheduling. In both variants for each job  $j$ , a setup time  $s_j$  is given. Each job may be partitioned into multiple parts that can be assigned to different machines, but before any part of the job can be processed the setup time has to be paid. In the splittable model, job parts belonging to the same job can be processed in parallel, and therefore beside the partition of the jobs, it suffices to find an assignment of the job parts to machines. This is not the case for the preemptive model, in which additionally a starting time for each job part has to be found, and two

■ **Figure 1** On the left, there is a schematic representation of the configuration IP. There are constant different sizes each occurring a super-constant number of times. The sizes are directly mapped to configurations. On the right, there is a schematic representation of the MCIP. There is a super-constant number of classes, each containing a constant number of sizes which have super-constant multiplicities. The elements from the class are mapped to a constant number of different modules, which have a constant number of sizes. These module sizes are mapped to configurations.

parts of the same job may not be processed in parallel. In 1999 Schuurman and Woeginger [26] presented a polynomial time algorithm for the preemptive model with approximation guarantee  $4/3 + \epsilon$ , and for the splittable case a guarantee of  $5/3$  was achieved by Chen, Ye and Zhang [5]. These are the best known approximation guarantees for the problems at hand. We show that solutions arbitrarily close to the optimum can be found in polynomial time:

► **Theorem 1.** *There is an efficient PTAS with running time  $2^{f(1/\epsilon)} \text{poly}(|I|)$  for minimum makespan scheduling on identical parallel machines in the setup-class model, as well as in the preemptive and splittable setup models.*

More precisely, we get a running time of  $2^{\mathcal{O}(1/\epsilon^3 \log^4 1/\epsilon)} K^2 nm \log(Km)$  in the setup class model,  $2^{\mathcal{O}(1/\epsilon^2 \log^3 1/\epsilon)} n^2 \log^3(nm)$  in the splittable, and  $2^{2^{\mathcal{O}(1/\epsilon \log 1/\epsilon)}} n^2 m \log m \log(nm)$  in the preemptive model (remember that  $n$ ,  $m$ , and  $K$  denote the number of jobs, machines, and setup classes). Note that all three problems are strongly NP-hard, due to trivial reductions from machine scheduling, and our results are therefore in some sense best possible.

Summing up, the main achievement of this work is the development of the module configuration IP and its application in the development of approximation schemes. Up to now, EPTAS or even PTAS results seemed out of reach for the considered problems, and for the preemptive model we provide the first improvement in 20 years. The simplification techniques developed for the splittable and preemptive model in order to employ the MCIP are original and in the latter case quite elaborate, and therefore interesting by themselves. Furthermore, we expect the MCIP to be applicable to other packing and scheduling problems as well, in particular for variants of machine scheduling and bin packing with additional class depended constraints. On a more conceptual level, we gave a first demonstration of the potential of  $n$ -fold integer programming in the theory of approximation algorithms, and hope to inspire further studies in this direction.

We conclude this paragraph with a more detailed overview of our results and their presentation. For all three EPTAS results we employ the classical dual approximation framework by Hochbaum and Shmoys [13] to get a guess of the makespan  $T$ . This approach is

introduced in Section 2 together with  $n$ -fold IPs and formal definitions of the problems. In the following section, we develop the module configuration IP, in its basic form and argue that it is indeed an  $n$ -fold IP. The EPTAS results described in the last section follow the same basic approach described above for machine scheduling: We find a schedule for a simplified instance via the MCIP and transform it into a schedule for the original one. The simplification steps typically include rounding of the processing and setup times using standard techniques, as well as, the removal of certain jobs, which later can be reinserted via carefully selected greedy procedures. For the splittable and preemptive model, we additionally have to prove that schedules with a certain simple structure exist, and in the preemptive model, the MCIP has to be extended. Missing proofs and details can be found in the long version of the paper [14].

**Related work.** For an overview on  $n$ -fold IPs and their applications, we refer to the book by Onn [24]. There have been recent applications of  $n$ -fold integer programming to scheduling problems in the context of parameterized algorithms: Knop and Koutecký [18] showed, among other things, that the problem of makespan minimization on unrelated parallel machines, where the processing times are dependent on both jobs and machines, is fixed-parameter tractable with respect to the maximum processing time and the number of distinct machine types. This was generalized to the parameters maximum processing time and rank of the processing time matrix by Chen et al. [6]. Furthermore, Knop, Koutecký and Mnich [19] provided an improved algorithm for a special type of  $n$ -fold IPs yielding improved running times for several applications of  $n$ -fold IPs including results for scheduling problems.

There is extensive literature concerning scheduling problems with setup times. We highlight a few closely related results and otherwise refer to the surveys [1, 2]. In the following, we use the term  $\alpha$ -approximation as an abbreviation for polynomial time algorithms with approximation guarantee  $\alpha$ . The setup class model was first considered by Mäcker et al. [22] in the special case that all classes have the same setup time. They designed a 2-approximation and additionally a  $3/2 + \varepsilon$ -approximation for the case that the overall length of the jobs from each class is bounded. Jansen and Land [16] presented a simple 3-approximation with linear running time, a  $2 + \varepsilon$ -approximation, and the aforementioned PTAS for the general setup class model. As indicated before, Chen et al. [5] developed a  $5/3$ -approximation for the splittable model. A generalization of this, in which both setup and processing times are job and machine dependent, has been considered by Correa et al. [7]. They achieve a  $(1 + \phi)$ -approximation, where  $\phi$  denotes the golden ratio, using a newly designed linear programming formulation. Moreover, there are recent results concerning machine scheduling in the splittable model considering the sum of the (weighted) completion times as the objective function, e.g. [25, 8]. For the preemptive model, a PTAS for the special case that all jobs have the same setup time has been developed by Schuurman and Woeginger [26]. The mentioned  $(4/3 + \varepsilon)$ -approximation for the general case [26] follows the same approach. Furthermore, a combination of the setup class and the preemptive model has been considered, in which the jobs are scheduled preemptively, but the setup times are class dependent. Monma and Potts [23] presented, among other things, a  $(2 - 1/(\lfloor m/2 \rfloor + 1))$ -approximation for this model, and later Chen [4] achieved improvements for some special cases.

## 2 Preliminaries

In the following, we establish some concepts and notations, formally define the considered problems, and outline the dual approximation approach by Hochbaum and Shmoys [13], as well as  $n$ -fold integer programs.

For any integer  $n$ , we denote the set  $\{1, \dots, n\}$  by  $[n]$ ; we write  $\log(\cdot)$  for the logarithm with basis 2; and we will usually assume that some instance  $I$  of the problem considered in the respective context is given together with an accuracy parameter  $\varepsilon \in (0, 1)$  such that  $1/\varepsilon$  is an integer. Furthermore for any two sets  $X, Y$  we write  $Y^X$  for the set of functions  $f : X \rightarrow Y$ . If  $X$  is finite, we say that  $Y$  is indexed by  $X$  and sometimes denote the function value of  $f$  for the argument  $x \in X$  by  $f_x$ .

**Problems.** For all three of the considered models, a set  $\mathcal{J}$  of  $n$  jobs with processing times  $p_j \in \mathbb{Q}_{>0}$  for each job  $j \in \mathcal{J}$  and a number of machines  $m$  is given. In the preemptive and the splittable model, the input additionally includes a setup time  $s_j \in \mathbb{Q}_{>0}$  for each job  $j \in \mathcal{J}$ ; while in the setup class model, it includes a number  $K$  of setup classes, a setup class  $k_j \in [K]$  for each job  $j \in \mathcal{J}$ , as well as setup times  $s_k \in \mathbb{Q}_{>0}$  for each  $k \in [K]$ .

We take a closer look at the definition of a schedule in the preemptive model. The jobs may be split. Therefore, partition sizes  $\kappa : \mathcal{J} \rightarrow \mathbb{Z}_{>0}$ , together with processing time fractions  $\lambda_j : [\kappa(j)] \rightarrow (0, 1]$ , such that  $\sum_{k \in [\kappa(j)]} \lambda_j(k) = 1$ , have to be found, meaning that job  $j$  is split into  $\kappa(j)$  many parts and the  $k$ -th part for  $k \in [\kappa(j)]$  has processing time  $\lambda_j(k)p_j$ . This given, we define  $\mathcal{J}' = \{(j, k) \mid j \in \mathcal{J}, k \in [\kappa(j)]\}$  to be the set of job parts. Now, an assignment  $\sigma : \mathcal{J}' \rightarrow [m]$  along with starting times  $\xi : \mathcal{J}' \rightarrow \mathbb{Q}_{>0}$  has to be determined, such that any two job parts assigned to the same machine or belonging to the same job do not overlap. More precisely, we have to assure that for each two job parts  $(j, k), (j', k') \in \mathcal{J}'$  with  $\sigma(j, k) = \sigma(j', k')$  or  $j = j'$ , we have  $\xi(j, k) + s_j + \lambda_j(k)p_j \leq \xi(j')$  or  $\xi(j', k') + s_{j'} + \lambda_{j'}(k')p_{j'} \leq \xi(j)$ . A schedule is given by  $(\kappa, \lambda, \sigma, \xi)$  and the makespan can be defined as  $C_{\max} = \max_{(j,k) \in \mathcal{J}'} (\xi(j, k) + s_j + \lambda_j(k)p_j)$ . Note that the variant of the problem in which overlap between a job part and setup of the same job is allowed is equivalent to the one presented above. This was pointed out by Schuurmann and Woeginger [26] and can be seen with a simple swapping argument.

In the splittable model, it is not necessary to determine starting times for the job parts, because, given the assignment  $\sigma$ , the job parts assigned to each machine can be scheduled as soon as possible in arbitrary order without gaps. Hence, in this case, the output is of the form  $(\kappa, \lambda, \sigma)$  and the makespan can be defined as  $C_{\max} = \max_{i \in [m]} \sum_{(j,k) \in \sigma^{-1}(i)} s_j + \lambda_j(k)p_j$ .

Lastly, in the setup class model the jobs are not split and given an assignment, the jobs assigned to each machine can be scheduled in batches comprised of the jobs of the same class assigned to the machine without overlaps and gaps. The output is therefore just an assignment  $\sigma : \mathcal{J} \rightarrow [m]$  and the makespan is given by  $C_{\max} = \max_{i \in [m]} \sum_{j \in \sigma^{-1}(i)} p_j + \sum_{k \in \{k_j \mid j \in \sigma^{-1}(i)\}} s_k$ .

Note that in the preemptive and the setup class model, we can assume that the number of machines is bounded by the number of jobs: If there are more machines than jobs, placing each job on a private machine yields an optimal schedule in both models and the remaining machines can be ignored. This, however, is not the case in the splittable model.

**Dual Approximation.** All of the presented algorithms follow the dual approximation framework introduced by Hochbaum and Shmoys [13]: Instead of solving the minimization version of a problem directly, it suffices to find a procedure that for a given bound  $T$  on the objective value either correctly reports that there is no solution with value  $T$  or returns a solution with value at most  $(1 + a\varepsilon)T$  for some constant  $a$ . If we have some initial upper bound  $B$  for the optimal makespan  $\text{OPT}$  with  $B \leq b\text{OPT}$  for some  $b$ , we can define a PTAS by trying different values  $T$  from the interval  $[B/b, B]$  in a binary search fashion, and find a value  $T^* \leq (1 + \mathcal{O}(\varepsilon))\text{OPT}$  after  $\mathcal{O}(\log b/\varepsilon)$  iterations. Note that for all of the considered problems

there are known simple approximation algorithms. Hence, we always assume that a target makespan  $T$  is given. Furthermore, we assume that the setup times and in the preemptive and setup class cases also the processing times are bounded by  $T$ , because otherwise we can reject  $T$  immediately.

**$n$ -fold Integer Programs.** We briefly define  $n$ -fold integer programs (IP) following the notation of [12] and [18] and state the main algorithmic result needed in the following. Let  $n, r, s, t \in \mathbb{Z}_{>0}$  be integers and  $A$  be an integer  $((r + ns) \times nt)$ -matrix of the following form:

$$A = \begin{pmatrix} A_1 & A_1 & \cdots & A_1 \\ A_2 & 0 & \cdots & 0 \\ 0 & A_2 & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & A_2 \end{pmatrix}$$

The matrix  $A$  is the so-called  $n$ -fold product of the bimatrix  $\begin{pmatrix} A_1 \\ A_2 \end{pmatrix}$ , with  $A_1$  an  $r \times t$  and  $A_2$  an  $s \times t$  matrix. Furthermore, let  $w, \ell, u \in \mathbb{Z}^{nt}$  and  $b \in \mathbb{Z}^{r+ns}$ . Then the  $n$ -fold integer programming problem is given by:

$$\min\{wx \mid Ax = b, \ell \leq x \leq u, x \in \mathbb{Z}^{nt}\}$$

The variables  $x$  can naturally be partitioned into *bricks*  $x^{(a)}$  of dimension  $t$  for each  $q \in [n]$ , such that  $x = (x^{(1)}, \dots, x^{(n)})$ . Furthermore, we denote the constraints corresponding to  $A_1$  as *globally uniform* and the ones corresponding to  $A_2$  as *locally uniform*. Hence,  $r$  is the number of globally and  $s$  the number of locally uniform constraints (ignoring their  $n$ -fold duplication);  $t$  the *brick size* and  $n$  the *brick number*. We set  $\Delta$  to be the maximum absolute value occurring in  $A$ . Up to recently the best known algorithm for solving  $n$ -fold IPs was due to Hemmecke, Onn and Romanchuk [12]:

► **Theorem 2.** *Let  $\varphi$  be the encoding length of  $w, b, \ell, u$  and  $\Delta$ . The  $n$ -fold integer programming problem can be solved in time  $\mathcal{O}(\Delta^{3t(rs+st+r+s)}n^3\varphi)$ , when  $r, s$  and  $t$  are fixed.*

However, in 2018 both Eisenbrand, Hunkenschröder and Klein [20] and independently Koutecký, Levin and Onn [20] developed algorithms with improved and very similar running times. We state a variant due to Eisenbrand et al. that is adapted to our needs:

► **Theorem 3.** *Let  $\varphi$  be the encoding length of the largest number occurring in the input, and  $\Phi = \max_i(u_i - \ell_i)$ . The  $n$ -fold integer programming problem can be solved in time  $(rs\Delta)^{\mathcal{O}(r^2s+rs^2)}t^2n^2\varphi \log(\Phi) \log(nt\Phi)$ .*

### 3 Module Configuration IP

In this section, we state the configuration IP for machine scheduling and introduce a basic version of the module configuration IP (MCIP) that is already sufficiently general to work for both the splittable and setup class model. Before that, however, we formally introduce the concept of *configurations*. Given a set of objects  $A$ , a configuration  $C$  of these objects is a vector of multiplicities indexed by the objects, i.e.,  $C \in \mathbb{Z}_{\geq 0}^A$ . For given sizes  $\Lambda(a)$  of the objects  $a \in A$ , the size  $\Lambda(C)$  of a configuration  $C$  is defined as  $\sum_{a \in A} C_a \Lambda(a)$ . Moreover, for a given bound  $B$ , we define  $\mathcal{C}_A(B)$  to be the set of configurations of  $A$  that are bounded in size by  $B$ , that is,  $\mathcal{C}_A(B) = \{C \in \mathbb{Z}_{\geq 0}^A \mid \Lambda(C) \leq B\}$ .

**Configuration IP.** We give a recollection of the configuration IP for scheduling on identical parallel machines. Let  $P$  be the set of processing times for some instance  $I$  with multiplicities  $n_p$  for each  $p \in P$ , meaning,  $I$  includes exactly  $n_p$  jobs with processing time  $p$  ( $\Lambda(p) = p$  in this context). Furthermore, let  $T$  be a guess of the optimal makespan. The configuration IP for  $I$  and  $T$  is given by variables  $x_C \geq 0$  for each  $C \in \mathcal{C}_P(T)$  and the following constraints:

$$\sum_{C \in \mathcal{C}_P(T)} x_C = m \quad (1)$$

$$\sum_{C \in \mathcal{C}_P(T)} C_p x_C = n_p \quad \forall p \in P \quad (2)$$

Due to constraint (1), exactly one configuration is chosen for each machine, while (2) ensures that the correct number of jobs or job sizes is covered.

**Module Configuration IP.** Let  $\mathcal{B}$  be a set of basic objects (e.g. jobs or setup classes) and let there be  $D$  integer values  $B_1, \dots, B_D$  for each basic object  $B \in \mathcal{B}$  (e.g. processing time or numbers of different kinds of jobs). Our approach is to cover the basic objects with so-called *modules*  $\mathcal{M}$  and in turn cover the modules with configurations. Depending on the context, modules correspond to batches of jobs or job piece sizes together with a setup time and can also encompass additional information like a starting time. Corresponding to the basic objects, each module  $M \in \mathcal{M}$  also has  $D$  integer values  $M_1, \dots, M_D$ , as well as a size  $\Lambda(M)$  and a set of eligible basic objects  $\mathcal{B}(M)$ . The latter is needed because not all modules are compatible with all basic objects, e.g., because they do not have the right setup times. Let  $H$  be the set of distinct module sizes, i.e.,  $H = \{\Lambda(M) \mid M \in \mathcal{M}\}$ , and for each module size  $h \in H$  let  $\mathcal{M}(h)$  be the set of modules with size  $h$ . We consider the set  $\mathcal{C}$  of configurations of module sizes which are bounded in size by a guess of the makespan  $T$ , i.e.,  $\mathcal{C} = \mathcal{C}_H(T)$ . In the preemptive case configurations need to additionally encompass information about starting times of modules, and therefore the definition of configurations will be slightly more complicated in that case.

Since we want to chose configurations for each machine, we have variables  $x_C$  for each  $C \in \mathcal{C}$  and constraints corresponding to (1). Furthermore, we chose modules with variables  $y_M$  for each  $M \in \mathcal{M}$  and because we want to cover the chosen modules with configurations, we have some analogue of constraint (2), say  $\sum_{C \in \mathcal{C}(T)} C_h x_C = \sum_{M \in \mathcal{M}(h)} y_M$  for each module size  $h \in H$ . It turns out however, that to properly cover the basic objects with modules, we need the variables  $y_M$  for each basic object, and this is where  $n$ -fold IPs come into play: The variables stated so far form a brick of the variables of the  $n$ -fold IP and there is one brick for each basic object, that is, we have, for each  $B \in \mathcal{B}$ , variables  $x_C^{(B)}$  for each  $C \in \mathcal{C}$ , and  $y_M^{(B)}$  for each  $M \in \mathcal{M}$ . Using the upper bounds of the  $n$ -fold model, variables  $y_M^{(B)}$  are set to zero, if  $B$  is not eligible for  $M$ ; and we set the lower bounds of all variables to zero. Sensible upper bounds for the remaining variables, will be typically clear from context. Besides that, the module configuration integer program MCIP (for  $\mathcal{B}$ ,  $\mathcal{M}$  and  $\mathcal{C}$ ) is given by the following constraints.

$$\sum_{B \in \mathcal{B}} \sum_{C \in \mathcal{C}} x_C^{(B)} = m \quad (3)$$

$$\sum_{B \in \mathcal{B}} \sum_{C \in \mathcal{C}(T)} C_h x_C^{(B)} = \sum_{B \in \mathcal{B}} \sum_{M \in \mathcal{M}(h)} y_M^{(B)} \quad \forall h \in H \quad (4)$$

$$\sum_{M \in \mathcal{M}} M_d y_M^{(B)} = B_d \quad \forall B \in \mathcal{B}, d \in [D] \quad (5)$$

It is easy to see that the constraints (3) and (4) are globally uniform. They are the mentioned adaptations of (1) and (2). The constraint (5), on the other hand, is locally uniform and ensures that the basic objects are covered.

Note that, while the duplication of the configuration variables does not carry meaning, it also does not upset the model: Consider the modified MCIP that is given by not duplicating the configuration variables. A solution  $(\tilde{x}, \tilde{y})$  for this IP gives a solution  $(x, y)$  for the MCIP by fixing some basic object  $B^*$ , setting  $x_C^{(B^*)} = \tilde{x}_C$  for each configuration  $C$ , setting the remaining configuration variables to 0, and copying the remaining variables. Given a solution  $(x, y)$  for the MCIP, on the other hand, gives a solution for the modified version  $(\tilde{x}, \tilde{y})$  by setting  $\tilde{x}_C = \sum_{B \in \mathcal{B}} x_C^B$  for each configuration  $C$ . Summarizing we get:

► **Observation 1.** *The MCIP is an  $n$ -fold IP with brick-size  $t = |\mathcal{M}| + |\mathcal{C}|$ , brick number  $n = |\mathcal{B}|$ ,  $r = |H| + 1$  globally uniform and  $s = D$  locally uniform constraints.*

Moreover, in all the considered applications we will minimize the overall size of the configurations, i.e.,  $\sum_{B \in \mathcal{B}} \sum_{C \in \mathcal{C}} \Lambda(C) x_C^{(B)}$ . This will be required, because in the simplification steps of our algorithms some jobs are removed and have to be reinserted later, and we therefore have to make sure that no space is wasted.

## 4 EPTAS results

In this section, we present approximation schemes for each of the three considered problems. Each of the results follows the same approach: The instance is carefully simplified, a schedule for the simplified instance is found using the MCIP, and this schedule is transformed into a schedule for the original instance. The presentation of the result is also similar for each problem: We first discuss how the instance can be sensibly simplified, and how a schedule for the simplified instance can be transformed into a schedule for the original one. Next, we discuss how a schedule for the simplified instance can be found using the MCIP, and lastly, we summarize and analyze the taken steps.

For the sake of clarity, we have given rather formal definitions for the problems at hand in Section 2. In the following, however, we will use the terms in a more intuitive fashion for the most part, and we will, for instance, often take a geometric rather than a temporal view on schedules and talk about the *length* or the *space* taken up by jobs and setups on machines rather than time. In particular, given a schedule for an instance of any one of the three problems together with an upper bound for the makespan  $T$ , the *free space* with respect to  $T$  on a machine is defined as the summed up lengths of time intervals between 0 and  $T$  in which the machine is idle. The free space (with respect to  $T$ ) is the summed up free space of all the machines. For bounds  $T$  and  $L$  for the makespan and the free space, we say that a schedule is a  $(T, L)$ -schedule if its makespan is at most  $T$  and the free space with respect to  $T$  is at least  $L$ .

When transforming the instance we will increase or decrease processing and setup times and fill in or remove extra jobs. Consider a  $(T', L')$ -schedule, where  $T'$  and  $L'$  denote some arbitrary makespan or free space bounds. If we fill in extra jobs or increase processing or setup times, but can bound the increase on each machine by some bound  $b$ , we end up with a  $(T' + b, L')$ -schedule for the transformed instance. In particular we have the same bound for the free space, because we properly increased the makespan bound. If, on the other hand, jobs are removed or setup times decreased, we obviously still have a  $(T', L')$ -schedule for the transformed instance. This will be used frequently in the following.

### 4.1 Setup Class Model

In the setup class model, simplification steps similar to the ones developed by Jansen and Land [16] can be used. We give a brief overview:

The set of big setup jobs  $\mathcal{J}^{\text{bst}}$  is given by the jobs belonging to classes with setup times at least  $\varepsilon^3 T$  and the small setup jobs  $\mathcal{J}^{\text{sst}}$  are all the others. Furthermore, we call a job *tiny* or *small*, if its processing time is smaller than  $\varepsilon^4 T$  or  $\varepsilon T$  respectively, and *big* or *large* otherwise. For any given set of jobs  $J$ , we denote the subset of tiny jobs from  $J$  with  $J_{\text{tiny}}$  and the small, big and large jobs analogously. We simplify the instance in four steps, aiming for an instance that exclusively includes big jobs with big setup times and additionally only a constant number of distinct processing and setup times: We remove the small jobs with small setup times  $\mathcal{J}_{\text{small}}^{\text{sst}}$ ; increase the setup times of the remaining classes with small setup times to  $\varepsilon^3 T$ ; replace the tiny jobs from  $\mathcal{J}_{\text{tiny}}^{\text{bst}}$  with placeholders of size  $\varepsilon^4 T$ ; and round up the resulting processing and setup times in a geometric and a subsequent arithmetic rounding step. The above steps yield certain makespan bounds  $\bar{T} \leq \check{T} = (1 + \mathcal{O}(\varepsilon))T$ , and for the resulting instance  $I'$ , the sets  $P$  and  $S$  of distinct processing and setup times have bounded cardinality, that is,  $|P|, |S| \in \mathcal{O}(1/\varepsilon \log 1/\varepsilon)$ , and each processing and setup time is a multiple of  $\varepsilon^5 T$ . An obvious lower bound on the space taken up by the jobs from  $\mathcal{J}_{\text{small}}^{\text{sst}}$  in any schedule is given by  $L = \sum_{j \in \mathcal{J}_{\text{small}}^{\text{sst}}} p_j + \sum_{k \in Q} s_k$ .

► **Theorem 4.** *If there is a schedule for  $I$  with makespan  $T$ , there is a  $(\bar{T}, L)$ -schedule for  $I'$ ; and if there is a  $(\bar{T}, L)$ -schedule for  $I'$ , there is a schedule for  $I$  with makespan  $\check{T}$ . ◀*

**Utilization of the MCIP.** At this point, we can employ the module configuration IP. The basic objects in this context are the setup classes, i.e.,  $\mathcal{B} = [K']$ , and the different values are the numbers of jobs with a certain processing time, i.e.,  $D = |P|$ . We set  $n_{k,p}$  to be the number of jobs from setup class  $k \in [K']$  with processing time  $p \in P$ . The modules correspond to batches of jobs together with a setup time. Batches of jobs can be modeled as configurations of processing times, that is, multiplicity vectors indexed by the processing times. Hence, we define the set of modules  $\mathcal{M}$  to be the set of pairs of configurations of processing times and setup times with a summed up size bounded by  $\bar{T}$ , i.e.,  $\mathcal{M} = \{(C, s) \mid C \in \mathcal{C}_P(\bar{T}), s \in S, s + \Lambda(C) \leq \bar{T}\}$ , and write  $M_p = C_p$  and  $s_M = s$  for each module  $M = (C, s) \in \mathcal{M}$ . The values of a module  $M$  are given by the numbers  $M_p$  and its size  $\Lambda(M)$  by  $s_M + \sum_{p \in P} M_p p$ . Remember that the configurations  $\mathcal{C}$  are the configurations of module sizes  $H$  that are bounded in size by  $\bar{T}$ , i.e.,  $\mathcal{C} = \mathcal{C}_H(\bar{T})$ . A setup class is eligible for a module, if the setup times fit, i.e.,  $\mathcal{B}_M = \{k \in [K'] \mid s_k = s_M\}$ . Lastly, we establish  $\varepsilon^5 T = 1$  by scaling.

For the sake of readability, we state the resulting constraints of the MCIP with adapted notation and without duplication of the configuration variables:

$$\sum_{C \in \mathcal{C}} x_C = m \tag{6}$$

$$\sum_{C \in \mathcal{C}} C_h x_C = \sum_{k \in [K']} \sum_{M \in \mathcal{M}(h)} y_M^{(k)} \quad \forall h \in H \tag{7}$$

$$\sum_{M \in \mathcal{M}} M_p y_M^{(k)} = n_{k,p} \quad \forall k \in [K'], p \in P \tag{8}$$

Note that the coefficients are all integral and this includes those of the objective function, i.e.,  $\sum_C \Lambda(C) x_C$ , because of the scaling step.

► **Lemma 5.** *With the above definitions, there is a  $(\bar{T}, L)$ -schedule for  $I'$ , iff the MCIP has a solution with objective value at most  $m\bar{T} - L$ .*

**Proof.** Let there be a  $(\bar{T}, L)$ -schedule for  $I'$ . Then the schedule on a given machine corresponds to a distinct configuration  $C$  that can be determined by counting for each possible group size  $a$  the batches of jobs from the same class whose length together with the setup time adds up to an overall length of  $a$ . Note that the length of this configuration is equal to the used up space on that machine. We fix an arbitrary setup class  $k$  and set the variables  $x_C^{(k)}$  accordingly (and  $x_C^{(k')} = 0$  for  $k' \neq k$  and  $C \in \mathcal{C}$ ). By this setting, we get an objective value of at most  $m\bar{T} - L$  because there was  $L$  free space in the schedule. For each class  $k$  and module  $M$ , we count the number of machines on which there are exactly  $M_p$  jobs with processing time  $p$  from class  $k$  for each  $p \in P$ , and set  $y_M^{(k)}$  accordingly. It is easy to see that the constraints are satisfied by these definitions.

Given a solution  $(x, y)$  of the MCIP, we define a corresponding schedule: Because of (6), we can match the machines to configurations such that each machine is matched to exactly one configuration. If machine  $i$  is matched to  $C$ , we create  $C_G$  slots of length  $\Lambda(G)$  on  $i$  for each group  $G$ . Next, we divide the setup classes into batches. For each class  $k$  and module  $M$ , we create  $y_M^{(k)}$  batches of jobs from class  $k$  with  $M_p$  jobs with processing time  $p$  for each  $p \in P$  and place the batch together with the corresponding setup time into a fitting slot on some machine. Because of (8) and (7) all jobs can be placed by this process. Note that the used space equals the overall size of the configurations and we therefore have free space of at least  $L$ . ◀

**Result.** To analyze the running time of the resulting procedure, we mainly have to bound the parameters of the MCIP. We have  $|\mathcal{B}| = K' \leq K$  and  $D = |P|$  by definition, and  $|\mathcal{M}| = \mathcal{O}(|S|(1/\varepsilon^3)^{|P|}) = 2^{\mathcal{O}(1/\varepsilon \log^2 1/\varepsilon)}$ , because  $|S|, |P| \in \mathcal{O}(1/\varepsilon \log 1/\varepsilon)$ . This is true, due to the last rounding step, which also implies  $|H| \in \mathcal{O}(1/\varepsilon^5)$ , yielding  $|\mathcal{C}| = |H|^{\mathcal{O}(1/\varepsilon^3)} = 2^{\mathcal{O}(1/\varepsilon^3 \log 1/\varepsilon)}$ . According to Observation 1, this yields a brick size of  $t = 2^{\mathcal{O}(1/\varepsilon^3 \log 1/\varepsilon)}$ , a brick number of  $K$ ,  $\mathcal{O}(1/\varepsilon^5)$  globally, and  $\mathcal{O}(1/\varepsilon \log 1/\varepsilon)$  locally uniform constraints for the MCIP. We have  $\Delta = \mathcal{O}(1/\varepsilon^5)$ , because all occurring values in the processing time matrix are bounded in  $\bar{T}$ , and we have  $\bar{T} = \mathcal{O}(1/\varepsilon^5)$ , due to the scaling. Furthermore, the values of the objective function, the right hand side, and the upper and lower bounds on the variables are bounded by  $\mathcal{O}(n/\varepsilon^5)$ , yielding a bound of  $\mathcal{O}(\log n/\varepsilon^5)$  for the encoding length of the biggest number in the input  $\varphi$ . Lastly, all variables can be bounded by 0 from below and  $\mathcal{O}(m/\varepsilon^3)$  from above, yielding  $\Phi = \mathcal{O}(m/\varepsilon^3)$ .

By Theorem 3 and some arithmetic, the MCIP can be solved in time:

$$(rs\Delta)^{\mathcal{O}(r^2s+rs^2)} t^2 n^2 \varphi \log(\Phi) \log(nt\Phi) = 2^{\mathcal{O}(1/\varepsilon^{11} \log^2 1/\varepsilon)} K^2 \log n \log m \log Km$$

When building the actual schedule, we iterate through the jobs and machines, yielding an additional term that is linear in  $n$  and  $m$ . To get the running time stated below Theorem 1, additional rounding steps for the module sizes and slightly altered modules are needed. For details we refer to the long version of the paper.

## 4.2 Splittable Model

The approximation scheme for the splittable model presented in this section is probably the easiest one discussed in this work. There is, however, one problem concerning this procedure: Its running time is polynomial in the number of machines, which might be exponential in

the input size. In the long version, we show how this problem can be overcome and further improve the running time.

For the simplification of the instance, similar ideas to the setup class case can be employed. We give a brief overview:

In this context, the set of big setup jobs  $\mathcal{J}^{\text{bst}}$  is given by the jobs with setup times at least  $\varepsilon T$  and the small setup jobs  $\mathcal{J}^{\text{sst}}$  are all the others. Let  $L = \sum_{j \in \mathcal{J}^{\text{sst}}} (s_j + p_j)$ . Because every job has to be scheduled and every setup has to be paid at least once,  $L$  is a lower bound on the summed up space due to small jobs in any schedule. The instance is simplified in two steps: First, all the small setup jobs are removed, and next the remaining processing and setup times are rounded up to multiples of  $\varepsilon^2 T$ . These steps yield certain makespan bounds  $\bar{T} \leq \tilde{T} = (1 + \mathcal{O}(\varepsilon))T$ , and for the resulting instance  $I'$ , the sets  $P$  and  $S$  of distinct processing and setup times have bounded cardinality, that is,  $|P|, |S| \in \mathcal{O}(1/\varepsilon^2)$ .

► **Theorem 6.** *If there is a schedule with makespan  $T$  for  $I$ , there is also a  $(\bar{T}, L)$ -schedule for  $I'$  in which the length of each job part is a multiple of  $\varepsilon^2 T$ ; and if there is a  $(\bar{T}, L)$ -schedule for  $I'$ , there is also a schedule for  $I$  with makespan at most  $\tilde{T}$ .*

We will use the MCIP to find a  $(\bar{T}, L)$ -schedule for  $I'$  in which the length of each job part is a multiple of  $\varepsilon^2 T$ .

**Utilization of the MCIP.** The basic objects in this context are the (big setup) jobs, i.e.,  $\mathcal{B} = \mathcal{J}^{\text{bst}}$ , and they have only one value ( $D = 1$ ), namely, their processing time. Moreover, the modules are defined as the set of pairs of job piece sizes and setup times, i.e.,  $\mathcal{M} = \{(q, s) \mid s, q \in S \times P\}$ , and we write  $s_M = s$  and  $q_M = q$  for each module  $M = (q, s) \in \mathcal{M}$ . Corresponding to the value of the basic objects the value of a module  $M$  is  $q_M$ , and its size  $\Lambda(M)$  is given by  $q_M + s_M$ . A job is eligible for a module, if the setup times fit, i.e.,  $\mathcal{B}_M = \{j \in \mathcal{J}' \mid s_j = s_M\}$ . In order to ensure integral values, we establish  $\varepsilon^2 T = 1$  via scaling. The set of configurations  $\mathcal{C}$  is comprised of all configurations of module sizes  $H$  that are bounded in size by  $\bar{T}$ , i.e.,  $\mathcal{C} = \mathcal{C}_{\mathcal{M}}(\bar{T})$ . We state the constraints of the MCIP for the above definitions with adapted notation and without duplication of the configuration variables:

$$\sum_{C \in \mathcal{C}} x_C = m \tag{9}$$

$$\sum_{C \in \mathcal{C}} C_h x_C = \sum_{j \in \mathcal{J}'} \sum_{M \in \mathcal{M}(h)} y_M^{(j)} \quad \forall h \in H \tag{10}$$

$$\sum_{M \in \mathcal{M}} q_M y_M^{(j)} = p_j \quad \forall j \in \mathcal{J}' \tag{11}$$

Note that we additionally minimize the summed up size of the configurations, via the objective function  $\sum_C \Lambda(C) x_C$ .

► **Lemma 7.** *With the above definitions, there is a  $(\bar{T}, L)$ -schedule for  $I'$  in which the length of each job piece is a multiple of  $\varepsilon^2 T$ , iff MCIP has a solution with objective value at most  $m\bar{T} - L$ .*

**Proof.** Given such a schedule for  $I'$ , the schedule on each machine corresponds to exactly one configuration  $G$  that can be derived by counting the job pieces and setup times with the same summed up length  $a$  and setting  $C_G$  accordingly, where  $G$  is the group of modules with length  $a$ . The size of the configuration  $C$  is equal to the used space on the respective machine. Therefore, we can fix some arbitrary job  $j$  and set the variables  $x_C^{(j)}$  to the number of machines whose schedule corresponds to  $C$  (and  $x_C^{(j')} = 0$  for  $j' \neq j$  and  $C \in \mathcal{C}$ ). Since

there is at least a free space of  $L$  for the schedule, the objective value is bounded by  $m\bar{T} - L$ . Furthermore, for each job  $j$  and job part length  $q$ , we count the number of times a piece of  $j$  with length  $q$  is scheduled and set  $y_{(q,s_j)}^{(j)}$  accordingly. It is easy to see that the constraints are satisfied.

Now, let  $(x, y)$  be a solution to the MCIP with objective value at most  $m\bar{T} - L$ . We use the solution to construct a schedule: For job  $j$  and configuration  $C$ , we reserve  $x_C^{(j)}$  machines. On each of these machines, we create  $C_h$  slots of length  $h$ , for each module size  $h \in H$ . Note that, because of (9), there is the exact right number of machines for this. Next, consider each job  $j$  and possible job part length  $q$  and create  $y_{(q,s_j)}^{(j)}$  split pieces of length  $q$  and place them together with a setup of  $s_j$  into a slot of length  $s_j + q$  on any machine. Because of (11), the entire job is split up by this, and because of (10), there are enough slots for all the job pieces. Note that the used space in the created schedule is equal to the objective value of  $(x, y)$ , and therefore there is at least  $L$  free space. ◀

**Result.** To assess the running time of the procedure, we mainly need to bound the parameters of the MCIP, namely  $|\mathcal{B}|$ ,  $|H|$ ,  $|\mathcal{M}|$ ,  $|\mathcal{C}|$  and  $D$ . By definition, we have  $|\mathcal{B}| \leq n$  and  $D = 1$ . Since all setup times and job piece lengths are multiples of  $\varepsilon^2 T$  and bounded by  $T$ , we have  $|\mathcal{M}| = \mathcal{O}(1/\varepsilon^4)$  and  $|H| = \mathcal{O}(1/\varepsilon^2)$ . This yields  $|\mathcal{C}| \leq |H|^{\mathcal{O}(1/\varepsilon+2)} = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ , because the size of each module is at least  $\varepsilon T$  and the size of the configurations bounded by  $(1 + 2\varepsilon)T$ .

According to Observation 1, we now have brick-size  $t = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ , brick number  $|\mathcal{B}| = n$ ,  $r = |\Gamma| + 1 = \mathcal{O}(1/\varepsilon^2)$  globally uniform and  $s = D = 1$  locally uniform constraints. Because of the scaling step, all occurring numbers in the constraint matrix of the MCIP are bounded by  $1/\varepsilon^2$  and therefore  $\Delta \leq 1/\varepsilon^2$ . Furthermore, each occurring number can be bounded by  $\mathcal{O}(m/\varepsilon^2)$  and this is an upper bound for each variable as well, yielding  $\varphi = \mathcal{O}(\log m/\varepsilon^2)$  and  $\Phi = \mathcal{O}(m/\varepsilon^2)$ . Hence the MCIP, can be solved in time:

$$(rs\Delta)^{\mathcal{O}(r^2s+rs^2)} t^2 n^2 \varphi \log(\Phi) \log(nt\Phi) = 2^{\mathcal{O}(1/\varepsilon^4 \log 1/\varepsilon)} n^2 \log^2 m \log nm$$

When building the actual schedule, we iterate through the jobs and machines, yielding an additional term that is linear in  $n$  and  $m$ . To get the running time stated below Theorem 1, some additional considerations are needed. For details, we refer to the long version of the paper.

### 4.3 Preemptive Model

In the preemptive model, we have to actually consider the time-line of the schedule on each machine instead of just the assignment of the jobs or job pieces, and this causes some difficulties. For instance, we will have to argue that it suffices to look for a schedule with few possible starting points, and we will have to introduce additional constraints in the IP in order to ensure that pieces of the same job do not overlap. Our first step, in dealing with this extra difficulty is to introduce some concepts and notation: For a given schedule with a makespan bound  $T$ , we call a job piece together with its setup a *block*, and we call the schedule  $X$ -layered, for some value  $X$ , if each block starts at a multiple of  $X$ . Corresponding to this, we call the time in the schedule between two directly succeeding multiples of  $X$  a *layer* and the corresponding time on a single machine a *slot*. We number the layers bottom to top and identify them with their number, that is, the set of layers  $\Xi$  is given by  $\{\ell \in \mathbb{Z}_{>0} \mid (\ell - 1)X \leq T\}$ . Note that in an  $X$ -layered schedule, there is at most one block in each slot and for each layer there can be at most one block of each job present. Furthermore, for  $X$ -layered schedules, we slightly alter the definition of free space: We solely count the

space from slots that are completely free. If in such a schedule, for each job there is at most one slot occupied by this job but not fully filled, we additionally call the schedule *layer-compliant*.

**Simplification of the Instance.** In the preemptive model, we distinguish *big*, *medium* and *small* setup jobs, using two parameters  $\delta$  and  $\mu$ : The big setup jobs  $\mathcal{J}^{\text{bst}}$  are those with setup time at least  $\delta T$ , the small  $\mathcal{J}^{\text{sst}}$  have a setup time smaller than  $\mu T$ , and the medium  $\mathcal{J}^{\text{mst}}$  are the ones in between. We set  $\mu = \varepsilon^2 \delta$  and we choose  $\delta \in \{\varepsilon^1, \dots, \varepsilon^{2/\varepsilon^2}\}$  such that the summed up processing time together with the summed up setup time of the medium setup jobs is upper bounded by  $m\varepsilon T$ , i.e.,  $\sum_{j \in \mathcal{J}^{\text{mst}}} (s_j + p_j) \leq m\varepsilon T$ . If there is a schedule with makespan  $T$ , such a choice is possible, because of the pidgeon hole principle, and because the setup time of each job has to occur at least once in any schedule. Similar arguments are widely used, e.g. in the context of geometrical packing algorithms. Furthermore, we distinguish the jobs by processing times, calling those with processing time at least  $\varepsilon T$  *big* and the others *small*. For a given set of jobs  $J$ , we call the subsets of big or small jobs  $J_{\text{big}}$  or  $J_{\text{small}}$  respectively. We perform three simplification steps, aiming for an instance in which the small and medium setup jobs are big; small setup jobs have setup time 0; and for which an  $\varepsilon \delta T$ -layered, layer-compliant schedule exists.

Let  $I_1$  be the instance we get by removing the small jobs with medium setup times  $\mathcal{J}_{\text{small}}^{\text{mst}}$  from the given instance  $I$ .

► **Lemma 8.** *If there is a schedule with makespan at most  $T$  for  $I$ , there is also such a schedule for  $I_1$ , and if there is a schedule with makespan at most  $T'$  for  $I_1$  there is a schedule with makespan at most  $T' + (\varepsilon + \delta)T$  for  $I$ .*

**Proof.** The first claim is obvious. For the second, we create a sequence containing the jobs from  $\mathcal{J}_{\text{small}}^{\text{mst}}$  each directly preceded by its setup time. Recall that the overall length of the objects in this sequence is at most  $m\varepsilon T$ , and the length of each job is bounded by  $\varepsilon T$ . We greedily insert the objects from the sequence, considering each machine in turn. On the current machine we start at time  $T' + \delta T$  and keep inserting until  $T' + \delta T + \varepsilon T$  is reached. If the current object is a setup time, we discard it and continue with the next machine and object. If, on the other hand, it is a job, we split it such that the remaining space on the current machine can be perfectly filled. We can place all objects like this, however the first job part placed on a machine might be missing a setup. We can insert the missing setups because they have length at most  $\delta T$  and between time  $T'$  and  $T' + \delta T$  there is free space. ◀

Next, we consider the jobs with small setup times: Let  $I_2$  be the instance we get by removing the small jobs with small setup times  $\mathcal{J}_{\text{small}}^{\text{sst}}$  and setting the setup time of the big jobs with small setup times to zero, i.e.,  $\bar{s}_j = 0$  for each  $j \in \mathcal{J}_{\text{big}}^{\text{sst}}$ . Note that in the resulting instance each small job has a big setup time. Furthermore, let  $L := \sum_{j \in \mathcal{J}_{\text{small}}^{\text{sst}}} p_j + s_j$ . Then  $L$  is an obvious lower bound for the space taken up by the jobs from  $\mathcal{J}_{\text{small}}^{\text{sst}}$  in any schedule.

► **Lemma 9.** *If there is a schedule with makespan at most  $T$  for  $I_1$ , there is also a  $(T, L)$ -schedule for  $I_2$ ; and if there is a  $\gamma T$ -layered  $(T', L)$ -schedule for  $I_2$ , with  $T'$  a multiple of  $\gamma T$ , there is also a schedule with makespan at most  $(1 + \gamma^{-1}\mu)T' + (\mu + \varepsilon)T$  for  $I_1$ .*

**Proof.** The first claim is obvious, and for the second consider a  $\gamma T$ -layered  $(T', L)$ -schedule for  $I_2$ . We create a sequence that contains the jobs of  $\mathcal{J}_{\text{small}}^{\text{sst}}$  and their setups such that each job is directly preceded by its setup. Remember that the remaining space in partly filled slots is not counted as free space. Hence, since the overall length of the objects in the

sequence is  $L$ , there is enough space in the free slots of the schedule to place them. We do so in a greedy fashion guaranteeing that each job is placed on exactly one machine: We insert the objects from the sequence into the free slots, considering each machine in turn and starting on the current machine from the beginning of the schedule and moving on towards its end. If an object cannot be fully placed into the current slot there are two cases: If its a setup we discard it and if its a job, we cut it and continue placing it in the next slot, or, if the current slot was the last one, we place the rest at the end of the schedule. The resulting schedule is increased by at most  $\varepsilon T$ , which is caused by the last job placed on a machine.

To get a proper schedule for  $I_1$  we have to insert some setup times: For the large jobs with small setup times and for the jobs that were cut in the greedy procedure. We do so by inserting a time window of length  $\mu T$  at each multiple of  $\gamma T$  and at the end of the original schedule on each machine. By this, the schedule is increased by at most  $\gamma^{-1}\mu T' + \mu T$ . Since all the job parts in need of a setup are small and did start at multiples of  $\mu T$  or at the end, we can insert the missing setups. Note that blocks that span over multiple layers are cut by the inserted time windows. This, however, can easily be repaired by moving the cut pieces properly down. ◀

We continue by rounding the medium and big setup and all the processing times. In particular, we round the processing times and the big setup times up to the next multiple of  $\varepsilon\delta T$  and the medium setup times to the next multiple of  $\varepsilon\mu T$ , i.e.,  $\bar{p}_j = \lceil p_j/(\varepsilon\delta T) \rceil \varepsilon\delta T$  for each job  $j$ ,  $\bar{s}_j = \lceil s_j/(\varepsilon\delta T) \rceil \varepsilon\delta T$  for each big setup job  $j \in \mathcal{J}^{\text{bst}}$ , and  $\bar{s}_j = \lceil s_j/(\varepsilon\mu T) \rceil \varepsilon\mu T$  for each medium setup job  $j \in \mathcal{J}_{\text{big}}^{\text{mst}}$ .

► **Lemma 10.** *If there is a  $(T, L)$ -schedule for  $I_2$ , there is also an  $\varepsilon\delta T$ -layered, layer-compliant  $((1 + 3\varepsilon)T, L)$ -schedule for  $I_3$ ; and if there is a  $\gamma T$ -layered  $(T', L)$ -schedule for  $I_3$ , there is also such a schedule for  $I_2$ .*

While the second claim is easy to see, the proof of the first is rather elaborate and can be found in the long version of the paper.

For the big and small setup jobs both processing and setup times are multiples of  $\varepsilon\delta T$ . Therefore, the length of each of their blocks in an  $\varepsilon\delta T$ -layered, layer-compliant schedule is a multiple of  $\varepsilon\delta T$ . For a medium setup job, on the other hand, we know that the overall length of its blocks has the form  $x\varepsilon\delta T + y\varepsilon\mu T$ , with non-negative integers  $x$  and  $y$ . In particular it is a multiple of  $\varepsilon\mu T$ , because  $\varepsilon\delta T = (1/\varepsilon^2)\varepsilon\mu T$ . In a  $\varepsilon\delta T$ -layered, layer-compliant schedule, for each medium setup job the length of all but at most one block is a multiple of  $\varepsilon\delta T$  and therefore a multiple of  $\varepsilon\mu T$ . If both the overall length and the lengths of all but one block are multiples of  $\varepsilon\mu T$ , this is also true for the one remaining block. Hence, we will use the MCIP not to find an  $\varepsilon\delta T$ -layered, layer-compliant schedule in particular, but an  $\varepsilon\delta T$ -layered one with block sizes as described above and maximum free space.

Based on the simplification steps, we define two makespan bounds  $\bar{T}$  and  $\check{T}$ : Let  $\bar{T}$  be the makespan bound we get by the application of the Lemmata 8-10, i.e.,  $\bar{T} = (1 + \mathcal{O}(\varepsilon))T$ . We will use the MCIP to find an  $\varepsilon\delta T$ -layered  $(\bar{T}, L)$ -schedule for  $I_3$ , and apply the Lemmata 8-10 backwards to get schedule for  $I$  with makespan at most  $\check{T} = (1 + \mathcal{O}(\varepsilon))\bar{T} = (1 + \mathcal{O}(\varepsilon))T$ .

**Utilization of the MCIP.** Similar to the splittable case, the basic objects are the (big) jobs, i.e.,  $\mathcal{B} = \mathcal{J}_{\text{big}}$ , and their single value is their processing time ( $D = 1$ ). The modules, on the other hand, are more complicated, because they additionally need to encode which layers are exactly used and, in case of the medium jobs, to which degree the last layer is filled. For the latter, we introduce buffers, representing the unused space in the last layer, and define modules as tuples  $(\ell, q, s, b)$  of starting layer, job piece size, setup time and buffer size. For a

module  $M = (\ell, q, s, b)$ , we write  $\ell_M = \ell$ ,  $q_M = q$ ,  $s_M = s$  and  $b_M = b$ , and we define the size  $\Lambda(M)$  of  $M$  as  $s + q + b$ . The overall set of modules  $\mathcal{M}$  is the union of the modules for big, medium and small setup jobs  $\mathcal{M}^{\text{bst}}$ ,  $\mathcal{M}^{\text{mst}}$  and  $\mathcal{M}^{\text{sst}}$  that are defined in the following. For this let  $Q^{\text{bst}} = \{q \mid q = x\varepsilon\delta T, x \in \mathbb{Z}_{>0}, q \leq \bar{T}\}$  and  $Q^{\text{mst}} = \{q \mid q = x\varepsilon\mu T, x \in \mathbb{Z}_{>0}, q \leq \bar{T}\}$  be the sets of possible job piece sizes of big and medium setup jobs;  $S^{\text{bst}} = \{s \mid s = x\varepsilon\delta T, x \in \mathbb{Z}_{\geq 1/\varepsilon}, s \leq \bar{T}\}$  and  $S^{\text{mst}} = \{s \mid s = x\varepsilon\mu T, x \in \mathbb{Z}_{\geq 1/\varepsilon}, s \leq \delta T\}$  be the sets of possible big and medium setup times;  $B = \{b \mid b = x\varepsilon\mu T, x \in \mathbb{Z}_{\geq 0}, b < \varepsilon\delta T\}$  the set of possible buffer sizes; and  $\Xi = \{1, \dots, 1/(\varepsilon\delta) + 3/\delta\}$  the set of layers. We set:

$$\begin{aligned} \mathcal{M}^{\text{bst}} &= \{(\ell, q, s, 0) \mid \ell \in \Xi, q \in Q^{\text{bst}}, s \in S^{\text{bst}}, (\ell - 1)\varepsilon\delta T + s + q \leq \bar{T}\} \\ \mathcal{M}^{\text{mst}} &= \{(\ell, q, s, b) \in \Xi \times Q^{\text{mst}} \times S^{\text{mst}} \times B \mid x = s + q + b \in \varepsilon\delta T\mathbb{Z}_{>0}, (\ell - 1)\varepsilon\delta T + x \leq \bar{T}\} \\ \mathcal{M}^{\text{sst}} &= \{(\ell, \varepsilon\delta T, 0, 0) \mid \ell \in \Xi\} \end{aligned}$$

Concerning the small setup modules, note that the small setup jobs have a setup time of 0 and therefore may be covered slot by slot. We establish  $\varepsilon\mu T = 1$  via scaling, to ensure integral values. A big, medium or small job is eligible for a module, if it is also big, medium or small respectively and the setup times fit.

We have to avoid that two modules  $M_1, M_2$ , whose corresponding time intervals overlap, are used to cover the same job or in the same configuration. Such an overlap is given, if there is some layer  $\ell$  used by both of them, that is,  $(\ell_{M_1} - 1)\varepsilon\delta T \leq (\ell - 1)\varepsilon\delta T < (\ell_{M_2} - 1)\varepsilon\delta T + \Lambda(M_2)$  for both  $M \in \{M_1, M_2\}$ . Hence, for each layer  $\ell \in \Xi$ , we set  $\mathcal{M}_\ell \subseteq \mathcal{M}$  to be the set of modules that use layer  $\ell$ . Furthermore, we partition the modules into groups  $\Gamma$  by size and starting layer, i.e.,  $\Gamma = \{G \subseteq \mathcal{M} \mid M, M' \in G \Rightarrow \Lambda(M) = \Lambda(M') \wedge \ell_M = \ell_{M'}\}$ . The size of a group  $G \in \Gamma$  is the size of a module from  $G$ , i.e.  $\Lambda(G) = \Lambda(M)$  for  $M \in G$ . Unlike before, we consider *configurations of module groups* rather than module sizes. More precisely, the set of configurations  $\mathcal{C}$  is given by the configurations of groups, such that for each layer at most one group using this layer is chosen, i.e.,  $\mathcal{C} = \{C \in \mathbb{Z}_{\geq 0}^\Gamma \mid \forall \ell \in \Xi : \sum_{G \subseteq \mathcal{M}_\ell} C_G \leq 1\}$ . With this definition, we prevent overlap conflicts on the machines. Note that unlike in the cases considered so far, the size of a configuration does not correspond to a makespan in the schedule, but to used space, and the makespan bound is realized in the definition of the modules instead of in the definition of the configurations. To also avoid conflicts for the jobs, we extend the basic MCIP with additional locally uniform constraints. In particular, the constraints of the extended MCIP for the above definitions with adapted notation and without duplication of the configuration variables are given by:

$$\sum_{C \in \mathcal{C}} x_C = m \tag{12}$$

$$\sum_{C \in \mathcal{C}(T)} C_G x_C = \sum_{j \in \mathcal{J}} \sum_{M \in G} y_M^{(j)} \quad \forall G \in \Gamma \tag{13}$$

$$\sum_{M \in \mathcal{M}} q_M y_M^{(j)} = p_j \quad \forall j \in \mathcal{J} \tag{14}$$

$$\sum_{M \in \mathcal{M}_\ell} y_M^{(j)} \leq 1 \quad \forall j \in \mathcal{J}, \ell \in \Xi \tag{15}$$

Like in the first two cases, we minimize the summed up size of the configurations, via the objective function  $\sum_C \Lambda(C)x_C$ . Note that in this case the size of a configuration does not have to equal its height. It is easy to see that the last constraint is indeed locally uniform. However, since we have an inequality instead of an equality, we have to introduce  $|\Xi|$  slack variables in each brick, yielding:

► **Observation 2.** *The MCIP extended like above is an  $n$ -fold IP with brick-size  $t = |\mathcal{M}| + |\mathcal{C}| + |\Xi|$ , brick number  $n = |\mathcal{J}|$ ,  $r = |\Gamma| + 1$  globally uniform and  $s = D + |\Xi|$  locally uniform constraints.*

► **Lemma 11.** *With the above definitions, there is an  $\varepsilon\delta T$ -layered  $(\bar{T}, L)$ -schedule for  $I_3$  in which the length of a block is a multiple of  $\varepsilon\delta T$ , if it belongs to a small or big setup job, or a multiple of  $\varepsilon\mu T$  otherwise, iff the extended MCIP has a solution with objective value at most  $m\bar{T} - L$ .*

**Proof.** We first consider such a schedule for  $I_3$ . For each machine, we can derive a configuration that is given by the starting layers of the blocks together with the summed up length of the slots the respective block is scheduled in. The size of the configuration  $C$  is equal to the used space on the respective machine. Hence, we can fix some arbitrary job  $j$  and set  $x_C^{(j)}$  to the number of machines corresponding to  $j$  (and  $x_C^{(j')} = 0$  for  $j' \neq j$ ). Keeping in mind that in an  $\varepsilon\delta T$ -layered schedule the free space is given by the free slots, the above definition yields an objective value bounded by  $m\bar{T} - L$ , because there was free space of at least  $L$ . Next, we consider the module variables for each job  $j$  in turn: If  $j$  is a small setup job, we set  $y_{(\ell, \varepsilon\delta T, 0, 0)}^{(j)}$  to 1, if the  $j$  occurs in  $\ell$ , and to 0 otherwise. Now, let  $j$  be a big setup job. For each of its blocks, we set  $y_{(\ell, z-s_j, s_j, 0)}^{(j)} = 1$ , where  $\ell$  is the starting layer and  $z$  the length of the block. The remaining variables are set to 0. Lastly, let  $j$  be a medium setup job. For each of its blocks, we set  $y_{(\ell, z-s_j, s_j, b)}^{(j)} = 1$ , where  $\ell$  is the starting layer of the block,  $z$  its length and  $b = \lceil z/(\varepsilon\delta T) \rceil \varepsilon\delta T - z$ . Again, the remaining variables are set to 0. It is easy to verify that all constraints are satisfied by this solution.

If, on the other hand, we have a solution  $(x, y)$  to the MCIP with objective value at most  $m\bar{T} - L$ , we reserve  $\sum_j x_C^{(j)}$  machines for each configuration  $C$ . There are enough machines to do this, because of (12). On each of these machines we reserve space: For each  $G \in \Gamma$ , we create an allocated space of length  $\Lambda(G)$  starting from the starting layer of  $G$ , if  $C_G = 1$ . Let  $j$  be a job and  $\ell$  be a layer. If  $j$  has a small setup time, we create  $y_{(\ell, \varepsilon\delta T, 0, 0)}^{(j)}$  pieces of length  $\varepsilon\delta T$  and place these pieces into allocated spaces of length  $\varepsilon\delta T$  in layer  $\ell$ . If, on the other hand,  $j$  is a big or medium setup job, we consider each possible job part length  $q \in Q^{\text{bst}}$  or  $q \in Q^{\text{mst}}$ , create  $y_{(\ell, q, s_j, 0)}^{(j)}$  or  $y_{(\ell, q, s_j, b)}^{(j)}$ , with  $b = \lceil q/(\varepsilon\delta T) \rceil \varepsilon\delta T - q$ , pieces of length  $q$ , and place them together with their setup time into allocated spaces of length  $q$  in layer  $\ell$ . Because of (14) the entire job is split up by this, and because of (13) there are enough allocated spaces for all the job pieces. The makespan bound is ensured by the definition of the modules, and overlaps are avoided, due to the definition of the configurations and (15). Furthermore, the used slots have an overall length equal to the objective value of  $(x, y)$  and therefore there is at least  $L$  free space. ◀

**Result.** We analyze the running time of the procedure, and start by bounding the parameters of the extended MCIP. We have  $|\mathcal{B}| = n$  and  $D = 1$  by definition, and the number of layers  $|\Xi|$  is obviously  $\mathcal{O}(1/(\varepsilon\delta)) = \mathcal{O}(1/\varepsilon^{2/\varepsilon+1}) = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ . Furthermore, it is easy to see that  $|Q^{\text{bst}}| = \mathcal{O}(1/(\varepsilon\delta))$ ,  $|Q^{\text{mst}}| = \mathcal{O}(1/(\varepsilon^3\delta))$ ,  $|S^{\text{bst}}| = \mathcal{O}(1/(\varepsilon\delta))$ ,  $|S^{\text{mst}}| = \mathcal{O}(1/\varepsilon^3)$ , and  $|B| = \mathcal{O}(1/\varepsilon^2)$ . This gives us  $\mathcal{M}^{\text{bst}} \leq |\Xi||Q^{\text{bst}}||S^{\text{bst}}|$ ,  $\mathcal{M}^{\text{mst}} \leq |\Xi||Q^{\text{mst}}||S^{\text{mst}}||B|$  and  $\mathcal{M}^{\text{sst}} = |\Xi|$ , and therefore  $|\mathcal{M}| = |\mathcal{M}^{\text{bst}}| + |\mathcal{M}^{\text{mst}}| + |\mathcal{M}^{\text{sst}}| = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ . Since their are  $\mathcal{O}(1/(\delta\varepsilon))$  distinct module sizes, the number of groups  $|\Gamma|$  can be bounded by  $\mathcal{O}(|\Xi|/(\varepsilon\delta)) = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ . Hence, for the number of configurations we get  $|\mathcal{C}| = \mathcal{O}((1/(\varepsilon\delta))^{|\Gamma|}) = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ . By Observation 2, the modified MCIP has  $r = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$  many globally and  $s = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$  many locally uniform constraints; its brick number is  $n$ , and its brick size is  $t = 2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ . All occurring values in the matrix are bounded by  $\bar{T}$ , yielding  $\Delta \leq \bar{T} = 1/(\varepsilon\mu) + 1/\mu =$

$2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$ , due to the scaling step. Furthermore, the numbers in the input can be bounded by  $m2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}$  and all variables can be upper bounded by  $\mathcal{O}(m)$ . Hence, we have  $\varphi = \mathcal{O}(\log m + 1/\varepsilon \log 1/\varepsilon)$  and  $\Phi = \mathcal{O}(m)$ , and due to Theorem 3 we can solve the MCIP in time:

$$(rs\Delta)^{\mathcal{O}(r^2s+rs^2)} t^2 n^2 \varphi \log(\Phi) \log(nt\Phi) = 2^{2^{\mathcal{O}(1/\varepsilon \log 1/\varepsilon)}} n^2 \log^2 m \log nm$$

When building the actual schedule we iterate through the jobs and machines yielding the slightly increased running time stated below Theorem 1.

## 5 Conclusion

We presented a more advanced version of the classical configuration IP, showed that it can be solved efficiently using algorithms for  $n$ -fold IPs, and developed techniques to employ the new IP for the formulation of efficient polynomial time approximation schemes for three scheduling problems with setup times, for which no such algorithms were known before.

For further research the immediate questions are whether improved running times for the considered problems, in particular for the preemptive model, can be achieved; whether the MCIP can be solved more efficiently; and to which other problems it can be reasonably employed. From a broader perspective, it would be interesting to further study the potential of new algorithmic approaches in integer programming for approximation, and, on the other hand, further study the respective techniques themselves.

## Abstract

We consider a variation of the problem of corruption detection on networks posed by Alon, Mossel, and Pemantle '15. In this model, each vertex of a graph can be either truthful or corrupt. Each vertex reports about the types (truthful or corrupt) of all its neighbors to a central agency, where truthful nodes report the true types they see and corrupt nodes report adversarially. The central agency aggregates these reports and attempts to find a single truthful node. Inspired by real auditing networks, we pose our problem for arbitrary graphs and consider corruption through a computational lens. We identify a key combinatorial parameter of the graph  $m(G)$ , which is the minimal number of corrupted agents needed to prevent the central agency from identifying a single corrupt node. We give an efficient (in fact, linear time) algorithm for the central agency to identify a truthful node that is successful whenever the number of corrupt nodes is less than  $m(G)/2$ . On the other hand, we prove that for any constant  $\alpha > 1$ , it is NP-hard to find a subset of nodes  $S$  in  $G$  such that corrupting  $S$  prevents the central agency from finding one truthful node and  $|S| \leq \alpha m(G)$ , assuming the Small Set Expansion Hypothesis (Raghavendra and Steurer, STOC '10). We conclude that being corrupt requires being clever, while detecting corruption does not.

Our main technical insight is a relation between the minimum number of corrupt nodes required to hide all truthful nodes and a certain notion of vertex separability for the underlying graph. Additionally, this insight lets us design an efficient algorithm for a corrupt party to decide which graphs require the fewest corrupted nodes, up to a multiplicative factor of  $O(\log n)$ .

## 1 Introduction

### 1.1 Corruption Detection and Problem Set-up

We study the problem of identifying truthful nodes in networks, in the model of *corruption detection on networks* posed by Alon, Mossel, and Pemantle [1]. In this model, we have a network represented by a (possibly directed) graph. Nodes can be *truthful* or *corrupt*. Each node audits its outgoing neighbors to see whether they are truthful or corrupt, and sends reports of their identities to a central agency. The central agent, who is not part of the graph, aggregates the reports and uses them to identify truthful and corrupt nodes. Truthful nodes report truthfully (and correctly) on their neighbors, while corrupt nodes have no such restriction: they can assign arbitrary reports to their neighbors, regardless of whether their neighbors are truthful or corrupt, and coordinate their efforts with each other to prevent the central agency from gathering useful information.

In [1], the authors consider the problem of recovering the identities of almost all nodes in a network in the presence of many corrupt nodes; specifically, when the fraction of corrupt nodes can be very close to  $1/2$ . They call this the *corruption detection* problem. They show that the central agency can recover the identity of most nodes correctly even in certain bounded-degree graphs, as long as the underlying graph is a sufficiently good expander. The required expansion properties are known to hold for a random graph or Ramanujan graph of sufficiently large (but constant) degree, which yields undirected graphs that are amenable to corruption detection. Furthermore, they show that some level of expansion is necessary for identifying truthful nodes, by demonstrating that the corrupt nodes can stop the central agency from identifying any truthful node when the graph is a very bad expander (e.g. a cycle), even if the corrupt nodes only make up 0.01 fraction of the network.

This establishes that very good expanders are very good for corruption detection, and very bad expanders can be very bad for corruption detection. We note that this begs the question of how effective graphs that do not fall in either of these categories are for corruption detection. In the setting of [1], we could ask the following: given an *arbitrary* undirected graph, what is the smallest number of corrupt nodes that can prevent the identification of almost all nodes? When there are fewer than this number, can the central agency *efficiently* identify almost all nodes correctly? Alon, Mossel, and Pemantle study these questions for the special cases of highly expanding graphs and poorly expanding graphs, but do not address general graphs.

Additionally, [1] considers corruption detection when the corrupt agencies can choose their locations and collude arbitrarily, with no bound on their computational complexity. This is perhaps overly pessimistic: after all, it is highly unlikely that corrupt agencies can solve NP-hard problems efficiently and if they can, thwarting their covert operations is unlikely to stop their world domination. We suggest a model that takes into account computational considerations, by factoring in the computation time required to select the nodes in a graph that a corrupt party chooses to control. This yields the following question from the viewpoint of a corrupt party: given a graph, can a corrupt party compute the smallest set of nodes it needs to corrupt *in polynomial time*?

In addition to being natural from a mathematical standpoint, these questions are also well-motivated socially. It would be naïve to assert that we can weed out corruption in the real world by simply designing auditing networks that are expanders. Rather, these

networks may already be formed, and infeasible to change in a drastic way. Given this, we are less concerned with finding certain graphs that are good for corruption detection, but rather discerning how good *existing* graphs are; specifically, how many corrupt nodes they can tolerate. In particular, since the network structure could be out of the control of the central agency, algorithms for the central agency to detect corruption on arbitrary graphs seem particularly important.

It is also useful for the *corrupt* agency to have an algorithm with guarantees for any graph. Consider the following example of a corruption detection problem from the viewpoint of a corrupt organization. Country A wants to influence policy in country B, and wants to figure out the most efficient way to place corrupted nodes within country B to make this happen. However, if the central government of B can confidently identify truthful nodes, they can weight those nodes' opinions more highly, and thwart country A's plans. Hence, the question country A wants to solve is the following: given the graph of country B, can country A compute the optimal placement of corrupt nodes to prevent country B from finding truthful nodes? We note that in this question, too, the graph of country B is fixed, and hence, country A would like to have an algorithm that takes as input *any* graph and computes the optimal way to place corrupt nodes in order to hide all the truthful nodes.

We study the questions above for a variant of the corruption detection problem in [1], in which the goal of the central agency is to find a single truthful node. While this goal is less ambitious than the goal of identifying almost all the nodes, we think it is a very natural question in the context of corruption. For one, if the central agency can find a single truthful node, they can use the trusted reports from that node to identify more truthful and corrupt nodes that it might be connected to. The central agency may additionally weight the opinions of the truthful nodes more when making policy decisions (as alluded to in the example above), and can also incentivize truthfulness by rewarding truthful nodes that it finds and giving them more influence in future networks if possible (by increasing their out-degrees). Moreover, our proofs and results extend to finding larger number of truthful nodes as we discuss below.

Our results stem from a tie between the problem of finding a single truthful node in a graph and a measure of vertex separability of the graph. This tie not only yields an efficient and relatively effective algorithm for the central agency to find a truthful node, but also allows us to relate corrupt party's strategy to the problem of finding a good vertex separator for the graph. Hence, by analyzing the purely graph-theoretic problem of finding a good vertex separator, we can characterize the difficulty of finding a good set of nodes to corrupt. Similar notions of vertex separability have been studied previously (e.g. [13, 17, 3]), and we prove NP-hardness for the notion relevant to us assuming the Small Set Expansion Hypothesis (SSEH). The *Small Set Expansion Hypothesis* is a hypothesis posed by Raghavendra and Steurer [19] that is closely related to the famous Unique Games Conjecture of Khot [11]. In fact, [19] shows that the SSEH implies the Unique Games Conjecture. The SSEH yields hardness results that are not known to follow directly from the UGC, especially for graph problems like sparsest cut and treewidth ([20] and [2] respectively), among others.

## 1.2 Our Results

We now outline our results more formally. We analyze the variant of corruption detection where the central agency's goal is to find a single truthful node. First, we study how effectively the central agency can identify a truthful node on an arbitrary graph, given a set of reports.

Given an undirected graph<sup>4</sup>  $G$ , we let  $m(G)$  denote the minimal number of corrupted nodes required to stop the central agency from finding a truthful node, where the minimum is taken over all strategies of the corrupt party (not just computationally bounded ones). We informally call  $m(G)$  the “critical” number of corrupt nodes for a graph  $G$ . Then, we show the following:

► **Theorem 1.** *Fix a graph  $G$  and suppose that the corrupt party has a budget  $b \leq m(G)/2$ . Then the central agency can identify a truthful node, regardless of the strategy of the corrupt party, and without knowledge of either  $m(G)$  or  $b$ . Furthermore, the central agency's algorithm runs in linear time (in the number of edges in the graph  $G$ ).*

Next, we consider the question from the viewpoint of the corrupt party: can the corrupt party efficiently compute the most economical way to allocate nodes to prevent the central agency from finding a truthful node? Concretely, we focus on a natural decision version of the question: given a graph  $G$  and an upper bound on the number of possible corrupted nodes  $k$ , can the corrupt party prevent the central agency from finding a truthful node?

We actually focus on an easier question: can the corrupt party accurately compute  $m(G)$ , the minimum number of nodes that they need to control to prevent the central agency from finding a truthful node? Not only do we give evidence that computing  $m(G)$  exactly is computationally hard, but we also provide evidence that  $m(G)$  is hard to approximate. Specifically, we show that approximating  $m(G)$  to any constant factor is NP-hard under the Small Set Expansion Hypothesis (SSEH); or in other words, that it is SSE-hard.

► **Theorem 2.** *For every  $\beta > 1$ , there is a constant  $\epsilon > 0$  such that the following is true. Given a graph  $G = (V, E)$ , it is SSE-hard to distinguish between the case where  $m(G) \leq \epsilon \cdot |V|$  and  $m(G) \geq \beta \cdot \epsilon \cdot |V|$ . Or in other words, the problem of approximating the critical number of corrupt nodes for a graph to within any constant factor is SSE-hard.*

This Theorem immediately implies the following Corollary 25.

► **Corollary 25 (restated).** Assume the SSE Hypothesis and that  $P \neq NP$ . Fix any  $\beta > 1$ . There does not exist a polynomial-time algorithm that takes as input an arbitrary graph  $G = (V, E)$  and outputs a set of nodes  $S$  with size  $|S| \leq O(\beta \cdot m(G))$ , such that corrupting  $S$  prevents the central agency from finding a truthful node.

We note that in Corollary 25, the bad party's input is only the graph  $G$ : specifically, they do not have knowledge about the value of  $m(G)$ .

Our proof for Theorem 2 is similar to the proof of Austrin, Pitassi, and Wu [2] for the SSE-hardness of approximating treewidth. This is not a coincidence: in fact, the “soundness” in their reduction involves proving that their graph does not have a good  $1/2$  vertex separator, where the notion of vertex separability (from [4]) is very related to the version we use to categorize the problem of hiding a truthful vertex. We give the proof of Theorem 2 in Section 3.2.

However, if one allows for an approximation factor of  $O(\log |V|)$ , then  $m(G)$  can be approximated efficiently. Furthermore, this yields an approximation algorithm that the corrupt party can use to find a placement that hinders detection of a truthful node.

► **Theorem 3.** *There is a polynomial-time algorithm that takes as input a graph  $G = (V, E)$  and outputs a set of nodes  $S$  with size  $|S| \leq O(\log |V| \cdot m(G))$ , such that corrupting  $S$  prevents the central agency from finding a truthful node.*

---

<sup>4</sup> Unless explicitly specified, all graphs are undirected by default.

The proof of Theorem 3, given in Section 3.2, uses a bi-criterion approximation algorithm for the  $k$ -vertex separator problem given by [13]. As alluded to in Section 1.1, Theorems 2 and 3 both rely on an approximate characterization of  $m(G)$  in terms of a measure of vertex separability of the graph  $G$ , which we give in Section 3.

Additionally, we note that we can adapt Theorems 1 and 2 (as well as Corollary 25) to a more general setting, where the central agency wants to recover some arbitrary number of truthful nodes, where the number of nodes can be proportional to the size of the graph. We describe how to modify our proofs to match this more general setting in Section 5 in full-length version [8].

Together, Theorems 1 and 2 uncover a surprisingly positive result for corruption detection: it is computationally easy for the central agency to find a truthful node when the number of corrupted nodes is only somewhat smaller than the “critical” number for the underlying graph, but it is in general computationally hard for the corrupt party to hide the truthful nodes even when they have a budget that far exceeds the “critical” number for the graph.

### 1.2.1 Results for Directed Graphs

As noted in [1], it is unlikely that real-world auditing networks are undirected. For example, it is likely that the FBI has the authority to audit the Cambridge police department, but it is also likely that the reverse is untrue. Therefore, we would like the central agency to be able to find truthful nodes in directed graphs in addition to undirected graphs. We notice that the algorithm we give in Theorem 1 extends naturally to directed graphs.

► **Theorem 4.** *Fix a directed graph  $D$  and suppose that the corrupt party has a budget  $b \leq m(D)/2$ . Then the central agency can identify a truthful node, regardless of the strategy of the corrupt party, and without the knowledge of either  $m(D)$  or  $b$ . Furthermore, the central agency’s algorithm runs in linear time.*

The proof of Theorem 4 is similar to the proof of Theorem 1, and effectively relates the problem of finding a truthful node on directed graphs to a similar notion of vertex separability, suitably generalized to directed graphs.

### 1.2.2 Results for Finding An Arbitrary Number of Good Nodes

In fact, the problem of finding one good node is just a special case of finding an arbitrary number of good nodes,  $g$ , on the graph  $G$ . We define  $m(G, g)$  as the minimal number of bad nodes required to prevent the identification of  $g$  good nodes on the graph  $G$ . We relate it to an analogous vertex separation notion, and prove the following two theorems, which are extensions of Theorems 1 and 2 to this setting.

► **Theorem 5.** *Fix a graph  $G$  and the number of good nodes to recover,  $g$ . Suppose that the corrupt party has a budget  $b \leq m(G, g)/2$ . If  $g < |V| - 2b$ , then the central agency can identify  $g$  truthful nodes, regardless of the strategy of the corrupt party, and without knowledge either of  $m(G, g)$  or  $b$ . Furthermore, the central agency’s algorithm runs in linear time.*

► **Theorem 6.** *For every  $\beta > 1$  and every  $0 < \delta < 1$ , there is a constant  $\epsilon > 0$  such that the following is true. Given a graph  $G = (V, E)$ , it is SSE-hard to distinguish between the case where  $m(G, \delta|V|) \leq \epsilon \cdot |V|$  and  $m(G, \delta|V|) \geq \beta \cdot \epsilon \cdot |V|$ . Or in other words, the problem of approximating the critical number of corrupt nodes such that it is impossible to find  $\delta|V|$  good nodes within any constant factor is SSE-hard.*

The proof of Theorem 6 is similar to the proof of Theorem 1, and the hardness of approximation proof also relies on the same graph reduction and SSE conjecture. Proofs are presented in Section 5 in our full-length paper [8].

### 1.3 Related Work

The model of corruptions posed by [1] is identical to a model first suggested by Preparata, Metze, and Chien [18], who introduced the model in the context of detecting failed components in digital systems. This work (as well as many follow-ups, e.g. [9, 12]) looked at the problem of characterizing which networks can detect a certain number of corrupted nodes. Xu and Huang [22] give necessary and sufficient conditions for identifying a single corrupted node in a graph, although their characterization is not algorithmically efficient. There are many other works on variants of this problem (e.g. [21, 5]), including recovering node identities with one-sided or two-sided error probabilities in the local reports [14] and adaptively finding truthful nodes [7].

We note that our model of a computationally bounded corrupt party and our stipulation that the graph is fixed ahead of time rather than designed by the central agency, which are our main contributions to the model, seem more naturally motivated in the setting of corruptions than in the setting of designing digital systems. Even the question of identifying a single truthful node could be viewed as more naturally motivated in the setting of corruptions than in the setting of diagnosing systems. We believe there are likely more interesting theoretical questions to be discovered by approaching the PMC model through a corruptions lens.

The identifiability of a single node in the corruptions setting was studied in a recent paper of Mukwembi and Mukwembi [15]. They give a linear time greedy algorithm to recover the identify of a single node in many graphs, *provided that corrupt nodes always report other corrupt nodes as truthful*. Furthermore, this assumption allows them to reduce identifying all nodes to identifying a single node. They argue that such an assumption is natural in the context of corruptions, where corrupt nodes are selfishly incentivized not to out each other. However, in our setting, corrupt nodes can not only betray each other, but are in fact incentivized to do so for the good of the overarching goal of the corrupt party (to prevent the central agency from identifying a truthful node). Given [15], it is not a surprise that the near-optimal strategies we describe for the corrupt party in this paper crucially rely on the fact that the nodes can report each other as corrupt.

Our problem of choosing the best subset of nodes to corrupt bears intriguing similarities to the problem of influence maximization studied by [10], where the goal is to find an optimal set of nodes to target in order to maximize the adoption of a certain technology or product. It is an interesting question to see if there are further similarities between these two areas. Additionally, social scientists have studied corruption extensively (e.g. [6], [16]), though to the best of our knowledge they have not studied it in the graph-theoretic way that we do in this paper.

### 1.4 Comparison to Corruption in Practice

Finally, we must address the elephant in the room. Despite our theoretical results, corruption *is* prevalent in many real-world networks, and yet in many scenarios it is not easy to pinpoint even a single truthful node. One reason for that is that some of assumptions do not seem to hold in some real world networks. For example, we assume that audits from the truthful nodes are not only non-malicious, but also perfectly reliable. In practice this assumption is unlikely to be true: many truthful nodes could be non-malicious but simply unable to audit

their neighbors accurately. Further assumptions that may not hold in some scenarios include the notion of a central agency that is both uncorrupted and has access to reports from every agency, and possibly even the assumption that the number of corrupt nodes is less than  $|V|/2$ . In addition, networks  $G$  may have very low critical numbers  $m(G)$  in practice. For example, there could be a small set of three nodes (named, “President”, “Congress” and “Houses”) that is all corrupt, and all audits in the graph are performed by one of these three nodes. It is thus plausible that a corrupt party could use the structure of realistic auditing networks for their corruption strategy to overcome our worst-case hardness result.

While this points to some shortcomings of our model, it also points out ways to change policy that would potentially bring the real world closer to our idealistic scenario, where a corrupt party has a much more difficult computational task than the central agency. For example, we can speculate that perhaps information should be gathered by a transparent centralized agency, that significant resources should go into ensuring that the centralized agency is not corrupt, and that networks ought to have good auditing structure (without important agencies that can be audited by very few nodes).

## 2 Preliminaries

### 2.1 General Preliminaries

We denote undirected graphs by  $G = (V, E)$ , where  $V$  is the vertex set of the graph and  $E$  is the edge set. We denote directed graphs by  $D = (V, E_D)$ . When the underlying graph is clear, we may drop the subscripts. Given a vertex  $u$  in an undirected graph  $G$ , we let  $\mathcal{N}(u)$  denote the *neighborhood* (set of neighbors) of the vertex in  $G$ . Similarly, given a vertex  $u$  in a directed graph  $D$ , let  $\mathcal{N}(u)$  denote the set of *outgoing* neighbors of  $u$ : that is, vertices  $v \in V$  such that  $(u, v) \in E_D$ .

#### 2.1.1 Vertex Separator

► **Definition 7** (*k*-vertex separator, [17], [3]). For any  $k \geq 0$ , we say a subset of vertices  $U \subseteq V$  is *k*-vertex separator of a graph  $G$ , if after removing  $U$  and incident edges, the remaining graph forms a union of connected components, each of size at most  $k$ .

Furthermore, let

$$S_G(k) = \min (|U| : U \text{ is a } k\text{-vertex separator of } G)$$

denote the size of the minimal *k*-vertex separator of graph  $G$ .

#### 2.1.2 Small Set Expansion Hypothesis

In this section we define the Small Set Expansion (SSE) Hypothesis introduced in [19]. Let  $G = (V, E)$  be an undirected  $d$ -regular graph.

► **Definition 8** (*Normalized edge expansion*). For a set  $S \subseteq V$  of vertices, denote  $\Phi_G(S)$  as the normalized edge expansion of  $S$ ,

$$\Phi_G(S) = \frac{|E(S, V \setminus S)|}{d|S|},$$

where  $|E(S, V \setminus S)|$  is the number of edges between  $S$  and  $V \setminus S$ .

The *Small Set Expansion Problem* with parameters  $\eta$  and  $\delta$ , denoted  $\text{SSE}(\eta, \delta)$ , asks whether  $G$  has a small set  $S$  which does not expand or all small sets of  $G$  are highly expanding.

► **Definition 9** ( $SSE(\eta, \delta)$ ). Given a regular graph  $G = (V, E)$ , distinguish between the following two cases:

- **Yes** There is a set of vertices  $S \subseteq V$  with  $|S| = \delta|V|$  and  $\Phi_G(S) \leq \eta$
- **No** For every set of vertices  $S \subseteq V$  with  $|S| = \delta|V|$  it holds that  $\Phi_G(S) \geq 1 - \eta$

The *Small Set Expansion Hypothesis* is the conjecture that deciding  $SSE(\eta, \delta)$  is NP-hard.

► **Conjecture 10** (Small Set Expansion Hypothesis [19]). *For every  $\eta > 0$ , there is a  $\delta > 0$  such that  $SSE(\eta, \delta)$  is NP-hard.*

We say that a problem is *SSE-hard* if it is at least as hard to solve as the SSE problem. The form of conjecture most relevant to our proof is the following “stronger” form of the SSE Hypothesis. [20] showed that the SSE-problem can be reduced to a quantitatively stronger form of itself. In order to state this version, we first need to define the *Gaussian noise stability*.

► **Definition 11** (Gaussian Noise Stability). Let  $\rho \in [-1, 1]$ . Define  $\Gamma_\rho : [0, 1] \mapsto [0, 1]$  by

$$\Gamma_\rho(\mu) = Pr[X \leq \Phi^{-1}(\mu) \wedge Y \leq \Phi^{-1}(\mu)]$$

where  $X$  and  $Y$  are jointly normal random variables with mean 0 and covariance matrix  $\begin{pmatrix} 1 & \rho \\ \rho & 1 \end{pmatrix}$ .

The only fact that we will use for stating the stronger form of SSEH is the asymptotic behavior of  $\Gamma_\rho(\mu)$  when  $\rho$  is close to 1 and  $\mu$  bounded away from 0.

► **Fact 12.** *There is a constant  $c > 0$  such that for all sufficiently small  $\epsilon$  and all  $\mu \in [1/10, 1/2]$ ,*<sup>5</sup>

$$\Gamma_{1-\epsilon}(\mu) \leq \mu(1 - c\sqrt{\epsilon}).$$

► **Conjecture 13** (SSE Hypothesis, Equivalent Formulation [20]). *For every integer  $q > 0$  and  $\epsilon, \gamma > 0$ , it is NP-hard to distinguish between the following two cases for a given regular graph  $G = (V, E)$ :*

- **Yes** There is a partition of  $V$  into  $q$  equi-sized sets  $S_1, \dots, S_q$  such that  $\Phi_G(S_i) \leq 2\epsilon$  for every  $1 \leq i \leq q$ .
- **No** For every  $S \subseteq V$ , letting  $\mu = |S|/|V|$ , it holds that  $\Phi_G(S) \geq 1 - (\Gamma_{1-\epsilon/2}(\mu) + \gamma)/\mu$ , where the  $\Gamma_{1-\epsilon/2}(\mu)$  is the Gaussian noise stability.

We present two remarks about the Conjecture 13 from [2], which are relevant to our proof of Theorem 2.

► **Remark 14.** [2] The **Yes** instance of Conjecture 13 implies that the number of edges leaving each  $S_i$  is at most  $4\epsilon|E|/q$ , so the total number of edges not contained in one of the  $S_i$  is at most  $2\epsilon|E|$ .

► **Remark 15.** [2] The **No** instance of Conjecture 13 implies that for  $\epsilon$  sufficiently small, there exists some constant  $c'$  such that  $\Phi_G(S) \geq c'\sqrt{\epsilon}$ , provided that  $\mu \in [1/10, 1/2]$  and setting  $\gamma \leq \sqrt{\epsilon}$ . In particular,  $|E(S, V \setminus S)| \geq \Omega(\sqrt{\epsilon}|E|)$ , for any  $|V|/10 \leq |S| \leq 9|V|/10$ .<sup>6</sup>

<sup>5</sup> Note that the lower bound on  $\mu$  can be taken arbitrarily close to 0. So the statement holds with  $\mu \in [c', 1/2]$  for any constant  $c' > 0$ .

<sup>6</sup> Recall that Fact 12 is true for  $\mu \in [c', 1/2]$  for any constant  $c' > 0$ . Therefore, Remark (15) can be strengthened and states, for any  $c'|V| \leq |S| \leq (1 - c')|V|$ ,  $|E(S, V \setminus S)| \geq \Omega(\sqrt{\epsilon}|E|)$ . This will be a useful fact for proving hardness of approximation of  $m(G, g)$  for finding many truthful nodes in Section 5 in full length paper [8].

Remark 14 follows from the definition of normalized edge expansion and the fact that sum of degree is two times number of edges. Remark 15 follows from Fact 12. The strong form of SSE Hypothesis 13, Remark 14 and Remark 15 will be particularly helpful for proving our SSE-hardness of approximation result (Theorem 2).

## 2.2 Preliminaries for Corruption Detection on Networks

We model networks as directed or undirected graphs, where each vertex in the network can be one of two types: truthful or corrupted. At times, we will informally call truthful vertices “good” and corrupt vertices “bad.” We say that the corrupt party has *budget*  $b$  if it can afford to corrupt at most  $b$  nodes of the graph. Given a vertex set  $V$ , and a budget  $b$ , the corrupt entity will choose to control a subset of nodes  $B \subseteq V$  under the constraint  $|B| \leq b$ . The rest of the graph remains as truthful vertices, i.e.,  $T = V \setminus B \subseteq V$ . We assume that there are more truthful than corrupt nodes ( $b < |V|/2$ ). It is easy to see that in the case where  $|B| \geq |T|$ , the corrupt nodes can prevent the identification of even one truthful node, by simulating truthful nodes (see e.g. [1]).

Each node audits and reports its (outgoing) neighbors’ identities. That is, each vertex  $u \in V$  will report the type of each  $v \in \mathcal{N}(u)$ , which is a vector in  $\{0, 1\}^{|\mathcal{N}(u)|}$ . Truthful nodes always report the truth, i.e., it reports its neighbor  $v \in T$  if  $v$  is truthful,  $v \in B$  if  $v$  is corrupt. The corrupt nodes report their neighbors’ identities adversarially. In summary, a strategy of the bad agents is composed of a strategy to take over at most  $b$  nodes on the graph, and reports on the nodes that neighbor them.

► **Definition 16** (Strategy for a corrupt party). A strategy for the corrupt party is a function that maps a graph  $G$  and budget  $b$  to a subset of nodes  $B$  with size  $|B| \leq b$ , and a set of reports that each node  $v \in B$  gives about its neighboring nodes,  $\mathcal{N}(v)$ .

► **Definition 17** (Computationally bounded corrupt party). We say that the corrupt party is computationally bounded if its strategy can only be a polynomial-time computable function.

The task for the central agency is to find a good node on this corrupted network, based on the reports. It is clear that the more budget the corrupt party has, the harder the task of finding one truthful node becomes. It was observed in [1] that, for any graph, it is not possible to find one good node if  $b \geq |V|/2$ . If  $b = 0$ , it is clear that the entire set  $V$  is truthful. Therefore, given an arbitrary graph  $G$ , there exists a critical number  $m(G)$ , such that if the bad party has budget lower than  $m(G)$ , it is always possible to find a good node; if the bad party has budget greater than or equal to  $m(G)$ , it may not be possible to find a good node. In light of this, we define the critical number of bad nodes on a graph  $G$ . First, we formally define what we mean when we say it is impossible to find a truthful node on a graph  $G$ .

► **Definition 18** (Impossibility of finding one truthful node). Given a graph  $G = (V, E)$ , the bad party’s budget  $b$  and reports, we say that it is *impossible to identify one truthful node* if for any  $v \in V$ , there exists a configuration of the identities of the nodes where  $v$  is bad, at most  $b$  nodes are bad, and the configuration is consistent with the given reports.

► **Definition 19** (Critical number of bad nodes on a graph  $G$ ,  $m(G)$ ). Given an arbitrary graph  $G = (V, E)$ , we define  $m(G)$  as the minimum number  $b$  such that there is a way to distribute  $b$  corrupt nodes and set their corresponding reports such that it is impossible to find *one* truthful node on the graph  $G$ , given  $G$ , the reports and that the bad party’s budget is at most  $b$ .

For example, for a star graph  $G$  with  $|V| \geq 5$ , the critical number of bad nodes is  $m(G) = 2$ . If there is at most 1 corrupt node on  $G$ , the central agency can always find a good node, thus  $m(G) > 1$ . If there are at most 2 bad nodes on  $G$ , then the bad party can control the center node and one of the leaves. Then for any node  $v$  in the graph, there exists a configuration where  $v$  is bad, only two nodes are assigned bad, and the configuration is consistent with observed reports. Therefore, it is impossible for central agency to find one good node,  $m(G) = 2$ .

Given a graph  $G$ , by definition there exists a set of nodes of size  $m(G)$  that can make it impossible to find a good node if they are corrupted. However, this does not mean that the corrupt party can necessarily find this set in polynomial time. Indeed, Theorem 2 establishes that they cannot always find this set in polynomial time if we assume the SSE Hypothesis (Conjecture 13) and that  $P \neq NP$ .

### 3 Proofs and Main Lemmas

In the following section, we state our main results by first presenting the close relation of our problem to the  $k$ -vertex separator problem. Then we use this characterization to prove Theorem 1. This characterization will additionally be useful for the proofs of Theorems 2 and 3, which we will sketch in Section 3.2, and provide in Section 3.3 in our full length paper [8].

#### 3.1 2-Approximation by Vertex Separation

► **Lemma 20** (2-Approximation by Vertex Separation). *The critical number of corrupt nodes for graph  $G$ ,  $m(G)$ , can be bounded by the minimal sum of  $k$ -vertex separator and  $k$ ,  $\min_k (S_G(k) + k)$ , up to a factor of 2. i.e.,*

$$\frac{1}{2} \min_k (S_G(k) + k) \leq m(G) \leq \min_k (S_G(k) + k)$$

**Proof of Lemma 20.** The direction  $m(G) \leq \min_k S_G(k) + k$  follows simply. Let  $k^* = \arg \min_k (S_G(k) + k)$ . If the corrupt party is given  $S_G(k^*) + k^*$  nodes to corrupt on the graph, it can first assign  $S_G(k^*)$  nodes to the separator, thus the remaining nodes are partitioned into components of size at most  $k^*$ . Then it arbitrarily assigns one of the components to be all bad nodes. The bad nodes in the connected components report the nodes in the same component as good, and report any node in the separator as bad. The nodes in the separator can effectively report however they want (e.g. report all neighboring nodes as bad). It is impossible to identify even one single good node, because all connected components of size  $k$  can potentially be bad, and all vertices in the separator are bad.

The direction  $1/2 \min_k (S_G(k) + k) \leq m(G)$  can be proved as follows. When there are  $b = m(G)$  corrupt nodes distributed optimally in  $G$ , it is impossible to find a single good node by definition, and therefore, in particular, the following algorithm (Algorithm 1) cannot always find a good node:

---

**Algorithm 1** Finding one truthful vertex on undirected graph  $G$ .

---

Input: Undirected graph  $G$

- If the reports on edge  $(u, v)$  does not equal to  $(u \in T, v \in T)$ , remove both  $u, v$  and any incident edges. Remove a pair of nodes in each round, until there are no bad reports left.
  - Call the remaining graph  $H$ . Declare the largest component of  $H$  as good.
-

Run Algorithm 1 on  $G$ , and suppose the first step terminates in  $i$  rounds, then:

- No remaining node reports neighbors as corrupt
- $|V| - 2i$  nodes remain in graph
- $\leq b - i$  bad nodes remain in the graph, because each time we remove an edge with bad report, and one of the end points must be a corrupt vertex.

Note that if two nodes report each other as good, they must be the same type (either both truthful, or both corrupt.) Since graph  $H$  only contains good reports, nodes within a connected component of  $H$  have the same types. If there exists a component of size larger than  $b - i$ , it exceeds bad party's budget, and must be all good. Therefore, Algorithm 1 would successfully find a good node.

Since Algorithm 1 cannot find a good node, the bad party must have the budget to corrupt the largest component of  $H$ , which means it has size at most  $b - i$ . Hence,  $S_G(b - i) \leq 2i$ . Plugging in  $b = m(G)$ , we get that

$$m(G) = \frac{2i}{2} + b - i \geq \min_k (S_G(k)/2 + k) \geq \frac{1}{2} \min_k (S_G(k) + k),$$

where the first inequality comes from  $2i \geq S_G(b - i)$ . ◀

Furthermore, the upper bound in Lemma 20 additionally tells us that if corrupt party's budget  $b \leq m(G)/2$ , the set output by Algorithm 1 is guaranteed to be good.

► **Theorem 1 (restated).** Fix a graph  $G$  and suppose that the corrupt party has a budget  $b \leq m(G)/2$ . Then the central agency can identify a truthful node, regardless of the strategy of the corrupt party, and without knowledge of either  $m(G)$  or  $b$ . Furthermore, the central agency's algorithm runs in linear time (in the number of edges in the graph  $G$ ).

**Proof of Theorem 1.** Suppose the corrupt party has budget  $b \leq m(G)/2$ . Run Algorithm 1. We remove  $2i$  nodes in the first step, and separate the remaining graph  $H$  into connected components. Notice each time we remove an edge with bad report, at least one of the end point is a corrupt vertex. So we have removed at most  $2b \leq m(G) \leq \lceil |V|/2 \rceil$  nodes. Therefore, the graph  $H$  is nonempty, and the nodes in any connected component of  $H$  have the same identity. Let  $k^* \geq 1$  be the size of the maximum connected component of  $H$ . We can conclude that  $S_G(k^*) \leq 2i$ , since  $2i$  is a possible size of  $k^*$ -vertex separator of  $G$ .

Notice there are at most  $b - i \leq m(G)/2 - i$  bad nodes in  $H$  by the same fact that at least one bad node is removed each round. By the upper bound in Lemma 20,

$$b - i \leq m(G)/2 - i \leq \min_k (S_G(k) + k)/2 - i \leq (2i + k^*)/2 - i \leq \frac{k^*}{2}.$$

Since  $k^* \geq 1$ , the connected component of size  $k^*$  exceeds the bad party's remaining budget  $k^*/2$ , and must be all good.

Algorithm 1 is linear time because it loops over all edges and removes any "bad" edge that does not have reports  $(T, T)$  (takes  $\leq |E|$  time when we use a list with "bad" edges at the front), and counts the size of the remaining components ( $\leq |V|$  time), and thus is linear in  $|E|$ . ◀

► **Remark 21.** Both bounds in Lemma 20 are tight. For the lower bound, consider a complete graph with an even number of nodes. For the upper bound, consider a complete bipartite graph with one side smaller than the other.

A tight lower bound and a tight upper bound example can be found in full-length version of our paper [8].

We end by discussing that the efficient algorithm given in this section does not address the regime when the budget of the bad party,  $b$ , falls in  $m(G)/2 < b \leq m(G)$ . Though by definition of  $m(G)$ , the central agency can find at least one truthful node as long as  $b \leq m(G)$ , by, for example, enumerating all possible assignments of good/bad nodes consistent with the report, and check the intersection of the assignment of good nodes. However, it is not clear that the central agency has a polynomial time algorithm for doing this. Of course, one can always run Algorithm 1, check whether the output set exceeds  $b - i/2$ , and concludes that the output set is truthful if that is the case. However, there is no guarantee that the output set will be larger than  $b - i/2$  if  $m(G)/2 < b \leq m(G)$ . We propose the following conjecture:

► **Conjecture 22.** *Fix a graph  $G$  and suppose that the corrupt party has a budget  $b$  such that  $m(G)/2 < b \leq m(G)$ . The problem of finding one truthful node given the graph  $G$ , bad party's budget  $b$  and the reports is NP-hard.*

### 3.2 SSE-Hardness of Approximation for $m(G)$

In this section, we present the hardness of approximation result for  $m(G)$  within any constant factor under the Small Set Expansion (SSE) Hypothesis [19]. Specifically, we give essential steps for proving Theorem 2.

► **Theorem 2 (restated).** For every  $\beta > 1$ , there is a constant  $\epsilon > 0$  such that the following is true. Given a graph  $G = (V, E)$ , it is SSE-hard to distinguish between the case where  $m(G) \leq \epsilon \cdot |V|$  and  $m(G) \geq \beta \cdot \epsilon \cdot |V|$ . Or in other words, the problem of approximating the critical number of corrupt nodes for a graph to within any constant factor is SSE-hard.

In order to prove Theorem 2, we construct a reduction similar to [2], and show that the bad party can control auxiliary graph of the **Yes** case of SSE with  $b = O(\epsilon|V'|)$  and cannot control the auxiliary graph of the **No** case of SSE with  $b = \Omega(\epsilon^{0.51}|V'|)$ . In the following, we present the arguments for the **No** case.

Given an undirected  $d$ -regular graph  $G = (V, E)$ , construct an auxiliary undirected graph  $G' = (V', E')$  in the following way [2]. Let  $r = d/2$ . For each vertex  $v^i \in V$ , make  $r$  copies of  $v^i$  and add to the vertex set of  $G'$ , denoted  $v_1^i, \dots, v_r^i$ . Denote the resulting set of vertices as  $\tilde{V} = V \times \{1, \dots, r\}$ . Each edge  $e^k \in E$  of  $G$  becomes a vertex in  $G'$ , denoted  $e^k$ . Denote this set of vertices as  $\tilde{E}$ . In other words,  $V' = \tilde{V} \cup \tilde{E} = V \times \{1, \dots, r\} \cup E$ . There exists an edge between a vertex  $v_j^i$  and a vertex  $e^k$  of  $G'$  if  $v^i$  and  $e^k$  were adjacent edge and vertex pair in  $G$ . Note that  $G'$  is a bipartite  $d$ -regular graph with  $d/2|V| + |E| = 2|E|$  vertices.

► **Lemma 23.** *Suppose  $q = 1/\epsilon$ , and  $G$  can be partitioned into  $q$  equi-sized sets  $S_1, \dots, S_q$  such that  $\Phi_G(S_i) \leq 2\epsilon$  for every  $1 \leq i \leq q$ . Then the bad party can control the auxiliary graph  $G'$  with at most  $3\epsilon|E| = 1.5\epsilon|V'|$  nodes.*

**Proof of Lemma 23.** Notice by Remark (2.1.1), the total number of edges in  $G$  not contained in one of the  $S_i$  is at most  $2\epsilon|E|$ .

This implies that a strategy for the bad party to control graph  $G'$  is as follows. Control vertex  $e^k \in \tilde{E}$  if  $e^k \in E$  is not contained in any of the  $S_i$ s in  $G$ . Call the set of such vertices  $E^* \subseteq \tilde{E}$ . Let  $S_i^* \subseteq V'$  be the set that contains all  $r$  copies of nodes in  $S_i \subseteq V$ . Control one of the  $S_i^*$ s, say  $S_1^*$ . Corrupt nodes in  $S_1^*$  report their neighbors in  $S_1^*$  as good, and report  $E^*$  as bad. Nodes in  $E^*$  can effectively report however they want; suppose they report every neighboring node as bad. Then, it is impossible to identify even one truthful node, since assigning any  $S_i^*$  as corrupt is consistent with the report and within bad party's budget.

If  $q = 1/\epsilon$ , this strategy amounts to controlling  $2\epsilon|E| + d/2 \cdot |V|/q = 3\epsilon|E|$  nodes on  $G'$ . Notice, this number is guaranteed to be smaller than  $1/2|V'|$ , as long as  $q > 4$ , because the bad party controls less than  $2/q$  of all the “edge vertices”  $\tilde{E}$ , and controls less than  $1/q$  of all the “vertex vertices”  $\tilde{V}$ . ◀

Note that, different from the argument in [2], we cannot take  $r$  to be arbitrarily large (e.g.  $> O(|V||E|)$ ). This is because when  $r$  is large,  $2\epsilon|E| + r \cdot |V|/q = O(\epsilon(|E| + |V'|)) = O(\epsilon|V'|)$ , and will not be comparable with the  $O(\sqrt{\epsilon}|E|)$  in Lemma 24.

► **Lemma 24.** *Let  $G = (V, E)$  be an undirected  $d$ -regular graph with the property that for every  $|V|/10 \leq |S| \leq 9|V|/10$  we have  $|E(S, V \setminus S)| \geq \Omega(\sqrt{\epsilon}|E|)$ . If bad party controls  $O(\epsilon^{0.51}|E|) = O(\epsilon^{0.51}|V'|) < 1/2|V'|$  nodes on the auxiliary graph  $G'$  constructed from  $G$ , we can always find a truthful node on  $G'$ .*

Combining Lemma 23 and Lemma 24, Theorem 2 follows in standard fashion. The proofs for Lemma 24 and Theorem 2 are presented in our full-length paper [8].

We also obtain the following Corollary 25 from Theorem 2.

► **Corollary 25.** *Assume the SSE Hypothesis and that  $P \neq NP$ . Fix any  $\beta > 1$ . There does not exist a polynomial-time algorithm that takes as input an arbitrary graph  $G = (V, E)$  and outputs a set of nodes  $S$  with size  $|S| \leq O(\beta \cdot m(G))$ , such that corrupting  $S$  prevents the central agency from finding a truthful node.*

In summary, the analysis in this section tells us that given an arbitrary graph, it is hard for bad party to corrupt the graph with minimal resources. Moreover, it is still hard for the bad party to corrupt the graph even if they are given a budget of  $\beta m(G)$ , for any  $\beta \geq 1$ . On the other hand, if the budget of the bad party is a factor of two less than  $m(G)$ , a good node can always be detected with an efficient algorithm, e.g. using Algorithm 1. This contrast highlights that the corruption detection problem of finding one good node (and, as later proven, finding any arbitrary fraction of good nodes) is easier for the good party and harder for the bad party.

Finally, the existence of efficient algorithms for good party to detect one good node on directed graphs (i.e. Theorem 4), and detect any fraction of the good nodes (i.e. Theorem 5) follows from analogous notions of vertex-separators to Definition 7. The hardness of approximation results for finding any arbitrary fraction of good nodes, i.e. 6 can be proven following similar constructions and arguments as in the proof sketch of Theorem 2. Then, we give a simple a gadget reduction that extends the result to  $\delta \in [1/2, 1)$ . The full details of this proof can be found in the full version of our paper, together with the proofs of Theorem 3, 4, 5, 6.

# Simulating Random Walks on Graphs in the Streaming Model

## Abstract

We study the problem of approximately simulating a  $t$ -step random walk on a graph where the input edges come from a single-pass stream. The straightforward algorithm using reservoir sampling needs  $O(nt)$  words of memory. We show that this space complexity is near-optimal for directed graphs. For undirected graphs, we prove an  $\Omega(n\sqrt{t})$ -bit space lower bound, and give a near-optimal algorithm using  $O(n\sqrt{t})$  words of space with  $2^{-\Omega(\sqrt{t})}$  simulation error (defined as the  $\ell_1$ -distance between the output distribution of the simulation algorithm and the distribution of perfect random walks). We also discuss extending the algorithms to the turnstile model, where both insertion and deletion of edges can appear in the input stream.

## 1 Introduction

Graphs of massive size are used for modeling complex systems that emerge in many different fields of study. Challenges arise when computing with massive graphs under memory constraints. In recent years, graph streaming has become an important model for computation on massive graphs. Many space-efficient streaming algorithms have been designed for solving classical graph problems, including connectivity [2], bipartiteness [2], minimum spanning tree [2], matching [8, 12, 1], spectral sparsifiers [14, 13], etc. We will define the streaming model in Section 1.1.

Random walks on graphs are stochastic processes that have many applications, such as connectivity testing [17], clustering [18, 3, 4, 5], sampling [11] and approximate counting [10]. Since random walks are a powerful tool in algorithm design, it is interesting to study them in the streaming setting. A natural problem is to find the space complexity of simulating random walks in graph streams. Das Sarma et al. [7] gave a multi-pass streaming algorithm that simulates a  $t$ -step random walk on a directed graph using  $O(\sqrt{t})$  passes and only  $O(n)$  space. By further extending this algorithm and combining with other ideas, they obtained space-efficient algorithms for estimating PageRank on graph streams. However, their techniques crucially rely on reading multiple passes of the input stream.

In this paper, we study the problem of simulating random walks in the *one-pass* streaming model. We show space lower bounds for both directed and undirected versions of the problem, and present algorithms that nearly match with the lower bounds. We summarize our results in Section 1.3.

### 1.1 One-pass streaming model

Let  $G = (V, E)$  be a graph with  $n$  vertices. In the insertion-only model, the input graph  $G$  is defined by a stream of edges  $(e_1, \dots, e_m)$  seen in arbitrary order, where each edge  $e_i$  is specified by its two endpoints  $u_i, v_i \in V$ . An algorithm must process the edges of  $G$  in the order that they appear in the input stream. The edges can be directed or undirected, depending on the problem setting. Sometimes we allow multiple edges in the graph, where the multiplicity of an edge equals its number of occurrences in the input stream.

In the turnstile model, we allow both insertion and deletion of edges. The input is a stream of updates  $((e_1, \Delta_1), (e_2, \Delta_2), \dots)$ , where  $e_i$  encodes an edge and  $\Delta_i \in \{1, -1\}$ . The multiplicity of edge  $e$  is  $f(e) = \sum_{e_i=e} \Delta_i$ . We assume  $f(e) \geq 0$  always holds for every edge  $e$ .

### 1.2 Random walks

Let  $f(u, v)$  denote the multiplicity of edge  $(u, v)$ . The degree of  $u$  is defined by  $d(u) = \sum_{v \in V} f(u, v)$ . A  $t$ -step random walk starting from a vertex  $s \in V$  is a random sequence of vertices  $v_0, v_1, \dots, v_t$  where  $v_0 = s$  and  $v_i$  is a vertex uniformly randomly chosen from the vertices that  $v_{i-1}$  connects to, i.e.,  $\mathbb{P}[v_i = v | v_{i-1} = u] = f(u, v)/d(u)$ . Let  $\mathcal{RW}_{s,t} : V^{t+1} \rightarrow [0, 1]$  denote the distribution of  $t$ -step random walks starting from  $s$ , defined by<sup>1</sup>

$$\mathcal{RW}_{s,t}(v_0, \dots, v_t) = \mathbf{1}[v_0 = s] \prod_{i=0}^{t-1} \frac{f(v_i, v_{i+1})}{d(v_i)}. \quad (1)$$

For two distributions  $P, Q$ , we denote by  $|P - Q|_1$  their  $\ell_1$  distance. We say that a randomized algorithm can simulate a  $t$ -step random walk starting from  $v_0$  within error  $\varepsilon$ , if the distribution  $\mathbb{P}_w$  of its output  $w \in V^{t+1}$  satisfies  $|\mathbb{P}_w - \mathcal{RW}_{v_0,t}|_1 \leq \varepsilon$ . We say the random walk simulation is perfect if  $\varepsilon = 0$ .

We study the problem of simulating a  $t$ -step random walk within error  $\varepsilon$  in the streaming model using small space. We assume the length  $t$  is specified at the beginning. Then the algorithm reads the input stream. When a query with parameter  $v_0$  comes, the algorithm should simulate and output a  $t$ -step random walk starting from vertex  $v_0$ .

It is without loss of generality to assume that the input graph has no self-loops. If we can simulate a random walk on the graph with self-loops removed, we can then turn it into a random walk of the original graph by simply inserting self-loops after  $u$  with probability  $d_{\text{self}}(u)/d(u)$ . The values  $d_{\text{self}}(u), d(u)$  can be easily maintained by a streaming algorithm using  $O(n)$  words.

The random walk is not well-defined when it starts from a vertex  $u$  with  $d(u) = 0$ . For undirected graphs, this can only happen at the beginning of the random walk, and we simply let our algorithm return FAIL if  $d(v_0) = 0$ . For directed graphs, one way to fix this is to continue the random walk from  $v_0$ , by adding an edge  $(u, v_0)$  for every vertex  $u$  with  $d(u) = 0$ . We will not deal with  $d(u) = 0$  in the following discussion.

### 1.3 Our results

We will use  $\log x = \log_2 x$  throughout this paper.

The following two theorems give space lower bounds on directed and undirected versions of the problem. Note that the lower bounds hold even for simple graphs<sup>2</sup>.

<sup>1</sup> For a statement  $p$ , define  $\mathbf{1}[p] = 1$  if  $p$  is true, and  $\mathbf{1}[p] = 0$  if  $p$  is false.

<sup>2</sup> A *simple* graph is a graph with no multiple edges.

► **Theorem 1.** For  $t \leq n/2$ , simulating a  $t$ -step random walk on a simple directed graph in the insertion-only model within error  $\varepsilon = \frac{1}{3}$  requires  $\Omega(nt \log(n/t))$  bits of memory.

► **Theorem 2.** For  $t = O(n^2)$ , simulating a  $t$ -step random walk on a simple undirected graph in the insertion-only model within error  $\varepsilon = \frac{1}{3}$  requires  $\Omega(n\sqrt{t})$  bits of memory.

Theorem 3 and Theorem 4 give near optimal space upper bounds for the problem in the insertion-only streaming model.

► **Theorem 3.** We can simulate a  $t$ -step random walk on a directed graph in the insertion-only model perfectly using  $O(nt)$  words<sup>3</sup> of memory. For simple directed graphs, the memory can be reduced to  $O(nt \log(n/t))$  bits, assuming  $t \leq n/2$ .

► **Theorem 4.** We can simulate a  $t$ -step random walk on an undirected graph in the insertion-only model within error  $\varepsilon$  using  $O\left(n\sqrt{t} \cdot \frac{q}{\log q}\right)$  words of memory, where  $q = 2 + \frac{\log(1/\varepsilon)}{\sqrt{t}}$ . In particular, the algorithm uses  $O(n\sqrt{t})$  words of memory when  $\varepsilon = 2^{-\Theta(\sqrt{t})}$ .

Our algorithms also extend to the turnstile model.

► **Theorem 5.** We can simulate a  $t$ -step random walk on a directed graph in the turnstile model within error  $\varepsilon$  using  $O(n(t + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits of memory.

► **Theorem 6.** We can simulate a  $t$ -step random walk on an undirected graph in the turnstile model within error  $\varepsilon$  using  $O(n(\sqrt{t} + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits of memory.

## 2 Directed graphs in the insertion-only model

The simplest algorithm uses  $O(n^2)$  words of space (or only  $O(n^2)$  bits, if we assume the graph is simple) to store the adjacency matrix of the graph. When  $t \ll n$ , a better solution is to use reservoir sampling.

► **Lemma 7** (Reservoir sampling). Given a stream of  $n$  items as input, we can uniformly sample  $m$  of them without replacement using  $O(m)$  words of memory.

We can also sample  $m$  items from the stream *with* replacement in  $O(m)$  words of memory using  $m$  independent reservoir samplers each with capacity 1.

► **Theorem 8.** We can simulate a  $t$ -step random walk on a directed graph in the insertion-only model perfectly using  $O(nt)$  words of memory.

**Proof.** For each vertex  $u \in V$ , we sample  $t$  edges  $e_{u,1}, \dots, e_{u,t}$  outgoing from  $u$  with replacement. Then we perform a random walk using these edges. When  $u$  is visited for the  $i$ -th time ( $i \leq t$ ), we go along edge  $e_{u,i}$ . ◀

By treating an undirected edge as two opposite directed edges, we can achieve the same space complexity in undirected graphs.

Now we show a space lower bound for the problem. We will use a standard result from communication complexity.

► **Definition 9.** In the INDEX problem, Alice has an  $n$ -bit vector  $X \in \{0, 1\}^n$  and Bob has an index  $i \in [n]$ . Alice sends a message to Bob, and then Bob should output the bit  $X_i$ .

<sup>3</sup> A word has  $\Theta(\log \max\{n, m\})$  bits.

► **Lemma 10** ([15]). *For any constant  $1/2 < c \leq 1$ , solving the INDEX problem with success probability  $c$  requires sending  $\Omega(n)$  bits.*

► **Theorem 11.** *For  $t \leq n/2$ , simulating a  $t$ -step random walk on a simple directed graph in the insertion-only model within error  $\varepsilon = \frac{1}{3}$  requires  $\Omega(nt \log(n/t))$  bits of memory.*

**Proof.** We prove by showing a reduction from the INDEX problem. Before the protocol starts, Alice and Bob agree on a family  $\mathcal{F}$  of  $t$ -subsets of  $[n]$ <sup>4</sup> such that the condition  $|S \cap S'| < t/2$  is satisfied for every  $S, S' \in \mathcal{F}, S \neq S'$ . For two independent uniform random  $t$ -subsets  $S, S' \subseteq [n]$ , let  $p = \mathbb{P}[|S \cap S'| \geq t/2] \leq \binom{t}{t/2} (\frac{t}{n})^{t/2} < (\frac{4t}{n})^{t/2}$ . By union bound over all pairs of subsets, a randomly generated family  $\mathcal{F}$  satisfies the condition with probability at least  $1 - \binom{|\mathcal{F}|}{2} p$ , which is positive when  $|\mathcal{F}| = \lceil \sqrt{1/p} \rceil \geq (\frac{n}{4t})^{t/4}$ . So we can choose such family  $\mathcal{F}$  with  $\log |\mathcal{F}| = \Omega(t \log(n/t))$ .

Assume  $|\mathcal{F}|$  is a power of two. Alice encodes  $n \log |\mathcal{F}|$  bits as follows. Let  $G$  be a directed graph with vertex set  $\{v_0, v_1, \dots, v_{2n}\}$ . For each vertex  $u \in \{v_{n+1}, v_{n+2}, \dots, v_{2n}\}$ , Alice chooses a set  $S_u \in \mathcal{F}$ , and inserts an edge  $(u, v_i)$  for every  $i \in S_u$ .

Suppose Bob wants to query  $S_u$ . He adds an edge  $(v, u)$  for every  $v \in \{v_0, v_1, v_2, \dots, v_n\}$ , and then simulates a random walk starting from  $v_0$ . The random walk visits  $u$  every two steps, and it next visits  $v_i$  for some random  $i \in S_u$ . At least  $t/2$  different elements from  $S_u$  can be seen in  $2t$  samples with probability at least  $1 - \binom{t}{t/2} (\frac{1}{2})^{2t} \geq 1 - 2^{-t}$ , so  $S_u$  can be uniquely determined by an  $O(t)$ -step random walk (simulated within error  $\varepsilon$ ) with probability  $1 - 2^{-t} - \frac{\varepsilon}{2} > \frac{1}{2}$ . By Lemma 10, the space usage for simulating the  $O(t)$ -step random walk is at least  $\Omega(n \log |\mathcal{F}|) = \Omega(nt \log(n/t))$  bits. The theorem is proved by scaling down  $n$  and  $t$  by a constant factor. ◀

For simple graphs, we can achieve an upper bound of  $O(nt \log(n/t))$  bits.

► **Theorem 12.** *For  $t \leq n/2$ , we can simulate a  $t$ -step random walk on a simple directed graph in the insertion-only model perfectly using  $O(nt \log(n/t))$  bits of memory.*

**Proof.** For every  $u \in V$ , we run a reservoir sampler with capacity  $t$ , which samples (at most)  $t$  edges from  $u$ 's outgoing edges *without* replacement. After reading the entire input stream, we begin simulating the random walk. When  $u$  is visited during the simulation, in the next step we choose at random an outgoing edge used before with probability  $d_{\text{used}}(u)/d(u)$ , or an unused edge from the reservoir sampler with probability  $1 - d_{\text{used}}(u)/d(u)$ , where  $d_{\text{used}}(u)$  is the number of edges in  $u$ 's sampler that are previously used in the simulation. We maintain a  $t$ -bit vector to keep track of these used samples.

The number of different possible states of a sampler is at most  $\sum_{0 \leq i \leq t} \binom{n}{i} \leq (t+1) \binom{en}{t}$ , so it can be encoded using  $\lceil \log \left( (t+1) \binom{en}{t} \right) \rceil = O(t \log(n/t))$  bits. The total space is  $O(nt \log(n/t))$  bits. ◀

### 3 Undirected graphs in the insertion-only model

#### 3.1 A space lower bound

► **Theorem 13.** *For  $t = O(n^2)$ , simulating a  $t$ -step random walk on a simple undirected graph in the insertion-only model within error  $\varepsilon = \frac{1}{3}$  requires  $\Omega(n\sqrt{t})$  bits of memory.*

<sup>4</sup> Define  $[n] = \{1, 2, \dots, n\}$ . A  $t$ -subset is a subset of size  $t$ .

■ **Figure 1** Proof of Theorem 13.

**Proof.** Again we show a reduction from the INDEX problem.

Alice encodes  $\Omega(n\sqrt{t})$  bits as follows. Let  $G$  be an undirected graph with vertex set  $V_0 \cup V_1 \cup \dots \cup V_{n/\sqrt{t}}$ , where each  $V_j$  has size  $2\sqrt{t}$ , and the starting vertex  $v_0 \in V_0$ . For each  $j \geq 1$ ,  $V_j$  is divided into two subsets  $A_j, B_j$  with size  $\sqrt{t}$  each, and Alice encodes  $|A_j| \times |B_j| = t$  bits by inserting a subset of edges from  $\{(u, v) : u \in A_j, v \in B_j\}$ . In total she encodes  $t \cdot n/\sqrt{t} = n\sqrt{t}$  bits.

Suppose Bob wants to query some bit, i.e., he wants to see whether  $a$  and  $b$  are connected by an edge. Assume  $(a, b) \in A_j \times B_j$ . He adds an edge  $(u, v)$  for every  $u \in A_j$  and every  $v \in V_0$  (see Figure 1). A perfect random walk starting from  $v_0 \in V_0$  will be inside the bipartite subgraph  $(A_j, B_j \cup V_0)$ . Suppose the current vertex of the perfect random walk is  $v_i \in A_j$ . If  $a, b$  are connected by an edge, then

$$\begin{aligned}
 & \mathbb{P}[(v_{i+2}, v_{i+3}) = (a, b) \mid v_i] \\
 & \geq \mathbb{P}[v_{i+1} \in V_0 \mid v_i] \mathbb{P}[v_{i+2} = a \mid v_{i+1} \in V_0] \mathbb{P}[v_{i+3} = b \mid v_{i+2} = a] \\
 & \geq \frac{|V_0|}{|V_0| + |B_j|} \cdot \frac{1}{|A_j|} \cdot \frac{1}{|V_0| + |B_j|} \\
 & \geq \frac{2}{9t},
 \end{aligned}$$

so in every four steps the edge  $(a, b)$  is passed with probability  $\Omega(\frac{1}{t})$ . Then a  $O(t)$ -step perfect random walk will pass the edge  $(a, b)$  with probability 0.9. Hence Bob can know whether the edge  $(a, b)$  exists by looking at the random walk (simulated within error  $\varepsilon$ ) with success probability  $0.9 - \frac{\varepsilon}{2} > 1/2$ . By Lemma 10, the space usage for simulating the  $O(t)$ -step random walk is at least  $\Omega(n\sqrt{t})$  bits. The theorem is proved by scaling down  $n$  and  $t$  by a constant factor. ◀

### 3.2 An algorithm for simple graphs

Now we describe our algorithm for undirected graphs in the insertion-only model. As a warm-up, we consider simple graphs in this section. We will deal with multi-edges in Section 3.3.

### Intuition

We start by informally explaining the intuition of our algorithm for simple undirected graphs.

We maintain a subset of  $O(n\sqrt{t})$  edges from the input graph, and use them to simulate the random walk after reading the entire input stream.

For a vertex  $u$  with degree smaller than  $\sqrt{t}$ , we can afford to store all its neighboring edges in memory. For  $u$  with degree greater than  $\sqrt{t}$ , we can only sample and store  $O(\sqrt{t})$  of its neighboring edges. During the simulation, at every step we first toss a coin to decide whether the next vertex has small degree or large degree. In the latter case, we have to pick a sampled neighboring edge and walk along it. If all sampled neighboring edges have already been used, our algorithm fails. Using the large degree and the fact that edges are undirected, we can show that the failure probability is low.

### Description of the algorithm

We divide the vertices into two types according to their degrees: the set of *big* vertices  $B = \{u \in V : d(u) \geq C + 1\}$ , and the set of *small* vertices  $S = \{u \in V : d(u) \leq C\}$ , where parameter  $C$  is a positive integer to be determined later.

We use *arc*  $(u, v)$  to refer to an edge when we want to specify the direction  $u \rightarrow v$ . So an undirected edge  $(u, v)$  corresponds to two different<sup>5</sup> arcs,  $\text{arc}(u, v)$  and  $\text{arc}(v, u)$ .

We say an arc  $(u, v)$  is *important* if  $v \in S$ , or *unimportant* if  $v \in B$ . Denote the set of important arcs by  $E_1$ , and the set of unimportant arcs by  $E_0$ . The total number of important arcs equals  $\sum_{s \in S} d(s) \leq |S|C$ , so it is possible to store  $E_1$  in  $O(nC)$  words of space.

The set  $E_0$  of unimportant arcs can be huge, so we only store a subset of  $E_0$ . For every vertex  $u$ , we sample with replacement  $C$  unimportant arcs outgoing from  $u$ , denoted by  $a_{u,1}, \dots, a_{u,C}$ .

To maintain the set  $E_1$  of important arcs and the samples of unimportant arcs after every edge insertion, we need to handle the events when some small vertex becomes big. This procedure is straightforward, as described by `PROCESSINPUT` in Figure 2. Since  $|E_1|$  never exceeds  $nC$ , and each of the  $n$  samplers uses  $O(C)$  words of space, the overall space complexity is  $O(nC)$  words.

We begin simulating the random walk after `PROCESSINPUT` finishes. When the current vertex of the random walk is  $v$ , with probability  $d_1(v)/d(v)$  the next step will be along an important arc, where  $d_1(v)$  denotes the number of important arcs outgoing from  $v$ . In this case we simply choose a uniform random vertex from  $\{u : (v, u) \in E_1\}$  as the next vertex. However, if the next step is along an unimportant arc, we need to choose an unused sample  $a_{v,j}$  and go along this arc. If at this time all  $C$  samples  $a_{v,j}$  are already used, then our algorithm fails (and is allowed to return an arbitrary walk). The pseudocode of this simulating procedure is given in Figure 3.

In a walk  $w = (v_0, \dots, v_t)$ , we say vertex  $u$  *fails* if  $|\{i : v_i = u \text{ and } (v_i, v_{i+1}) \in E_0\}| > C$ . If no vertex fails in  $w$ , then our algorithm will successfully return  $w$  with probability  $\mathcal{RW}_{v_0,t}(w)$ . Otherwise our algorithm will fail after some vertex runs out of the sampled unimportant arcs. To ensure the output distribution is  $\varepsilon$ -close to  $\mathcal{RW}_{v_0,t}$  in  $\ell_1$  distance, it suffices to make our algorithm fail with probability at most  $\varepsilon/2$ , by choosing a large enough capacity  $C$ .

<sup>5</sup> We have assumed no self-loops exist, so  $u \neq v$ .

```

procedure INSERTARC( $u, v$ )
   $d(v) \leftarrow d(v) + 1$ 
  if  $d(v) = C + 1$  then                                     ▷  $v$  changes from small to big
    for  $x \in V$  such that  $(x, v) \in E_1$  do                 ▷ arc  $(x, v)$  becomes unimportant
       $E_1 \leftarrow E_1 \setminus \{(x, v)\}$ 
      Feed arc  $(x, v)$  into  $x$ 's sampler
    end for
  end if
  if  $d(v) \leq C$  then                                     ▷  $v \in S$ 
     $E_1 \leftarrow E_1 \cup \{(u, v)\}$ 
  else                                                       ▷  $v \in B$ 
    Feed arc  $(u, v)$  into  $u$ 's sampler
  end if
end procedure
procedure PROCESSINPUT
   $E_1 \leftarrow \emptyset$                                      ▷ Set of important arcs
  for  $u \in V$  do
     $d(u) \leftarrow 0$ 
    Initialize  $u$ 's sampler (initially empty) which maintains  $a_{u,1}, \dots, a_{u,C}$ 
  end for
  for undirected edge  $(u, v)$  in the input stream do
    INSERTARC( $u, v$ )
    INSERTARC( $v, u$ )
  end for
end procedure

```

## 46:8 Simulating Random Walks on Graphs in the Streaming Model

To bound the probability  $\mathbb{P}[\text{at least one vertex fails} \mid v_0 = s]^6$ , we will bound the individual failure probability of every vertex, and then use union bound.

► **Lemma 14.** *Suppose for every  $u \in V$ ,  $\mathbb{P}[u \text{ fails} \mid v_0 = u] \leq \delta$ . Then for any starting vertex  $s \in V$ ,  $\mathbb{P}[\text{at least one vertex fails} \mid v_0 = s] \leq t\delta$ .*

**Proof.** Fix a starting vertex  $s$ . For any particular  $u \in V$ ,

$$\begin{aligned} & \mathbb{P}[u \text{ fails} \mid v_0 = s] \\ &= \mathbb{P}[u \text{ fails, and } \exists i \leq t-1, v_i = u \mid v_0 = s] \\ &= \mathbb{P}[\exists i \leq t-1, v_i = u \mid v_0 = s] \mathbb{P}[u \text{ fails} \mid v_0 = s, \text{ and } \exists i \leq t-1, v_i = u] \\ &\leq \mathbb{P}[\exists i \leq t-1, v_i = u \mid v_0 = s] \mathbb{P}[u \text{ fails} \mid v_0 = u] \\ &\leq \mathbb{P}[\exists i \leq t-1, v_i = u \mid v_0 = s] \cdot \delta. \end{aligned}$$

By union bound,

$$\begin{aligned} & \mathbb{P}[\text{at least one vertex fails} \mid v_0 = s] \\ &\leq \sum_{u \in V} \mathbb{P}[u \text{ fails} \mid v_0 = s] \\ &\leq \sum_{u \in V} \mathbb{P}[\exists i \leq t-1, v_i = u \mid v_0 = s] \cdot \delta \\ &= \mathbb{E}[\text{number of distinct vertices visited in } \{v_0, \dots, v_{t-1}\} \mid v_0 = s] \cdot \delta \\ &\leq t\delta. \end{aligned} \quad \blacktriangleleft$$

► **Lemma 15.** *We can choose integer parameter  $C = O\left(\sqrt{t} \cdot \frac{q}{\log q}\right)$ , where  $q = 2 + \frac{\log(1/\delta)}{\sqrt{t}}$ , so that  $\mathbb{P}[u \text{ fails} \mid v_0 = u] \leq \delta$  holds for every  $u \in V$ .*

**Proof.** Let  $d_0(u) = |\{v : (u, v) \in E_0\}|$ .

For any  $u \in V$ ,

$$\begin{aligned} & \mathbb{P}[u \text{ fails} \mid v_0 = u] \\ &\leq \mathbb{P}[u \text{ fails} \mid v_0 = u, (v_0, v_1) \in E_0]. \end{aligned}$$

We rewrite this probability as the sum of probabilities of possible random walks in which  $u$  fails. Recall that  $u$  fails if and only if  $|\{i : v_i = u, (v_i, v_{i+1}) \in E_0\}| \geq C + 1$ . In the summation over possible random walks, we only keep the shortest prefix  $(v_0, \dots, v_k)$  in which  $u$  fails, i.e., the last step  $(v_{k-1}, v_k)$  is the  $(C + 1)$ -st time walking along an unimportant arc outgoing from  $u$ . We have

$$\begin{aligned} & \mathbb{P}[u \text{ fails} \mid v_0 = u, (v_0, v_1) \in E_0] \\ &= \sum_{k \leq t} \sum_{\text{walk}(v_0, \dots, v_k)} \mathbf{1} \left[ \begin{array}{l} v_0 = v_{k-1} = u, (v_0, v_1), (v_{k-1}, v_k) \in E_0, \\ |\{i : v_i = u, (v_i, v_{i+1}) \in E_0\}| = C + 1 \end{array} \right] \frac{1}{d_0(u)} \prod_{i=1}^{k-1} \frac{1}{d(v_i)} \\ &= \sum_{k \leq t} \sum_{\text{walk}(v_0, \dots, v_{k-1})} \mathbf{1} \left[ \begin{array}{l} v_0 = v_{k-1} = u, (v_0, v_1) \in E_0, \\ |\{i : v_i = u, (v_i, v_{i+1}) \in E_0\}| = C \end{array} \right] \prod_{i=1}^{k-1} \frac{1}{d(v_i)}. \end{aligned} \quad (2)$$

<sup>6</sup> If not specified, assume the probability space is over all  $t$ -step random walks  $(v_0, \dots, v_t)$  starting from  $v_0$ .

Let  $v'_i = v_{k-1-i}$ . Since the graph is undirected, the vertex sequence  $(v'_0, \dots, v'_{k-1})$  (the reversal of walk  $(v_0, \dots, v_{k-1})$ ) is also a walk starting from and ending at  $u$ . So the summation (2) equals

$$\begin{aligned} & \sum_{k \leq t} \sum_{\text{walk}(v'_0, \dots, v'_{k-1})} \mathbf{1} \left[ v'_0 = v'_{k-1} = u, (v'_{k-1}, v'_{k-2}) \in E_0, \right. \\ & \quad \left. |\{i : v'_i = u, (v'_i, v'_{i-1}) \in E_0\}| \geq C \right] \prod_{i=0}^{k-2} \frac{1}{d(v'_i)} \\ &= \mathbb{P}_{\text{random walk}(v'_0, \dots, v'_{t-1})} \left[ |\{i : v'_i = u, (v'_i, v'_{i-1}) \in E_0\}| \geq C \mid v'_0 = u \right]. \end{aligned}$$

Recall that  $(v'_i, v'_{i-1}) \in E_0$  if and only if  $v'_{i-1} \in B$ . For any  $1 \leq i \leq t-1$  and any fixed prefix  $v'_0, \dots, v'_{i-1}$ ,

$$\begin{aligned} & \mathbb{P}[v'_i = u, (v'_i, v'_{i-1}) \in E_0 \mid v'_0, \dots, v'_{i-1}] \\ & \leq \mathbf{1}[v'_{i-1} \in B] \cdot \frac{1}{d(v'_{i-1})} \\ & < \frac{1}{C}. \end{aligned} \tag{3}$$

Hence the probability that  $|\{1 \leq i \leq t-1 : v'_i = u, (v'_i, v'_{i-1}) \in E_0\}| \geq C$  is at most

$$\begin{aligned} & \binom{t-1}{C} \left(\frac{1}{C}\right)^C \\ & \leq \left(\frac{e(t-1)}{C}\right)^C \left(\frac{1}{C}\right)^C \\ & < \left(\frac{et}{C^2}\right)^C. \end{aligned}$$

We set  $C = \lceil 4\sqrt{t} q / \log q \rceil$ , where  $q = 2 + \log(1/\delta)/\sqrt{t} > 2$ . Notice that  $q/\log^2 q > 1/4$ . Then

$$C \log \left(\frac{C^2}{et}\right) \geq \frac{4\sqrt{t}q}{\log q} \log \left(\frac{16q^2}{e \log^2 q}\right) > \frac{4\sqrt{t}q}{\log q} \log(4q/e) > 4\sqrt{t}q > \log(1/\delta),$$

so

$$\left(\frac{et}{C^2}\right)^C < \delta.$$

Hence we have made  $\mathbb{P}[u \text{ fails} \mid v_0 = u] < \delta$  by choosing  $C = O(\sqrt{t}q / \log q)$ .  $\blacktriangleleft$

► **Theorem 16.** *We can simulate a  $t$ -step random walk on a simple undirected graph in the insertion-only model within error  $\varepsilon$  using  $O\left(n\sqrt{t} \cdot \frac{q}{\log q}\right)$  words of memory, where  $q = 2 + \frac{\log(1/\varepsilon)}{\sqrt{t}}$ .*

**Proof.** The theorem follows from Lemma 14 and Lemma 15 by setting  $\delta = \frac{\varepsilon}{2t}$ .  $\blacktriangleleft$

### 3.3 On graphs with multiple edges

When the undirected graph contains multiple edges, condition (3) in the proof of Lemma 15 may not hold, so we need to slightly modify our algorithm.

## 46:10 Simulating Random Walks on Graphs in the Streaming Model

We still maintain the multiset  $E_1$  of important arcs. Whether an arc is important will be determined by our algorithm. (This is different from the previous algorithm, where important arcs were simply defined as  $(u, v)$  with  $d(v) \leq C$ .) We will ensure that condition (3) still holds, i.e., for any  $u \in V$  and any fixed prefix of the random walk  $v_0, \dots, v_{i-1}$ ,

$$\mathbb{P}[(v_i, v_{i-1}) \notin E_1, \text{ and } v_i = u \mid v_0, \dots, v_{i-1}] < 1/C. \quad (4)$$

Note that there can be both important arcs and unimportant arcs from  $u$  to  $v$ . Let  $f(u, v)$  denote the number of undirected edges between  $u, v$ . Then there are  $f(u, v)$  arcs  $(u, v)$ . Suppose  $f_1(u, v)$  of these arcs are important, and  $f_0(u, v) = f(u, v) - f_1(u, v)$  of them are unimportant. Then we can rewrite condition (4) as

$$\frac{f_0(u, v_{i-1})}{d(v_{i-1})} < 1/C, \quad (5)$$

for every  $u, v_{i-1} \in V$ .

Similarly as before, we need to store the multiset  $E_1$  using only  $O(nC)$  words of space. And we need to sample with replacement  $C$  unimportant arcs  $a_{u,1}, \dots, a_{u,C}$  outgoing from  $u$ , for every  $u \in V$ . Finally we use the procedure SIMULATERANDOMWALK in Figure 3 to simulate a random walk.

The multiset  $E_1$  is determined as follows: For every vertex  $v \in V$ , we run Misra-Gries algorithm [16] on the sequence of all  $v$ 's neighbors. We will obtain a list  $L_v$  of at most  $C$  vertices, such that for every vertex  $u \notin L_v$ ,  $\frac{f(u,v)}{d(v)} < \frac{1}{C}$ . Moreover, we will get a frequency estimate  $A_v(u) > 0$  for every  $u \in L_v$ , such that  $0 \leq f(u, v) - A_v(u) < \frac{d(v)}{C}$ . Assuming  $A_v(u) = 0$  for  $u \notin L_v$ , we can satisfy condition (5) for all  $u \in V$  by setting  $f_1(u, v) = A_v(u)$ . Hence we have determined all the important arcs, and they can be stored in  $O(\sum_v |L_v|) = O(nC)$  words. To sample from the unimportant arcs, we simply insert the arcs discarded by Misra-Gries algorithm into the samplers. The pseudocode is given in Figure 4.

► **Lemma 17.** *After PROCESSINPUT (in Figure 4) finishes,  $|L_v| \leq C$ . For every  $u \in L_v$ ,  $0 \leq f(u, v) - A_v(u) \leq \frac{d(v)}{C+1}$ . For every  $u \notin L_v$ ,  $f(u, v) \leq \frac{d(v)}{C+1}$ .*

**Proof.** Every time the **for** loop in procedure INSERTARC finishes, the newly added vertex  $u$  must have been removed from  $L_v$ , so  $|L_v| \leq C$  still holds. Let  $W = \{w_1, \dots, w_{C+1}\}$  be the set of vertices in  $L_v$  before this **for** loop begins. Then for every  $u \in V$ ,  $f(u, v) - A_v(u)$  equals the number of times  $u$  is contained in  $W$  (assuming  $A_v(u) = 0$  for  $u \notin L_v$ ), which is at most  $\frac{1}{C+1} \sum_W |W| \leq \frac{d(v)}{C+1}$ . ◀

► **Corollary 18.** *Procedure PROCESSINPUT in Figure 4 computes the multiset  $E_1$  of important edges and stores it using  $O(nC)$  words. It also samples with replacement  $C$  unimportant arcs  $a_{u,1}, \dots, a_{u,C}$  outgoing from  $u$ , for every  $u \in V$ . Moreover,*

$$\frac{f_0(u, v)}{d(v)} < \frac{1}{C}$$

holds for every  $u, v \in V$ .

Now we analyze the failure probability of SIMULATERANDOMWALK (in Figure 3), similar to Lemma 15.

► **Lemma 19.** *We can choose integer parameter  $C = O\left(\sqrt{t} \cdot \frac{q}{\log q}\right)$ , where  $q = 2 + \frac{\log(1/\delta)}{\sqrt{t}}$ , so that  $\mathbb{P}[u \text{ fails} \mid v_0 = u] \leq \delta$  holds for every  $u \in V$ .*

```

procedure INSERTARC( $u, v$ )
   $d(v) \leftarrow d(v) + 1$ 
  if  $u \in L_v$  then
     $A_v(u) \leftarrow A_v(u) + 1$ 
  else
    Insert  $u$  into  $L_v$ 
     $A_v(u) \leftarrow 1$ 
    if  $|L_v| \geq C + 1$  then
      for  $w \in L_v$  do
        Feed arc  $(w, v)$  into  $w$ 's sampler
         $A_v(w) \leftarrow A_v(w) - 1$ 
        if  $A_v(w) = 0$  then
          Remove  $w$  from  $L_v$ 
        end if
      end for
    end if
  end if
end procedure
procedure PROCESSINPUT
  for  $u \in V$  do
     $d(u) \leftarrow 0$ 
    Initialize  $u$ 's sampler (initially empty) which maintains  $a_{u,1}, \dots, a_{u,C}$ 
    Initialize empty list  $L_u$ 
  end for
  for undirected edge  $(u, v)$  in the input stream do
    INSERTARC( $u, v$ )
    INSERTARC( $v, u$ )
  end for
   $E_1 \leftarrow \bigcup_{v \in V} \bigcup_{u \in L_v} \{A_v(u) \text{ copies of arc } (u, v)\}$  ▷ Multiset of important arcs
end procedure

```

■ **Figure 4** Pseudocode for processing the input stream (for undirected graphs with possibly multiple edges).

**Proof.** Let  $d_0(u) = \sum_{v \in V} f_0(u, v)$ . As before, we rewrite this probability as a sum over possible random walks. Here we distinguish between important and unimportant arcs. Denote  $s_i = \mathbf{1}[\text{step } (v_{i-1}, v_i) \text{ is along an important arc}]$ . Then for any  $u \in V$ ,

$$\begin{aligned}
& \mathbb{P}[u \text{ fails} \mid v_0 = u] \\
& \leq \mathbb{P}[u \text{ fails} \mid v_0 = u, \text{ arc } (v_0, v_1) \text{ is unimportant}] \\
& = \frac{d(u)}{d_0(u)} \sum_{k \leq t} \sum_{(v_0, \dots, v_k)} \sum_{s_1, \dots, s_k} \mathbf{1} \left[ v_0 = v_{k-1} = u, s_1 = s_k = 0, \right. \\
& \quad \left. |\{i : v_i = u, s_{i+1} = 0\}| = C + 1 \right] \prod_{i=0}^{k-1} \frac{f_{s_{i+1}}(v_i, v_{i+1})}{d(v_i)} \\
& = \sum_{k \leq t} \sum_{(v_0, \dots, v_{k-1})} \sum_{s_1, \dots, s_{k-1}} \mathbf{1} \left[ v_0 = v_{k-1} = u, s_1 = 0, \right. \\
& \quad \left. |\{i : v_i = u, s_{i+1} = 0\}| = C \right] \prod_{i=0}^{k-2} \frac{f_{s_{i+1}}(v_i, v_{i+1})}{d(v_i)}.
\end{aligned}$$

## 46:12 Simulating Random Walks on Graphs in the Streaming Model

Let  $v'_i = v_{k-1-i}$ ,  $s'_i = s_{k-i}$ . Then this sum equals

$$\begin{aligned} & \sum_{k \leq t} \sum_{(v'_0, \dots, v'_{k-1})} \sum_{(s'_1, \dots, s'_{k-1})} \mathbf{1} \left[ \begin{array}{l} v'_0 = v'_{k-1} = u, s'_{k-1} = 0, \\ |\{i : s'_i = 0, v'_i = u\}| = C \end{array} \right] \prod_{i=1}^{k-1} \frac{f_{s'_i}(v'_i, v'_{i-1})}{d(v'_{i-1})} \\ &= \mathbb{P}_{\text{random walk } (v'_0, \dots, v'_{t-1})} \left[ |\{i : v'_i = u, \text{arc } (v'_i, v'_{i-1}) \text{ is unimportant}\}| \geq C \mid v'_0 = u \right]. \end{aligned}$$

Notice that for any  $i$  and any fixed prefix  $v'_0, \dots, v'_{i-1}$ ,

$$\mathbb{P} \left[ v'_i = u, \text{arc } (v'_i, v'_{i-1}) \text{ is unimportant} \mid v'_0, v'_1, \dots, v'_{i-1} \right] = \frac{f_0(u, v'_{i-1})}{d(v'_{i-1})} < \frac{1}{C}$$

by Corollary 18. The rest of the proof is the same as in Lemma 15.  $\blacktriangleleft$

► **Theorem 20.** *We can simulate a random walk on an undirected graph with possibly multiple edges in the insertion-only model within error  $\varepsilon$  using  $O\left(n\sqrt{t} \cdot \frac{q}{\log q}\right)$  words of memory, where  $q = 2 + \frac{\log(1/\varepsilon)}{\sqrt{t}}$ .*

**Proof.** The theorem follows from Lemma 14 and Lemma 19 by setting  $\delta = \frac{\varepsilon}{2t}$ .  $\blacktriangleleft$

### 4 Turnstile model

In this section we consider the turnstile model where both insertion and deletion of edges can appear.

► **Lemma 21** ( $\ell_1$  sampler in the turnstile model, [9]). *Let  $f \in \mathbb{R}^n$  be a vector defined by a stream of updates to its coordinates of the form  $f_i \leftarrow f_i + \Delta$ , where  $\Delta$  can either be positive or negative. There is an algorithm which reads the stream and returns an index  $i \in [n]$  such that for every  $j \in [n]$ ,*

$$\mathbb{P}[i = j] = \frac{|f_j|}{\|f\|_1} + O(n^{-c}), \quad (6)$$

where  $c \geq 1$  is some arbitrary large constant. It is allowed to output FAIL with probability  $\delta$ , and in this case it will not output any index. The space complexity of this algorithm is  $O(\log^2 n \log(1/\delta))$  bits.

► **Remark.** For  $\varepsilon \ll 1/n$ , the  $O(n^{-c})$  error term in (6) can be reduced to  $O(\varepsilon^c)$  by running the  $\ell_1$  sampler on  $f \in \mathbb{R}^{\lceil 1/\varepsilon \rceil}$ , using  $O(\log^2(1/\varepsilon) \log(1/\delta))$  bits of space.

We will use the  $\ell_1$  sampler for sampling neighbors (with possibly multiple edges) in the turnstile model. The error term  $O(n^{-c})$  (or  $O(\varepsilon^c)$ ) in (6) can be ignored in the following discussion, by choosing sufficiently large constant  $c$  and scaling down  $\varepsilon$  by a constant.

#### 4.1 Directed graphs

► **Theorem 22.** *We can simulate a  $t$ -step random walk on a directed graph in the turnstile model within error  $\varepsilon$  using  $O(n(t + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits of memory.*

**Proof.** For every  $u \in V$ , we run  $C' = 2t + 16 \log(2t/\varepsilon)$  independent  $\ell_1$  samplers each having failure probability  $\delta = 1/2$ . We use them to sample the outgoing edges of  $u$  (as in the algorithm of Theorem 8). By Chernoff bound, the probability that less than  $t$  samplers succeed is at most  $\varepsilon/(2t)$ .

We say a vertex  $u$  fails if  $u$  has less than  $t$  successful samplers, and  $u \in \{v_0, v_1, \dots, v_{t-1}\}$  (where  $v_0, v_1, \dots, v_t$  is the random walk). Then  $\mathbb{P}[u \text{ fails}] \leq \frac{\varepsilon}{2t} \mathbb{P}[u \in \{v_0, \dots, v_{t-1}\}]$ . By union bound,  $\mathbb{P}[\text{at least one vertex fails}] \leq \frac{\varepsilon}{2t} \sum_{u \in V} \mathbb{P}[u \in \{v_0, \dots, v_{t-1}\}] \leq \frac{\varepsilon}{2}$ . Hence, with probability  $1 - \frac{\varepsilon}{2}$ , every vertex  $u$  visited (except the last one) has at least  $t$  outgoing edges sampled, so our simulation can succeed. The space usage is  $O(nC' \log^2 \max\{n, 1/\varepsilon\} \log(1/\delta)) = O(n(t + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits. ◀

## 4.2 Undirected graphs

We slightly modify the PROCESSINPUT procedure of our previous algorithm in Section 3.3. We will use the  $\ell_1$  heavy hitter algorithm in the turnstile model.

► **Lemma 23** ( $\ell_1$  heavy hitter, [6]). *Let  $f \in \mathbb{R}^n$  be a vector defined by a stream of updates to its coordinates of the form  $f_i \leftarrow f_i + \Delta$ , where  $\Delta$  can either be positive or negative. There is a randomized algorithm which reads the stream and returns a subset  $L \subseteq [n]$  such that  $i \in L$  for every  $|f_i| \geq \frac{\|f\|_1}{k}$ , and  $i \notin L$  for every  $|f_i| \leq \frac{\|f\|_1}{2k}$ . Moreover it returns a frequency estimate  $\tilde{f}_i$  for every  $i \in L$ , which satisfies  $0 \leq f_i - \tilde{f}_i \leq \frac{\|f\|_1}{2k}$ . The failure probability of this algorithm is  $O(n^{-c})$ . The space complexity is  $O(k \log^2 n)$  bits.*

► **Remark.** For  $\varepsilon \ll 1/n$ , the  $O(n^{-c})$  failure probability of this  $\ell_1$  heavy hitter algorithm can be reduced to  $O(\varepsilon^c)$  by running the algorithm on  $f \in \mathbb{R}^{\lceil 1/\varepsilon \rceil}$ , using  $O(k \log^2(1/\varepsilon))$  bits of space. In the following discussion, this failure probability can be ignored by making the constant  $c$  sufficiently large.

► **Theorem 24.** *We can simulate a  $t$ -step random walk on an undirected graph in the turnstile model within error  $\varepsilon$  using  $O(n(\sqrt{t} + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits of memory.*

**Proof.** Similar to the previous insertion-only algorithm (in Figure 4), we perform two *arc updates*  $((u, v), \Delta)$ ,  $((v, u), \Delta)$  when we read an *edge update*  $((u, v), \Delta)$  from the stream.

For every  $u \in V$ , we run  $C' = 2C + 16 \log(2t/\varepsilon)$  independent  $\ell_1$  samplers each having failure probability  $\delta = 1/2$ , where  $C$  is the same constant as in the proof of Lemma 19 and Theorem 20. By Chernoff bound, the probability that less than  $C$  samplers succeed is at most  $\varepsilon/(2t)$ . For every arc update  $((u, v), \Delta)$ , we send update  $(v, \Delta)$  to  $u$ 's  $\ell_1$  sampler.

In addition, for every  $v \in V$ , we run  $\ell_1$  heavy hitter algorithm with  $k = C$ . For every arc update  $((u, v), \Delta)$ , we send update  $(u, \Delta)$  to  $v$ 's heavy hitter algorithm. In the end, we will get a frequency estimate  $A_v(u)$  for every  $u \in V$ , such that  $f(u, v) - \frac{d(v)}{C} \leq A_v(u) \leq f(u, v)$ . We then insert  $A_v(u)$  copies of arc  $(u, v)$  into  $E_1$  (the multiset of important arcs), and send update  $(v, -A_v(u))$  to  $u$ 's  $\ell_1$  sampler. Then we use the  $\ell_1$  samplers to sample unimportant arcs for every  $u$ .

As before, we use the procedure SIMULATERANDOMWALK (in Figure 3) to simulate the random walk. The analysis of the failure probability of the  $\ell_1$  samplers is the same as in Theorem 22. The analysis of the failure probability of procedure SIMULATERANDOMWALK is the same as in Lemma 19. The space usage of the algorithm is  $O(nC' \log^2 \max\{n, 1/\varepsilon\} \log \delta) = O(n(\sqrt{t} + \log \frac{1}{\varepsilon}) \log^2 \max\{n, 1/\varepsilon\})$  bits. ◀

## 5 Conclusion

We end our paper by discussing some related questions for future research.

- The output distribution of our insertion-only algorithm for undirected graphs is  $\varepsilon$ -close to the random walk distribution. What if the output is required to be perfectly random, i.e.,  $\varepsilon = 0$ ?
- For insertion-only simple undirected graphs, we proved an  $\Omega(n\sqrt{t})$ -bit space lower bound. Our algorithm uses  $O(n\sqrt{t} \log n)$  bits (for not too small  $\varepsilon$ ). Can we close the gap between the lower bound and the upper bound, as in the case of directed graphs?
- In the undirected version, suppose the starting vertex  $v_0$  is drawn from a distribution (for example, the stationary distribution of the graph) rather than being specified. Is it possible to obtain a better algorithm in this new setting? Notice that our proof of the  $\Omega(n\sqrt{t})$  lower bound does not work here, since it requires  $v_0$  to be specified.
- We required the algorithm to output all vertices on the random walk. If only the last vertex is required, can we get a better algorithm or prove non-trivial lower bounds?

## Abstract

---

The fundamental theorem of symmetric polynomials states that for a symmetric polynomial  $f_{\text{Sym}} \in \mathbb{C}[x_1, x_2, \dots, x_n]$ , there exists a unique “witness”  $f \in \mathbb{C}[y_1, y_2, \dots, y_n]$  such that  $f_{\text{Sym}} = f(e_1, e_2, \dots, e_n)$ , where the  $e_i$ ’s are the elementary symmetric polynomials.

In this paper, we study the arithmetic complexity  $L(f)$  of the witness  $f$  as a function of the arithmetic complexity  $L(f_{\text{Sym}})$  of  $f_{\text{Sym}}$ . We show that the arithmetic complexity  $L(f)$  of  $f$  is bounded by  $\text{poly}(L(f_{\text{Sym}}), \deg(f), n)$ . To the best of our knowledge, prior to this work only exponential upper bounds were known for  $L(f)$ . The main ingredient in our result is an algebraic analogue of Newton’s iteration on power series. As a corollary of this result, we show that if  $\text{VP} \neq \text{VNP}$  then there exist symmetric polynomial families which have super-polynomial arithmetic complexity.

Furthermore, we study the complexity of testing whether a function is symmetric. For polynomials, this question is equivalent to arithmetic circuit identity testing. In contrast to this, we show that it is hard for Boolean functions.

## 1 Introduction

Lipton and Regan [10] ask the question whether understanding the arithmetic complexity of symmetric polynomials is enough to understand the arithmetic complexity of all polynomials. We here answer this question in the affirmative. The fundamental theorem of symmetric polynomials establishes a bijection between symmetric polynomials and arbitrary polynomials. It states that for every symmetric polynomial  $f_{\text{Sym}} \in \mathbb{C}[x_1, x_2, \dots, x_n]$ , there exists a unique polynomial  $f \in \mathbb{C}[y_1, y_2, \dots, y_n]$  such that  $f_{\text{Sym}} = f(e_1, e_2, \dots, e_n)$ , where the  $e_i$ ’s are the elementary symmetric polynomials. We prove that the arithmetic circuit complexity of  $f$  and  $f_{\text{Sym}}$  are polynomially related.

An arithmetic circuit  $C$  is a directed acyclic graph with the following kind of nodes (gates):

## 47:2 Complexity of Symmetric Polynomials

- Nodes with in-degree zero labeled by variables or scalars, these are called input gates.
- Nodes labeled by addition (+), subtraction (−) or multiplication (×) gates, these gates have in-degree two and unbounded out-degree.
- Nodes with out-degree zero (it can be an input, +, − or × gate), these are called output gates.

Each gate of such a circuit computes a multivariate polynomial in the following way:

- Input gates compute the polynomial by which they are labeled.
- A  $\circ$  gate  $g$  computes the polynomial  $g_1 \circ g_2$ , if the children gates of  $g$  compute the polynomials  $g_1$  and  $g_2$ , here  $\circ \in \{+, -, \times\}$ .

If the output gates of  $C$  compute the polynomials  $g_1, g_2, \dots, g_t$  then we say that  $C$  computes the set  $\{g_1, g_2, \dots, g_t\}$  of polynomials. In the literature, it is usually assumed that any arithmetic circuit  $C$  has a unique output gate and thus  $C$  computes a single multivariate polynomial. The *size* of an arithmetic circuit  $C$  is defined as the number of gates in  $C$ .

We can naturally model computations over a field by arithmetic circuits and thus the study of arithmetic circuits is essential in studying the computational complexity in algebraic models of computation. Valiant [15] defined the complexity classes  $\mathbf{VP}$  and  $\mathbf{VNP}$  as algebraic analogues of the classes  $\mathbf{P}$  and  $\mathbf{NP}$ . In algebraic complexity theory, complexity classes such as  $\mathbf{VP}$  and  $\mathbf{VNP}$  are defined as sets of polynomial families. For the precise definitions of  $\mathbf{VP}$  and  $\mathbf{VNP}$ , see section A in the appendix. For a polynomial  $f$ ,  $L(f)$  is defined as the size of the smallest circuit computing  $f$ . We use the same notation  $L(S)$  to denote the size of the smallest circuit computing a set of polynomials  $S$ . There is also a notion of oracle complexity  $L^g(f)$  of a polynomial  $f$  with respect to some polynomial  $g$ , see Definition 9.

Let  $\mathfrak{S}_n$  be the symmetric group defined as the set of all permutations of the set  $\{1, 2, \dots, n\}$ . A Boolean function  $f : \{0, 1\}^n \rightarrow \{0, 1\}$  is said to be *symmetric* if  $f(x_1, x_2, \dots, x_n) = f(x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(n)})$  for all  $(x_1, x_2, \dots, x_n) \in \{0, 1\}^n, \sigma \in \mathfrak{S}_n$ . It is easy to see that all symmetric Boolean functions can be computed by constant depth threshold circuits, that is, are contained in the class  $\mathbf{TC}^0$ . The notion of symmetric polynomials can also be defined similarly. It is natural to ask whether symmetric polynomials can also be computed efficiently, *i.e.*, whether the arithmetic complexity of symmetric polynomials is also small? This is the question we study in this paper.

### 1.1 Previous Work

It is well known that for every symmetric polynomial  $g \in \mathbb{C}[x_1, x_2, \dots, x_n]$ , there exists a unique polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$  such that  $g = f(e_1, e_2, \dots, e_n)$ . Here,  $e_1, e_2, \dots, e_n$  denote the elementary symmetric polynomials in  $x_1, x_2, \dots, x_n$ . For an arbitrary polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$ , let  $f_{\text{Sym}}$  defined by  $f_{\text{Sym}} \stackrel{\text{def}}{=} f(e_1, e_2, \dots, e_n)$  be the symmetric polynomial corresponding to  $f$  (see Section 2). We want to study the relation between the complexities  $L(f)$  and  $L(f_{\text{Sym}})$ . The question was studied and partially solved in [7, 6, 10]. More specifically, the following theorems were proved in [7, 6, 10].

► **Theorem 1** (Theorem 1 in [7]). *For any polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$ ,  $L(f) \leq \Delta(n)L(f_{\text{Sym}}) + 2$ , where  $\Delta(n) \leq 4^n(n!)^2$ .*

Whereas [7] showed the bound on  $L(f)$  for exact computation, [10] investigated a related problem of approximating the value of  $f$  at a given point by using an arithmetic circuit computing  $f_{\text{Sym}}$ .

► **Theorem 2** ([10]). *For any polynomial  $f \in \mathbb{Q}[x_1, x_2, \dots, x_n]$ , there is an algorithm that computes the value  $f(a)$  within  $\epsilon$  in time  $L(f_{\text{Sym}}) + \text{poly}(\log \|a\|, n, \log \frac{1}{\epsilon})$  for any  $a \in \mathbb{Q}^n$ .*

Note that Theorem 2 does not compute a circuit for  $f$  but only gives an algorithm to approximate the value of  $f$  at a given point. The results in [6] were in a much more general setting. [6] studied the in-variance under general finite matrix groups, not just under  $\mathfrak{S}_n$  as we do in this paper. By specializing the theorems in [6] for the finite matrix group  $\mathfrak{S}_n$ , we get the following result.

► **Theorem 3** ([6]). *For any polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$ , we have  $L(f) \leq ((n+1)!)^6 L(f_{\text{Sym}})$ .*

The upper bound in [6] (Theorem 3) is worse than that of [7] (Theorem 1) but this is to be expected because [6] solves a more general problem.

## 1.2 Our results

It is easy to see that  $L(f_{\text{Sym}}) \leq L(f) + n^{O(1)}$  (see [10]). All the exact bounds (with respect to  $L(f_{\text{Sym}})$ ) on  $L(f)$  above are exponential. It was left as an open question in [10] whether  $L(f)$  can be bounded polynomially with respect to  $L(f_{\text{Sym}})$ . In this paper, we demonstrate that  $L(f)$  can be polynomially bounded in terms of  $L(f_{\text{Sym}})$ . In whatever follows, the complexity notation  $\tilde{O}$  hides poly-logarithmic factors. The following Theorem 4 is the main contribution of this paper.

► **Theorem 4.** *For any polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$  of degree  $d$  with  $d_{\text{Sym}} \stackrel{\text{def}}{=} \deg(f_{\text{Sym}})$ , we have the following upper bounds on  $L^{f_{\text{Sym}}}(f)$  and  $L(f)$ :*

$$\begin{aligned} L^{f_{\text{Sym}}}(f) &\leq \tilde{O}(n^3 \cdot d^2 \cdot d_{\text{Sym}}), \\ L(f) &\leq \tilde{O}(d^2 L(f_{\text{Sym}}) + d^2 n^2). \end{aligned}$$

► **Remark.** It can be shown that  $d_{\text{Sym}} \leq dn$  and  $d \leq d_{\text{Sym}}$ . Thus Theorem 4 implies that  $L^{f_{\text{Sym}}}(f) \leq \tilde{O}(n^4 \cdot d^3)$ .

From Theorem 4, it easily follows that there exist families of symmetric polynomials of super-polynomial arithmetic complexity (assuming  $\text{VP} \neq \text{VNP}$ ).

In addition, we also consider the following problems:

1. SFT (symmetric function testing)
2. SPT (symmetric polynomial testing)

► **Problem 5** (SFT). *Given a Boolean circuit  $C$  computing the Boolean function  $f(x_1, x_2, \dots, x_n)$ , check if  $f$  is symmetric, that is, if  $f(x_1, x_2, \dots, x_n) = f(x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(n)})$  for all  $\sigma \in \mathfrak{S}_n$ ?*

► **Problem 6** (SPT). *Given an arithmetic circuit  $C$  computing the polynomial  $f(x_1, x_2, \dots, x_n)$ , check if  $f$  is a symmetric polynomial?*

Let CSAT be the problem of deciding whether a given Boolean circuit has a satisfying assignment, that is, computes a non-zero function (see [8]). ACIT is the problem of deciding whether the polynomial computed by a given arithmetic circuit is zero (see [1]). We prove the following results on the complexity of SPT and SFT.

► **Lemma 7.** *SFT and CSAT are polynomial time Turing reducible to each other, i.e.,  $\text{SFT} \leq_{\text{P}}^{\text{T}} \text{CSAT}$  and  $\text{CSAT} \leq_{\text{P}}^{\text{T}} \text{SFT}$ .*

► **Lemma 8.** *SPT and ACIT are polynomial time many one reducible to each other, i.e.,  $\text{SPT} \leq_{\text{P}} \text{ACIT}$  and  $\text{ACIT} \leq_{\text{P}} \text{SPT}$ .*

## 47:4 Complexity of Symmetric Polynomials

In light of above results, we notice the following contrasting situations in Boolean and algebraic models of computation:

- All symmetric Boolean functions are easy to compute but the problem of deciding the symmetry of a Boolean function is hard.
- There exist families of symmetric polynomials which are hard to compute (assuming  $VP \neq VNP$ ) but deciding the symmetry of a polynomial is easy.

### 1.3 Proof ideas

The main proof idea is much easier to demonstrate in the case of  $n = 2$ . Let  $B(y)$  be the following uni-variate polynomial in  $y$  with coefficients in  $\mathbb{C}[x_1, x_2]$ :

$$B(y) \stackrel{\text{def}}{=} y^2 - (x_1 + x_2)y + x_1x_2.$$

Note that the roots of  $B(y)$  are  $x_1, x_2$ . Hence we have the following equalities:

$$x_1 = \frac{x_1 + x_2 + \sqrt{(x_1 + x_2)^2 - 4x_1x_2}}{2},$$

$$x_2 = \frac{x_1 + x_2 - \sqrt{(x_1 + x_2)^2 - 4x_1x_2}}{2}.$$

We use the symbols  $e_1, e_2$  for the elementary symmetric polynomials:  $e_1 \stackrel{\text{def}}{=} (x_1 + x_2)$  and  $e_2 \stackrel{\text{def}}{=} x_1x_2$ . Thus we have the following equalities:

$$x_1 = \frac{e_1 + \sqrt{e_1^2 - 4e_2}}{2}, \tag{1}$$

$$x_2 = \frac{e_1 - \sqrt{e_1^2 - 4e_2}}{2}. \tag{2}$$

Let  $f_{\text{Sym}} \in \mathbb{C}[x_1, x_2]$  be a symmetric polynomial and  $\deg(f) = d$ .

If we substitute the above radical expressions (in Equation 1 and Equation 2) for  $x_1$  and  $x_2$  in  $f_{\text{Sym}}(x_1, x_2)$ , then we obtain  $f(e_1, e_2)$ . But unfortunately, we can not perform these kind of substitutions in our model of computation. This is because we cannot compute expressions of the form  $\sqrt{e_1^2 - 4e_2}$  with arithmetic circuits.

If we use the substitution  $e_2 \leftarrow e_2 - 1$  in Equation 1 and Equation 2 and thereafter substitute  $x_1$  and  $x_2$  in  $f_{\text{Sym}}(x_1, x_2)$ , we shall obtain  $f(e_1, e_2 - 1)$ . The degree of  $f(e_1, e_2 - 1)$  is also bounded by  $d$ . Even by using this substitution, the expressions in Equation 1 and Equation 2 cannot be computed by arithmetic circuits. But this substitution allows us to use Taylor expansion on  $\sqrt{e_1^2 - 4(e_2 - 1)}$  to obtain a power series in  $e_1, e_2$ . Since  $f(e_1, e_2 - 1)$  has degree at most  $d$ , we only need to substitute truncations of degree  $d$  of these Taylor series to obtain  $f(e_1, e_2 - 1)$  (also some additional junk terms which can be removed efficiently) and subsequently use the substitution  $e_2 \leftarrow e_2 + 1$  to obtain  $f(e_1, e_2)$ .

This method works for two variables. It can be extended to work for at most four variables because it is well known that polynomials of degree more than four are not solvable by radicals (see e.g. Section 15.9 in [2]). To make this idea work in general, we shall substitute  $e_n$  by  $e_n + (-1)^{n-1}$  and then compute degree  $d$  truncation of roots of  $B(y)$  using Newton's iteration.

## 1.4 Organization

Section 2 introduces elementary symmetric polynomials and also formally states the fundamental theorem of symmetric polynomials. We also state a folklore result about computing the homogeneous components of a polynomial. Section 3 describes the complexity of the problems SFT and SPT. Section 4 describes the main contribution of this paper, we use the classical Newton's iteration to prove Theorem 4 in this section. As an easy consequence of Theorem 4, Section 5 proves that there exist hard symmetric polynomial families (assuming  $VP \neq VNP$ ).

## 2 Preliminaries

### 2.1 Notation and background

For a positive integer  $n$ , we use the notation  $[n]$  to denote the set  $\{1, 2, \dots, n\}$ . Similarly,  $[[n]]$  is used to denote the set  $\{0, 1, 2, \dots, n\}$ . Now we formally define the notion of oracle computations [5].

► **Definition 9** ([5]). The oracle complexity  $L^g(f)$  of a polynomial  $f \in \mathbb{F}[x_1, x_2, \dots, x_n]$  with respect to the oracle polynomial  $g$  is the minimum number of arithmetic operations  $+$ ,  $-$ ,  $\times$  and evaluations of  $g$  (at previously computed values) that are sufficient to compute  $f$  from the indeterminates  $x_i$  and constants in  $\mathbb{F}$ .

► **Definition 10.** The  $i^{\text{th}}$  elementary symmetric polynomial  $e_i^n$  in  $n$  variables  $x_1, x_2, \dots, x_n$  is defined as the following polynomial:

$$e_i^n \stackrel{\text{def}}{=} \sum_{1 \leq j_1 < j_2 < \dots < j_i \leq n} x_{j_1} \cdot x_{j_2} \cdot \dots \cdot x_{j_i}.$$

For an arbitrary polynomial  $f \in \mathbb{F}[x_1, x_2, \dots, x_n]$ , we define the polynomial  $f_{\text{Sym}}$  as:

$$f_{\text{Sym}} \stackrel{\text{def}}{=} f(e_1^n, e_2^n, \dots, e_n^n). \quad (3)$$

Whenever  $n$  is clear from the context, we use the notation  $e_i$  to denote the  $i^{\text{th}}$  elementary symmetric polynomial  $e_i^n$ . Note that  $f_{\text{Sym}}$  is a symmetric polynomial. So Equation 3 is a method to create symmetric polynomials. The fundamental theorem of symmetric polynomials states that Equation 3 is the only way to create symmetric polynomials.

► **Theorem 11** (see [3]). *If  $g \in \mathbb{C}[x_1, x_2, \dots, x_n]$  is a symmetric polynomial, then there exists a unique polynomial  $f \in \mathbb{C}[y_1, y_2, \dots, y_n]$  such that  $g = f(e_1^n, e_2^n, \dots, e_n^n)$ .*

Theorem 11 states that every symmetric polynomial  $g$  can be uniquely written as  $f_{\text{Sym}}$  for some  $f$ . Thus in whatever follows, we always use the notation of the kind  $f_{\text{Sym}}$  to denote a symmetric polynomial.

### 2.2 Basic tools

Suppose we have a circuit  $C$  computing a polynomial  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$  of degree  $d$ . It might be the case that  $f$  is not homogeneous. For some applications, it might be better to work with homogeneous polynomials. So we want to know if there exist “small” circuits also for the homogeneous components of  $f$ . For a polynomial  $f$ ,  $f^{[m]}$  is used to denote the degree  $m$  homogeneous component of  $f$ . The following Lemma 12 proves that the homogeneous components of  $f$  also have “small” arithmetic circuits.

## 47:6 Complexity of Symmetric Polynomials

► **Lemma 12** (Folklore). *Let  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$  be a polynomial with  $d = \deg(f)$ . For any  $0 \leq m \leq d$ , we have:  $L^f(f^{[m]}) \leq O(nd)$ .*

**Proof.** For a fresh indeterminate  $y$ , consider the polynomial  $f(yx_1, yx_2, \dots, yx_n)$ . We consider  $f(yx_1, yx_2, \dots, yx_n)$  as a uni-variate polynomial in  $y$  of degree  $d$ , with coefficients in  $\mathbb{C}[x_1, x_2, \dots, x_n]$ . We observe that for any  $0 \leq m \leq d$ , the coefficient of  $y^m$  in  $f(yx_1, yx_2, \dots, yx_n)$  is  $f^{[m]}$ . Let  $\alpha_1, \alpha_2, \dots, \alpha_{d+1}$  be  $d+1$  distinct constants in  $\mathbb{C}$ . By interpolation, we know that for any  $0 \leq m \leq d$ , the coefficient  $f^{[m]}$  of  $y^m$  is a  $\mathbb{C}$ -linear combination of  $d+1$  evaluations  $f(\alpha_i x_1, \alpha_i x_2, \dots, \alpha_i x_n)$  of  $f(yx_1, yx_2, \dots, yx_n)$  at  $\alpha_i \in \{\alpha_1, \alpha_2, \dots, \alpha_{d+1}\}$ . Formally, for any  $0 \leq m \leq d$  we have:

$$f^{[m]} \in \langle \{f(\alpha_i x_1, \alpha_i x_2, \dots, \alpha_i x_n) \mid \alpha_i \in \{\alpha_1, \alpha_2, \dots, \alpha_{d+1}\}\} \rangle. \quad (4)$$

It is easy to observe that  $L^f(f(\alpha_i x_1, \alpha_i x_2, \dots, \alpha_i x_n)) = O(n)$ . Equation 4 implies that  $L^f(f^{[m]}) \leq O(nd)$ . ◀

Lemma 12 implies that  $L(f^{[m]}) \leq O(L(f) \cdot n \cdot d)$ , this bound depends on the degree  $d$  of  $f$ . But if we do not care about the oracle complexity, the following bound (independent of degree of  $f$ ) on  $L(f^{[m]})$  is known.

► **Lemma 13** ([13, 14]). *Let  $f \in \mathbb{C}[x_1, x_2, \dots, x_n]$  be a polynomial and  $m$  be a non-negative integer. Then we have:*

$$L(\{f^{[0]}, f^{[1]}, \dots, f^{[m]}\}) \leq O(m^2 L(f)).$$

### 3 Complexity of SFT and SPT

Here we prove Lemma 7 and Lemma 8.

**Proof of Lemma 7.** Given a Boolean circuit  $C$ , we want to check if the function  $f(x_1, x_2, \dots, x_n)$  computed by  $C$  is symmetric. As the permutation group  $\mathfrak{S}_n$  is generated by two permutations  $\sigma \stackrel{\text{def}}{=} (1, 2)$  and  $\pi \stackrel{\text{def}}{=} (1, 2, \dots, n)$  [4], it is necessary and sufficient to check if the given function  $f$  is invariant under these two permutations of variables. Thus we define the following Boolean functions:

$$\begin{aligned} g(x_1, x_2, \dots, x_n) &\stackrel{\text{def}}{=} f(x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(n)}), \\ h(x_1, x_2, \dots, x_n) &\stackrel{\text{def}}{=} f(x_{\pi(1)}, x_{\pi(2)}, \dots, x_{\pi(n)}). \end{aligned}$$

Now note that the equality of two Boolean variables  $x, y$  can be checked by the following equality gadget:

$$(x \stackrel{?}{=} y) = (\neg x \vee y) \wedge (x \vee \neg y).$$

Thus we only need to check if both  $(\neg f \vee g) \wedge (f \vee \neg g)$  and  $(\neg f \vee h) \wedge (f \vee \neg h)$  are tautologies (always equal to 1). This can be checked by two oracle calls to CSAT. Thus  $\text{SFT} \leq_{\mathbb{P}}^T \text{CSAT}$ .

Now we prove the other direction. Given a Boolean circuit  $C$ , we want to check if the function  $f(x_1, x_2, \dots, x_n)$  computed by  $C$  is always zero. First we make an oracle call to SFT to check if  $f$  is symmetric. If  $f$  is not symmetric then obviously  $f$  is a non-zero function because the zero function is trivially symmetric. Thus we can assume  $f$  to be symmetric. Now we ask the SFT oracle if the function  $h \stackrel{\text{def}}{=} f \wedge x_1$  is symmetric? If  $f$  was the zero

function then so is  $h$ , therefore SFT oracle will answer that  $h$  is symmetric. So if SFT oracle answers  $h$  to be non-symmetric then obviously  $f$  was non-zero. If  $h$  also turns out to be symmetric then we know that:

$$\forall (a_1, a_2, \dots, a_n) \in \{0, 1\}^n : f \wedge a_1 = f \wedge a_2 = \dots = f \wedge a_n. \quad (5)$$

Suppose  $f$  evaluated to 1 on a point  $(a_1, a_2, \dots, a_n) \notin \{(0, 0, \dots, 0), (1, 1, \dots, 1)\}$ . This means that there exists  $(a_1, a_2, \dots, a_n) \in \{0, 1\}^n$  such that  $f(a_1, a_2, \dots, a_n) = 1$  with  $a_i = 1, a_j = 0$  for some  $i, j \in [n]$ . Then obviously we have  $f(a_1, a_2, \dots, a_n) \wedge a_i = 1$  and  $f(a_1, a_2, \dots, a_n) \wedge a_j = 0$ . Hence Equation 5 can not to be true. Thus  $f$  can only be non-zero on the set  $\{(0, 0, \dots, 0), (1, 1, \dots, 1)\}$ . The value of  $f$  at both these points can be checked manually to check whether  $f$  is the zero function or not. Therefore  $\text{CSAT} \leq_{\text{P}}^{\text{T}} \text{SFT}$ . ◀

**Proof of Lemma 8.** Given an arithmetic circuit  $C$ , we want to check if the polynomial  $f(x_1, x_2, \dots, x_n)$  computed by  $C$  is symmetric.

As in the proof of the Lemma 7, we use the fact that permutation group  $\mathfrak{S}_n$  is generated by two permutations  $\sigma \stackrel{\text{def}}{=} (1, 2)$  and  $\pi \stackrel{\text{def}}{=} (1, 2, \dots, n)$ . It is necessary and sufficient to check if the given polynomial  $f$  is invariant under these two permutations of variables. Analogous to the proof of the Lemma 7, we define the following polynomials:

$$g(x_1, x_2, \dots, x_n) \stackrel{\text{def}}{=} f(x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(n)}),$$

$$h(x_1, x_2, \dots, x_n) \stackrel{\text{def}}{=} f(x_{\pi(1)}, x_{\pi(2)}, \dots, x_{\pi(n)}).$$

Thus  $f$  is symmetric iff  $f - g = f - h = 0$ . Consider the polynomial  $F = y(f - g) + z(f - h)$ , here  $y, z$  are fresh variables. Thus  $f$  is symmetric iff  $F$  is the zero polynomial. Hence  $\text{SPT} \leq_{\text{P}} \text{ACIT}$ .

Now we prove the reverse direction. Given an arithmetic circuit  $C$ , we want to check if the polynomial  $f(x_1, x_2, \dots, x_n)$  computed by  $C$  is the zero polynomial or not. Consider the polynomial  $G \stackrel{\text{def}}{=} f(x_1^2, x_2^2, \dots, x_n^2) \cdot x_1$ . We know that  $f$  is non-zero iff  $G$  is non-zero. Suppose that  $G \neq 0$ . Now observe that in every monomial  $\mathcal{M}$  of  $G$ , the degree of  $x_1$  in  $\mathcal{M}$  is odd and the degrees of the other variables  $x_2, \dots, x_n$  in  $\mathcal{M}$  are even. Now consider the polynomial  $H \stackrel{\text{def}}{=} G(x_{\sigma(1)}, x_{\sigma(2)}, \dots, x_{\sigma(n)})$  where  $\sigma \stackrel{\text{def}}{=} (1, 2)$ . In every monomial  $\mathcal{M}'$  of  $H$ , the degree of  $x_2$  in  $\mathcal{M}'$  is odd and the degrees of the other variables  $x_1, x_3, \dots, x_n$  in  $\mathcal{M}'$  are even. Thus  $H \neq G$ . Hence if  $G$  is non-zero then  $G$  is not symmetric because it is not invariant under the permutation  $\sigma \stackrel{\text{def}}{=} (1, 2)$ . Thus  $G$  is symmetric iff  $f = 0$ . Hence  $\text{ACIT} \leq_{\text{P}} \text{SPT}$ . ◀

## 4 Main algorithm

### 4.1 Roots as power series

Let  $F(y) = F(y, u_1, u_2, \dots, u_n) = y^n + f_1(u_1, u_2, \dots, u_n)y^{n-1} + \dots + f_n(u_1, u_2, \dots, u_n)$  be a monic square-free polynomial in variables  $y$  and  $u_1, u_2, \dots, u_n$ , here  $f_i \in \mathbb{C}[u_1, u_2, \dots, u_n]$ . Let  $A(u_1, u_2, \dots, u_n)$  be a root of  $F$  with respect to  $y$ . The root is usually an algebraic function in  $u_1, u_2, \dots, u_n$  but not a power series. The following Lemma 14 formalizes a sufficient condition when roots of  $F(y)$  can be expressed as power series in  $u_1, u_2, \dots, u_n$ .

► **Lemma 14** (Condition A in [12]). *Let  $F(y, u_1, u_2, \dots, u_n)$  be square free and monic with respect to  $y$ . If  $F(y, 0, 0, \dots, 0)$  has no multiple root (as a uni-variate polynomial in  $y$ ) then the roots  $A_i(u_1, u_2, \dots, u_n)$  of  $F(y, u_1, u_2, \dots, u_n)$  can be expanded into power series in  $u_1, u_2, \dots, u_n$ .*

---

**Algorithm 1** Newton's Method.

---

**Input:** A square free monic polynomial  $F(y) = F(y, u_1, u_2, \dots, u_n) \in \mathbb{C}[u_1, u_2, \dots, u_n][y]$  with respect to  $y$  of degree  $n$  such that  $F(y, 0, 0, \dots, 0)$  has  $n$  simple roots. A positive integer  $d$  with  $d = 2^\ell$  for some  $\ell \in \mathbb{N}$ . We assume that  $A_1, A_2, \dots, A_n \in \mathbb{C}[[u_1, u_2, \dots, u_n]]$  are the roots of  $F(y)$ .

**Output:** Degree  $d$  truncations  $A_1^{(\ell)}, A_2^{(\ell)}, \dots, A_n^{(\ell)}$  of the  $n$  roots  $(A_1, A_2, \dots, A_n)$  of  $F(y)$ , that is,  $A_i^{(\ell)} \equiv A_i \pmod{I^d}$  with  $I \stackrel{\text{def}}{=} (u_1, u_2, \dots, u_n)$  for all  $i \in [n]$ .

1:  $\{\alpha_1, \alpha_2, \dots, \alpha_n\} \leftarrow$  Roots of  $F(y, 0, 0, \dots, 0)$ .

2: **for**  $1 \leq i \leq n$  **do**

3:      $A_i^{(0)} \leftarrow \alpha_i$ .

4:     **for**  $0 \leq k \leq \ell - 1$  **do**

5:          $A_i^{(k+1)} \leftarrow A_i^{(k)} - \frac{F(A_i^{(k)})}{F'(A_i^{(k)})}$ .

6:     **end for**

7: **end for**

8: **return**  $A_1^{(\ell)}, A_2^{(\ell)}, \dots, A_n^{(\ell)}$ .

---

As stated above, we are interested in the following special case:

$$F(y, e_1, e_2, \dots, e_n) = y^n - e_1 y^{n-1} + \dots + (-1)^n e_n.$$

This  $F$  is being considered as a uni-variate polynomial in  $y$  over the power series ring  $\mathbb{C}[[e_1, e_2, \dots, e_n]]$ . In this case, the roots of  $F(y, e_1, e_2, \dots, e_n)$  are  $x_1, x_2, \dots, x_n$ . We want to express roots of this  $F$  as power series in  $e_1, e_2, \dots, e_n$ . For this purpose, we consider a slightly modified version of  $F$ . More specifically, consider:

$$F(y, e_1, e_2, \dots, e_n) = y^n - e_1 y^{n-1} + \dots + (-1)^n (e_n + (-1)^{n-1}). \quad (6)$$

Notice that  $F(y, 0, 0, \dots, 0)$  has  $n$  distinct roots, namely the  $n^{\text{th}}$  roots of unity. Thus the roots of this  $F(y)$  (Equation 6) can be expressed as power series in  $e_1, e_2, \dots, e_n$ , this follows from Lemma 14. Let us record this as corollary 15.

► **Corollary 15.** *If  $F$  is as in Equation 6, then there exist  $n$  power series  $A_1, A_2, \dots, A_n \in \mathbb{C}[[e_1, e_2, \dots, e_n]]$  such that  $F(A_i) = 0$  for all  $i \in [n]$ .*

Now we show how to compute the degree  $d$  truncations of such roots  $A_1, A_2, \dots, A_n$ . This already follows from [9]. For the reader's convenience, we describe the algorithm here and a proof of correctness can be found in Appendix A.

## 4.2 Newton's Method

For the analysis of Algorithm 1, define the ideal  $I$  as:

$$I \stackrel{\text{def}}{=} (u_1, u_2, \dots, u_n).$$

► **Theorem 16.** *In Algorithm 1,  $A_i^{(k)} \equiv A_i \pmod{I^{2^k}}$  for all  $0 \leq k \leq \ell$  and for all  $i \in [n]$ .*

In Algorithm 1, we need to compute the inverse of  $F'(A^{(k)})$ , since we want to compute  $A^{(k+1)}$ , it is enough to compute the inverse of  $F'(A^{(k)}) \pmod{I^{2^{k+1}}}$ . This also follows from [9]. We explicitly describe this in Algorithm 2.

► **Lemma 17.** *Algorithm 2 computes a polynomial  $p$  such that  $p \equiv g^{-1} \pmod{I^d}$ .*

**Algorithm 2** Inverse computation.

**Input:** A circuit  $C$  computing the polynomial  $g(u_1, u_2, \dots, u_n)$  such that  $g(0, 0, \dots, 0) \neq 0$  and a positive integer  $d$  with  $d = 2^\ell$  for some  $\ell \in \mathbb{N}$ .

**Output:** A circuit  $D$  for computing a polynomial  $p(u_1, u_2, \dots, u_n)$  such that  $p \equiv g^{-1} \pmod{I^d}$ , here  $I = (u_1, u_2, \dots, u_n)$  and  $g^{-1}$  is the inverse of  $g$  in  $\mathbb{C}[[u_1, u_2, \dots, u_n]]$ .

```

1:  $p_0 \leftarrow \frac{1}{g(0,0,\dots,0)}$ .
2: for  $0 \leq k \leq \ell - 1$  do
3:    $p_{k+1} \leftarrow p_k \cdot (2 - g \cdot p_k)$ .
4: end for
5: return  $p_\ell$ .

```

We can also prove that there is a “small” circuit for  $p$  in Lemma 17.

► **Lemma 18.** *Let  $g(u_1, u_2, \dots, u_n)$  be a polynomial such that  $g(0, 0, \dots, 0) \neq 0$ . For any positive integer  $d$  with  $d = 2^\ell$  for some  $\ell \in \mathbb{N}$ , there is a polynomial  $p \in \mathbb{C}[u_1, u_2, \dots, u_n]$  such that  $p \equiv g^{-1} \pmod{I^d}$ . Moreover,  $L(p) \leq L(g) + O(\ell)$ .*

**Proof.** In Algorithm 2, we need three arithmetic operations to compute  $p_{k+1}$  from  $p_k$ . It follows from Lemma 17 that  $p_\ell = g^{-1} \pmod{I^d}$ . Thus there exists a circuit of size  $L(g) + 3 \cdot \ell = L(g) + O(\ell)$  computing  $p \equiv g^{-1} \pmod{I^d}$ . ◀

Now the following Theorem 19 follows by applying Lemma 18 and Theorem 16.

► **Theorem 19.** *Let  $F(y, e_1, e_2, \dots, e_n) = y^n - e_1 y^{n-1} + \dots + (-1)^n (e_n + (-1)^{n-1})$  and let  $A_1, A_2, \dots, A_n \in \mathbb{C}[[e_1, e_2, \dots, e_n]]$  such that  $F(A_i, e_1, e_2, \dots, e_n) = 0$  for all  $i \in [n]$ . Let  $d$  be a positive integer with  $d = 2^\ell$  for some  $\ell \in \mathbb{N}$  and let  $I = (e_1, e_2, \dots, e_n)$  be the ideal generated by  $e_1, e_2, \dots, e_n$  in the polynomial ring  $\mathbb{C}[e_1, e_2, \dots, e_n]$ . Let polynomials  $D_i$  be such that  $D_i \equiv A_i \pmod{I^d}$ . Then  $L(\{D_1, D_2, \dots, D_n\}) \leq O(n^2 \ell + n \ell^2)$ .*

**Proof.** We construct a circuit  $D$  whose outputs are  $D_1, D_2, \dots, D_n$ . We construct the desired circuit  $D$  by using Algorithm 1 on  $F(y, e_1, e_2, \dots, e_n)$  and  $s = (0, 0, \dots, 0)$ . It is enough to describe a circuit computing each  $D_i$  such that  $D_i \equiv A_i \pmod{I^d}$ . The circuit for  $A_i^{(0)}$  in Algorithm 1 is trivially of size one. By Step 5 of Algorithm 1, a circuit for  $A_i^{(k+1)}$  can be constructed given any circuits for  $A_i^{(k)}$ ,  $F(A_i^{(k)})$  and  $F'(A_i^{(k)})$ . Note that there are circuits of size  $O(n)$  computing  $F(y, e_1, e_2, \dots, e_n)$  and  $F'(y, e_1, e_2, \dots, e_n) \stackrel{\text{def}}{=} \frac{\partial F(y, e_1, e_2, \dots, e_n)}{\partial y}$ . Thus if  $A_i^{(k)}$  has a circuit of size  $s$ , then there exists a size  $s + O(n + \log d)$  circuit computing  $A_i^{(k+1)}$ , this follows from Lemma 18. In particular, there exists a circuit computing  $D_i \stackrel{\text{def}}{=} A_i^{(\lceil \log d \rceil)}$  of size  $O(n \log d + \log^2 d)$ . By Theorem 16, it follows that  $D_i \equiv A_i \pmod{I^d}$ . We combine the circuits computing  $D_i$ 's to construct the desired circuit  $D$  of size  $O(n \cdot n \log d + n \log^2 d) = O(n^2 \log d + n \log^2 d)$ . ◀

Now we are ready to prove Theorem 4.

**Proof of Theorem 4.** The main idea is what we have hinted above. Namely, let  $F(y, e_1, e_2, \dots, e_n)$  be the following polynomial:

$$F(y, e_1, e_2, \dots, e_n) = y^n - e_1 y^{n-1} + \dots + (-1)^n (e_n). \quad (7)$$

Here  $e_i = e_i^n$  is the  $i^{\text{th}}$  elementary symmetric polynomial. We know that the roots (as a uni-variate polynomial in  $y$ ) of  $F$  are  $x_1, x_2, \dots, x_n$ . Therefore,  $x_1, x_2, \dots, x_n$  are algebraic functions in  $e_1, e_2, \dots, e_n$ . Thus  $x_i = A_i(e_1, e_2, \dots, e_n)$  for some algebraic function  $A_i$ .

## 47:10 Complexity of Symmetric Polynomials

Let  $C_{\text{Sym}}(x_1, x_2, \dots, x_n)$  be a circuit of size  $L(f_{\text{Sym}})$  computing  $f_{\text{Sym}}(x_1, x_2, \dots, x_n)$ . If we could substitute the  $x_i$ 's by the  $A_i$ 's in  $C_{\text{Sym}}(x_1, x_2, \dots, x_n)$ , we would obtain a circuit for  $f$ . But we cannot compute algebraic functions using arithmetic circuits. Now replace  $e_n$  by  $e_n + (-1)^{n-1}$  in Equation 7. Thus the new  $F(y, e_1, e_2, \dots, e_n)$  is:

$$F(y, e_1, e_2, \dots, e_n) = y^n - e_1 y^{n-1} + \dots + (-1)^n (e_n + (-1)^{n-1}). \quad (8)$$

We call the roots of  $F(y)$  in Equation 8 again  $A_1, A_2, \dots, A_n$ . By using Lemma 14, we know that the  $A_i$ 's are in  $\mathbb{C}[[e_1, e_2, \dots, e_n]]$ . The following Equation 9 follows from the above discussion:

$$C_{\text{Sym}}(A_1, A_2, \dots, A_n) = f(e_1, e_2, \dots, e_n + (-1)^{n-1}). \quad (9)$$

To compute  $f$ , it is enough to substitute the degree  $d$  truncations of the  $A_i$ 's in Equation 9, instead of the exact infinite power series  $A_i$ . Let  $D_1, D_2, \dots, D_n$  be the outputs of the circuit  $D$  obtained by applying Theorem 19 with degree  $2^{\lceil \log d \rceil}$ . We substitute the  $x_i \rightarrow D_i$  in the circuit  $C_{\text{Sym}}(x_1, x_2, \dots, x_n)$ . We obtain the following equality:

$$h \stackrel{\text{def}}{=} C_{\text{Sym}}(D_1, D_2, \dots, D_n) = f(e_1, e_2, \dots, e_n + (-1)^{n-1}) + g. \quad (10)$$

In the above Equation 10,  $g$  is a polynomial with all its monomials of degree at least  $d+1$ , i.e.,  $g \in I^{d+1}$  with  $I = (e_1, e_2, \dots, e_n)$ . Hence it follows that:

$$f(e_1, e_2, \dots, e_n + (-1)^{n-1}) = \sum_{i=0}^d h^{[i]}.$$

By applying Theorem 19, we know that  $L^{f_{\text{Sym}}}(h) \leq (n^2 \log d + n \log^2 d)$ . Note that the degree of each  $D_i$  is at most  $2^{\lceil \log d \rceil}$ , which is at most  $2d$ . Thus the degree of  $h$  is at most  $2dd_{\text{Sym}}$ . By using Lemma 12, we conclude that for any  $0 \leq i \leq \deg(h)$ :

$$L^h(h^{[i]}) \leq O(n \cdot d \cdot d_{\text{Sym}}). \quad (11)$$

Equation 11 implies that  $L^h(\sum_{i=0}^d h^{[i]}) \leq O(n \cdot d^2 \cdot d_{\text{Sym}})$ . By using  $L^{f_{\text{Sym}}}(h) \leq (n^2 \log d + n \log^2 d)$ , we obtain that:

$$\begin{aligned} L^{f_{\text{Sym}}}\left(\sum_{i=0}^d h^{[i]}\right) &\leq O(n \cdot d^2 \cdot d_{\text{Sym}} \cdot (n^2 \log d + n \log^2 d)) \\ &= \tilde{O}(n^3 \cdot d^2 \cdot d_{\text{Sym}}). \end{aligned}$$

By using the substitution  $e_n \rightarrow e_n - (-1)^{n-1}$ , we obtain that:

$$L^{f_{\text{Sym}}}(f) \leq \tilde{O}(n^3 \cdot d^2 \cdot d_{\text{Sym}}).$$

If we use Lemma 13 instead of Lemma 12 in the above argument, we obtain that:

$$\begin{aligned} L(f) &\leq O(d^2(L(f_{\text{Sym}}) + n^2 \log d + n \log^2 d)) \\ &= \tilde{O}(d^2 L(f_{\text{Sym}}) + d^2 n^2). \end{aligned}$$

This concludes the proof. ◀

► **Remark.** In contrast to results in [7, 6], our results do depend on the degree  $d$ . But if the degree  $d$  is  $\text{poly}(n)$  then our upper bound on  $L(f)$  is polynomial in  $n$  and  $L(f_{\text{Sym}})$ . This upper bound was exponential in [7, 6].

## 5 Hard Symmetric Polynomials

By using Theorem 4, we are ready to prove that there exist *hard* symmetric polynomials. To this end, the following Theorem 20 suffices.

► **Theorem 20.** *Let  $(f_n)_{n \in \mathbb{N}}$  be a VNP-complete family. Then the corresponding symmetric polynomial family  $((f_n)_{\text{Sym}})_{n \in \mathbb{N}}$  is VNP-complete under  $c$ -reductions.*

**Proof.** Let  $d = \deg(f_n)$  and  $d_{\text{Sym}} = \deg((f_n)_{\text{Sym}})$ . Since  $(f_n)_{n \in \mathbb{N}} \in \text{VNP}$ , we know that both  $d$  and  $d_{\text{Sym}}$  are polynomially bounded in  $n$ . By using Theorem 4, we know that  $L^{f_{\text{Sym}}}(f) \leq \tilde{O}(n^3 \cdot d^2 \cdot d_{\text{Sym}}) = \tilde{O}(\text{poly}(n))$ . Thus  $((f_n)_{\text{Sym}})_{n \in \mathbb{N}}$  is VNP-hard under  $c$ -reductions. It is also easy to see that  $((f_n)_{\text{Sym}})_{n \in \mathbb{N}}$  is in VNP. Therefore  $((f_n)_{\text{Sym}})_{n \in \mathbb{N}}$  is VNP-complete under  $c$ -reductions. ◀

► **Corollary 21.** *The polynomial family  $(q_n)_{n \in \mathbb{N}}$  defined by  $q_n \stackrel{\text{def}}{=} (\text{per}_n)_{\text{Sym}}$  is VNP-complete under  $c$ -reductions. Therefore if  $\text{VP} \neq \text{VNP}$ , then the polynomial family  $(q_n)_{n \in \mathbb{N}}$  is not in VP.*

## A Appendix

### A.1 Algebraic complexity theory

Analogous to the idea of classical complexity classes, we can also define algebraic complexity classes. We refer the reader to [5, 11] for a more comprehensive introduction to algebraic complexity classes. In this section, a  $p$ -bounded function is simply a polynomially bounded function.

► **Definition 22** (Arithmetic Circuit Complexity). For a polynomial  $p \in \mathbb{F}[x_1, x_2, \dots, x_n]$ , the (arithmetic) circuit complexity  $L(p)$  of  $p$  is defined as the size of smallest arithmetic circuit computing  $p$ , that is

$$L(p) \stackrel{\text{def}}{=} \min\{s \mid \exists \text{ size } s \text{ arithmetic circuit computing } p\}.$$

► **Definition 23** ( $p$ -family). A family (or a sequence)  $(f_n)_{n \in \mathbb{N}}$  of (multivariate) polynomials over the field  $\mathbb{F}$  is said to be a  $p$ -family iff the number of variables as well as the degree of  $f_n$  are  $p$ -bounded functions of  $n$ .

Now we define the notion of *efficient* polynomial families.

► **Definition 24** ( $p$ -computable). A  $p$ -family  $(f_n)_{n \in \mathbb{N}}$  is called  $p$ -computable iff the arithmetic complexity  $L(f_n)$  is a  $p$ -bounded function of  $n$ .

$p$ -computable polynomial families define the algebraic analogue of the P, called VP.

► **Definition 25** (Class VP). The (algebraic complexity) class VP is the set of all  $p$ -computable polynomial families.

► **Definition 26** (Class VNP). A  $p$ -family  $(f_n)_{n \in \mathbb{N}}$  is said to be in the (algebraic complexity) class VNP if there exists a polynomial family  $(g_n)_{n \in \mathbb{N}} \in \text{VP}$  with  $g_n \in \mathbb{F}[x_1, x_2, \dots, x_{q(n)}]$  such that:

$$f_n(x_1, x_2, \dots, x_{p(n)}) = \sum_{e \in \{0,1\}^{q(n)-p(n)}} g_n(x_1, x_2, \dots, x_{p(n)}, e_1, e_2, \dots, e_{q(n)-p(n)}).$$

Similar to the Boolean case, there is an algebraic notion of reduction also, called the  $p$ -projections.

► **Definition 27** (Projection). A polynomial  $f(x_1, x_2, \dots, x_n) \in \mathbb{F}[x_1, x_2, \dots, x_n]$  is said to be a projection of a polynomial  $g(y_1, y_2, \dots, y_m) \in \mathbb{F}[y_1, y_2, \dots, y_m]$ , if there exists a map  $\alpha : \{y_1, y_2, \dots, y_m\} \rightarrow \{x_1, x_2, \dots, x_n\} \cup \mathbb{F}$  such that  $f = g$  under the substitution map  $\alpha$ . We write  $f \leq g$  to denote that  $f$  is a projection of  $g$ .

► **Definition 28** (*p*-projection). A polynomial family  $(f_n)_{n \in \mathbb{N}}$  is said to be a *p*-projection of a polynomial family  $(g)_{n \in \mathbb{N}}$  if there is a *p*-bounded function  $\beta : \mathbb{N} \rightarrow \mathbb{N}$  and  $n_0 \in \mathbb{N}$  such that:

$$\forall n \geq n_0 : f_n \leq g_{\beta(n)}.$$

We denote  $(f_n)_{n \in \mathbb{N}}$  being a *p*-projection of  $(g)_{n \in \mathbb{N}}$  by  $f \leq_p g$ .

Definition 9 naturally lends to the following definition:

► **Definition 29** ([5]). Let  $f = (f_n), g = (g_n)$  be two polynomial families. We say that  $f$  is a *c*-reduction of  $g$ , denoted by  $f \leq_c g$ , iff there is a *p*-bounded function  $t : \mathbb{N} \rightarrow \mathbb{N}$  such that  $L^{g^{t(n)}}(f_n)$  is a *p*-bounded function of  $n$ .

Now the idea of completeness and hardness can be defined as in the case of Boolean case.

► **Definition 30** (Hardness and Completeness). For an algebraic complexity classic  $\mathcal{C}$ , a *p*-family  $f = (f_n)_{n \in \mathbb{N}}$  is said to be a  $\mathcal{C}$ -hard if  $g \leq_p f$  for all  $g \in \mathcal{C}$ ,  $f$  is called  $\mathcal{C}$ -complete if  $f$  is  $\mathcal{C}$ -hard and  $f \in \mathcal{C}$ . Similarly, we can define the notion of hardness under *c*-reductions.

► **Theorem 31** ([15], see also [5]). *Over the fields  $\mathbb{F}$  with  $\text{char}(\mathbb{F}) \neq 2$ , the *p*-family  $(\text{per}_n)$  is VNP-complete.*

The holy grail of algebraic complexity theory is to show that  $\text{VP} \neq \text{VNP}$ . For this it is enough to show that  $(\text{per}_n) \notin \text{VP}$  over fields  $\mathbb{F}$  with  $\text{char}(\mathbb{F}) \neq 2$ . Note that  $\text{per}_n$  and  $\text{det}_n$  are the same polynomials if  $\text{char}(\mathbb{F}) = 2$ . Thus if  $\text{char}(\mathbb{F}) = 2$  then  $(\text{per}_n) \in \text{VP}$  hence  $(\text{per}_n)$  is unlikely to VNP-complete over fields of characteristic two.

## A.2 Missing proofs

We provide some proofs of known results used in this work for the reader's convenience.

**Proof of Lemma 13.** Let  $C$  be a circuit of size  $L(f)$  computing  $f$ . We create  $m + 1$  copies of each arithmetic gate in  $C$ , i.e., each  $\{+, -, \times\}$ -gate  $G$  has  $m + 1$  copies  $G_0, G_1, \dots, G_m$ . If the gate  $G$  computes the polynomial  $g$  then  $G_i$  computes the polynomial  $g^{[i]}$ . This can be trivially done for input and constant gates. Suppose  $G = G_1 + G_2$  is a “+” gate and  $g_1, g_2$  are the polynomials computed by gates  $G_1$  and  $G_2$  respectively. Now we know that  $g^{[i]} = g_1^{[i]} + g_2^{[i]}$  for all  $i \in [[m]]$ . A similar statement is true for “−” gates also. If  $G = G_1 \times G_2$  is a “×” gate, then we have the following equality:

$$g^{[i]} = \sum_{j=0}^i g_1^{[j]} \cdot g_2^{[i-j]}. \tag{12}$$

Suppose we already have the gates for  $g_1^{[j]}, g_2^{[j]}$  for all  $j \in [[m]]$ . Then one  $g^{[i]}$  in Equation 12 can be computed using  $2(i + 1)$  additional gates. Thus the gates  $G_0, G_1, \dots, G_m$  can be constructed using  $\sum_{k=0}^m 2(k + 1) = O(m^2)$  gates. Hence every gate in  $C$  corresponds to at most  $O(m^2)$  new gates. Therefore:

$$L(\{f^{[0]}, f^{[1]}, \dots, f^{[m]}\}) \leq O(m^2 L(f)). \quad \blacktriangleleft$$

**Proof of Theorem 16.** Our claim is obviously true for  $k = 0$ . We prove the theorem by induction on  $k$ . We prove it simultaneously for all  $i \in [n]$ , so for the sake of brevity we use  $A^{(k)}$  to denote  $A_i^{(k)}$  and  $\alpha$  to denote  $\alpha_i$ . Consider the following equalities for a root  $A = A_i$  of  $F(y)$ :

$$\begin{aligned} 0 &= F(A) = F(A^{(k)} + (A - A^{(k)})) \\ &= F(A^{(k)}) + (A - A^{(k)})F'(A^{(k)}) + \sum_{j>1} \frac{(A - A^{(k)})^j}{j!} F^{(j)}(A^{(k)}). \end{aligned} \tag{13}$$

## 47:14 Complexity of Symmetric Polynomials

Here  $F^{(j)} \stackrel{\text{def}}{=} \frac{\partial^j F(y, u_1, u_2, \dots, u_n)}{\partial y^j}$  is the  $j^{\text{th}}$  derivative of  $F(y)$  with respect to  $y$ . Since  $\alpha$  is a simple root of  $F(y, 0, 0, \dots, 0)$ , we know that:

$$\text{constant term of } F'(A^{(k)}) = F'(\alpha) \neq 0.$$

Thus  $F'(A_k)$  is invertible in the ring  $\mathbb{C}[[u_1, u_2, \dots, u_n]]$  of power series. Therefore we have:

$$\begin{aligned} A - A^{(k+1)} &= A - \left( A^{(k)} - \frac{F(A^{(k)})}{F'(A^{(k)})} \right) \\ &= - \sum_{j>1} \frac{(A - A^{(k)})^j F^{(j)}(A^{(k)})}{j! \cdot F'(A^{(k)})}. \end{aligned} \quad (\text{by using Equation 13})$$

Since  $A - A^{(k)} \in I^{2^k}$ , the right hand side of the above equation is in  $I^{2^{k+1}}$ . Thus  $A^{(k+1)} \equiv A \pmod{I^{2^{k+1}}}$ . ◀

**Proof of Lemma 17.** We again prove it by induction on  $k$ , the induction hypothesis is that  $p_k \equiv g^{-1} \pmod{I^{2^k}}$ . This induction hypothesis is trivially true for  $k = 0$ . Consider:

$$\begin{aligned} \frac{1}{g} - p_{k+1} &= \frac{1}{g} - p_k(2 - g \cdot p_k) \\ &= g \cdot \left( \frac{1}{g^2} - \frac{2p_k}{g} + p_k^2 \right) \\ &= g \cdot \left( \frac{1}{g} - p_k \right)^2. \end{aligned}$$

By using the induction hypothesis, we know that  $\frac{1}{g} - p_k \in I^{2^k}$ . Therefore it implies that  $\frac{1}{g} - p_{k+1} \in I^{2^{k+1}}$ . Now the lemma follows from the fact that  $\ell = \lceil \log d \rceil$ . ◀

# The Orthogonal Vectors Conjecture for Branching Programs and Formulas

## Abstract

---

In the **ORTHOGONAL VECTORS (OV)** problem, we wish to determine if there is an orthogonal pair of vectors among  $n$  Boolean vectors in  $d$  dimensions. The *OV Conjecture (OVC)* posits that **OV** requires  $n^{2-o(1)}$  time to solve, for all  $d = \omega(\log n)$ . Assuming the OVC, optimal time lower bounds have been proved for many prominent problems in **P**, such as Edit Distance, Frechet Distance, Longest Common Subsequence, and approximating the diameter of a graph.

We prove that OVC is true in several computational models of interest:

- For all sufficiently large  $n$  and  $d$ , **OV** for  $n$  vectors in  $\{0, 1\}^d$  has branching program complexity  $\tilde{\Theta}(n \cdot \min(n, 2^d))$ . In particular, the lower and upper bounds match up to polylog factors.
- **OV** has Boolean formula complexity  $\tilde{\Theta}(n \cdot \min(n, 2^d))$ , over all complete bases of  $O(1)$  fan-in.
- **OV** requires  $\tilde{\Theta}(n \cdot \min(n, 2^d))$  wires, in formulas comprised of gates computing arbitrary symmetric functions of unbounded fan-in.

Our lower bounds basically match the best known (quadratic) lower bounds for *any* explicit function in those models. Analogous lower bounds hold for many related problems shown to be hard under OVC, such as Batch Partial Match, Batch Subset Queries, and Batch Hamming Nearest Neighbors, all of which have very succinct reductions to **OV**.

The proofs use a certain kind of input restriction that is different from typical random restrictions where variables are assigned independently. We give a sense in which independent random restrictions cannot be used to show hardness, in that OVC is false in the “average case” even for  $AC^0$  formulas:

For all  $p \in (0, 1)$  there is a  $\delta_p > 0$  such that for every  $n$  and  $d$ , **OV** instances with input bits independently set to 1 with probability  $p$  (and 0 otherwise) can be solved with  $AC^0$  formulas of  $O(n^{2-\delta_p})$  size, on all but a  $o_n(1)$  fraction of instances. Moreover,  $\lim_{p \rightarrow 1} \delta_p = 1$ .

**2012 ACM Subject Classification** Theory of computation  $\rightarrow$  Circuit complexity

**Keywords and phrases** fine-grained complexity, orthogonal vectors, branching programs, symmetric functions, Boolean formulas

## 1 Introduction

We investigate the following basic problem:

**ORTHOGONAL VECTORS (OV)**  
 Given:  $n$  vectors  $v_1, \dots, v_n \in \{0, 1\}^d$   
 Decide: Are there  $i, j$  such that  $\langle v_i, v_j \rangle = 0$ ?

An instructive way of viewing the **OV** problem is that we have a collection of  $n$  sets over  $[d]$ , and wish to find two disjoint sets among them. The obvious algorithm runs in time  $O(n^2 \cdot d)$ , and  $\log(n)$  factors can be shaved [33]. For  $d < \log_2(n)$ , stronger improvements are possible: there are folklore  $O(n \cdot 2^d \cdot d)$ -time and  $\tilde{O}(n + 2^d)$ -time algorithms (for a reference, see [1]). Truly subquadratic-time algorithms have recently been developed for even larger dimensionalities: the best known result in this direction is that for all constants  $c \geq 1$ , **OV** with  $d = c \log n$  dimensions can be solved in  $n^{2-1/O(\log c)}$  time [7, 19]. However, it seems inherent that, as the vector dimension  $d$  increases significantly beyond  $\log n$ , the time complexity of **OV** approaches the trivial  $n^2$  bound.

Over the last several years, a significant body of work has been devoted to understanding the following plausible lower bound conjecture:

► **Conjecture 1** (Orthogonal Vectors Conjecture (OVC) [37, 6, 9, 3]). *For every  $\varepsilon > 0$ , there is a  $c \geq 1$  such that **OV** cannot be solved in  $n^{2-\varepsilon}$  time on instances with  $d = c \log n$ .*

In other words, OVC states that **OV** requires  $n^{2-o(1)}$  time on instances of dimension  $\omega(\log n)$ . The popular Strong Exponential Time Hypothesis [27, 18] (on the time complexity of CNF-SAT) implies OVC [37]. For this reason, and the fact that the **OV** problem is very simple to work with, the OVC has been the engine under the hood of many recent conditional lower bounds on classic problems solvable within P. For example, the OVC implies nearly-quadratic time lower bounds for Edit Distance [9], approximating the diameter of a graph [34], Frechet Distance [13, 15], Longest Common Substring and Local Alignment [6], Regular Expression Matching [10], Longest Common Subsequence, Dynamic Time Warping, and other string similarity measures [3, 14], Subtree Isomorphism and Largest Common Subtree [2], Curve Simplification [16], intersection emptiness of two finite automata [35], first-order properties on sparse finite structures [24] as well as average-case hardness for quadratic-time [11]. Other works surrounding the OVC (or assuming it) include [38, 36, 5, 20, 8, 23, 26, 17, 30, 22].

Therefore it is of strong interest to prove the OVC in reasonable computational models. Note that **OV** can be naturally expressed as a depth-three formula with unbounded fan-in: an OR of  $n^2$  NORs of  $d$  ANDs on two input variables: an  $AC^0$  formula of size  $O(n^2 \cdot d)$ . Are there smaller formulas for **OV**?

### 1.1 OVC is True in Restricted Models

In this paper, we study how well **OV** can be solved in the Boolean formula and branching program models. Among the aforementioned **OV** algorithms, only the first two seem to be efficiently implementable by formulas and branching programs: for example, there are DeMorgan formulas for **OV** of size only  $O(n^2 d)$  and size  $O(nd2^d)$ , respectively (see Proposition 4).

The other algorithms do not seem to be implementable in small space, in particular with small-size branching programs. Our first theorem shows that the simple constructions solving **OV** with  $O(n^2 \cdot d)$  and  $O(n \cdot 2^d \cdot d)$  work are essentially optimal for all choices of  $d$  and  $n$ :

► **Theorem 2** (OVC For Formulas of Bounded Fan-in). *For every constant  $c \geq 1$ , **OV** on  $n$  vectors in  $d$  dimensions does not have  $c$ -fan-in formulas of size  $O(\min\{n^2/(\log d), n \cdot 2^d/(d^{1/2} \log d)\})$ , for all sufficiently large  $n, d$ .*

► **Theorem 3** (OVC For Branching Programs). ***OV** on  $n$  vectors in  $d$  dimensions does not have branching programs of size  $O(\min\{n^2, n \cdot 2^d/(d^{1/2})\}/(\log(nd) \log(d)))$ , for all sufficiently large  $n, d$ .*

As far as we know, size- $s$  formulas of constant fan-in may be more powerful than size- $s$  branching programs (but note that DeMorgan formulas can be efficiently simulated with branching programs). Thus the two lower bounds are incomparable. These lower bounds are tight up to the (negligible) factor of  $\min\{\sqrt{\log n}, d^{1/2}\} \log(d) \log(nd)$ , as the following simple construction shows:

► **Proposition 4.** ***OV** has  $AC^0$  formulas (and branching programs) of size  $O(dn \cdot \min(n, 2^d))$ .*

**Proof.** The  $O(dn^2)$  bound is obvious: take an OR over all  $\binom{n}{2}$  pairs of vectors, and use an  $AND \circ OR$  of  $O(d)$  size to determine orthogonality of the pair. For the  $O(dn2^d)$  bound, our strategy is to try all  $2^d$  vectors  $v$ , and look for a  $v$  that is equal to one input vector and is orthogonal to another input vector. To this end, take an OR over all  $2^d$  possible vectors  $w$  over  $[d]$ , and take the AND of two conditions:

1. There is a vector  $v$  in the input such that  $v = w$ . This can be computed with an OR over all  $n$  vectors of an  $O(d)$ -size formula, in  $O(nd)$  size.
2. There is a vector  $u$  in the input such that  $\langle u, w \rangle = 0$ . This can be computed with a *parallel* OR over all  $n$  vectors of an  $O(d)$ -size formula, in  $O(nd)$  size.

Note that the above formulas have constant-depth, with unbounded fan-in AND and OR gates. Since DeMorgan formulas of size  $s$  can be simulated by branching programs of size  $O(s)$ , the proof is complete.<sup>3</sup> ◀

### Formulas with symmetric gates

As mentioned above, **OV** can be naturally expressed as a depth-three formula of unbounded fan-in: an  $AC_3^0$  formula of  $O(n^2d)$  wires. We show that this wire bound is also nearly optimal, even when we allow arbitrary symmetric Boolean functions as gates. Note this circuit model subsumes both  $AC$  (made up of AND, OR, and NOT gates) and  $TC$  (made up of MAJORITY and NOT gates).

► **Theorem 5** (OVC For TC Formulas). *Every formula computing **OV** composed of arbitrary symmetric functions with unbounded fan-in needs at least  $\Omega(\min\{n^2/(\log d), n \cdot 2^d/(d^{1/2} \log d)\})$  wires, for all  $n$  and  $d$ .*

## 1.2 Lower Bounds for Batch Partial Match, Batch Subset Query, Batch Hamming Nearest Neighbors, etc.

A primary reason for studying **OV** is its ubiquity as a “bottleneck” special case of many other basic search problems. In particular, many problems have very succinct reductions from **OV** to them, and our lower bounds extend to these problems.

<sup>3</sup> This should be folklore, but we couldn’t find a reference; see the Appendix B. An anonymous referee thought we should attribute Borodin [12], but that reference only shows that circuits of depth  $s$  can be simulated in space  $O(s)$ . We need something much stronger: branching programs of size  $O(s)$  correspond to  $\log_2(s) + O(1)$  space. Lynch [31] showed that formulas of size  $s$  can be simulated in  $O(\log s)$  space, but in our case we need  $\log_2(s) + O(1)$  space.

We say that a *linear projection reduction* from a problem  $A$  to problem  $B$  is a circuit family  $\{C_n\}$  where each  $C_n$  has  $n$  input and  $O(n)$  outputs, each output of  $C_n$  depends on at most one input, and  $x \in A$  if and only if  $C_{|x|}(x) \in B$ , for all possible inputs  $x$ . Under this constrained reduction notion, it is easy to see that if **OV** has a linear projection reduction to  $B$ , then size lower bounds for **OV** (even in our restricted settings) imply analogous lower bounds for  $B$  as well. Via simple linear projection reductions which preserve both  $n$  and  $d$  (up to constant multiplicative factors), analogous lower bounds hold for many other problems which have been commonly studied, such as:

BATCH PARTIAL MATCH

Given:  $n$  “database” vectors  $v_1, \dots, v_n \in \{0, 1\}^d$  and  $n$  queries  $q_1, \dots, q_n \in \{0, 1, \star\}^d$   
Decide: Are there  $i, j$  such that  $v_i$  is a partial match of  $q_j$ , i.e. for all  $k$ ,  $q_j[k] \in \{v_i[k], \star\}$ ?

BATCH SUBSET QUERY

Given:  $n$  sets  $S_1, \dots, S_n \subseteq [d]$  and  $n$  queries  $T_1, \dots, T_n \subseteq [d]$   
Decide: Are there  $i, j$  such that  $S_i \subseteq T_j$ ?

BATCH HAMMING NEAREST NEIGHBORS

Given:  $n$  points  $p_1, \dots, p_n \in \{0, 1\}^d$  and  $n$  queries  $q_1, \dots, q_n \in \{0, 1\}^d$ , integer  $k$   
Decide: Are there  $i, j$  such that  $p_i$  and  $q_j$  differ in at most  $k$  positions?

### 1.3 “Average-Case” OVC is False, Even for AC<sup>0</sup>

The method of proof in the above lower bounds is an input restriction method that does *not* assign variables independently (to 0, 1, or  $\star$ ) at random. (Our restriction method could be viewed as a random process, just not one that assigns variables independently.) Does **OV** become easier under natural product distributions of instances, e.g., with each bit of each vector being an independent random variable? Somewhat surprisingly, we show that a reasonable parameterization of average-case OVC is false, even for AC<sup>0</sup> formulas.

For  $p \in (0, 1)$ , and for a given  $n$  and  $d$ , we call  $\mathbf{OV}(p)_{n,d}$  the distribution of **OV** instances where all bits of the  $n$  vectors are chosen independently, set to 1 with probability  $p$  and 0 otherwise. We would like to understand when  $\mathbf{OV}(p)_{n,d}$  can be efficiently solved on almost all instances (i.e., with probability  $1 - o(1)$ ). We give formulas of truly sub-quadratic size for every  $p > 0$ :

► **Theorem 6.** *For every  $p \in (0, 1)$ , and every  $n$  and  $d$ , there is an AC<sup>0</sup> formula of size  $n^{2-\varepsilon_p}$  that correctly answers all but a  $o_n(1)$  fraction of  $\mathbf{OV}(p)_{n,d}$  instances on  $n$  vectors and  $d$  dimensions, for an  $\varepsilon_p > 0$  such that  $\varepsilon_p \rightarrow 1$  as  $p \rightarrow 1$ .*

Interestingly, our AC<sup>0</sup> formulas have one-sided error, even in the worst case: if there is no orthogonal pair in the instance, our formulas *always* output 0. However, they may falsely report that there is no orthogonal pair, but this only occurs with probability  $o(1)$  on a random  $\mathbf{OV}(p)_{n,d}$  instance, for any  $n$  and  $d$ .

## 1.4 Intuition

Our lower bounds give some insight into why **OV** is hard. There are two main ideas:

1. **OV** instances with  $n$   $d$ -dimensional vectors can encode difficult Boolean functions on  $d$  inputs, requiring circuits of size  $\tilde{\Omega}(\min(2^d, n))$ . This can be accomplished by encoding those strings with “middle” Hamming weight from the truth table of a hard function with the vectors in an **OV** instance, in such a way that finding an orthogonal pair is equivalent to evaluating the hard Boolean function at a given  $d$ -bit input. This is an inherent property of **OV** that is independent of the computational model.
2. Because we are working with simple computational models, we can generally make the following kind of claim: given an algorithm for solving **OV** and given a partial assignment to all input vectors except for one appropriately chosen vector, we can propagate this partial assignment through the algorithm, and “shrink” the size of the algorithm by a factor of  $\Omega(n)$ . This sort of argument was first used by Nechiporuk [32] in the context of branching program lower bounds, and can be also applied to formulas.

Combining the two ideas, if we can “shrink” our algorithm by a factor of  $n$  by restricting the inputs appropriately, and argue that the remaining subfunction requires circuits of size  $\tilde{\Omega}(\min(2^d, n))$ , we can conclude that the original algorithm for **OV** must have had size  $\tilde{\Omega}(\min(n2^d, n^2))$ . (Of course, there are many details to verify, but this is the basic idea.)

The small  $\text{AC}^0$  formulas for **OV**( $p$ ) (the average-case setting) involve several ideas. First, given the probability  $p \in (0, 1)$  of 1 and the number of vectors  $n$ , we observe a simple phase transition phenomenon: there is only a particular range of dimensionality  $d$  in which the problem is non-trivial, and outside of this range, almost all instances are either “yes” instances or “no” instances. Second, within this “hard” range of  $d$ , the orthogonal vector pairs are expected to have a special property: with high probability, at least one orthogonal pair in a “yes” instance has noticeably fewer ones than a typical vector in the distribution. To obtain a sub-quadratic size  $\text{AC}^0$  formula from these observations, we partition the instance into small groups such that the orthogonal pair (if it exists) is the only “sparse” vector in its group, whp. Over all pairs of groups  $i, j$  in parallel, we take the component-wise OR of all sparse vectors in group  $i$  (call the resulting vector  $u_i$ ), and similarly for group  $j$  (call the result  $v_j$ ). Then we test if  $u_i$  and  $v_j$  are orthogonal. By doing so, if our formula ever reports 1, then there is some orthogonal pair in the instance (even in the worst case).

## 2 Lower Bounds

### Functions hard for the middle layer of the hypercube

In our lower bound proofs, we will use functions on  $d$ -inputs for which every small circuit fails to agree with the function on inputs of Hamming weight about  $d/2$ . Let  $\binom{[d]}{k}$  denote the set of all  $d$ -bit vectors of Hamming weight  $k$ .

► **Lemma 7.** *Let  $d$  be even, let  $\mathcal{C}$  be a set of Boolean functions, let  $N(d, s)$  be the number of functions in  $\mathcal{C}$  on  $d$  inputs of size at most  $s$ , and let  $s^* \in \mathbb{N}$  satisfy  $\log_2(N(d, s^*)) < \binom{[d]}{d/2}$ .*

*Then there is a sequence  $S$  of  $\binom{[d]}{d/2}$  pairs  $(x_i, y_i) \in \binom{[d]}{d/2} \times \{0, 1\}$ , such that each  $x_i \in \binom{[d]}{d/2}$  appears exactly once among the pairs in  $S$ , and every function  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  satisfying  $f(x_i) = y_i$  (for all  $i = 1, \dots, \binom{[d]}{d/2}$ ) requires  $\mathcal{C}$ -size at least  $s^*$ .*

**Proof.** By definition, there are  $N(d, s)$  functions of size  $s$  on  $d$  inputs from  $\mathcal{C}$ , and there are  $2^{\binom{[d]}{d/2}}$  possible input/output sequences  $(x_i, y_i) \in \binom{[d]}{d/2} \times \{0, 1\}$  defined over all  $d$ -bit vectors of Hamming weight  $d/2$ . When  $2^{\binom{[d]}{d/2}} > N(d, s)$ , there is at least one input/output sequence that is not satisfied by any function in  $\mathcal{C}$  of size  $s$ . ◀

Note that it does not matter *what* is meant by “size” in the above lemma: the size measure could be gates, wires, etc., and the lemma still holds (as it is just counting). The above simple lemma applies to formulas, as follows:

► **Corollary 8.** *Let  $c \geq 2$  be a constant. There are  $\binom{d}{d/2}$  pairs  $(x_i, y_i) \in \binom{[d]}{d/2} \times \{0, 1\}$ , such that every function  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  satisfying  $f(x_i) = y_i$  (for all  $i = 1, \dots, \binom{d}{d/2}$ ) needs  $c$ -fan-in formulas of size at least  $\Omega(2^d / (d^{1/2} \log d))$ .*

**Proof.** There are  $N(d, s) \leq d^{k_c \cdot s}$  formulas of size  $s$  on  $d$  inputs, where the constant  $k_c$  depends only on  $c$ . When  $2^{\binom{d}{d/2}} > d^{k_c \cdot s}$ , Lemma 7 says that there is an input/output sequence of length  $\binom{d}{d/2}$  that *no* formula of size  $s$  can satisfy. Thus to satisfy that sequence, we need a formula of size  $s$  at least large enough that  $2^{\binom{d}{d/2}} \leq d^{k_c \cdot s}$ , i.e.,  $s \geq \Omega\left(\binom{d}{d/2} / \log(d)\right) \geq \Omega(2^d / (d^{1/2} \log d))$ . ◀

## 2.1 Lower Bound for Constant Fan-in Formulas

We are now ready to prove the lower bound for Boolean formulas of constant fan-in:

► **Reminder of Theorem 2.** *For every constant  $c \geq 1$ , **OV** on  $n$  vectors in  $d$  dimensions does not have  $c$ -fan-in formulas of size  $O(\min\{n^2 / (\log d), n \cdot 2^d / (d^{1/2} \log d)\})$ , for all sufficiently large  $n, d$ .*

All of the lower bound proofs have a similar structure. We will give considerably more detail in the proof of Theorem 2 to aid the exposition of the later lower bounds.

**Proof.** To simplify the calculations, assume  $d$  is even in the following. Let  $F_{n,d+1}(v_1, \dots, v_n)$  be a  $c$ -fan-in formula of minimal size  $s$  computing **OV** on  $n$  vectors of dimension  $d + 1$ , where each  $v_i$  denotes a sequence of  $d + 1$  Boolean variables  $(v_{i,1}, \dots, v_{i,d+1})$ .

Let  $\ell$  be the number of leaves of  $F_{n,d+1}$ . Since  $F_{n,d+1}$  is minimal, each gate has fan-in at least two (gates of fan-in 1 can be “merged” into adjacent gates). Therefore (by an easy induction on  $s$ ) we have

$$s \geq \ell \geq s/2. \tag{1}$$

Observe there must be a vector  $v_{i^*}$  (for some  $i^* \in [n]$ ) whose  $d + 1$  Boolean variables appear on at most  $\ell/n$  leaves of the formula  $F_{n,d}$ . Our plan now is to leave the  $d + 1$  variables corresponding to  $v_{i^*}$  free, and set all other variables in a particular way, so that the remaining subfunction requires many gates. We consider two cases (based on how  $d$  compares with  $n$ ), which determine how we set those variables.

**Case 1.** Suppose  $\binom{d}{d/2} \leq n - 1$ . Let  $\{(x_i, y_i)\} \subseteq \binom{[d]}{d/2} \times \{0, 1\}$  be a list of hard pairs from Corollary 8, and let  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  be any function that satisfies  $f(x_i) = y_i$ , for all  $i$ . By Corollary 8, such an  $f$  needs  $c$ -fan-in formulas of size at least  $\Omega(2^d / (d^{1/2} \log d))$ . Let  $\{x'_1, \dots, x'_t\} \subseteq \binom{[d]}{d/2}$  be those  $d$ -bit strings of Hamming weight  $d/2$  such that  $f(x'_i) = 1$ , for some  $t \leq \binom{d}{d/2} \leq n - 1$ .

**Case 2.** Suppose  $\binom{d}{d/2} \geq n - 1$ . Then we claim that there is a list of input/output pairs  $(x_1, y_1), \dots, (x_{n-1}, y_{n-1}) \in \binom{[d]}{d/2} \times \{0, 1\}$  such that for every  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  satisfying  $f(x_i) = y_i$ , for all  $i$ ,  $f$  needs formulas of size at least  $\Omega(n / \log d)$ . To see this, note that if we take  $n - 1$  distinct strings  $x_1, \dots, x_{n-1}$  from  $\binom{[d]}{d/2}$ , there are  $2^{n-1}$  possible choices for the list of pairs. So when  $2^{n-1} > d^{k_c \cdot s}$ , there is a list of hard pairs  $(x_1, y_1), \dots,$

$(x_{n-1}, y_{n-1})$  that no formula of size  $s$  satisfies. For any function  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  such that  $f(x_i) = y_i$  for all  $i = 1, \dots, n-1$ , its formula size  $s$  must be at least  $\Omega(n/\log d)$  in this case.

Let  $\{x'_1, \dots, x'_t\} \subseteq \binom{[d]}{d/2}$  be those  $d$ -bit strings of Hamming weight  $d/2$  such that  $(x'_i, 1)$  is on the list of hard pairs, for some  $t \leq n-1$ .

In either of the two cases, we will use the list of  $t \leq \min\{n-1, \binom{d}{d/2}\}$  strings  $\{x'_1, \dots, x'_t\}$  to assign all variables  $v_i$  of our **OV** formula, for all  $i \neq i^*$ . In particular, for the first  $t$  integers  $i \in [n]$  such that  $i \neq i^*$ , we substitute each  $(d+1)$ -bit input vector  $v_i$  with a distinct  $(d+1)$ -bit string  $\overline{1x'_{i'}}$  (the bit 1 concatenated with the complement of  $x_{i'}$ , obtained by flipping all the bits of  $x'_{i'}$ ). If  $t < n-1$  (which can happen in Case 1), we also substitute all other input vectors  $v_j$  where  $j \neq i^*$  with the  $(d+1)$ -bit vector  $\vec{1}$ . Note that all of the pairs of vectors substituted so far are not orthogonal to each other: for all  $i \neq i'$ , we have  $\langle \overline{1x'_i}, \overline{1x'_{i'}} \rangle \neq 0$ , and for all  $i$  we have  $\langle \overline{1x'_i}, \vec{1} \rangle \neq 0$ . Finally, we substitute a 0 in the first input bit of  $\vec{v}_{i^*}$ .

After these substitutions, the remaining formula  $F'_n$  has only  $d$  inputs, namely the last  $d$  bits of the vector  $v_{i^*}$ . Moreover,  $F'_n$  is a formula with at most  $\ell/n$  leaves labeled by literals: the rest of the leaves are labeled with 0/1 constants. After simplifying the formula (replacing all gates with some 0/1 inputs by equivalent functions of smaller fan-in, and replacing gates of fan-in 1 by wires), the total number of leaves of  $F'_n$  is now at most  $\ell/n$ . Therefore by (1) we infer that

$$\text{size}(F'_n) \leq 2\ell/n. \quad (2)$$

Since  $F_{n,d+1}$  computes **OV**, it follows that for every input vector  $z \in \{0, 1\}^d$  of Hamming weight  $d/2$ ,  $F'_n$  on input  $z$  outputs 1 if and only if there is some  $i$  such that  $\langle \overline{1x'_i}, 0z \rangle = 0$ . Note that since both  $\overline{1x'_i}$  and  $z$  have Hamming weight exactly  $d/2$ , we have  $\langle \overline{1x'_i}, 0z \rangle = 0$  if and only if  $z = x_i$ .

Let  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  be any function that is consistent with the list of hard pairs  $\{(x_i, y_i)\}$  (from Corollary 8 in case 1, and our claim in case 2). By our choice of  $x_i$ 's, it follows that for all  $z \in \{0, 1\}^d$  of Hamming weight  $d/2$ ,  $F'_n(z) = 1$  if and only if  $f(z) = 1$ . By our choice of  $f$ , we must have

$$\text{size}(F'_n) \geq \min\{\Omega(2^d/(d^{1/2} \log d)), \Omega(n/\log d)\}, \quad (3)$$

depending on whether  $\binom{d}{d/2} \leq n-1$  or not (case 1 or case 2). Combining (2) and (3), we infer that

$$\ell \geq \Omega(n \cdot \min\{2^d/(d^{1/2} \log d), n/\log d\}). \quad (4)$$

Therefore the overall lower bound on formula size is  $s \geq \Omega\left(\min\left\{\frac{n^2}{\log d}, \frac{n \cdot 2^d}{d^{1/2} \log d}\right\}\right)$ .  $\blacktriangleleft$

### Remark on a Red-Blue Variant of **OV**

In the literature, **OV** is sometimes posed in a different form, where half of the vectors are colored red, half are colored blue, and we wish to find a red-blue pair which is orthogonal. Calling this form **OV'**, we note that **OV'** also exhibits the same lower bound up to constant factors. Given an algorithm/formula/circuit  $A$  for computing **OV'** on  $2n$  vectors ( $n$  of which are red, and  $n$  of which are blue), it is easy to verify that an algorithm/formula/circuit for **OV** on  $n$  vectors results by simply putting two copies of the set of vectors in the red and blue parts. Thus our lower bounds hold for the red-blue variant as well.

## 2.2 Lower Bound for Branching Programs

Recall that a branching program of size  $S$  on  $n$  variables is a directed acyclic graph  $G$  on  $S$  nodes, with a distinguished start node  $s$  and exactly two sink nodes, labeled 0 and 1 respectively. All non-sink nodes are labeled with a variable  $x_i$  from  $\{x_1, \dots, x_n\}$ , and have one outgoing edge labeled  $x_i = 1$  and another outgoing edge labeled  $x_i = 0$ . The branching program  $G$  evaluated at an input  $(a_1, \dots, a_n) \in \{0, 1\}^n$  is the subgraph obtained by only including edges of the form  $x_i = a_i$ , for all  $i = 1, \dots, n$ . Note that after such an evaluation, the remaining subgraph has a unique path from the start node  $s$  to a sink; the sink reached on this unique path (be it 0 or 1) is defined to be the output of  $G$  on  $(a_1, \dots, a_n)$ .

► **Reminder of Theorem 3.** **OV** on  $n$  vectors in  $d$  dimensions does not have branching programs of size  $O(\min\{n^2, n \cdot 2^d / (d^{1/2})\} / (\log(nd) \log(d)))$ , for all sufficiently large  $n, d$ .

**Proof Sketch.** The proof is similar to Theorem 2; here we focus on the steps of the proof that are different. Let  $G$  be a branching program with  $S$  nodes computing **OV** on  $n$  vectors in  $d + 1$  dimensions. Each node of  $G$  reads a single input bit from one of the input vectors; thus there is an input vector  $v_{i^*}$  that is read only  $O(S/n)$  times in the entire branching program  $G$ .

We will assign all variables other than the  $d + 1$  variables that are part of  $v_{i^*}$ . Using the same encoding as Theorem 2, by assigning  $n - 1$  other vectors, we can implement a function  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  that is hard for branching programs to compute on the  $d$ -bit inputs in  $\binom{[d]}{[d/2]}$ . In particular, we substitute  $(d + 1)$ -bit vectors which represent inputs from  $f^{-1}(1) \cap \binom{[d]}{[d/2]}$  for all  $n - 1$  input vectors different from  $v_{i^*}$ . For each of these assignments, we can reduce the size of the branching program accordingly: for each input bit  $x_j$  that is substituted with the bit  $a_j$ , we remove all edges with the label  $x_j = \neg a_j$ , so that every node labeled  $x_j$  now has outdegree 1. After the substitution, two properties hold:

1. There is a hard function  $f$  such that the minimum size  $T$  of a branching program computing  $f$  on the  $n - 1$  inputs satisfies  $T \log_2(T) \geq \Omega(\min\{\binom{[d]}{[d/2]}, n\} / \log(d))$ . To see that such an  $f$  exists, we again use a counting argument. First note there are  $d^T \cdot 2^{\Theta(T \log(T))}$  branching programs of size  $T$  on  $d$  inputs (there are  $d^T$  choices for the node labels, and  $2^{\Theta(T \log(T))}$  choices for the remaining graph on  $T$  nodes). In contrast, there are at least  $2^{\min\{\binom{[d]}{[d/2]}, n-1\}}$  choices for the hard function  $f$ 's values on  $d$ -bit inputs of Hamming weight  $d/2$ . Therefore there is a function  $f$  such that  $d^T \cdot 2^{\Theta(T \log(T))} \geq 2^{\min\{\binom{[d]}{[d/2]}, n-1\}}$ , or

$$T + \Theta(T \log(T)) \geq \min \left\{ \binom{[d]}{[d/2]}, n - 1 \right\} / \log_2(d).$$

2. The minimum size of a branching program computing a function  $f : \{0, 1\}^d \rightarrow \{0, 1\}$  on the remaining  $d$  bits of input is at most  $O(S/n)$ . This follows because every node  $v$  with outdegree 1 can be removed from the branching program without changing its functionality: for every arc  $(u, v)$  in the graph, we can replace it with the arc  $(u, v')$ , where  $(v, v')$  is the single edge out of  $v$ , removing the node  $v$ .

Combining these two points, we have  $(S/n) \cdot \log(S/n) \geq \Omega\left(\min\left\{\binom{[d]}{[d/2]}, n\right\} / \log(d)\right)$ , or

$$S \geq \Omega\left(\frac{\min\{n \binom{[d]}{[d/2]}, n^2\}}{\log(S/n) \cdot \log(d)}\right).$$

Since  $S \leq n^2 d$ , we have

$$S \geq \Omega\left(\frac{\min\{n \binom{[d]}{[d/2]}, n^2\}}{\log(nd) \cdot \log(d)}\right) \geq \Omega\left(\frac{\min\{n \cdot 2^d / d^{1/2}, n^2\}}{\log(nd) \cdot \log(d)}\right).$$

This concludes the proof. ◀

## 2.3 Formulas With Symmetric Gates

We will utilize a lower bound on the number of functions computable by symmetric-gate formulas with a small number of wires:

► **Lemma 9.** *There are  $n^{O(w)}$  symmetric-gate formulas with  $w$  wires and  $n$  inputs.*

**Proof.** There is an injective mapping from the set of trees of unbounded fan-in and  $w$  wires into the set of binary trees with at most  $2w$  nodes: simply replace each node of fan-in  $k$  with a binary tree of at most  $2k$  nodes. The number of such binary trees is  $O(4^{2w})$  (by upper bounds on Catalan numbers). This counts the number of “shapes” for the symmetric formula; we also need to count the possible gate assignments. There are  $2^{k+1}$  symmetric functions on  $k$  inputs. So for a symmetric-gate formula with  $g$  gates, where the  $i$ th gate has fan-in  $w_i$  for  $i = 1, \dots, g$ , the number of possible assignments of symmetric functions to its gates is  $\prod_{i=1}^g 2^{w_i+1} = 2^{g+\sum_i w_i} = 2^{g+w}$ . There are at most  $w$  leaves, and there are  $n^w$  ways to choose the variables read at each leaf. Since  $g \leq w$ , we conclude that there are at most  $4^{2w} \cdot 2^{2w} \cdot n^w \leq n^{O(w)}$  symmetric-gate formulas with  $w$  wires. ◀

► **Reminder of Theorem 5.** *Every formula computing  $\mathbf{OV}$  composed of arbitrary symmetric functions with unbounded fan-in needs at least  $\Omega(\min\{n^2/(\log d), n \cdot 2^d/(d^{1/2} \log d)\})$  wires, for all  $n$  and  $d$ .*

**Proof.** (Sketch) With Lemma 9 in hand, the proof is quite similar to the previous lower bounds, so we just sketch the ideas. Let  $F$  be a symmetric-gate formula for computing  $\mathbf{OV}$  with unbounded fan-in and  $w$  wires. Let  $w_i$  be the number of wires touching inputs and  $w_g$  be the number of wires that do not touch inputs. Since  $F$  is a formula, we have (by a simple induction argument) that  $w_i \geq w_g$ , thus

$$w \leq 2w_i. \tag{5}$$

As before, each leaf of the formula is labeled by an input from one of the input  $n$  vectors; in this way, every leaf is “owned” by one of the  $n$  input vectors. We will substitute a 0/1 variable assignment to all vectors, except the vector  $\vec{z}^*$  which owns the fewest leaves. This gives a 0/1 assignment to all but  $O(w_i/n)$  of the  $w_i$  wires that touch inputs.

After any such variable assignment, we can simplify  $F$  as follows. For every symmetric-function gate  $g$  which has  $w_g$  input wires with  $k$  wires assigned 0/1, we can replace  $g$  with a symmetric function  $g'$  that has only  $w_g - k$  inputs, and no input wires assigned 0/1 (a partial 0/1 assignment to a symmetric function just yields another symmetric function on a smaller set of inputs). If  $g'$  is equivalent to a constant function itself, then we remove it from the formula and substitute its output wire with that constant, repeating the process on the gates that use the output of  $g$  as input. When this process completes, our new formula  $F'$  has  $d$  inputs and no wires that are assigned constants. So  $F'$  has  $O(w_i/n)$  wires touching inputs, and therefore by (5) the total number of wires in  $F'$  is  $O(w/n)$ .

As described earlier, the  $n - 1$  vectors we assign can implement  $2^{\min\{n-1, \binom{d}{d/2}\}}$  different functions on  $d$ -bit inputs, but there are at most  $d^{O(w/n)}$  functions computable by the symmetric formula remaining, by Lemma 9. Thus the number of wires  $w$  must satisfy  $d^{O(w/n)} \geq 2^{\min\{n-1, \binom{d}{d/2}\}}$ , or

$$w \geq \Omega(\min\{n^2, n \cdot 2^d/(d^{1/2})\}/(\log d)).$$

This completes the proof. ◀

### 3 Small Formulas for OV in the Average Case

Recall that for  $p \in (0, 1)$  and for a fixed  $n$  and  $d$ , we say that  $\mathbf{OV}(p)_{n,d}$  is the distribution of  $\mathbf{OV}$  instances where all bits of the  $n$  vectors from  $\{0, 1\}^d$  are chosen independently, set to 1 with probability  $p$  and 0 otherwise. We will often say that a vector is “sampled from  $\mathbf{OV}(p)$ ” if each of its bits are chosen independently in this way. We would like to understand how efficiently  $\mathbf{OV}(p)_{n,d}$  can be solved on almost all instances (i.e., with probability  $1 - o(1)$ ), for every  $n$  and  $d$ .

► **Reminder of Theorem 6.** *For every  $p \in (0, 1)$ , and every  $n$  and  $d$ , there is an  $\text{AC}^0$  formula of size  $n^{2-\varepsilon_p}$  that correctly answers all but a  $o_n(1)$  fraction of  $\mathbf{OV}(p)_{n,d}$  instances on  $n$  vectors and  $d$  dimensions, for an  $\varepsilon_p > 0$  such that  $\varepsilon_p \rightarrow 1$  as  $p \rightarrow 1$ .*

**Proof.** Let  $\varepsilon > 0$  be sufficiently small in the following. First, we observe that  $\mathbf{OV}(p)_{n,d}$  is very easy, unless  $d$  is close to  $(2/\log_2(1/(1-p^2)))\log_2(n)$ . In particular, for dimensionality  $d$  that is significantly smaller (or larger, respectively) than this quantity, all but a  $o(1)$  fraction of the  $\mathbf{OV}(p)_{n,d}$  instances are “yes” (or “no”, respectively). To see this, note that two randomly chosen  $d$ -dimensional vectors under the  $\mathbf{OV}(p)_{n,d}$  distribution are orthogonal with probability  $(1-p^2)^d$ . For  $d = (2/\log_2(1/(1-p^2)))\log_2(n)$ , a random pair is orthogonal with probability

$$(1-p^2)^{(2/\log_2(1/(1-p^2)))\log_2(n)} = 1/n^2.$$

Thus an  $\mathbf{OV}(p)_{n,d}$  instance with  $n$  vectors has nontrivial probability of being a yes instance for  $d$  approximately  $(2/\log_2(1/(1-p^2)))\log_2(n)$ .

Therefore if  $d > (2/\log_2(1/(1-p^2)) + \varepsilon)\log_2(n)$ , or  $d < (2/\log_2(1/(1-p^2)) - \varepsilon)\log_2(n)$ , then the random instance is either almost surely a “yes” instance, or almost surely a “no” instance, respectively. These comparisons could be done with the quantities  $(2/\log_2(1/(1-p^2)) - \varepsilon)\log_2(n)$  and  $(2/\log_2(1/(1-p^2)) + \varepsilon)\log_2(n)$  (which can be hard-coded in the input) with a  $\text{poly}(d, \log n)$ -size branching program, which can output 0 and 1 respectively if this is the case.<sup>4</sup>

From here on, assume that

$$d \in [(2/\log_2(1/(1-p^2)) - \varepsilon)\log_2(n), (2/\log_2(1/(1-p^2)) + \varepsilon)\log_2(n)].$$

Note that for  $p$  sufficiently close to 1, the dimensionality  $d$  is  $\delta \log n$  for a small constant  $\delta > 0$  that is approaching 0. Thus in the case of large  $p$ , the  $\text{AC}^0$  formula given in Proposition 4 has sub-quadratic size. In particular, the size is

$$O(n \cdot 2^d \cdot d) \leq n^{1+2/\log_2(1/(1-p^2))+o(1)}. \quad (6)$$

For  $p \geq 0.867 > \sqrt{3/4}$ , this bound is sub-quadratic. For smaller  $p$ , we will need a more complex argument.

Suppose  $u, v \in \{0, 1\}^d$  are randomly chosen according to the distribution of  $\mathbf{OV}(p)$  (we will drop the  $n, d$  subscript, as we have fixed  $n$  and  $d$  at this point).

We now claim that, conditioned on the event that  $u, v$  is an orthogonal pair, both  $u$  and  $v$  are expected to have between  $(p/(1+p) - \varepsilon)d$  and  $(p/(1+p) + \varepsilon)d$  ones, with  $1 - o(1)$

<sup>4</sup> As usual,  $\text{poly}(m)$  refers to an unspecified polynomial of  $m$  of fixed degree.

probability. The event that both  $u[i] = v[i] = 1$  holds with probability  $p^2$ ; conditioned on this event never occurring, we have

$$\begin{aligned}\Pr[u[i] = 0, v[i] = 0 \mid \neg(u[i] = v[i] = 1)] &= (1-p)^2/(1-p^2), \\ \Pr[u[i] = 1, v[i] = 0 \mid \neg(u[i] = v[i] = 1)] &= p(1-p)/(1-p^2), \\ \Pr[u[i] = 0, v[i] = 1 \mid \neg(u[i] = v[i] = 1)] &= p(1-p)/(1-p^2).\end{aligned}$$

Hence the expected number of ones in  $u$  (and in  $v$ ) is only  $p(1-p)d/(1-p^2) = pd/(1+p)$ , and the number of ones is within  $(-\varepsilon d, \varepsilon d)$  of this quantity with probability  $1 - o(1)$ . (For example, in the case of  $p = 1/2$ , the expected number of ones is  $d/3$ , while a typical vector has  $d/2$  ones.)

Say that a vector  $u$  is *light* if it has at most  $(p/(1+p) + \varepsilon)d$  ones. It follows from the above discussion that, conditioned on an  $\mathbf{OV}(p)$  instance being a “yes” instance, there is an orthogonal pair with two light vectors, with probability  $1 - o(1)$ . Since the expected number of ones is  $pd$ , the probability that a randomly chosen  $u$  is light is

$$\begin{aligned}\Pr\left[u \text{ has } \leq \left(\frac{p}{1+p} + \varepsilon\right)d = pd\left(1 - \frac{p}{p+1} + \frac{\varepsilon}{p}\right) \text{ ones}\right] &\leq e^{-(p/(p+1) - \varepsilon/p)^2 pd/2} \\ &= e^{-p^3 d / (2(p+1)^2) + \Theta_p(\varepsilon)d},\end{aligned}$$

by a standard Chernoff tail bound (see Theorem 11 in Appendix A). So with high probability, there are at most  $n \cdot e^{-p^3 d / (2(p+1)^2) + \Theta_p(\varepsilon)d} = n^{1-\alpha}$  light vectors in an  $\mathbf{OV}(p)$  instance, where

$$\alpha = \frac{\log_2(e) \cdot p^3}{(p+1)^2 \log_2(1/(1-p^2))} + \Theta_p(\varepsilon) / \log_2(1/(1-p^2)).$$

Divide the  $n$  vectors of the input arbitrarily into  $n^{1-\alpha(1-\varepsilon)}$  groups  $G_1, \dots, G_{n^{1-\alpha(1-\varepsilon)}}$ , of  $O(n^{\alpha(1-\varepsilon)})$  vectors each. WLOG, suppose an orthogonal pair  $u, v$  lies in different groups  $u \in G_i$  and  $v \in G_j$ , with  $i \neq j$  (note that, conditioned on there being an orthogonal pair, this event also occurs with  $1 - o(1)$  probability). Since every vector is independently chosen, and given that  $\Pr_v[v \text{ is light}] \leq 1/n^\alpha$ , note that

$$\Pr_{v_1, \dots, v_{n^{\alpha(1-\varepsilon)}}} [\text{all } v_i \text{ in group } G_a \text{ are not light}] \geq (1 - 1/n^\alpha)^{n^{\alpha(1-\varepsilon)}} \geq 1 - 1/n^{\varepsilon\alpha},$$

for every group  $G_a$ . Thus the groups  $G_i$  and  $G_j$  have at most one light vector with probability  $1 - o(1)$ .

Let  $Light(v)$  be the function which outputs 1 if and only if the  $d$ -bit input vector  $v$  is light. Since every symmetric function has  $\text{poly}(d)$ -size formulas [29],  $Light(v)$  also has  $\text{poly}(d)$ -size formulas. We can now describe our formula for  $\mathbf{OV}(p)$ , in words:

Take the OR over all  $n^{2-2\alpha(1-\varepsilon)}$  pairs  $(i, j) \in [n^{1-\alpha(1-\varepsilon)}]^2$  with  $i < j$ :  
 Take the  $\neg$ OR over all  $k = 1, \dots, d$ , of the AND of two items:  
 1. The OR over all  $O(n^{\alpha(1-\varepsilon)})$  vectors  $u$  in group  $G_i$  of  $(Light(u) \wedge u[k])$ .  
 2. The OR over all  $O(n^{\alpha(1-\varepsilon)})$  vectors  $v$  in group  $G_j$  of  $(Light(v) \wedge v[k])$ .

To see that this works, we observe:

- If there is an orthogonal pair  $u, v$  in the instance, then recall that with probability  $1 - o(1)$ , (a)  $u$  and  $v$  are light, (b)  $u$  and  $v$  appear in different groups  $G_i$  and  $G_j$ , and (c) there are no other light vectors in  $G_i$  and no other light vectors in  $G_j$ . Thus the inner ORs

- over the group  $G_i$  (and respectively  $G_j$ ) will only output the bits of the vector  $u$  (and respectively  $v$ ). Thus the above formula, by guessing the pair  $(i, j)$ , and checking over all  $k = 1, \dots, d$  that  $(u[k] \wedge v[k])$  is *not* true, will find that  $u, v$  are orthogonal, and output 1.
- If there is no orthogonal pair, then we claim that the formula *always* outputs 0. Suppose the formula outputs 1. Then there is some  $(i, j) \in [n^{1-\alpha(1-\varepsilon)}]^2$  such that the inner product of two vectors  $V_i$  and  $W_j$  is 0, where  $V_i$  is the OR of *all* light vectors in group  $G_i$  and  $W_j$  is the OR of all light vectors in group  $G_j$ . But for these two vectors to have zero inner product, it must be that *all* pairs of light vectors (one from  $G_i$  and one from  $G_j$ ) are orthogonal to each other. Thus there is an orthogonal pair in the instance.

Using the  $\text{poly}(d)$ -size formulas for *Light*, the DeMorgan formula has size

$$O(n^{2-2\alpha(1-\varepsilon)} \cdot d \cdot n^{\alpha(1-\varepsilon)} \cdot \text{poly}(d)) \leq O(n^{2-\alpha(1-\varepsilon)} \cdot \text{poly}(d)). \tag{7}$$

Substituting in the value for  $\alpha$ , the exponent becomes

$$2 - \frac{p^3(1-\varepsilon)}{(p+1)^2 \ln(1/(1-p^2))} + \Theta_p(\varepsilon)/\ln(1/(1-p^2)).$$

Recalling that we are setting  $\varepsilon$  to be arbitrarily small (its value only affects the  $o(1)$  probability of error), the formula size is

$$n^{2 - \frac{p^3}{2(p+1)^2 \ln(1/(1-p^2))} + o(1)}.$$

Observe that our formula can in fact be made into an  $\text{AC}^0$  formula of similar size; this is easy to see except for the  $\text{poly}(d)$ -size formula for *Light*. But for  $d = O(\log n)$ , any formula of  $\text{poly}(\log n)$ -size on  $O(\log n)$  bits can be converted into an  $\text{AC}^0$  circuit of depth  $c/\varepsilon$  and size  $2^{(\log n)^\varepsilon}$ , for some constant  $c \geq 1$  and any desired  $\varepsilon > 0$ .

The final formula is the minimum of the formulas of (6) and (7). For every fixed  $p \in (0, 1]$ , we obtain a bound of  $n^{2-\varepsilon_p}$  for an  $\varepsilon_p > 0$ . ◀

## 4 Conclusion

Let us highlight two interesting directions for future work.

### Lower Bounds for AC0 Circuits?

While we give fairly strong lower bounds for Boolean formulas, our results seem to leave open the following compelling conjecture about the difficulty of **OV** with low-depth circuits:

► **Conjecture 10.** *There is a  $\delta > 0$  such that **OV** is not computable by depth-3  $\text{AC}^0$  circuits with  $n^{2-\varepsilon}$  wires.*

The obvious translation of a depth-3 circuit into a formula would blow up the size too much, so our formula lower bounds do not (easily) extend to resolve the above conjecture. Typical random restriction methods (e.g., [25]) appear to be too coarse to handle such conjectures, but perhaps deterministic restriction methods (e.g., [21]) can.

### Generalizations of OV?

It is important to note that the *largest* known lower bound for branching programs computing any explicit function is due to Neciporuk [32] from 1966, and is only  $\Omega(N^2/\log^2 N)$  for inputs of length  $N$ . A similar statement holds for Boolean formulas over the full binary basis (see for

example [28]). Our lower bounds for **OV** match these bounds up to polylogarithmic factors. Thus it would be a significant breakthrough to generalize our results to other problems believed to require *cubic* time, such as:

3-ORTHOGONAL VECTORS (3-**OV**)  
 Given:  $n$  vectors  $v_1, \dots, v_n \in \{0, 1\}^d$   
 Decide: Are there  $i, j, k$  such that  $\sum_{\ell=1}^d v_i[\ell] \cdot v_j[\ell] \cdot v_k[\ell] = 0$ ?

It is known that the Strong Exponential Time Hypothesis also implies that 3-**OV** requires  $n^{3-o(1)}$  for dimensionality  $d = \omega(\log n)$  [37, 4].

## A Chernoff Bound

We use the following standard tail bound:

► **Theorem 11.** *Let  $p \in (0, 1)$  and let  $X_1, \dots, X_d \in \{0, 1\}$  be independent random variables, such that for all  $i$  we have  $\Pr[X_i = 1] = p$ . Then for all  $\delta \in (0, 1)$ ,*

$$\Pr \left[ \sum_i X_i < (1 - \delta)pd \right] \leq e^{-\delta^2 pd/2}.$$

## B DeMorgan Formulas into Branching Programs

Here we describe at a high level how to convert a DeMorgan formula (over AND, OR, NOT) of size  $s$  into a branching program of size  $O(s)$ . Our construction is similar to the log-space algorithm for formula evaluation of Lynch [31], except we have to be extremely careful with the time and space efficiency to get a branching program with only  $O(s)$  total nodes (corresponding to  $\log_2(s) + O(1)$  space).

Our branching program will perform an in-order traversal of the DeMorgan formula, maintaining a counter (from 1 to  $s$ ) of the current node being visited in the formula. The branching program begins at the root (output) of the formula. If the current node is a leaf, its value  $b$  is returned to the parent node. If the current node is not a leaf, the branching program recursively evaluates its left child (storing no memory about the current node).

The left child returns a value  $b$ . If the current node is an AND and  $b = 0$ , or the current node is an OR and  $b = 1$ , the branching program propagates the bit  $b$  up the tree (moving up to the parent). If the current node is a NOT, then the branching program moves to the parent with the value  $\neg b$ .

If none of the above cases hold, then the branching program erases the value  $b$ , and recursively evaluates the right child, which returns a value  $b$ . This value is simply propagated up the tree (note the fact that we visited the right child means that we know what the left child's value was).

Observe that we only hold the current node of the formula in memory, as well as  $O(1)$  extra bits.

## Abstract

Many previous Sum-of-Squares (SOS) lower bounds for CSPs had two deficiencies related to global constraints. First, they were not able to support a “cardinality constraint”, as in, say, the Min-Bisection problem. Second, while the pseudoexpectation of the objective function was shown to have some value  $\beta$ , it did not necessarily actually “satisfy” the constraint “objective =  $\beta$ ”. In this paper we show how to remedy both deficiencies in the case of random CSPs, by translating *global* constraints into *local* constraints. Using these ideas, we also show that degree- $\Omega(\sqrt{n})$  SOS does not provide a  $(\frac{4}{3} - \varepsilon)$ -approximation for Min-Bisection, and degree- $\Omega(n)$  SOS does not provide a  $(\frac{11}{12} + \varepsilon)$ -approximation for Max-Bisection or a  $(\frac{5}{4} - \varepsilon)$ -approximation for Min-Bisection. No prior SOS lower bounds for these problems were known.

## 1 Introduction

Consider the task of refuting a random 3SAT instance with  $n$  variables and  $50n$  clauses; i.e., certifying that it’s unsatisfiable (which it is, with very high probability). There is no known  $2^{o(n)}$ -time algorithm for this problem. An oft-cited piece of evidence for the exponential difficulty is the fact [9, 19] that the very powerful Sum-of-Squares (SOS) SDP hierarchy fails to refute such random 3SAT instances in  $2^{o(n)}$  time. Colloquially, degree- $\Omega(n)$  SOS “thinks” that the random 3SAT instance is satisfiable (with high probability).

But consider the following method of refuting satisfiability of a random  $50n$ -clause CNF  $\phi$ :

For all  $k \in \{0, 1, 2, \dots, n\}$ ,  
 refute “ $\phi$  is satisfiable by an assignment of Hamming weight  $k$ ”.

Could it be that  $O(1)$ -degree SOS succeeds in refuting random 3SAT instances in this manner? It seems highly unlikely, but prior to this work the possibility could not be ruled out.

### SOS lower bounds with Hamming weight constraints

Recall that the known SOS lower bounds for random 3SAT are actually stronger: they show degree- $\Omega(n)$  SOS thinks that random 3SAT instances are satisfiable even as *3XOR* (i.e., with every clause having an odd number of true literals). Hamming weight calculations are quite natural in the context of random 3XOR; indeed Grigoriev, Hirsch, and Pasechnik [10] showed that the *dynamic* degree-5 SOS proof system *can* refute random 3XOR instances by using integer counting techniques. Thus the above “refute solutions at each Hamming weight” strategy seems quite natural in the context of random CSPs.

In 2012, Yuan Zhou raised the question of proving strong SOS lower bounds for random 3XOR instances together with a global cardinality constraint such as  $\sum_i x_i = \frac{n}{2}$ . This would rule out the above refutation strategy. It is also a natural SOS challenge, seemingly combining the two strong SOS results known prior to 2012 – the bound for random 3XOR due to Grigoriev and Schoenebeck [9, 19] and the bound for Knapsack due to Grigoriev [8].

One may ask why the Grigoriev–Schoenebeck SOS lower bound doesn’t already satisfy  $\sum_i x_i = \frac{n}{2}$ . The difficulty is connected to the meaning of the word “satisfy”. One should think of the SOS Method as trying to find not just a satisfying assignment to a CSP, but more generally a *distribution* on satisfying assignments. The SOS algorithm finds a “degree- $d$  pseudodistribution” on satisfying assignments in  $n^{O(d)}$  time, provided one exists; roughly speaking, this means an object that “looks like” a distribution on satisfying assignment to all tests that are squared polynomials of degree at most  $d$ . For a random 3XOR instance with  $n$  variables and  $O(n)$  constraints, the Grigoriev–Schoenebeck degree- $\Omega(n)$  pseudodistribution indeed claims to have 100% of its probability mass on satisfying assignments. Furthermore, its assignments claim to give probability 50% to each of  $x_i = 0$  and  $x_i = 1$  for all  $i$ ; in other words, the “pseudoexpectation” of  $x_i$  is  $\frac{1}{2}$ , so the pseudoexpectation of  $\sum_i x_i$  is  $\frac{n}{2}$ . However, this *doesn’t* mean that the pseudodistribution “satisfies” the hard constraint  $\sum_i x_i = \frac{n}{2}$ . To actually “satisfy” this constraint, the expression  $\sum_i x_i$  must have *pseudovariance zero*; i.e., SOS must not only “think” it knows a distribution on 3XOR-satisfying assignments which has  $\sum_i x_i = \frac{n}{2}$  on average, it must think that *all* of these satisfying assignments have  $\sum_i x_i$  exactly  $\frac{n}{2}$ .

In this work we show how to upgrade any SOS lower bound for random CSPs based on  $t$ -wise uniformity so as to include the hard cardinality constraint  $\sum_i x_i = \frac{n}{2}$  (or indeed

$\sum_i x_i = \frac{n}{2} + k$  for any  $|k| = O(\sqrt{n})$ .<sup>3</sup> The idea is conceptually simple: just add a matching of 2XOR constraints,  $x_{2i-1} \neq x_{2i}$  for all  $1 \leq i \leq \frac{n}{2}$ .

### SOS lower bounds with exact objective constraints

A random 3AND CSP with  $n$  variables and  $m = \alpha n$  constraints (each an AND of 3 random literals) will have objective value  $\frac{1}{8} + \varepsilon$  with high probability, for  $\varepsilon$  arbitrarily small as a function of  $\alpha$ ; i.e., the best assignment will satisfy at most  $(\frac{1}{8} + \varepsilon)m$  constraints. On the other hand, it’s not too hard to show that the Grigoriev–Schoenebeck degree- $\Omega(n)$  pseudodistribution will give the objective function a pseudoexpectation of  $\frac{1}{4} \pm o(1)$ . (Roughly speaking, for almost all 3AND constraints, the SOS pseudodistribution will think it can obtain probability  $\frac{1}{4}$  on each of the 3XOR-satisfying assignments, and one of these, namely  $(1, 1, 1)$ , satisfies 3AND.) Thus it would appear that degree- $\Omega(n)$  SOS has an integrality gap of factor  $2 - \varepsilon$  on random 3AND instances.

But is this misleading? Suppose we solved the SOS SDP and it reported a solution with pseudoexpectation  $\frac{1}{4}$ . We might then “double-check” by re-running the SDP, together with an additional “equality constraint” specifying that the number of satisfied 3AND constraints is indeed  $\frac{1}{4}m$ .<sup>4</sup> As far as we know now, this run could return “infeasible”, actually *refuting* the possibility of  $\frac{1}{4}m$  constraints being satisfiable! Again, the issue is that under the Grigoriev–Schoenebeck SOS pseudodistribution, the objective function will have a pseudoexpectation like  $\frac{1}{4}$ , but will also have *nonzero pseudovariance*.

We show how to fix this issue – i.e., have the objective constraint be *exactly* SOS-satisfied – in the context of any SOS lower bound for random CSPs based on  $t$ -wise uniformity. Here we briefly express the idea of our solution, in the specific case of 3AND: We show that one can design a probability distribution  $\theta$  on  $r \times 3$  Boolean matrices such that two properties hold: (i)  $\theta$  is 2-wise uniform; (ii) for *every* outcome in the support of  $\theta$ , *exactly* a  $\frac{1}{4} - \varepsilon_r$  fraction of the  $r$  rows satisfy 3AND, where  $\varepsilon_r$  is an explicit positive constant depending on  $r$  that tends to 0 as  $r$  grows. We then use recent work [14] on constructing SOS lower bounds from  $t$ -wise uniform distributions to show that degree- $\Omega(n)$  SOS thinks it can “weakly satisfy” a random “distributional CSP” in which each constraint specifies that a random  $4r$ -tuple of variables should be distributed according to  $\theta$ . By “weak satisfaction”, we mean that SOS will at least think it can get a local distribution on each  $4r$ -tuple whose support is contained within  $\theta$ ’s support (and therefore always having exactly a  $\frac{1}{4} - \varepsilon_r$  fraction of rows satisfying 3AND). Now viewing each such tuple as the conjunction of  $r$  (random) 3AND constraints, we get that the SOS solution thinks it satisfies exactly a  $\frac{1}{4} - \varepsilon_r$  fraction of these constraints.

### Further consequences

Via our first result – satisfying global cardinality constraints – we open up the possibility of establishing SOS lower bounds for natural problems like Min- and Max-Bisection (by performing reductions within SOS, as in [21]). Previously, no such SOS integrality gaps were known (Guruswami, Sinop, and Zhou [11] had given an SOS integrality gap approaching  $\frac{11}{10}$  for the Balanced-Separator problem, which is like Min-Bisection but without a hard bisection constraint.) Under assumptions like  $\text{NP} \not\subseteq \bigcap_{\varepsilon > 0} \text{TIME}(2^{n^\varepsilon})$ , some hardness results were

<sup>3</sup> We also show in the full version that this is not too far from tight, in the sense that it is easier to refute XOR with Hamming weight constraints that are too imbalanced (if  $k = \omega(n^{1/4})$ ).

<sup>4</sup> Actually, it was recently observed that it is not clear we can definitely solve the associated SDP exactly [16, 18]. This does not affect the status of our lower bounds.

previously known: no PTAS for Min-Bisection (due to Khot [13]) and factor  $\frac{15}{16} + \varepsilon$  hardness for Max-Bisection (due to Holmerin and Khot [13], improving on the factor  $\frac{16}{17} + \varepsilon$  NP-hardness known for Max-Cut). However, in the context of SOS lower bounds, it makes sense to shoot for more: namely, hardness factors that are known subject to Feige’s R3SAT Hypothesis [7] (and similar hypotheses for random CSPs).

Feige himself [7] showed factor  $\frac{4}{3} - \varepsilon$  hardness for Min-Bisection under his hypothesis (with a quadratic size blowup). Also, it’s possible to show factor  $\frac{11}{12} + \varepsilon$  hardness for Max-Bisection (with linear size blowup) under Feige’s Hypothesis for 4XOR; this is arguably “folklore”, via the gadget techniques of Trevisan et al. [20] (see also [12, 17]). We are able to convert both of these results to SOS lower bounds, showing that degree- $\Omega(\sqrt{n})$  SOS fails to  $(\frac{4}{3} - \varepsilon)$ -approximate Min-Bisection, and degree- $\Omega(n)$  SOS fails to  $(\frac{5}{4} + \varepsilon)$ -approximate Min-Bisection. Our proof of the latter can also be modified to show that degree- $\Omega(n)$  SOS fails to  $(\frac{11}{12} + \varepsilon)$ -approximate Max-Bisection.

It is worth pointing out that the benefit of our second main result, the ability to enforce objective equality constraints exactly, also arises in these SOS Bisection lower bounds. For example, the  $(\frac{4}{3} - \varepsilon)$ -hardness for Min-Bisection is a kind of gadget reduction from random 3AND CSPs; showing that the “good cut” in the completeness case is an exact bisection relies on the “good assignment” in the 3AND instance satisfying exactly a  $\frac{1}{4}$  fraction of constraints.

## 1.1 Statement of main theorems

Recent work [3, 14] has established a general framework for showing lower bounds for SOS on random CSPs, using the idea of  $t$ -wise uniformity. The following is a fairly general example of what’s known:

► **Theorem 0** ([14]). *Let  $P : \{0, 1\}^k \rightarrow \{0, 1\}$  be a predicate, and suppose there is a  $(t - 1)$ -wise uniform distribution  $\nu$  on  $\{0, 1\}^k$  with  $\mathbb{E}_\nu[P] = \beta$ . Consider a random  $n$ -variable,  $m = \Delta n$ -constraint instance of  $\text{CSP}(P^\pm)$ , meaning that each constraint is  $P$  applied to  $k$  randomly chosen literals. Then with high probability, there is a degree- $\Omega\left(\frac{n}{\Delta^{2/(t-2)} \log \Delta}\right)$  SOS pseudodistribution  $\tilde{\mathbb{E}}[\cdot]$  with the following property:*

**Case 1:**  $\beta = 1$ . *In this case,  $\tilde{\mathbb{E}}[\cdot]$  satisfies all the CSP constraints as identities.*

**Case 2:**  $\beta < 1$ . *In this case,  $\mathbb{E}[\text{OBJ}(x)] = \beta \pm o(1)$ , where  $\text{OBJ}(x)$  denotes the objective value of the CSP.*

For example, the case of random 3SAT described in the previous section corresponds to  $P = \text{OR}_3$ ,  $t = 3$ ,  $\nu$  being the uniform distribution on triples satisfying  $\text{XOR}_3$ ,  $\beta = 1$ , and  $\Delta = 50$ ; the case of random 3AND has the same  $t$ ,  $\nu$ , and  $\Delta$ , but  $P = \text{AND}_3$  and  $\beta = \frac{1}{4}$ .

Our main theorems are now as follows:

► **Theorem 1.** *In the  $\beta = 1$  case of Theorem 0, one can additionally get the pseudodistribution  $\tilde{\mathbb{E}}$  to satisfy (with pseudovariance zero) the global bisection constraint  $\sum_{i=1}^n x_i = \frac{n}{2}$  (assuming  $n$  even). More generally, for any integer  $B \in [\frac{n}{2} - O(\sqrt{n}), \frac{n}{2} + O(\sqrt{n})]$ , we can ensure the pseudodistribution satisfies the global Hamming weight constraint  $\sum_{i=1}^n x_i = B$ .*

► **Theorem 2.** *In the  $\beta < 1$  case of Theorem 0, there exists a sequence of positive constants  $\varepsilon_r$  with  $\varepsilon_r \rightarrow 0$  such that for a random\*  $n$ -variable,  $m = \Delta n$ -constraint instance of  $\text{CSP}(P^\pm)$ , with high probability there is a degree- $\Omega_r\left(\frac{n}{\Delta^{2/(t-2)} \log \Delta}\right)$  SOS pseudodistribution  $\tilde{\mathbb{E}}$  which satisfies (with pseudovariance zero) the hard constraint “ $\text{OBJ}(x) = \beta - \varepsilon_r$ ”. Furthermore, we can also obtain cardinality constraints as in Theorem 1.*

In the full version, we show that Theorem 1 is not too far from tight, by demonstrating that random  $k$ -XOR instances become easier to refute when one imposes an imbalanced Hamming weight constraint  $\sum_{i=1}^n x_i = \frac{n}{2} \pm \omega(n^{1/4})$ .<sup>5</sup>

► **Remark.** In the above theorem we have written “random\*” with an asterisk because the random instance is not drawn precisely in the standard way. Rather, it is obtained by choosing  $m/r$  groups of random constraints, where in each group we fix a literal pattern and then choose  $r$  nonoverlapping constraints with this pattern. This technicality is an artifact of our proof; it seems likely that it is unnecessary. Indeed, it is possible that these two distributions on random hypergraphs are simply  $o(1)$ -close in total variation distance, at least when  $m = O(n)$ .<sup>6</sup> In any case, by alternate means (including the techniques from Theorem 1) we are able to show the following alternative result in Section 5.2: When  $m = o(n^{1.5})$ , with high probability a purely random instance of  $\text{CSP}(P^\pm)$  has an SOS pseudodistribution of the stated degree that exactly satisfies  $\text{OBJ}(x) = \beta - \varepsilon$  for some  $\varepsilon > 0$  that can be made arbitrarily small.

► **Remark.** Our proof of Theorem 2 only relies on the “Case 1,  $\beta = 1$ ” part of [14]’s Theorem 0. In fact, our Theorem 2 can actually be used to effectively *deduce* “Case 2,  $\beta < 1$ ” from “Case 1,  $\beta = 1$ ” in Theorem 0. This is of interest because [14]’s argument for Case 2 was not a black-box reduction from Case 1, but instead involved verifying a more technical expansion property in random graphs, as well as slightly reworking the proof of Case 2.

Finally, we obtain the following theorems concerning Bisection problems:

► **Theorem 3.** *For the Max-Bisection problem in a graph on  $n$  vertices, for  $d = \Omega(n)$ , the degree- $d$  Sum-of-Squares Method cannot obtain an approximation factor better than  $\frac{11}{12} - \varepsilon$  for any constant  $\varepsilon > 0$ .*

*For the Min-Bisection problem, for  $d' = \Omega(\sqrt{n})$ , the degree- $d'$  SOS Method cannot obtain an approximation factor better than  $\frac{4}{3} - \varepsilon$ , and for  $d = \Omega(n)$  the degree- $d$  SOS Method cannot obtain an approximation factor better than  $\frac{5}{4} - \varepsilon$ .*

The proofs are included in the full version.

## Organization of this paper

In Section 2, we provide some preliminaries and technical context for the study of CSPs and SOS. In Section 3, we extend the results of [14] to obtain lower bounds for CSPs with global cardinality constraints, proving Theorem 1. Section 4 shows how to construct local distributions over assignments to groups of disjoint predicates so that the number of satisfied constraints is always exactly the same, and Section 5 shows how to use such distributions to prove Theorem 2. In Section 5, one can also find a discussion of random vs. random\* CSPs. We wrap up with some concluding remarks and future directions in Section 6.

## 2 Preliminaries

### CSPs

A constraint satisfaction problem (CSP) is defined by an *alphabet*  $\Omega$  (usually  $\{0, 1\}$  or  $\{\pm 1\}$  in this paper) and a collection  $\mathcal{P}$  of *predicates*, each predicate being some  $P : \Omega^k \rightarrow \{0, 1\}$  (with different  $P$ ’s possibly having different *arities*,  $k$ ). An *instance*  $\mathcal{H}$  consists of a set  $V$  of

<sup>5</sup> We conjecture that Theorem 1 is tight, and that Hamming weight constraints with imbalance  $\omega(n^{1/2})$  already make  $k$ -XOR easier to refute.

<sup>6</sup> Thanks to Svante Janson for some observations in the direction of showing this.

$n$  variables, as well as  $m$  constraints. Each constraint  $h$  consists of a *scope*  $S$  and a predicate  $P \in \mathcal{P}$ , where  $S$  is a tuple of  $k$  distinct variables,  $k$  being the arity of  $P$ . An *assignment* gives a value  $x_i \in \Omega$  to the  $i$ th variable; it *satisfies* constraint  $h = (S, P)$  if  $P(x_{S_1}, \dots, x_{S_k}) = 1$ . We may sometimes write this as  $P(x_S) = 1$  for brevity. The associated *objective value* is the fraction of satisfied constraints,

$$\text{OBJ}(x) = \text{avg}_{h=(S,P) \in \mathcal{H}} \{P(x_S)\}.$$

Sometimes we are concerned with CSPs of the following type: the alphabet  $\Omega = \{\pm 1\}$  is Boolean, there is a single predicate  $P : \Omega^k \rightarrow \{0, 1\}$  (e.g.,  $P = \text{OR}_3$ , the 3-ary Boolean OR predicate), and the predicate set  $\mathcal{P}$  consists of all  $2^k$  versions of  $P$  in which inputs may be negated. We refer to this scenario as  $P$ -CSP with *literals*, denoted  $\text{CSP}(P^\pm)$ . For example, the case of  $P = \text{OR}_3$  is the classic “3SAT” CSP.

### Distributional CSPs

A *distributional CSP* is one where, rather than having a predicate associated with each scope, we have a probability distribution. More precisely, each *distributional constraint*  $h = (S, \nu)$  now consists of a scope  $S$  of some arity  $k$ , as well as a probability distribution  $\nu$  on  $\Omega^k$ . The optimization task involves finding a *global probability distribution*  $\mu$  on assignments. We say that  $\mu$  *satisfies* constraint  $h = (S, \nu)$  if the marginal  $\mu|_S$  of  $\mu$  on  $S$  is equal to  $\nu$ ; we say the distributional CSP is *satisfiable* if there is a  $\mu$  satisfying all constraints.

We may also say that  $\mu$  *weakly satisfies*  $h = (S, \nu)$  if  $\text{supp}(\mu|_S) \subseteq \text{supp}(\nu)$ . A “usual” (*predicative*, i.e., non-distributional) CSP can be viewed as a distributional CSP as follows: For each predicate  $P$ , select any distribution  $\nu_P$  whose support is exactly the satisfying assignments to  $P$ ; then the existence of a global assignment in the predicative CSP of objective value  $\beta$  is equivalent to the existence of a global probability distribution  $\mu$  that *weakly* satisfies a  $\beta$  fraction of constraints.

### Random CSPs

We are frequently concerned with CSPs chosen uniformly at random. Given a predicate set  $\mathcal{P}$ , a random CSP with  $n$  variables and  $m$  constraints is chosen as follows: For each constraint we first choose a random  $P \in \mathcal{P}$ . Supposing it has arity  $k$ , we then choose a uniformly random length- $k$  scope  $S$  from the  $n$  variables, and impose the constraint  $(S, P)$ . We can similarly define a random distributional CSP given a collection  $\mathcal{D}$  of distributions  $\nu$ . We remark that our choice of having exactly  $m$  constraints is not really essential, and not much would change if we had, e.g., a Poisson( $m$ ) number of random constraints, or if we chose each possible constraint independently with probability such that  $m$  constraints are expected.

### SOS

The SOS Method [5] can be thought of as an algorithmic technique for finding upper bounds on the best objective value achievable in a predicative or distributional CSP. For example, in a random 3SAT instance with  $m = 50n$ , it is very likely that every assignment  $x$  has  $\text{OBJ}(x) \leq \frac{7}{8} + o(1)$ ; ideally, the SOS Method could certify this, or could at least certify unsatisfiability, meaning an upper bound of  $\text{OBJ}(x) < 1$  for all assignments. The SOS Method has a tunable *degree* parameter  $d$ ; increasing  $d$  increases the effectiveness of the method, but also its run-time, which is essentially  $n^{O(d)}$  (though see [16, 18] for a more

precise discussion). In this work we are only concerned with showing negative results for the power of SOS. Showing that degree- $d$  SOS fails to certify a good upper bound on the maximum objective value is equivalent to showing that a *degree- $d$  pseudodistribution* exists under which the objective function has a large *pseudoexpectation*. We define these terms now.

For simplicity we restrict attention to CSPs with Boolean alphabet (either  $\Omega = \{0, 1\}$  or  $\Omega = \{\pm 1\}$ ), although it is straightforward to extend the definitions for larger alphabets.<sup>7</sup> The SOS method introduces *indeterminates*  $X_1, \dots, X_n$  associated to the CSP variables; intuitively, one thinks of them as standing for the outcome of a global assignment chosen from a supposed probability distribution on assignments. An associated *degree- $d$  pseudoexpectation* is a real-valued linear map  $\tilde{\mathbb{E}}$  on  $\mathbb{R}_{\leq d}[X_1, \dots, X_n]$  (the space of formal polynomials in  $X_1, \dots, X_n$  of degree at most  $d$ ) satisfying three properties:

1.  $\tilde{\mathbb{E}}[\text{multilin}(Q(X))] = \tilde{\mathbb{E}}[Q(X)]$ ; here  $\text{multilin}(Q(X))$  refers to the *multilinearization* of  $Q(X)$ , meaning the reduction mod  $X_i^2 = X_i$  (in case  $\Omega = \{0, 1\}$ ) or mod  $X_i^2 = 1$  (in case  $\Omega = \{\pm 1\}$ ).
2.  $\tilde{\mathbb{E}}[1] = 1$ ;
3.  $\tilde{\mathbb{E}}[Q(X)^2] \geq 0$  whenever  $\deg(Q) \leq d/2$ .

We tend to think of the first condition (as well as the linearity of  $\tilde{\mathbb{E}}$ ) as being “syntactically” enforced; i.e., given  $\tilde{\mathbb{E}}$ 's values on the multilinear monomials, its value on all polynomials is determined through multilinearization and linearity. It is not hard to show that every pseudoexpectation  $\tilde{\mathbb{E}}$  arises from a *signed probability distribution*  $\mu$ ; i.e., a (possibly negative) function  $\mu : \Omega^n \rightarrow \mathbb{R}$  with  $\sum_x \mu(x) = 1$ . We call this the associated *pseudodistribution*. Intuitively, we think of a degree- $d$  pseudodistribution as a “supposed” distribution on global assignments, which at least passes the tests in Item 3 above.

Given a CSP instance  $\mathcal{H}$ , if there is a degree- $d$  pseudodistribution with  $\tilde{\mathbb{E}}[\text{OBJ}(X)] \geq \beta$ , this means that the degree- $d$  SOS Method *fails* to certify an upper bound of  $\text{OBJ}(x) < \beta$  for the CSP. Informally, we say that degree- $d$  SOS “thinks” that there is a distribution on assignments under which the average objective value is at least  $\beta$ . Similarly, given a distributional CSP  $\mathcal{H}$ , if there is a degree- $d$  pseudodistribution in which  $\tilde{\mathbb{P}}[X_S = (a_1, \dots, a_k)] = \nu(a_1, \dots, a_k)$  for all constraints  $h = (S, \nu)$ , we say that degree- $d$  SOS “thinks” that  $\mathcal{H}$  is fully satisfiable. Here  $\tilde{\mathbb{P}}[X_S = (a_1, \dots, a_k)]$  means  $\tilde{\mathbb{E}}[1_{X_S=(a_1, \dots, a_k)}]$ , where  $1_{X_S=(a_1, \dots, a_k)}$  denotes the natural arithmetization of the 0-1 indicator as a degree- $k$  multilinear polynomial.

### Satisfaction of identities in SOS

Formally speaking, one says that a degree- $d$  pseudodistribution *satisfies an identity*  $Q(X) = b$  if  $\tilde{\mathbb{E}}[(Q(X) - b)R(X)] = 0$  for all polynomials  $R(X)$  of degree at most  $d - \deg(Q)$ . Note that this is *stronger* than simply requiring  $\tilde{\mathbb{E}}[Q(X)] = b$  (the  $R \equiv 1$  case). A great deal of this paper is concerned with precisely this distinction; it may be relatively easy to come up with a degree- $d$  pseudodistribution over  $\{0, 1\}^n$  satisfying, say,  $\tilde{\mathbb{E}}[\sum_i X_i] = \frac{n}{2}$ , but much harder to find one that “satisfies the identity  $\sum_i X_i = \frac{n}{2}$ ”. The terminology here is a little unfortunate; we will try to ameliorate things by introducing the following stronger phrase:

► **Definition 4.** We say that a degree- $d$  pseudodistribution satisfies identity  $Q(X) = b$  with *pseudovariance zero* if we have both  $\tilde{\mathbb{E}}[Q(X)] = b$  and *also*

$$\widetilde{\text{VAR}}[Q(X) - b] = \tilde{\mathbb{E}}[Q(X)^2] - b^2 = 0.$$

<sup>7</sup> Specifically, for each variable  $x$  and each alphabet element  $a \in \Omega$ , one introduces an indeterminate called  $1_{x=a}$  that is constrained as a  $\{0, 1\}$  value and is interpreted as the indicator of whether  $x$  is assigned  $a$ .

As is shown in [2, Lemma 3.5 (SOS Cauchy-Schwarz)], this condition is equivalent to the pseudodistribution “satisfying the identity  $Q(X) = b$ ” for  $Q$  of degree up to  $d/2$ .<sup>8</sup>

Intuitively, in this situation degree- $d$  SOS not only “thinks” that it knows a distribution on assignments  $x$  under which  $Q(x)$  has expectation  $b$ , it further thinks that *every* outcome  $x$  in the support of its supposed assignment has  $Q(x) = b$ .

### 3 Random CSPs with Hamming weight constraints

In this section we will prove Theorem 1, which extends the known random CSP lower bounds (as in Theorem 0) to CSPs with a hard Hamming weight constraint on the variable assignment.

#### 3.1 Hypergraph expansion and prior SOS lower bounds for random CSPs

The paper [14] works in the general setting of distributional CSPs with an upper bound of  $K$  on all constraint arities. An instance is thought of as a “factor graph”  $G$ : a bipartite graph with  $n$  variable-vertices,  $m$  constraint-vertices, and edges joining a constraint-vertex to the variable-vertices in its scope. More precisely, the neighborhood  $N(h)$  of each constraint-vertex  $h$  is defined to be an *ordered* tuple of  $k_h$  variable-vertices. We write  $\nu_h$  for the local probability distribution on  $\Omega^{N(h)}$  associated to constraint  $h$ . In [14], each  $\nu_h$  is assumed to be a  $(\tau - 1)$ -wise uniform distribution, where  $\tau$  is a global integer parameter satisfying  $3 \leq \tau \leq K$ . Finally, the graph  $G$  is assumed to satisfy a certain high-expansion condition (discussed in the full version) called the “Plausibility Assumption” involving two parameters  $0 < \zeta < 1$  and  $1 \leq \text{SMALL} \leq n/2$ , assumed to satisfy  $K \leq \zeta \cdot \text{SMALL}$ . In this case, the main theorem of [14] is that there is a SOS-pseudodistribution of degree  $\frac{1}{3}\zeta \cdot \text{SMALL}$  that weakly satisfies all constraints.

In [14] it is assumed that all constraint distributions  $\nu_h$  have the *same* level of uniformity, namely  $(\tau - 1)$ -wise uniformity,  $\tau \geq 3$ . In this work, in order to incorporate Hamming weight constraints on the assignment, we would like to consider the possibility that different constraint distributions have different levels of uniformity. To that end, suppose that each  $\nu_h$  is  $(t_h - 1)$ -wise uniform, where the  $t_h$ ’s are various integers. Slightly more broadly than [14], we allow  $1 \leq t_h \leq k_h + 1$  for all  $h$ , and we allow the constraints to have arity  $k_h$  as low as 1.

In the full version, we examine how these assumptions affect the proofs in [14]. The upshot is Theorem 5 below. Before we give the theorem, we briefly introduce some notation and comments: A “constraint-induced” subgraph  $H$  is a subgraph of the factor graph  $G$  given by choosing some set of constraints  $C$ , as well as all edges and constraint-vertices adjacent to  $C$ . We write  $c(H)$  for the number of constraints in  $H$ ,  $e(H)$  for the number of edges,  $v(H)$  for the number of variable-vertices, and  $T(H) = \sum_{h \in \text{cons}(H)} t_h$ . To reduce to (3.1) in the following theorem, we use the observation in the full version that adding edges to a subgraph to make it constraint-induced can only decrease “income”.

For notational simplicity we have also adjusted the parameters  $\zeta$  and  $\text{SMALL}$  by factors of 2.

<sup>8</sup> In this paper we are flexible when it comes to constant factors in the degree. For this reason we need not worry about this factor-2 loss in the degree, as a degree- $2d$  pseudoexpectation which satisfies an identity with pseudovariance 0 automatically gives a degree- $d$  pseudoexpectation which satisfies the identity exactly.

► **Theorem 5** (Essentially from [14]). *Let  $0 < \zeta < 1$ ,  $\text{SMALL} \leq n$  and assume all constraint-vertices in  $G$  have arity at most  $\zeta \cdot \text{SMALL}$ .*

*Suppose that for every set of nonempty constraint-induced subgraph  $H$  with  $c(H) \leq \text{SMALL}$ , it holds that*

$$v(H) \geq e(H) - \frac{T(H)}{2} + \zeta c(H). \quad (3.1)$$

*Then there is an SOS-pseudodistribution of degree  $\frac{1}{3}\zeta \cdot \text{SMALL}$  that weakly satisfies all constraints.*

There are a lot of parameters in the above theorem, and our goal is not to derive the most general possible quantitative result. Instead we’ll simply work out some of the basic consequences.

A basic setting treated in [14], relevant for Theorem 0, is the following. For a fixed small  $t$  we choose a random CSP with  $n$  variables and  $\Delta n$  constraints, with each constraint supporting a  $(t - 1)$ -wise uniform distribution. E.g., in random 3SAT,  $t = 3$ . Then if

$$\Delta = \text{const} \cdot \left( \frac{n}{\text{SMALL}} \right)^{\frac{t}{2} - 1 - \zeta}$$

for a sufficiently small positive constant, it is shown in [14] that the main condition (3.1) indeed holds with high probability. Choosing, say,  $\zeta = \frac{1}{\log n}$  and  $\text{SMALL} = \text{polylog}(n)$ , we see that, with high probability, we will have weakly satisfying pseudodistributions of degree  $\text{polylog}(n)$  even when  $\Delta = \tilde{\Theta}(n^{t/2-1})$ .

In fact, it’s possible to show that we have such pseudoexpectations when there are, simultaneously,  $n^{1.5}/\text{polylog}(n)$  2-wise-supporting constraints, and  $n^2/\text{polylog}(n)$  3-wise-supporting constraints, and  $n^{2.5}/\text{polylog}(n)$  4-wise-supporting constraints, . . . and also  $n/\text{polylog}(n)$  1-wise-supporting constraints, and  $n^5/\text{polylog}(n)$  0-wise-supporting constraints.

### 3.2 Expansion in the presence of matching and unary constraints

However, if we want to impose a cardinality constraint by way of adding 1-wise independent 2-ary  $\neq$  constraints, then  $n/\text{polylog}(n)$  such constraints will not suffice. Indeed, what we would like to now show is that if the 1-wise-supporting constraints are carefully chosen to not overlap, we can add a full, linear-sized “matching” of them without compromising the lower bound. Then, when  $\Omega = \{0, 1\}$ , we can impose the 1-wise-uniform constraints  $x_1 \oplus x_2 = 1$ ,  $x_3 \oplus x_4 = 1, \dots, x_{n-1} \oplus x_n = 1$  and thereby force the pseudoexpectation to satisfy the global constraint  $\sum_i x_i = \frac{n}{2}$ .

► **Theorem 6.** *Fix a uniformity parameter  $3 \leq t \leq O(1)$ , an arity  $k \leq O(1)$ , a number  $U = O(\sqrt{n})$  of “unary” constraints, and a small failure probability  $0 < p < 1/2$ . Assume also that  $\zeta \leq 1/2$ .*

*Suppose we form a random factor graph with  $n$  variable-vertices and  $\Delta n$  constraint-vertices  $\mathcal{C}$  of arity  $k$ ; assume each constraint-vertex is equipped with an associated  $(t - 1)$ -wise uniform distribution.*

*Furthermore, suppose we add in two sets  $\mathcal{M}_1, \mathcal{M}_2$  of nonrandom, nonoverlapping constraints, whose associated variable vertices partition  $[n]$ . The “unary” constraints of  $\mathcal{M}_1$  should satisfy  $|\mathcal{M}_1| \leq U$  and have an associated 0-wise uniform distribution; the “matching” constraints of  $\mathcal{M}_2$  should be of constant arity and have an associated 1-wise uniform distribution.*

Then provided

$$\Delta \leq \text{const} \cdot p \cdot \left( \frac{n}{\text{SMALL}} \right)^{\frac{t}{2}-1-\zeta'}$$

for a sufficiently small universal constant, and  $\zeta' = (k+1)\zeta$ , the expansion condition in Theorem 5 holds except with probability at most  $p$ .

The proof of Theorem 6, appearing in the full version, uses standard combinatorial techniques for verifying the expansion of random graphs. Due to the fact that the unary and matching constraints are deterministic, we must augment these standard techniques with some straightforward case analysis. In fact, we only prove the theorem under the assumption that the constraints of  $\mathcal{M}_2$  have arity 2; the more general case of constant arity is a slight elaboration that we omit.

### 3.3 Lower bound for CSPs with Hamming weight constraints

As in [14], we observe that for a given  $\Delta \geq 10$ , a good choice for  $\zeta$  is  $\frac{1}{\log \Delta}$ . This yields the following corollary, which we will show implies Theorem 1:

► **Theorem 7.** *Let  $\nu$  be a  $(t-1)$ -wise uniform distribution on  $\{0, 1\}^k$ . Consider a random  $n$ -variable,  $m = \Delta n$ -constraint  $k$ -ary distributional CSP, in which each constraint distribution is  $\nu$  up to a negation pattern in the  $k$  inputs. (All such “reorientations” are still  $(t-1)$ -wise uniform.) Suppose we also impose the following nonrandom distributional constraints:*

- *The 0-wise uniform constraints  $x_1 = b_1, x_2 = b_2, \dots, x_U = b_U$ , for some string  $b \in \{0, 1\}^U$  with  $U = O(\sqrt{n})$ ;*
- *The 1-wise uniform constraint that  $(x_{U+1}, x_{U+2})$  is uniform on  $\{(0, 1), (1, 0)\}$ , and similarly for the pairs  $(x_{U+3}, x_{U+4}), \dots, (x_{n-1}, x_n)$ .*

*Then with high probability, there is an SOS-pseudodistribution of degree  $D = \Omega\left(\frac{n}{\Delta^{2/(t-2)} \log \Delta}\right)$  that weakly satisfies all constraints.*

Let us now see why this implies Theorem 1. In this “ $\beta = 1$ ” scenario, we have a  $(t-1)$ -wise uniform  $\nu$  supported on the satisfying assignments for  $P$ . Whenever the random CSP( $P^\pm$ ) instance has a  $P$ -constraint with a particular literal pattern, we impose the analogous  $\nu$ -constraint with equivalent negation pattern. Now the SOS-pseudodistribution  $\tilde{\mathbb{E}}[\cdot]$  promised by Theorem 6 weakly satisfies all these  $\nu$ -constraints, and hence satisfies all the  $P$ -constraints. Furthermore, it also has  $\tilde{\mathbb{E}}[x_i] = b_i \in \{0, 1\}$  for all  $i \leq U$ , and  $\tilde{\mathbb{E}}[x_i(1-x_{i+1})] + \tilde{\mathbb{E}}[(1-x_i)x_{i+1}] = 1$  for all pairs  $(i, i+1) = (U+1, U+2), \dots, (n-1, n)$ , by weak satisfaction. Notice that the latter implies

$$\tilde{\mathbb{E}}[(x_i + x_{i+1} - 1)^2] = 1 - \tilde{\mathbb{E}}[x_i] - \tilde{\mathbb{E}}[x_{i+1}] + 2\tilde{\mathbb{E}}[x_i x_{i+1}] = 0,$$

and hence the SOS solution satisfies  $x_i + x_{i+1} = 1$  with pseudovariance zero. Similarly (and easier), it satisfies the identity  $x_i = b_i$  for all  $i \leq U$ . It now follows that the pseudodistribution satisfies the identity  $\sum_{i=1}^n x_i = \frac{n}{2} + (|b| - \frac{U}{2})$  with pseudovariance zero, and this completes the proof of Theorem 1, because we can take any  $|b| \in \{0, \dots, U\}$ .

## 4 Exact Local Distributions on Composite Predicates

In this section and in Section 5 we will show how to satisfy the constraint  $\text{OBJ}(x) = \beta$  exactly, with pseudovariance zero. Our strategy will be to group predicates together into “composite” predicates, and then prove that there is a local  $(t-1)$ -wise uniform distribution

which is moreover supported on variable assignments for which an exact  $\beta$ -fraction of the predicates within the composite predicate are satisfied. We'll then apply Theorem 6 to the composite predicates.

We begin with an easier proof for the case when there is a pairwise-uniform distribution over satisfying assignments to our predicate in Section 4.1, and later in Section 4.2 we handle  $t$ -wise uniform distributions for larger  $t$ . While the pairwise-uniform theorem is less general, the proof is simpler and it already suffices for all of our bisection applications.

#### 4.1 Pairwise-uniform distributions over $\beta$ -satisfying assignments

Recall our setting: we have a Boolean  $k$ -ary predicate  $P : \{\pm 1\}^k \rightarrow \{0, 1\}$  and a pairwise-uniform distribution  $\nu$  over assignments  $x \in \{\pm 1\}^k$  such that  $\mathbb{E}[P(x)] = \beta$ . The following theorem states that we can extend  $\nu$  into a distribution  $\theta$  over assignments to groups of  $r$  predicates at a time,  $\{\pm 1\}^{r \times k}$  so that exactly  $(\beta - \varepsilon) \cdot r$  of the  $r$  predicates are satisfied by any assignment  $y \sim \theta$ .

► **Theorem 8.** *Let  $P : \{\pm 1\}^k \rightarrow \{0, 1\}$  be a  $k$ -ary Boolean predicate, and let  $\nu$  be a pairwise-uniform distribution over assignments  $\{\pm 1\}^k$  with the property that  $\nu(x)$  is rational for each  $x \in \{\pm 1\}^k$ ; that is, there exist a multiset  $S \subseteq \{\pm 1\}^k$  such that for each  $x \in \{\pm 1\}^k$ ,  $\nu(x) = \mathbb{P}_{s \sim S}(s = x)$ . Suppose also that  $\mathbb{E}_{x \sim \nu}[P(x)] = \beta$ , and that this is more than the expectation under the uniform distribution, so  $\beta > \mathbb{E}_{x \sim \{\pm 1\}^k}[P(x)]$ .*

*Then for any constant  $\varepsilon > 0$ , there exists an integer  $r = O_{\varepsilon, k}(|S|^3)$  and a rational  $\tilde{\varepsilon} \leq \varepsilon$  so that there is a pairwise-uniform distribution  $\theta$  over assignments to groups of  $r$  predicates,  $\{\pm 1\}^{r \times k}$  such that exactly  $(\beta - \tilde{\varepsilon})r$  of the predicates are satisfied by any assignment  $y \sim \theta$ .*

Throughout we'll refer to the assignments in the support of  $\theta$  as *matrices*, with each row of the  $r \times k$  matrix corresponding to the assignment for a single copy of the predicate.

Since we have assumed that the probability of seeing any string in the support of  $\nu$  is rational, without loss of generality we can assume that  $\nu$  is uniform over some multiset  $S \subseteq \{\pm 1\}^k$ . As a first guess at  $\theta$ , one might try to take  $r = c \cdot |S|$  for some positive integer  $c$ , make  $c$  copies of the multiset  $S$ , and use a random permutation of the elements of this multiset to fill the rows of an  $r \times k$  matrix. But this distribution is not *quite* pairwise uniform. The issue is that because each individual bit is uniformly distributed, every column of the matrix will always be perfectly balanced between  $\pm 1$ . Therefore the expected product of two distinct bits in a given column is

$$\frac{1}{\binom{c|S|}{2}} \left( \binom{\frac{1}{2}c|S|}{2} (-1)^2 + \binom{\frac{1}{2}c|S|}{2} (+1)^2 + \binom{\frac{1}{2}c|S|}{2} (+1)(-1) \right) = -\frac{1}{c|S| - 1} \neq 0.$$

So, the bits within a particular column have a slight negative correlation.

We'll compensate for this shortcoming as follows: we will randomly choose an element  $s$  in the support of  $\nu$  to repeat multiple times. This may in turn alter the number of predicates satisfied out of the  $r$  copies of  $P$ , whereas our express goal was to satisfy the exact same number of predicates under every assignment. To adjust for this, we'll mix in some rows from the uniform distribution over  $\{\pm 1\}^k$ , where the number of rows we mix in will depend on whether  $P(s) = 1$  or  $0$ .

**Proof.** Let  $S$  be a multiset of strings in  $\{\pm 1\}^k$  such that  $\mathbb{P}_{s \sim S}(s = a) = \nu(a)$ . We will also require a multiset  $T \subseteq \{\pm 1\}^k$  which is a well-chosen mixture of  $\nu$  and the uniform distribution; the following claim shows that we can choose such a set. Here, we take some care in choosing this combination; the exact choice of parameters will not matter until later.

► **Claim 9.** For any constant  $\varepsilon > 0$ , there is a constant  $L = O(1/\varepsilon)$  and a constant  $R \geq 1$  so that there are multisets  $S', T \subseteq \{\pm 1\}^k$  with the following properties:  $S'$  is  $RL2^k$  copies of  $S$ ,  $T$  has size  $|T| = |S'| = LR2^k|S|$ , and  $\mathbb{P}_{x \sim T}[P(x) = 1] = \beta - \varepsilon'$ , where  $\varepsilon > \varepsilon' \stackrel{\text{def}}{=} \frac{1}{L}(\beta - \mathbb{E}_{x \sim \{\pm 1\}^k}[P(x)])$ .

**Proof.** Let  $s = |S|$ , and let  $U = \{\pm 1\}^k$ . Suppose that  $\eta 2^k$  of  $U$ 's assignments satisfy  $P$ . Define  $T$  to be the multiset given by  $2^k(L-1)R$  copies of  $S$  and  $sR$  copies of  $U$ . We have

$$\mathbb{P}_{x \sim T}[P(x) = 1] = \frac{1}{2^k L R s} (\beta s \cdot 2^k (L-1)R + \eta 2^k \cdot sR) = \beta - \frac{\beta - \eta}{L}.$$

By choosing  $L$  large as a function of  $\varepsilon$ , we can make this probability as small as we want. ◀

For convenience, let  $\ell = 2^k L R |S|$ . Set the number of rows  $r = d\ell$  for an integer  $d = O_\varepsilon(\ell^2)$  to be specified later. We also let  $a, b_1, b_0, c_1, c_0$  be integers which will specify the number of rows from  $S', T$ , and the repeated assignment set; we'll set the integers later, but we will require the property that

$$d = a + b_1 + c_1 = a + b_0 + c_0. \quad (4.1)$$

We generate a sample from  $\theta$  in the following fashion:

1. Sample  $s \sim S$ , and fill the first  $a\ell$  rows with copies of  $s$ . Call these the  $A$  rows.
2. Set  $i = P(s)$ , that is  $i = 1$  if  $s$  satisfies  $P$  and  $i = 0$  otherwise.
3. Fill the next  $b_i\ell$  rows with  $b_i$  copies of each string in  $S'$ . Call these the  $B$  rows.
4. Fill the last  $c_i\ell$  rows with  $c_i$  copies of each string in  $T$ . Call these the  $C$  rows.
5. Randomly permute the rows of the matrix.

If  $\delta\ell$  assignments in  $T$  are satisfying and  $\beta\ell$  assignments in  $S'$  are satisfying, to ensure that the number of satisfying rows is always the same we enforce the constraint

$$a\ell + b_1\beta\ell + c_1\delta\ell = b_0\beta\ell + c_0\delta\ell, \quad (4.2)$$

Now we handle uniformity. We will prove that all of the degree-1 and degree-2 moments of the bits in the matrix are uniform under  $\theta$ . First, we argue that the degree-1 moments are zero, and that the correlation of any two bits in the same row is zero.

► **Claim 10.** The bits in a single row of  $M$  are pairwise uniform.

**Proof.** We can condition on the row type,  $A, B$ , or  $C$ . For each type of row, there is a multiset  $U$  such that  $\mathbb{E}[M_{ij}] = \mathbb{E}_{x \sim U}[x_j] = 0$  by the pairwise uniformity of the uniform distribution over  $U$ . The same argument proves the statement for the product of two bits in a fixed row. ◀

Thus, it suffices to prove that the bits in each column are pairwise-uniform; this is because the pairwise uniformity of rows implies that we can fix the values of any entire column, and the remaining individual bits in other columns will remain uniformly distributed. So we turn to proving that the columns are pairwise-uniform.

► **Claim 11.** If we choose  $a, b_0, b_1, c_0, c_1$  so that

$$a(\ell - 1) - \beta(b_1 + c_1) - (1 - \beta)(b_0 + c_0) = 0,$$

then the bits in a single row of  $M$  are pairwise uniform.

**Proof.** We'll prove this by computing the expected product of two distinct bits,  $x$  and  $y$ , which both come from the  $i$ th column of  $M$ . We will compute the conditional expectation of  $xy$  given the group of rows that  $x, y$  were sampled from.

We first notice that conditioned on  $x$  coming from one type of row and  $y$  coming from another,  $x$  and  $y$  are independent of each other, and by the uniformity of individual bits in each group,  $\mathbb{E}[xy \mid x, y \sim \text{different groups}] = 0$ .

Restricting our attention now to pairs of bits from within the same group, we compute the conditional expectations. If both bits come from the  $A$  rows, they are perfectly correlated. On the other hand, if both bits come from the  $B$  or  $C$  rows their correlation is as we computed above,  $-\frac{1}{b\ell-1}$  or  $-\frac{1}{c\ell-1}$  respectively. Therefore we can simplify

$$\begin{aligned}
 \mathbb{E}[xy] &= \beta \cdot \mathbb{E}[xy \mid P(a) = 1] + (1 - \beta) \cdot \mathbb{E}[xy \mid P(a) = 0] \\
 &= +\beta \left( \frac{\binom{a\ell}{2}}{\binom{d\ell}{2}} + \mathbb{E}[xy \mid x, y \sim B, P(a) = 1] \cdot \frac{\binom{b_1\ell}{2}}{\binom{d\ell}{2}} + \mathbb{E}[xy \mid x, y \sim C, P(a) = 1] \cdot \frac{\binom{c_1\ell}{2}}{\binom{d\ell}{2}} \right) \\
 &\quad + (1 - \beta) \left( \frac{\binom{a\ell}{2}}{\binom{d\ell}{2}} + \mathbb{E}[xy \mid x, y \sim B, P(a) = 0] \cdot \frac{\binom{b_0\ell}{2}}{\binom{d\ell}{2}} + \mathbb{E}[xy \mid x, y \sim C, P(a) = 0] \cdot \frac{\binom{c_0\ell}{2}}{\binom{d\ell}{2}} \right) \\
 &= \frac{\ell}{2\binom{d\ell}{2}} \left( a(a\ell - 1) - \beta(b_1 + c_1) - (1 - \beta)(b_0 + c_0) \right), \tag{4.3}
 \end{aligned}$$

where (4.3) gives us the condition of the claim. ◀

Finally, we are done given that we can find positive integers satisfying the constraints

$$\begin{aligned}
 d - a &= b_1 + c_1 = b_0 + c_0 && \text{(from (4.1))} \\
 0 &= a + \beta(b_1 - b_0) + \delta(c_1 - c_0) && \text{(from (4.2))} \\
 0 &= a(\ell - 1) - \beta(b_1 + c_1) - (1 - \beta)(b_0 + c_0) && \text{(from (4.3))}
 \end{aligned}$$

The following can be verified to satisfy the constraints above:

$$\begin{aligned}
 a &:= 2(\beta - \delta)\ell; && b_1, c_0 := ((\beta - \delta)(\ell - 1) - 1)\ell; \\
 b_0, c_1 &:= ((\beta - \delta)(\ell - 1) + 1)\ell; && d := 2(\beta - \delta)\ell^2.
 \end{aligned}$$

By our choice of  $\ell = 2^k |S|LR$  and since  $\beta - \delta = \frac{\beta - \mathbb{E}[P(x)]}{L}$ , we can choose  $R$  large enough so that  $(\beta - \delta)(\ell - 1) > 1$ , and because  $\beta\ell$  and  $\delta\ell$  are integers, these are all also positive integers, as required.

We compute the number of satisfied assignments as a function of the total, which is

$$\beta \frac{b_0}{d} + \delta \frac{c_0}{d} = \beta - \frac{\varepsilon'}{2} + \frac{1}{\ell} \left( \frac{1 + \varepsilon'}{2} - \beta \right).$$

The conclusion thus holds, with  $\tilde{\varepsilon} \stackrel{\text{def}}{=} \frac{\varepsilon'}{2} - \frac{1}{\ell} \left( \frac{1 + \varepsilon'}{2} - \beta \right)$ . ◀

## 4.2 $t - 1$ -wise uniform distributions over $\beta$ -satisfying assignments

We now prove the generalization of the statement in the previous section to  $t$ -wise uniform distributions over  $\beta$ -satisfying assignments.

► **Theorem 12.** *Let  $P : \{\pm 1\}^k \rightarrow \{0, 1\}$  be a  $k$ -ary Boolean predicate, let  $t \geq 2$  be an integer, and let  $\nu$  be a  $(t-1)$ -wise uniform distribution over assignments  $\{\pm 1\}^k$  so that there exist a multiset  $S \subseteq \{\pm 1\}^k$  such that for each  $x \in \{\pm 1\}^k$ ,  $\nu(x) = \mathbb{P}_{s \sim S}(s = x)$ . Suppose also that  $\mathbb{E}_{x \sim \nu}[P(x)] = \beta > \mathbb{E}_{x \sim \{\pm 1\}^k}[P(x)]$ .*

*Then for any constant  $\varepsilon > 0$ , there exists an integer  $r = O_{\varepsilon, k}(|S|^4)$  and a rational  $\tilde{\varepsilon} \leq \varepsilon$  so that there is a  $(t-1)$ -wise uniform distribution  $\theta$  over assignments to groups of  $r$  predicates,  $\{\pm 1\}^{r \times k}$  such that exactly  $(\beta - \tilde{\varepsilon})r$  of the predicates are satisfied by any assignment  $y \sim \theta$ .*

The proof will use a similar, though slightly more involved, construction of  $\theta$  than in the pairwise case. It may be helpful to note that the choice of  $t = 3$  in Theorem 12 will not give the same construction as in Theorem 8 (although of course one could set  $t = 3$  and obtain a result for pairwise-uniform  $\nu$ ). In particular, it will not be enough to choose one string to repeat many times in order to improve the column-wise correlations. Instead, we will repair the correlations in one column at a time, by sampling some subset of the bits in each column from a bespoke distribution, designed to make the columns  $(t-1)$ -wise independent. We will have to be careful with the choice of distribution, so that we can still control the number of satisfying assignments in  $M$  as a whole.

**Proof.** As in the proof of Theorem 8, we will require a well-chosen convex combination of  $\nu$  and the uniform distribution to ensure that the number of satisfying assignments is always the same. We appeal to Claim 9, taking  $S'$  and  $T$  to be as described there, with  $L = O(1/\varepsilon\psi)$  (to be set more precisely later) and  $R = 1$ . For convenience let's let  $\ell \stackrel{\text{def}}{=} 2^k L |S|$  and let's let  $\delta = \beta - \varepsilon'$ .

We also call  $S'_{i=1}$  and  $S'_{i=-1}$  to be the sub-multisets of  $S'$  which have the  $i$ th bit set to 1 and  $-1$  respectively. We notice that a uniform sample from  $S'_{i=1}$  is equivalent to a uniform sample from  $\nu$  conditioned on the  $i$ th bit being 1. Also by the  $(t-1)$ -wise uniformity we have  $|S'_{i=1}| = \ell/2$ . Notice that since  $S'$  is made up of  $2^k L$  copies of  $S$ , the discrepancy in the number of satisfying assignments between  $S_{i=1}$  and  $S_{i=-1}$  is always an integer multiple of  $2^k L$ .

Set  $r$ , the number of rows, be an integer which we will specify later. We also choose the integer  $a$  to represent the size of the correction rows, and  $b_n, c_n$ , the number of copies of  $S'$  and  $T$  for each  $n \in [ak\ell/(2^k L)]$  (where  $n2^k L$  is the number of satisfying assignments in the correction rows). To make sure the number of rows always adds up to  $r$ , we'll need the constraint,

$$r = ak\ell + b_n\ell + c_n\ell \quad \forall z \in \{\pm 1\}^k \quad (4.4)$$

In order to make sure that the columns are  $(t-1)$ -wise independent, we require a ‘‘column repair’’ distribution  $\kappa$  over  $\{\pm 1\}^{a\ell}$ . We will specify this distribution later; for now, we need only that  $\kappa$  is symmetric and that the number of 1s in any  $z \sim \kappa$  is a multiple of  $\ell/2$ . The latter property is because, when we choose some part of column  $i$  according to  $\kappa$ , we will want to fix the rows with copies of  $S_{i=1}$  and  $S_{i=-1}$ .

We generate a sample  $M \in \{\pm 1\}^{r \times k}$  from  $\theta$  in the following fashion:

1. For each  $i \in [k]$ , independently sample a string  $z_i \sim \kappa$ . Add  $a\ell$  rows to  $M$ , where in the  $i$ th column we put the bits of  $z_i$ , and we set the remaining row bits so that if  $z_i$  has  $(a - a')\ell/2$  entries of value 1 and  $a'\ell/2$  entries of value  $-1$ , then we end up with  $a'$  copies of  $S'_{i=-1}$  and  $a - a'$  copies of  $S'_{i=1}$ . Call these rows  $A_i$ .
2. Compute the integer  $n$  such that  $n \cdot 2^k L$  is the number of rows in  $\cup_{i=1}^k A_i$  containing satisfying assignments to  $P$ , given our choices of  $z_i \forall i \in [k]$ .

3. Add  $b_n \ell$  rows to  $M$  which contain  $b_n$  copies of each string from  $S$ . Call these rows  $B$ .
4. Add  $c_n \ell$  rows to  $M$  which contain  $c_n$  copies of each string from  $T$ . Call these rows  $C$ .
5. Randomly permute the rows of  $M$ .

So that the number of satisfying assignments  $\Lambda$  is always the same, we require that

$$\Lambda = n2^k L + b_n \cdot \beta \ell + c_n \cdot \delta \ell \quad \forall n \in [ak\ell/(2^k L)] \quad (4.5)$$

Now, we will derive the conditions under which  $(t-1)$ -wise independence holds. As above, we first consider bits that are all contained in a fixed row.

► **Claim 13.** *The bits in a single row of  $M$  are  $(t-1)$ -wise uniform.*

**Proof.** We can condition on the row type,  $A_1, \dots, A_k, B$ , or  $C$ . Sampling a uniform row from  $B$  or  $C$  is equivalent to sampling from  $\nu$  or  $\gamma$ , which are  $(t-1)$ -wise uniform. Since  $\kappa$  is symmetric, sampling a row from  $A_i$  is equivalent to sampling from  $\nu$  as well, and we are done. ◀

From the claim above, if we condition on the value in  $d < t-2$  columns, the remaining  $t-2-d$  columns will remain identically distributed; this is because the rows are  $(t-1)$ -wise uniform, so after conditioning the distribution in each row will remain  $(t-1-d)$ -wise uniform. Thus, proving that each column is  $(t-1)$ -wise uniform suffices to prove  $(t-1)$ -wise uniformity on the whole.

The following lemma states that we may in fact choose  $\kappa$  so that this condition holds exactly.

► **Lemma 14.** *Let  $y \in \{\pm 1\}^{r-al}$  be a perfectly balanced string. If  $al > h_1 \cdot \sqrt{tr}$  for a fixed constant  $h_1$  and  $\sqrt{r} \geq (t-1)\ell 2^{h_2 t}$  for a fixed constant  $h_2$ , then there is a distribution  $\kappa$  over  $\{\pm 1\}^{al}$ , supported on strings which have a number of 1s which is a multiple of  $\ell/2$ , such that if  $x$  is sampled by choosing  $z \sim \kappa$ , concatenating  $z$  with  $y$  and applying a random permutation, then for any  $S \subset [r]$  with  $|S| \leq t-1$ ,  $\mathbb{E}[x^S] = 0$ .*

Since each column is distributed as the string  $x$  described in the lemma statement, the lemma suffices to give us  $(t-1)$ -wise uniformity of the columns. We'll prove the lemma below, but first we conclude the proof of the theorem statement.

We now choose the parameters to satisfy our constraints. We have the requirements:

$$\begin{aligned} \Lambda &= n2^k L + b_n \beta \ell + c_n \delta \ell \quad \forall n \in [ak\ell/(2^k L)] && \text{(from (4.5))} \\ r - ak\ell &= b_n \ell + c_n \ell \quad \forall n \in [ak\ell/(2^k L)] && \text{(from (4.4))} \\ al &\geq h_1 \sqrt{tr} && \text{(from Lemma 14)} \\ \sqrt{r} &\geq (t-1)\ell 2^{h_2 t} && \text{(from Lemma 14)} \end{aligned}$$

where  $h_1$  and  $h_2$  are universal constants. The below choice of integer parameters satisfies these requirements, as well as the requirement of always being non-negative:

$$\begin{aligned} u &= \left( \beta - \mathbb{E}_{x \sim \{\pm 1\}^k} [P(x)] \right) 2^k |S|; & L &= u \cdot \max(1, \lceil h_1 + h_2 \rceil) \cdot \left\lceil \frac{1}{\varepsilon} \right\rceil \cdot k; & \ell &= 2^k L |S|; \\ a &= \left\lceil h_1 2^{h_2 t/2} t k \right\rceil; & r &= \left\lceil \frac{a^2}{h_1^2 t} \right\rceil \cdot \ell^2; \\ b_0 &= \frac{1}{2} \left( \frac{1}{\ell} r - ak \right); & b_{n+1} &= b_n - \frac{2^k L}{u}; \end{aligned}$$

$$c_0 = \frac{1}{2} \left( \frac{1}{\ell} r - ak \right); \quad c_{n+1} = c_n + \frac{2^k L}{u}.$$

Finally, we have that the fraction of satisfying rows in  $M$  is always exactly

$$\frac{\Lambda}{r} = \frac{\frac{1}{2}(r - ak\ell)\beta + \frac{1}{2}(r - ak\ell)\delta}{r} = \beta - \frac{\varepsilon'}{2} - O\left(\frac{ak\ell}{r}\right).$$

The latter term is  $O(\frac{1}{\ell})$ , and we have chosen  $L$  large enough so that it is smaller than  $\varepsilon'/2$ .  $\blacktriangleleft$

**Proof of Lemma 14.** For convenience, call  $m \stackrel{\text{def}}{=} r - a\ell$ . Recall that we take  $x$  to be sampled by taking a balanced string  $y \in \{\pm 1\}^m$ , sampling  $z \sim \kappa$ , appending  $z$  to  $y$  and then applying a uniform permutation to the coordinates.

We will solve for  $\kappa$  with a linear program (LP) over the probability  $p_z$  of each string  $z \in \{\pm 1\}^{a\ell}$ . We have the program

$$\begin{aligned} \forall S \in [m], |S| \in \{1, \dots, t-1\} : & \sum_{\substack{z \in \{\pm 1\}^{a\ell} \\ (\ell/2) \mid \sum_j z_j}} \mathbb{E} \left[ x^S \mid \sum_i x_i = \sum_{j \in [a\ell]} z_j \right] \cdot p_z = 0 \\ \forall z \in \{\pm 1\}^{a\ell} \text{ s.t. } \frac{\ell}{2} \mid \sum_j z_j : & p_z \geq 0 \end{aligned}$$

Since we can take any solution to this LP and scale the  $p_z$  so that they sum to 1, the feasibility of this program implies our conclusion. So suppose by way of contradiction that this LP is infeasible. Then Farkas' lemma implies that there exists a  $q \in \mathbb{R}^{t-1}$  such that

$$\forall z \in \{\pm 1\}^{a\ell} \text{ s.t. } \frac{\ell}{2} \mid \sum_j z_j, \quad \sum_{\substack{S \subseteq [m] \\ |S| \in \{1, \dots, t-1\}}} \mathbb{E} \left[ x^S \mid \sum_i x_i = \sum_{j \in [a\ell]} z_j \right] \cdot y_S > 0.$$

Without loss of generality, we scale  $q$  so that  $\sum_S q_S^2 = 1$ . Moreover by the symmetry of the expectation over subsets  $S$ , we can assume that  $q_S = q_T$  whenever  $|S| = |T|$ . This implies that the degree- $t$  mean-zero polynomial

$$q(x) = \sum_{\substack{S \subseteq [m] \\ 1 \leq |S| \leq t-1}} q_S \cdot \chi_S(x)$$

has positive expectation over every layer of the hypercube with  $|\sum_i x_i| = d$  such that  $d \leq a\ell$  and  $\frac{\ell}{2} \mid d$ . Furthermore,  $q$  is a symmetric polynomial, which implies that it takes the same value on all inputs of a fixed Hamming weight; this implies that it takes positive values on every inputs  $x$  with  $|\sum x_i| \in [2a] \cdot \frac{\ell}{2}$ .

The following fact will give us the contradiction we desire:

► **Fact 15** (Tails of low-degree polynomials [6], see Theorem 4.1 in [1]). *Let  $f : \{0, 1\}^m \rightarrow \mathbb{R}$  be a degree- $t$  polynomial with mean zero and variance 1. Then, there exist universal constants  $c_1, c_2 > 0$  such that  $\mathbb{P}[p \leq -2^{-c_1 t}] \geq 2^{-c_2 t}$ .*

We will show that since  $q$  takes positive value on every hypercube slice of discrepancy  $\frac{\ell}{2} \cdot [2a]$ , this implies that it takes positive values on most hypercube slices with discrepancy at most  $a\ell$ . Because we have chosen  $a\ell$  so that this comprises the bulk of the hypercube, this in turn will contradict Fact 15.

In fact, because  $q$  is symmetric and of degree  $t - 1$  over the hypercube, we can equivalently write  $q$  as a degree- $(t - 1)$  polynomial in the single variable  $x' := \sum_i x_i$ ,  $q(x) = g(\sum_i x_i) = \sum_{s \in \{0, \dots, t-1\}} g_s \cdot (\sum_i x_i)^s$ . Viewing  $g$  as a univariate polynomial over the reals,  $g$  has at most  $t - 1$  roots. Therefore we conclude that  $q$  can only be non-positive on at most  $t - 1$  intervals of layers of discrepancy  $(i\ell/2, (i + 1)\ell/2)$ . So for at least  $2a\ell - (t - 1)\frac{\ell}{2}$  slices of the hypercube around 0,  $q$  takes positive value.

Each slice of the hypercube has probability mass at most  $\frac{1}{\sqrt{\frac{\pi}{2}(m+a\ell)}}$ . By our choice of  $a, \ell, m$  and by a Chernoff bound,

$$\mathbb{P}(q(x) > 0) \geq \mathbb{P}\left(\left|\sum_i x_i\right| \leq a\ell\right) - \frac{(t-1)\ell}{2\sqrt{m+a\ell}} > 1 - 2^{-c_2 t},$$

which contradicts Fact 15. ◀

## 5 SOS lower bounds for CSPs with exact objective constraints

In this section we put things together and show how to extend Theorem 12 to prove Theorem 2. As discussed briefly in Section 1.1, our random instance of the  $CSP(P^\pm)$  will be sampled in a somewhat non-standard way, which we will refer to as “batch-sampling.” This is because, in order to apply Theorem 12 to a random instance  $\Phi$  of a Boolean CSP, we need to partition  $\Phi$ ’s constraints into groups of  $r$  non-intersecting constraints for some integer  $r$ , while also maintaining the expansion properties required by Theorem 5.

We first prove Theorem 2 as stated, for random CSPs sampled from a slightly different distribution. Then in Section 5.2 we show that for a “standard” random CSP with  $m = o(n^{3/2})$  constraints, we can still get a theorem along the lines of Theorem 2.

### 5.1 Exact objective constraints for batch-sampled random CSPs

Suppose that  $P$  is a  $k$ -ary predicate, and let  $r$  be some positive integer which divides  $m$ . We’ll “batch-sample” an  $n$ -variate random  $CSP(P^\pm)$  with  $m$  clauses as follows:

1. Choose independently  $m/r$  subsets each of  $r \cdot k$  distinct variables uniformly at random from  $[n]$ ,  $S_1, \dots, S_m$
2. For each  $j \in [m/r]$ ,  $S_j = \{x_{i_1}, \dots, x_{i_{rk}}\}$ :
  - Choose a random signing of  $P$ ,  $z_j \in \{\pm 1\}^k$
  - To each block of  $k$  variables in  $S_j$ ,  $(x_{i_{(\ell-1) \cdot k+1}}, \dots, x_{i_{\ell k}})$  for  $\ell \in [r]$ , add the predicate  $P$  with signing  $z_j$ .

► **Theorem 16** (Restatement of Theorem 2). *Let  $P$  be a  $k$ -ary predicate, and let  $\nu$  be a  $(t - 1)$ -wise uniform distribution over  $\{\pm 1\}^k$  under which  $\mathbb{E}_\nu[P] = \beta$ . Then for each constant  $\varepsilon > 0$  there is a choice of positive integer  $r$  such that for a random instance of  $CSP(P^\pm)$  on  $n$  variables with  $m = \Delta n$  constraints for sufficiently large  $\Delta$  and  $r \mid m$ , sampled as detailed above, there is a degree- $\Omega(\frac{n}{\Delta^{2/(t-2)} \log \Delta})$  SOS pseudodistribution which satisfies with pseudovariance zero the constraint  $\text{OBJ}(x) = \beta - \varepsilon_r$ , where  $\varepsilon_r < \varepsilon$ . This is also true when cardinality constraints are imposed as in Theorem 1.*

**Proof.** This distribution over instances is equivalent to the standard notion of sampling a random CSP with  $m/r$  constraints in the composite predicates from Theorem 12: a scope is chosen independently and uniformly at random for each predicate. Therefore, if we replace each collection of constraints corresponding to  $S_j$  with the composite predicate from Theorem 12, and modify  $\nu$  in accordance with the signing  $z_j$ , we have a  $(t - 1)$ -wise uniform

distribution over solutions to the composite predicates supported entirely on assignments which satisfy exactly  $\beta - \varepsilon_r$  of the clauses. Combining this with the expansion theorem (Theorem 6), we have our conclusion. ◀

## 5.2 Exact objective constraints for sparse random CSPs.

Though the batch-sampled distribution over CSPs for which Theorem 2 holds is slightly non-standard, here we show that with minimal effort, we can prove a similar theorem for sparse random instances sampled in the usual manner, when  $m = o(n^{3/2})$ .

► **Theorem 17.** *Let  $P$  be a  $k$ -ary predicate, let  $\nu$  be a  $(t - 1)$ -wise uniform distribution over  $\{\pm 1\}^k$  such that  $\mathbb{E}_\nu[P] = \beta$ , and suppose we sample a random instance  $\Phi$  of a CSP( $P^\pm$ ) in the usual way, by selecting  $m$  random signed  $P$ -constraints on  $n$  variables. Then if  $m = \Delta n = o(n^{3/2})$  for sufficiently large  $\Delta$ , with high probability over the choice of  $\Phi$ , for each  $\varepsilon > 0$  there exists some constant  $\varepsilon_\Phi \leq \varepsilon$  such that there is a degree- $\Omega_\varepsilon(\frac{n}{\Delta^{2/(t-2)} \log \Delta})$  pseudodistribution which satisfies with pseudovariance zero the constraint  $\text{OBJ}(x) = \beta - \varepsilon_\Phi$  and a Hamming weight constraint  $\sum_{i \in [n]} x_i = B$  for  $|B| = O(\sqrt{n})$ .*

**Proof.** Fix  $\varepsilon$ , and let  $r$  be the corresponding constant required to achieve objective  $\text{OBJ}(x) = \beta - \varepsilon^*$  under Theorem 12 for  $\varepsilon^* < \varepsilon/2$ .

We first couple the standard sampling procedure for a random  $P$ -CSP to a different sampling procedure. For simplicity we at first ignore the possible signings of  $P$ , and assume we work only with un-negated variables; later we explain how to modify the proof to accomodate negative literals.

We sample a random CSP by independently and uniformly choosing  $m$  random scopes  $S_1, \dots, S_m$ . For each  $\ell \in \{0, 1, \dots, \lfloor m/r \rfloor - 1\}$ , the probability that  $S_{\ell r + 1}, \dots, S_{(\ell + 1)r}$  have non-intersecting scopes is at least

$$\mathbb{P}[\cap_{j \in [r]} S_j = \emptyset] = \prod_{i=2}^r \mathbb{P}[S_i \cap (\cap_{j < i} S_j) = \emptyset \mid \cap_{j < i} S_j = \emptyset] = \prod_{i=2}^r \left(1 - i \frac{k}{n}\right) \geq 1 - O\left(\frac{r \cdot k}{n}\right).$$

So with high probability for all but  $O(\frac{m}{n})$  of the intervals of constraints  $j \in [\ell \cdot r + 1, (\ell + 1)r]$ , the constraints will be non-intersecting. Call this the “non-intersecting configuration”.

Define a “collision configuration” to be a choice of scopes for which the above condition does not hold; that is, a specific way in which  $S_j$  intersects with one or more  $S_{j'}$  when  $j, j' \in [\ell \cdot r + 1, (\ell + 1)r]$ . Each of the  $\approx \binom{2kr}{r}$  collision configurations has a fixed probability of occurring (which may be easily calculated), and the total sum of these probabilities is at most  $O(r \cdot k/n)$ .

Let  $\mathcal{D}_r^{(m)}$  be the multinomial distribution which describes the number of occurrences of each configuration for a random CSP with  $m$  constraints ( $\lfloor m/r \rfloor$  configurations). We couple the standard sampling procedure with the following alternative sampling procedure: we first sample  $c \sim \mathcal{D}_r^{(m)}$  to determine how many configurations of each type there are. Then, for each collision configuration specified by  $c$ , sample the scope (of size  $< k \cdot r$ ) for each of the collision configurations independently and uniformly at random. Also, sample an additional  $(m \bmod r)$  scopes of  $k$  variables for the “leftover copies” of  $P$ . Finally, sample the scopes of the non-intersecting configurations specified by  $c$  independently uniformly at random. The coupling of the two processes is immediate.

Let  $C$  be the number of collision configurations plus  $(m \bmod r)$ , the number of leftover copies. As shown above, with high probability over  $c \sim \mathcal{D}_r^{(m)}$ , the number of collision configurations is at most  $O(m/n) = o(n^{1/2})$ , so  $C = o(n^{1/2}) = o(m)$ .

From our alternate sampling procedure, we conclude that with high probability we can meet the conditions of Theorem 6 by fixing an arbitrary variable assignment to any collision configuration. That is, we could alternately first sample the collision configurations and leftover copies, and then set all of the variables present inside be set to (say) False. We take note of how many constraints in the  $P$ -CSP are and are not satisfied by this unary assignment, and we correspondingly amend  $\varepsilon^*$  to  $\varepsilon_\Phi$ . Since with high probability at most  $o(m)$  constraints are fixed, we retain the property that  $\varepsilon_\Phi \leq \varepsilon^* + o(1) \leq \varepsilon$ .

Now, if we wish to satisfy a Hamming weight constraint, we add arbitrary matching and unary constraints to get the desired Hamming weight; at most  $O(C)$  unary constraints are needed to compensate for the  $\leq Ckr$  variables we set to False.

Finally, we sample the remaining non-intersecting configurations independently; by Theorem 6 when  $C = o(n^{1/2})$ , the expansion properties we require are met for the composite predicates on the non-intersecting configurations. Since this occurs with high probability, we are done.

To extend the argument to allow predicates on negative literals, we couple with a slightly more elaborate sampling procedure: for each signing pattern  $z \in \{\pm 1\}^k$ , we draw a separate set of  $m_z$  predicates (where  $m_z$  may either be deterministic or sampled from a multinomial distribution). For each signing separately we repeat the argument above, and then in the final sampling procedure we sample counts  $c_z$  for each signing  $z$ , add the leftover copies and collision configurations separately for each signing, add the unary constraints, and then sample the remaining non-intersecting copies. ◀

## 6 Conclusions

In this work we have shown that, in the context of random Boolean CSPs, the following strategies do *not* give SOS any additional refutation power: (i) trying out all possible Hamming weights for the solution; (ii) trying out all possible (exact) values for the objective function. We also gave the first known SOS lower bounds for the Min- and Max-Bisection problems.

We end by mentioning some open directions. There are two technical challenges arising in our work that look approachable. The first is to extend our results from Section 4 on “exactifying” distributions to the case of larger alphabets. The second is to prove (or disprove) that the “random\*” and “purely random” distributions discussed in Remark 1.1 are  $o(1)$ -close (depending on  $m(n)$ ).

Finally, we suggest investigating further strategies for handling hard constraints in the context of SOS lower bounds. Sometimes this is not too difficult, especially when reducing from linear predicates such as 3XOR, where there are perfectly satisfying SOS solutions. Other times, it’s of moderate difficulty, perhaps as in this paper’s main Theorem 1 and Theorem 2. In still other cases it appears to be very challenging.

One difficult case seems to be in the context of SOS lower bounds for refuting the existence of large cliques in random graphs. In [4] it is shown that in a  $G(n, 1/2)$  random graph, with high probability degree- $\Omega(\log n)$  SOS thinks there is a clique of size  $\omega := n^{1/2-\varepsilon}$ . (Here  $\varepsilon > 0$  can be any constant.) However, it’s merely the case that  $\tilde{\mathbb{E}}[\text{clique size}] \geq \omega$ , and it is far from clear how to upgrade the SOS solution so as to actually satisfy the constraint “clique size =  $\omega$ ” with pseudovariance zero. Besides being an improvement for its own sake, it would be very desirable to have such an SOS solution for the purposes of further reductions; for example, it would greatly simplify the recent proofs of SOS lower bounds for approximate Nash welfare in [15]. It also seems it might be useful for tackling SOS lower bounds for coloring and stochastic block models.

Finally, we leave as open one more “hard constraint” challenge that arises even in the simple context of random 3XOR or 3SAT. Suppose one tried to refute random  $m$ -constraint 3XOR instances by trying to refute the following statement for all quadruples  $(k_{001}, k_{010}, k_{100}, k_{111})$  that sum to  $m$ :

“exactly  $k_a$  constraints are satisfied with assignment  $a$ ”, for each  $a \in \{001, 010, 100, 111\}$ .

As far as we know, constant-degree SOS may succeed with this strategy when  $m = O(n)$ . It is natural to believe that there is (whp) an  $\Omega(n)$ -degree SOS pseudodistribution that satisfies all of the above constraints with pseudovariance zero when  $k_{001} = k_{010} = k_{100} = k_{111} = m/4$ , but we do not know how to construct one.

## Abstract

In this paper we introduce the *semi-online* model that generalizes the classical online computational model. The semi-online model postulates that the unknown future has a predictable part and an adversarial part; these parts can be arbitrarily interleaved. An algorithm in this model operates as in the standard online model, i.e., makes an irrevocable decision at each step.

We consider bipartite matching in the semi-online model. Our main contributions are competitive algorithms for this problem and a near-matching hardness bound. The competitive ratio of the algorithms nicely interpolates between the truly offline setting (i.e., no adversarial part) and the truly online setting (i.e., no predictable part).

## 1 Introduction

Modeling future uncertainty in data while ensuring that the model remains both realistic and tractable has been a formidable challenge facing the algorithms research community. One of the more popular, and reasonably realistic, such models is the online computational model. In its classical formulation, data arrives one at a time and upon each arrival, the algorithm has to make an irrevocable decision agnostic of future arrivals. Online algorithms boast a rich literature and problems such as caching, scheduling and matching, each of which

abstracts common practical scenarios, have been extensively investigated [4, 20]. Competitive analysis, which measures how well an online algorithm performs compared to the best offline algorithm that knows the future, has been a linchpin in the study of online algorithms.

While online algorithms capture some aspect of the future uncertainty in the data, the notion of competitive ratio is inherently worst-case and hence the quantitative guarantees it offers are often needlessly pessimistic. A natural question that then arises is : how can we avoid modeling the worst-case scenario in online algorithms? Is there a principled way to incorporate some knowledge we have about the future? There have been a few efforts trying to address this point from different angles. One line of attack has been to consider oracles that offer some advice on the future; such oracles, for instance, could be based on machine-learning methods. This model has been recently used to improve the performance of online algorithms for reserve price optimization, caching, ski-rental, and scheduling [19, 16, 14]. Another line of attack posits a distribution on the data [5, 17, 21] or the arrival model; for instance, random arrival models have been popular in online bipartite matching and are known to beat the worst-case bounds [10, 18]. A different approach is to assume a distribution on future inputs; the field of stochastic online optimization focuses on this setting [8]. The advice complexity model, where the partial information about the future is quantified as advice bits to an online algorithm, has been studied as well in complexity theory [3].

In this work we take a different route. At a very high level, the idea is to tease the future data apart into a predictable subset and the remaining adversarial subset. As the names connote, the algorithm can be assumed to know everything about the former but nothing about the latter. Furthermore, the predictable and adversarial subsets can arrive arbitrarily interleaved yet the algorithm still has to operate as in the classical online model, i.e., make irrevocable decisions upon each arrival. Our model thus offers a natural interpolation between the traditional offline and online models; we call ours the *semi-online* model. Our goal is to study algorithms in the semi-online model and to analyze their competitive ratios; unsurprisingly, the bounds depend on the size of the adversarial subset. Ideally, the competitive ratio should approach the offline optimum bounds if the adversarial fraction is vanishing and should approach the online optimum bounds if the predictable fraction is vanishing.

**Bipartite matching.** As a concrete problem in the semi-online setting, we focus on bipartite matching. In the well-known online version of the problem, which is motivated by online advertising, there is a bipartite graph with an offline side that is known in advance and an online side that is revealed one node at a time together with its incident edges. In the semi-online model, the nodes in the online side are partitioned into a predicted set of size  $n - d$  and an adversarial set of size  $d$ . The algorithm knows the incident edges of all the nodes in the former but nothing about the nodes in the latter. We can thus also interpret the setting as online matching with partial information and predictable uncertainty (pardon the oxymoron). In online advertising applications, there are many predictably unpredictable events. For example, during the soccer world cup games, we know the nature of web traffic will be unpredictable but nothing more, since the actual characteristics will depend on how the game progresses and which team wins.

We also consider a variant of semi-online matching in which the algorithm does not know which nodes are predictable and which are adversarial. In other words, the algorithm receives a prediction for all online nodes, but the predictions are correct only for some  $n - d$  of them. We call this the *agnostic* case.

**Main results.** In this paper, we assume that the optimum solution on the bipartite graph, formed by the offline nodes on one side and by the predicted and adversarial nodes on the other, is a perfect matching<sup>1</sup>. We present two algorithms and a hardness result for the semi-online bipartite matching problem. Let  $\delta = d/n$  be the fraction of adversarial nodes. The Iterative Sampling algorithm, described in Section 3, obtains a competitive ratio of  $(1 - \delta + \frac{\delta^2}{2}(1 - 1/e))^2$ . This algorithm “reserves” a set of offline nodes to be matched to the adversarial nodes by repeatedly selecting a random offline node that is unnecessary for matching the predictable nodes. It is easy to see that algorithms that deterministically reserve a set of offline nodes can easily be thwarted by the adversary.

The second algorithm, described in Section 4, achieves an improved competitive ratio of  $(1 - \delta + \delta^2(1 - 1/e))$ . This algorithm samples a maximum matching in the predicted graph by first finding a matching skeleton [7, 15] and then sampling a matching from each component in the skeleton using the dependent rounding scheme of [6]. This allows us to sample a set of offline nodes that, in expectation, has a large overlap with the set matched to adversarial nodes in the optimal solution. Surprisingly, in Section 5, we show that it is possible to sample from arbitrary set systems so that the same “large overlap” property is maintained. We prove the existence of such distributions using LP duality and believe that this result may be of independent interest.

To complement the algorithms, in Section 6 we obtain a hardness result showing that the above competitive ratios are near-optimal. In particular, no randomized algorithm can achieve a competitive ratio better than  $(1 - \delta e^{-\delta}) \approx (1 - \delta + \delta^2 - \delta^3/2 + \dots)$ . Note that this expression coincides with the best offline bound (i.e., 1) and the best online bound (i.e.,  $1 - 1/e$ ) at the extremes of  $\delta = 0$  and  $\delta = 1$ , respectively. We conjecture this to be the optimal bound for the problem.

**Extensions.** In Section 7, we explore variants of the semi-online matching model, including the agnostic version and fractional matchings, and present upper and lower bounds in those settings. To illustrate the generality of our semi-online model, we consider a semi-online version of the classical ski rental problem. In this version, the skier knows whether or not she’ll ski on certain days while other days are uncertain. Interestingly, there is an algorithm with a competitive ratio of the same form as our hardness result for matchings, namely  $1 - (1 - x)e^{-(1-x)}$ , where  $(1 - x)$  is a parameter analogous to  $\delta$  in the matching problem. We wonder if this form plays a role in semi-online algorithms similar to what  $(1 - 1/e)$  has in many online algorithms [11].

**Other related work.** The use of (machine learned) predictions for revenue optimization problems was first proposed in [19]. The concepts were formalized further and applied to online caching in [16] and ski rental and non-clairvoyant scheduling in [14]. Online matching with forecasts was first studied in [22]; however, that paper is on forecasting the demands rather than the structure of the graph as in our case. The problem of online matching when edges arrive in batches was considered in [15] where a  $(1/2 + 2^{-O(s)})$ -competitive ratio is shown, with  $s$  the number of stages. However, the batch framework differs from ours in that in our case, the nodes arrive one at a time and are arbitrarily interleaved.

<sup>1</sup> Our techniques extend to the case without a perfect matching; we defer the proof of the general case to the full version of the paper.

<sup>2</sup> Observe that an algorithm that ignores all the adversarial nodes and outputs a maximum matching in the predicted graph achieves a competitive ratio of only  $1 - \delta$ .

There has been a lot of work on online bipartite matching and its variants. The RANKING algorithm [13] selects a random permutation of the offline nodes and then matches each online node to its unmatched neighbor that appears earliest in the permutation. It is well-known to obtain a competitive ratio of  $(1 - 1/e)$ , which is best possible. For a history of the problem and significant advances, see the monograph [20]. The ski rental problem has also been extensively studied; the optimal randomized algorithm has ratio  $e/(e - 1)$  [12]. The term “semi-online” has been used in scheduling when an online scheduler knows the sum of the jobs’ processing times (e.g., see [1]) and in online bin-packing when a lookahead of the next few elements is available (e.g., see [2]); our use of the term is more quantitative in nature.

## 2 Model

We now formally define the *semi-online bipartite matching* problem. We have a bipartite graph  $G = (U, V, E_G)$  where  $U$  is the set of nodes available offline and nodes in  $V$  arrive online. Further, the online set  $V$  is partitioned into the *predicted* nodes  $V_P$  and the *adversarial* nodes  $V_A$ . The *predicted graph*  $H = (U, V_P, E_H)$  is the subgraph of  $G$  induced on the nodes in  $U$  and  $V_P$ . Initially, an algorithm only knows  $H$  and is unaware of edges between  $U$  and  $V_A$ . The algorithm is allowed to preprocess  $H$  before any online node actually arrives. In the online phase, at each step, one node of  $V$  is revealed with its incident edges, and has to be either irrevocably matched to some node in  $U$  or abandoned. Nodes of  $V$  are revealed in an arbitrary order<sup>3</sup> and the process continues until all of  $V$  has been revealed.

We note that when a node  $v \in V$  is revealed, the algorithm can “recognize” it by its edges, i.e., if there is some node  $v' \in V_P$  that has the same set of neighbors as  $v$  and has not been seen before, then  $v$  can be assumed to be  $v'$ . There could be multiple identical nodes in  $V_P$ , but it is not important to distinguish between them. If an online node comes that is not in  $V_P$ , then the algorithm can safely assume that it is from  $V_A$ . (In Section 7, we consider a model where the predicted graph can have errors and hence this assumption is invalid.)

We introduce a quantity  $\delta$  to measure the level of knowledge that the algorithm has about the input graph  $G$ . Competitive ratios that we obtain are functions of  $\delta$ . For any graph  $I$ , let  $\nu(I)$  denote the size of the maximum matching in  $I$ . Then we define  $\delta = \delta(G) = 1 - \frac{\nu(H)}{\nu(G)}$ . Intuitively, the closer  $\delta$  is to 0, the more information the predicted graph  $H$  contains and the closer the instance is to an offline problem. Conversely,  $\delta$  close to 1 indicates an instance close to the pure online setting. Note that the algorithm does not necessarily know  $\delta$ , but we use it in the analysis to bound the competitive ratio. For convenience, in this paper we assume that the input graph  $G$  contains a perfect matching. Let  $n = |U| = |V|$  be the number of nodes on each side and  $d = |V_A|$  be the number of adversarial online nodes. In this case,  $\delta$  simplifies to be the fraction of online nodes that are adversarial, i.e.,  $\delta = \frac{|V_A|}{|V|} = \frac{d}{n}$ .

## 3 Iterative Sampling Algorithm

In this section we give a simple polynomial time algorithm for bipartite matching in the semi-online model. We describe the algorithm in two phases: a *preprocessing phase* that finds a maximum matching  $M$  in the predicted graph  $H$  and an *online phase* that processes each node upon its arrival to find a matching in  $G$  that extends  $M$ .

<sup>3</sup> The arrival order can be adversarial, including interleaving the nodes in  $V_P$  and  $V_A$ .

**Algorithm 1:** Iterative Sampling: Preprocessing Phase.

---

```

Function: Preprocess( $H$ ):
  Data: Predicted graph  $H$ 
  Result: Maximum matching in  $H$ , a sequence of nodes from  $U$ 

  Let  $H_0 \leftarrow H, U_0 \leftarrow U$ ;
  for  $i = 1, 2, \dots, d$  do
     $U_i \leftarrow \{u \in U_{i-1} \mid \nu(H_{i-1} \setminus \{u\}) = n - d\}$ ;          /* Set of nodes whose
    removal does not change the size of the maximum matching. */
    Let  $u_i$  be a uniformly random node in  $U_i$ ;
     $H_i \leftarrow H_{i-1} \setminus \{u_i\}$ ;
   $M \leftarrow$  Arbitrary maximum matching in  $H_d$ ;
   $R \leftarrow$  Uniformly random permutation of  $\{u_1, \dots, u_d\}$ ;
  return  $M, R$ 

```

---

**Algorithm 2:** Online Phase.

---

```

 $M, R \leftarrow$  Preprocess( $H$ );
for  $v \in V$  arriving online do
  if  $v \in V_P$  then                                          /* predicted node */
    Match  $v$  to  $M(v)$ ;
  else                                                         /* adversarial node */
    Match  $v$  to the first unmatched neighbor in  $R$ , if one exists; /* RANKING */

```

---

**Preprocessing Phase**

The goal of the preprocessing phase is to find a maximum matching in the predicted graph  $H$ . However, if we deterministically choose a matching, the adversary can set up the neighborhoods of  $V_A$  so that all the neighbors of  $V_A$  are used in the chosen matching, and hence the algorithm is unable to match any node from  $V_A$ . Algorithm 1 describes our algorithm to sample a (non-uniform) random maximum matching from  $H$ .

**Online Phase**

In the online phase nodes from  $V$  arrive one at a time and we are required to maintain a matching such that the online nodes are either matched irrevocably or dropped. In this phase, we match the nodes in  $V_P$  as per the matching  $M$  obtained from the preprocessing phase, i.e., we match  $v \in V_P$  to node  $M(v) \in U$  where  $M(v)$  denotes the node matched to  $v$  by matching  $M$ . The adversarial nodes in  $V_A$  are matched to nodes in  $R$  that are not used by  $M$  using the RANKING algorithm [13]. Algorithm 2 describes the complete online phase of our algorithm.

**Analysis**

For the sake of analysis, we construct a sequence of matchings  $\{M_i^*\}_{i=0}^d$  as follows. Let  $M_0^*$  be an arbitrary perfect matching in  $G$ . For  $i \geq 1$ , by definition of  $U_i$ , there exists a matching  $M_i'$  in  $H_i$  of size  $n - d$  that does not match node  $u_i$ . Hence,  $M_i' \cup M_{i-1}^*$  is a union of disjoint paths and cycles such that  $u_i$  is an endpoint of a path  $P_i$ . Let  $M_i^* = M_{i-1}^* \oplus P_i$ ,

i.e. obtain  $M_i^*$  from  $M_{i-1}^*$  by adding and removing alternate edges from  $P_i$ . It's easy to verify that  $M_i^*$  is indeed a matching and  $|M_i^*| \geq |M_{i-1}^*| - 1$ . Since  $|M_0^*| = n$ , this yields  $|M_i^*| \geq n - i$ ,  $\forall 0 \leq i \leq d$ . Further, by construction,  $M_i^*$  does not match any nodes in  $\{u_1, \dots, u_i\}$ .

► **Lemma 1.** *For all  $0 \leq i \leq d$ , all nodes  $v \in V_P$  are matched by  $M_i^*$ . Further,  $|M_i^*(V_A)| \geq d - i$ , i.e. at least  $d - i$  adversarial nodes are matched by  $M_i^*$ .*

**Proof.** We prove the claim by induction. Since  $M_0^*$  is a perfect matching, the base case is trivially true. By the induction hypothesis, we assume that  $M_{i-1}^*$  matches all of  $V_P$ . Recall that  $M_i'$  also matches all of  $V_P$  and  $M_i^* = M_{i-1}^* \oplus P_i$  where  $P_i$  is a maximal path in  $M_i' \cup M_{i-1}^*$ . Since each node  $v \in V_P$  has degree 2 in  $M_i' \cup M_{i-1}^*$ ,  $v$  cannot be an end point of  $P_i$ . Hence, all nodes  $v \in V_P$  remain matched in  $M_i^*$ . Further, we have  $|M_i^*(V_A)| = |M_i^*| - |M_i^*(V_P)| \geq (n - i) - (n - d) = d - i$  as desired. ◀

Equipped with the sequence of matchings  $M_i^*$ , we are now ready to prove that, in expectation, a large matching exists between the set  $R$  of nodes left unmatched by the preprocessing phase and the set  $V_A$  of adversarial nodes.

► **Lemma 2.**  $\mathbb{E}[\nu(G[R \cup V_A])] \geq d^2/(2n)$  where  $G[R \cup V_A]$  is the graph induced by the reserved vertices  $R$  and the adversarial vertices  $V_A$ .

**Proof.** We construct a sequence of sets of edges  $\{N_i\}_{i=0}^d$  as follows. Let  $N_0 = \emptyset$ . If  $M_{i-1}^*(u_i) \in V_A$ , let  $e_i = \{u_i, M_{i-1}^*(u_i)\}$  be the edge of  $M_{i-1}^*$  incident with  $u_i$  and let  $N_i = N_{i-1} \cup \{e_i\}$ . Otherwise, let  $N_i = N_{i-1}$ . In other words, if the node  $u_i$  chosen during the  $i^{\text{th}}$  step is matched to an adversarial node by the matching  $M_{i-1}^*$ , add the matched edge to set  $N_i$ .

We show by induction that  $N_i$  is a matching for all  $i \geq 0$ .  $N_0$  is clearly a matching. When  $i > 0$ , either  $N_i = N_{i-1}$  (in which case we are done by the inductive hypothesis), or  $N_i = N_{i-1} \cup \{e_i\}$ . Let  $e_i = (u_i, v_i)$  and consider any other edge  $e_j = (u_j, v_j) \in N_{i-1}$ . Since  $u_j \notin H_{i-1}$ , we have  $u_j \neq u_i$ . By definition, node  $v_i$  is matched in  $M_{i-1}^*$ . By construction, this implies that  $v_i$  must be matched in all previous matchings in this sequence, in particular,  $v_i$  must be matched in  $M_j^*$  (since a node  $v \in V_A$  that is unmatched in  $M_{k-1}^*$  can never be matched by  $M_k^*$ ). However, since  $v_j = M_{j-1}^*(u_j)$ , the matching  $M_j^* = M_{j-1}^* \setminus \{e_j\}$  and hence  $v_j$  is not matched in  $M_j^*$ . Hence  $v_i \neq v_j$ . Thus we have shown that  $e_i$  does not share an endpoint with any  $e_j \in N_{i-1}$  and hence  $N_i$  is a matching.

By linearity of expectation we have the following.

$$\mathbb{E}[|N_i|] = \mathbb{E}[|N_{i-1}|] + \Pr_{u_i}[M_{i-1}^*(u_i) \in V_A]$$

However, by Lemma 1, since  $M_{i-1}^*$  matches all of  $V_P$ , we must have  $M_{i-1}^*(V_A) \subseteq U_i$ . Hence,

$$\mathbb{E}[|N_i|] \geq \mathbb{E}[|N_{i-1}|] + \frac{|M_{i-1}^*(V_A)|}{|U_i|} \geq \mathbb{E}[|N_{i-1}|] + \frac{d - (i - 1)}{n}$$

Solving the recurrence with  $|N_0| = 0$  gives

$$\mathbb{E}[|N_d|] \geq \sum_{i=1}^d \frac{i}{n} \geq \frac{d(d+1)}{2n}$$

The lemma follows since  $N_d$  is a matching in  $G[R \cup V_A]$ . ◀

► **Theorem 3.** *There is a randomized algorithm for the semi-online bipartite matching problem with a competitive ratio of at least  $(1 - \delta + (\delta^2/2)(1 - 1/e))$  in expectation.*

**Proof.** Algorithm 1 guarantees that the matching  $M$  found in the preprocessing phase matches all predicted nodes and has size  $n - d = n(1 - \delta)$ . Further, in the online phase, we use the RANKING [13] algorithm on the graph  $G[R \cup V_A]$ . Since RANKING is  $(1 - 1/e)$ -competitive, the expected number of adversarial nodes matched is at least  $(1 - 1/e)\nu(G[R \cup V_A])$ . By Lemma 2, this is at least  $(1 - 1/e)(\frac{d^2}{2n}) = (\delta^2 n/2)(1 - 1/e)$ .

Therefore, the total matching has expected size  $n(1 - \delta + (\delta^2/2)(1 - 1/e))$  as desired. ◀

Using a more sophisticated analysis, we can show that the iterative sampling algorithm yields a tighter bound of  $(1 - \delta + \delta^2/2 - \delta^3/2)$ . However we omit the proof because the next section presents an algorithm with an even better guarantee.

## 4 Structured Sampling

In this section we give a polynomial time algorithm for the semi-online bipartite matching that yields an improved competitive ratio of  $(1 - \delta + \delta^2(1 - 1/e))$ . We first discuss the main ideas in Section 4.1 and then describe the algorithm and its analysis in Section 4.2.

► **Theorem 4.** *There is a randomized algorithm for the semi-online bipartite matching problem with a competitive ratio of at least  $(1 - \delta + \delta^2(1 - 1/e))$  in expectation.*

### 4.1 Main Ideas and Intuition

As with the iterative sampling algorithm, we randomly choose a matching of size  $n - d$  (according to some distribution), and define the *reserved* set  $R$  to be the set of offline nodes that are not matched. As online nodes arrive, we follow the matching for the predicted nodes; for adversarial nodes, we run the RANKING algorithm on the reserved set  $R$ .

Let  $M^*$  be a perfect matching in  $G$ . For a set of nodes  $S$ , let  $M^*(S)$  denote the set of nodes matched to them by  $M^*$ . Call a node  $u \in U$  *marked* if it is in  $M^*(V_A)$ , i.e., it is matched to an adversarial node by the optimal solution. We argue that the number of marked nodes in the set  $R$  chosen by our algorithm is at least  $d^2/n$  in expectation. Since RANKING finds a matching of at least a factor  $(1 - 1/e)$  of optimum in expectation, this means that we find a matching of size at least  $d^2/n \cdot (1 - 1/e)$  on the reserved nodes in expectation. Combining this with the matching of size  $n - d$  on the predicted nodes, this gives a total of  $n - d + d^2/n \cdot (1 - 1/e) = n(1 - \delta + \delta^2(1 - 1/e))$ .

The crux of the proof lies in showing that  $R$  contains many marked nodes. Ideally, we would like to choose a random matching of size  $n - d$  in such a way that each node of  $U$  has probability  $d/n$  of being in  $R$ . Since there are  $d$  marked nodes total,  $R$  would contain  $d^2/n$  of them in expectation. However, such a distribution over matchings does not always exist.

Instead, we use a graph decomposition to guide the sampling process. The marginal probabilities for nodes of  $U$  to be in  $R$  may differ, but nevertheless  $R$  gets the correct total number of marked nodes in expectation.  $H$  is decomposed into bipartite pairs  $(S_i, T_i)$ , with  $|S_i| \leq |T_i|$ , so that the sets  $S_i$  partition  $V_P$  and the sets  $T_i$  partition  $U$ . This decomposition allows one to choose a random matching between  $S_i$  and  $T_i$  of size  $|S_i|$  so that each node in  $T_i$  is reserved with the same probability. Letting  $n_i = |T_i|$  and  $d_i = |T_i| - |S_i|$ , this probability is precisely  $d_i/n_i$ . Finally, we argue that the adversary can do no better than to mark  $d_i$  nodes in  $T_i$ , for each  $i$ . Hence, the expected number of nodes in  $R$  that are marked is at least  $\sum_i (d_i^2/n_i)$ , which we lower bound by  $d^2/n$ .

## 4.2 Proof of Theorem 4

We decompose the graph  $H$  into more structured pieces using a construction from [7] and utilize the key observation that the decomposition implies a *fractional matching*. Recall that a fractional matching is a function  $f$  that assigns a value in  $[0, 1]$  to each edge in a graph, with the property that  $\sum_{e \ni v} f(e) \leq 1$  for all nodes  $v$ . The quantity  $\sum_{e \ni v} f(e)$  is referred to as the *fractional degree* of  $v$ . We use  $\Gamma(S)$  to denote the set of neighbors of nodes in  $S$ .

► **Lemma 5** (Restatement of Lemma 2 from [15]). *Given a bipartite graph  $H = (U, V_P, E_H)$  with  $|U| \geq |V_P|$  and a maximum matching of size  $|V_P|$ , there exists a partition of  $V_P$  into sets  $S_0, \dots, S_m$  and a partition of  $U$  into sets  $T_0, \dots, T_m$  for some  $m$  such that the following holds:*

- $\Gamma(\bigcup_{i < j} S_i) = \bigcup_{i < j} T_i$  for all  $j$ .
- For all  $i < j$ ,  $\frac{|S_i|}{|T_i|} > \frac{|S_j|}{|T_j|}$ .
- There is a fractional matching in  $H$  of size  $|V_P|$ , where for all  $i$ , the fractional degree of each node in  $S_i$  is 1 and the fractional degree of each node in  $T_i$  is  $|S_i|/|T_i|$ . In this matching, nodes in  $S_i$  are only matched with nodes in  $T_i$  and vice versa.

Further, the  $(S_i, T_i)$  pairs can be found in polynomial time.

In [7] and [15], the sets in the decomposition with  $|S_i| < |T_i|$  are indexed with positive integers  $i > 0$ , the sets with  $|S_0| = |T_0|$  get an index of 0, and the ones with  $|S_i| > |T_i|$  get negative indices  $i < 0$ . Under our assumption that  $H$  supports a matching that matches all nodes of  $V_P$ , the decomposition does not contain sets with  $|S_i| > |T_i|$ , as the first such set would have  $|S_i| > |\Gamma(S_i)|$ , violating Hall's theorem. So we start the indices from 0.

Equipped with this decomposition, we choose a random matching between  $S_i$  and  $T_i$  such that each node in  $T_i$  is reserved<sup>4</sup> with the same probability. Since each  $(S_i, T_i)$  pair has a fractional matching, the dependent randomized rounding scheme of [6] allows us to do exactly that.

► **Lemma 6.** *Fix an index  $i$  and let  $S_i, T_i$  be defined as in Lemma 5. Then there is a distribution over matchings with size  $|S_i|$  between  $S_i$  and  $T_i$  such that for all  $u \in T_i$ , the probability that the matching contains  $u$  is  $|S_i|/|T_i|$ .*

**Proof.** Given any bipartite graph  $G'$  and a fractional matching over  $G'$ , the dependent rounding scheme of Gandhi et. al. [6] yields an integral matching such that the probability that any node  $v \in G'$  is matched exactly equals its fractional degree. Since Lemma 5 guarantees a fractional matching such that the fractional degree of each node in  $S_i$  is 1 and the fractional degree of each node in  $T_i$  is  $|S_i|/|T_i|$ , the lemma follows. ◀

We are now ready to complete the description of our algorithm. Algorithm 3 is the preprocessing phase, while the online phase remains the same as earlier (Algorithm 2). In the preprocessing phase, we find a decomposition of the predicted graph  $H$ , and sample a matching using Lemma 6 for each component in the decomposition. In the online phase, we match all predicted online nodes using the sampled matching and use RANKING to match the adversarial online nodes.

Let  $n_i = |T_i|$  and  $d_i = |T_i| - |S_i|$ , and let  $R_i = R \cap T_i$  be the set of reserved nodes in  $T_i$ . Then Lemma 6 says that each node in  $T_i$  lands in  $R_i$  with probability  $d_i/n_i$  (although not independently). We now argue in Lemmas 7 and 8 that the adversary can do no better than to choose  $d_i$  marked nodes in each  $T_i$ .

<sup>4</sup> Recall that we say a node  $u$  is reserved by an algorithm if  $u$  is *not* matched in the predicted graph  $H$ .

---

**Algorithm 3:** Structured Sampling: Preprocessing Phase.
 

---

**Function:** Preprocess( $H$ ):**Data:** Predicted graph  $H$ **Result:** Maximum matching in  $H$ , sequence of nodes from  $U$ Decompose  $H$  into  $\{(S_i, T_i)\}_{i=0}^m$  pairs using Lemma 5. $M_i \leftarrow$  Random matching between  $S_i$  and  $T_i$  using Lemma 6 $M \leftarrow \bigcup_i M_i$ Let  $R_{\text{set}} \subseteq U$  be the set of nodes unmatched by  $M$  $R \leftarrow$  Uniformly random permutation of  $R_{\text{set}}$ **return**  $M, R$ 

► **Lemma 7.** Let  $\ell_i = |M^*(V_A) \cap T_i|$ . That is, let  $\ell_i$  be the number of marked nodes in  $T_i$ . Then for all  $t \geq 0$ ,

$$\sum_{i \leq t} \ell_i \leq \sum_{i \leq t} d_i$$

**Proof.** Fix  $t \leq m$ , and let  $U' = U - \bigcup_{i \leq t} T_i$ . Since there is a perfect matching in the realized graph  $G$ , Hall's Theorem guarantees that there must be at least  $|U'| - |\Gamma_H(U')|$  marked nodes in  $U'$  where  $\Gamma_H(U')$  denotes the set of neighbors of  $U'$  in the predicted graph  $H$ . That is,

$$\sum_{i > t} \ell_i \geq |U'| - |\Gamma_H(U')|$$

But Lemma 5 tells us that  $\Gamma(\bigcup_{i \leq t} S_i) = \bigcup_{i \leq t} T_i$ , hence there is no edge between  $U'$  and  $\bigcup_{i \leq t} S_i$ . That is,  $\Gamma_H(U') \subseteq V_P - \bigcup_{i \leq t} S_i$ . Hence,

$$|\Gamma_H(U')| \leq |V_P| - \sum_{i \leq t} |S_i| = n - d - \sum_{i \leq t} (n_i - d_i)$$

Further,  $|U'| = |U| - |\bigcup_{i \leq t} T_i| = n - \sum_{i \leq t} n_i$ . Putting this together,

$$\begin{aligned} \sum_{i > t} \ell_i &\geq |U'| - |\Gamma_H(U')| \\ &\geq n - \sum_{i \leq t} n_i - \left( n - d - \sum_{i \leq t} (n_i - d_i) \right) \\ &= d - \sum_{i \leq t} d_i \end{aligned}$$

Recalling that  $\sum_{i \leq m} \ell_i = d$ , we see that  $\sum_{i \leq t} \ell_i = d - \sum_{i > t} \ell_i \leq \sum_{i \leq t} d_i$ , as desired. ◀

► **Lemma 8.** Let  $0 < a_0 \leq a_1 \leq \dots \leq a_m$  be a non-decreasing sequence of positive numbers, and  $\ell_0, \dots, \ell_m$  and  $k_0, \dots, k_m$  be non-negative integers, such that  $\sum_{i=0}^m \ell_i = \sum_{i=0}^m k_i$  and for all  $t \leq m$ ,  $\sum_{i \leq t} \ell_i \leq \sum_{i \leq t} k_i$ . Then

$$\sum_{i=0}^m \ell_i a_i \geq \sum_{i=0}^m k_i a_i.$$

**Proof.** We claim that for any fixed sequence  $k_0, \dots, k_m$ , the minimum of the left-hand side ( $\sum_i \ell_i a_i$ ) is attained when  $\ell_i = k_i$  for all  $i$ . Suppose for contradiction that  $\{\ell_i\}$  is the lexicographically-largest minimum-attaining assignment that is not equal to  $\{k_i\}$  and let  $j$  be the smallest index with  $\ell_j \neq k_j$ . It must be that  $\ell_j < k_j$  to satisfy  $\sum_{i \leq j} \ell_i \leq \sum_{i \leq j} k_i$ . Also,  $\sum_{i=0}^m \ell_i = \sum_{i=0}^m k_i$  implies that  $j < m$  and that there must be an index  $j' > j$  such that  $\ell_{j'} > k_{j'}$ . Let  $j'$  be the lowest such index.

Let  $\ell'_i = \ell_i$  for all  $i \notin \{j, j'\}$ . Set  $\ell'_j = \ell_j + 1$  and  $\ell'_{j'} = \ell_{j'} - 1$ . Notice that we still have  $\sum_{i \leq t} \ell'_i \leq \sum_{i \leq t} k_i$  for all  $t$  and  $\sum_{i=0}^m \ell'_i = \sum_{i=0}^m k_i$ , and  $\{\ell'_i\}$  is lexicographically larger than  $\{\ell_i\}$ . In addition,

$$\sum_i \ell'_i a_i = \sum_i \ell_i a_i + a_j - a_{j'} \leq \sum_i \ell_i a_i,$$

which is a contradiction. ◀

We need one last technical observation before the proof of the main result.

► **Lemma 9.** *Let  $d_i, n_i$  be positive numbers with  $\sum_i d_i = d$  and  $\sum_i n_i = n$ . Then*

$$\sum_i \frac{d_i^2}{n_i} \geq \frac{d^2}{n}$$

**Proof.** We invoke Cauchy-Schwartz, with vectors  $u$  and  $v$  defined by  $u_i = \frac{d_i}{\sqrt{n_i}}$  and  $v_i = \sqrt{n_i}$ . Since  $\|u\|^2 \geq |u \cdot v|^2 / \|v\|^2$ , the result follows. ◀

► **Theorem 10.** *Choose reserved set  $R$  according to Algorithm 2. Then the expected number of marked nodes in  $R$  is at least  $\delta^2 n$ . That is,  $|R \cap M^*(V_A)| \geq \delta^2 n$  in expectation.*

**Proof.** As in Lemma 7, let  $\ell_i = |M^*(V_A) \cap T_i|$ . Again, we have  $\sum_{i \leq t} \ell_i \leq \sum_{i \leq t} d_i$  for all  $t$  and  $\sum_{i \leq m} \ell_i = d = \sum_{i \leq m} d_i$ . For each  $i$ , the node  $u \in T_i$  is chosen to be in  $R$  with probability  $d_i/n_i$ , with the  $d_i/n_i$  forming an increasing sequence. So the expected size of  $|R \cap M^*(V_A)|$  is given by

$$\begin{aligned} \sum_i \frac{d_i}{n_i} \ell_i &\geq \sum_i \frac{d_i}{n_i} d_i && \text{by Lemma 8} \\ &\geq \frac{d^2}{n} && \text{by Lemma 9} \end{aligned}$$

Since  $\delta = d/n$ , the theorem follows. ◀

**Proof of Theorem 4.** The size of the matching, restricted to non-adversarial nodes, is  $\sum_i (n_i - d_i) = n - d = n - \delta n$ . Further, by Theorem 10, we have reserved at least  $\delta^2 n$  nodes that can be matched to the adversarial nodes. RANKING will match at least a  $(1 - 1/e)$  fraction of these in expectation. So in expectation, the total matching has size at least  $n - \delta n + \delta^2 n(1 - 1/e) = n(1 - \delta + \delta^2(1 - 1/e))$  as desired. ◀

## 5 Sampling From Arbitrary Set Systems

In Section 4, we used graph decomposition to sample a matching in the predicted graph such that, in expectation, there is a large overlap between the set of reserved (unmatched) nodes and the unknown set of marked nodes chosen by the adversary. In this section we prove the existence of probability distributions on sets, with this “large overlap” property, in settings more general than just bipartite graphs.

Let  $U$  be a universe of  $n$  elements and let  $\mathcal{S}$  denote a family of subsets of  $U$  with equal sizes, i.e.,  $|S| = d, \forall S \in \mathcal{S}$ . Suppose an adversary chooses a set  $T \in \mathcal{S}$ , which is unknown to us. Our goal is to find a probability distribution over  $\mathcal{S}$  such that the expected intersection size of  $T$  and a set sampled from this distribution is maximized. We prove in Theorem 11 that for any such set system, one can always guarantee that the expected intersection size is at least  $\frac{d^2}{n}$ .

The connection to matchings is as follows. Let  $U$ , the set of offline nodes in the matching problem, also be the universe of elements.  $\mathcal{S}$  is a collection of all maximal subsets  $R$  of  $U$  such that there is a perfect matching between  $U \setminus R$  and  $V_P$ . All these subsets have size  $d = |V_A| = \delta n$ . Notice that  $M^*(V_A)$  is one of the sets in  $\mathcal{S}$ , although of course we don't know which. What we would like is a distribution such that sampling a set  $R$  from it satisfies  $\mathbb{E}[|R \cap M^*(V_A)|] \geq d^2/n = \delta^2 n$ .

► **Theorem 11.** *For any set system  $(U, \mathcal{S})$  with  $|U| = n$  and  $|S| = d$  for all  $S \in \mathcal{S}$ , there exists a probability distribution  $\mathcal{D}$  over  $\mathcal{S}$  such that  $\forall T \in \mathcal{S}, \mathbb{E}_{S \sim \mathcal{D}}[|S \cap T|] \geq \frac{d^2}{n}$ .*

As an example, consider  $U = \{v, w, x, y, z\}$  and  $\mathcal{S} = \{\{v, w\}, \{w, x\}, \{x, y\}, \{y, z\}\}$ . Here  $n = 5$  and  $d = 2$ , so the theorem guarantees a probability distribution on the four sets such that each of them has an expected intersection size with the selected set of at least  $\frac{4}{5}$ . We can set  $\Pr[\{v, w\}] = \Pr[\{y, z\}] = \frac{3}{10}$  and  $\Pr[\{w, x\}] = \Pr[\{x, y\}] = \frac{1}{5}$ . Then the expected intersection size for the set  $\{v, w\}$  is  $\Pr[\{v, w\}] \cdot 2 + \Pr[\{w, x\}] \cdot 1 = \frac{4}{5}$  because the intersection size is 2 if  $\{v, w\}$  is picked and 1 if  $\{w, x\}$  is picked. Similarly, one can verify that the expected intersection for any set is at least  $\frac{4}{5}$ . However, in general, it is not trivial to find such a distribution via an explicit construction.

Theorem 11 is a generalization to Theorem 10, and we could have selected a matching and a reserved set  $R$  according to the methods used in its proof. Indeed, this gives the same competitive ratio. However, the set system generated by considering all matchings of size  $n - d$  is exponentially large in general. Hence the offline portion of the algorithm would not run in polynomial time.

## 5.1 Proof of Theorem 11

Let  $\mathcal{D}$  be a probability distribution over  $\mathcal{S}$  with the probability of choosing a set  $S$  denoted by  $p_S$ . Now, for any fixed set  $T \in \mathcal{S}$ , the expected intersection size is given by  $\mathbb{E}_{S \sim \mathcal{D}}[|S \cap T|] = \sum_{S \in \mathcal{S}} p_S \cdot |S \cap T| = \sum_{u \in T} \sum_{S \ni u} p_S$ . For a given set system  $(U, \mathcal{S})$ , consider the following linear program and its dual.

The primal constraints exactly capture the requirement that the expected intersection size is at least  $\frac{d^2}{n}$  for any choice of  $T$ . Thus, to prove the theorem, it suffices to show that the optimal primal solution has an objective value of at most 1. We show that any feasible solution to the dual linear program must have objective value at most 1 and hence the theorem follows from strong duality.

► **Lemma 12.** *For any set system  $(U, \mathcal{S})$ , the optimal solution to Dual-LP has objective value at most 1.*

$$\begin{array}{ll}
 \min \sum_{S \in \mathcal{S}} p_S & \max \sum_{T \in \mathcal{S}} q_T \\
 \text{s.t.} & \text{s.t.} \\
 \forall T \in \mathcal{S}, \sum_{u \in T} \sum_{S \ni u} p_S \geq \frac{d^2}{n} & \forall S \in \mathcal{S}, \sum_{u \in S} \sum_{T \ni u} q_T \leq \frac{d^2}{n} \quad (3) \\
 \forall S \in \mathcal{S}, p_S \geq 0 & \forall T \in \mathcal{S}, q_T \geq 0 \quad (4)
 \end{array}$$

■ Figure 1 Primal-LP.

■ Figure 2 Dual-LP.

**Proof.** Let  $\{q_T\}_{T \in \mathcal{S}}$  denote an optimal, feasible solution to Dual-LP. For any element  $u \in U$ , define  $w(u) = \sum_{T \ni u} q_T$  to be the total weight of all the sets that contain  $u$ . From the dual constraints, we have

$$\forall S \in \mathcal{S}, \sum_{u \in S} w(u) \leq \frac{d^2}{n}$$

Since each  $S \in \mathcal{S}$  has exactly  $d$  elements, we can rewrite the above as

$$\forall S \in \mathcal{S}, \sum_{u \in S} \left( w(u) - \frac{d}{n} \right) \leq 0$$

Multiplying each inequality by  $q_S$  and adding over all  $S \in \mathcal{S}$  yields

$$\begin{aligned}
 \sum_{S \in \mathcal{S}} \left( \sum_{u \in S} \left( w(u) - \frac{d}{n} \right) q_S \right) &\leq 0 \\
 \sum_{u \in U} \left( \sum_{S \ni u} \left( w(u) - \frac{d}{n} \right) q_S \right) &\leq 0 \\
 \sum_{u \in U} w(u) \left( w(u) - \frac{d}{n} \right) &\leq 0
 \end{aligned}$$

Using the fact that  $y(x - y) \leq x(x - y)$  for any two real numbers  $x$  and  $y$ , we get that  $\forall u \in U, \frac{d}{n}(w(u) - \frac{d}{n}) \leq w(u)(w(u) - \frac{d}{n})$ . Thus,

$$\begin{aligned}
 \sum_{u \in U} \frac{d}{n} \left( w(u) - \frac{d}{n} \right) &\leq 0 \\
 \sum_{u \in U} w(u) &\leq d \quad (5)
 \end{aligned}$$

On the other hand, we have  $\sum_{u \in U} w(u) = \sum_{u \in U} \sum_{T \ni u} q_T = \sum_{T \in \mathcal{S}} \sum_{u \in T} q_T = d \sum_{T \in \mathcal{S}} q_T$ . Inequality 5 then shows that  $\sum_{T \in \mathcal{S}} q_T \leq 1$ . ◀

■ **Figure 3** Hard instance for  $n = 12$ ,  $d = 6$ , and  $t = 1$ .

## 6 Hardness of Semi-Online Bipartite Matching

In this section, we show that no algorithm solving the semi-online bipartite matching problem can have a competitive ratio better than  $1 - \delta e^{-\delta}$ . The construction is similar in spirit to the original bound for online bipartite matching of [13]. However, rather than using a graph whose adjacency matrix is upper triangular, the core hardness comes from using a block upper triangular matrix.

### 6.1 Graph Construction

The constructed instance will have a perfect matching in  $G$ . Let  $d = |V_A| = \delta n$  be the number of adversarial online nodes and set  $t = d^{2/3}$  (it's only important that  $t = o(d)$ ). Assume for simplicity that  $\frac{t}{\delta}$  is an integer. We construct the graph as follows (refer to Figure 3 for an illustration).

- Let  $U = \{u_1, \dots, u_n\}$  be the  $n$  offline nodes,  $V_P = \{v_1, \dots, v_{n-d}\}$  be the  $n - d$  predicted online nodes and  $V_A = \{v_{n-d+1}, \dots, v_n\}$  be the  $d$  adversarial online nodes.
- Let the predicted graph  $H$  be a complete bipartite graph between  $U$  and  $V_P$ .
- Pick  $d$  nodes uniformly at random from  $U$  to be neighbors of  $V_A$ . Without loss of generality, let these nodes be  $U_A = \{u_{n-d+1}, \dots, u_n\}$ . Partition the  $d$  nodes in each of  $U_A$  and  $V_A$  in blocks of  $\frac{t}{\delta}$  consecutive nodes. Let  $U_A^k = \{u_{n-d+(k-1)\frac{t}{\delta}+1}, \dots, u_{n-d+(k)\frac{t}{\delta}}\}$  and  $V_A^k = \{v_{n-d+(k-1)\frac{t}{\delta}+1}, \dots, v_{n-d+(k)\frac{t}{\delta}}\}$  denote the  $k^{\text{th}}$  blocks of offline and online nodes respectively. For each  $j \leq k$ , connect all online nodes in  $V_A^j$  to all offline nodes in  $U_A^k$ . Notice that the adjacency matrix on this part of the graph looks like a block upper triangular matrix.
- Finally, the online nodes arrive in order, i.e.  $v_i$  arrives before  $v_j$  whenever  $i < j$ .

### 6.2 Analysis

After the first  $n - d$  nodes have arrived, any online algorithm can do no better than guess which offline nodes to leave unmatched uniformly at random. Let  $\tilde{d} \geq d$  be the number of offline nodes left unmatched by the best online algorithm after the arrival of all  $n - d$  predicted nodes. So at this point, we are left with a bipartite graph with  $d$  adversarial online nodes and  $\tilde{d}$  offline nodes such that each of the  $n$  total offline nodes is available with probability  $\tilde{d}/n = \tilde{\delta}$ .

Consider a block  $U_A^k$  of offline nodes. Since each node is available with probability  $\tilde{\delta}$ , in expectation  $\tilde{t} = \binom{\tilde{\delta}}{\delta} t$  nodes from the block remain available. Further, since nodes are chosen to remain available using sampling without replacement, we can obtain tight concentration

around  $\tilde{t}$ . In particular, if  $t_k$  denotes the number of available nodes remaining in block  $U_A^k$ , by Hoeffding bounds we obtain that  $\Pr(|t_k - \tilde{t}| \geq \tilde{t}^{2/3}) \leq 2e^{-\delta \cdot \tilde{t}^{1/3}}$ . Hence by a union bound over the  $\frac{\delta^2 n}{t}$  blocks, we have that *every* block has  $\tilde{t} \pm \tilde{t}^{2/3}$  available nodes with high probability (as  $t \rightarrow \infty$ ). At this point, it is somewhat clearer why blocks were chosen. Had we used single edges (as in the construction of [13]), many of them would have become unavailable, making the analysis difficult.

Let  $G'$  denote the remaining graph, that is, the graph with  $d$  adversarial online nodes and  $\tilde{d}$  remaining offline nodes. At this point, we'll analyze the water-filling algorithm [9] on  $G'$ . By [9], this is the best deterministic algorithm for *fractional* matching in the adversarial setting. Further, a lower bound on the performance of this algorithm provides a lower bound for any randomized algorithm for integer matchings.

► **Lemma 13.** *The water-filling algorithm achieves a fractional matching of total weight at most  $\delta n \cdot (1 - e^{-\delta(1+o(1))} + o(1))$  on the graph  $G'$ .*

**Proof.** Recall that in the water-filling algorithm, for each arriving online node, we spread its total weight of 1 across its incident edges so that the total fractional matching across the adjacent offline nodes is as even as possible. Let  $B = \frac{d}{t/\delta} = \frac{\delta^2 n}{t}$  be the number of blocks.

For simplicity, let's first assume that each block has exactly  $\tilde{t}$  available nodes, rather than  $\tilde{t} \pm o(\tilde{t})$ . By construction, each online node in the first block is connected to  $B\tilde{t}$  available nodes. Every online node in the second block is connected to  $(B-1)\tilde{t}$  available nodes, and so on, with every online node in the  $k$ -th block connected to  $(B-k+1)\tilde{t}$  available nodes. Hence, in the water-filling algorithm, for each of the first  $t/\delta$  online nodes, we will give  $1/(B\tilde{t})$  weight to every available offline node. Then we will give a weight of  $1/(B\tilde{t} - \tilde{t})$  to every available offline neighbor for each of the next  $t/\delta$  online nodes and so on. This process continues until the weight we have given to the last available offline node is 1, at which point we cannot allocate any more weight.

Consider the weight given to last available offline node. After seeing the first  $k+1$  blocks, this is

$$\frac{t}{\delta} \left( \frac{1}{\tilde{t}B} + \frac{1}{\tilde{t}(B-1)} + \dots + \frac{1}{\tilde{t}(B-k)} \right) \geq (1/\delta)(t/\tilde{t}) \cdot \int_{B-k+1}^{B+1} \frac{1}{x} dx = (1/\delta)(t/\tilde{t}) \ln \left( \frac{B+1}{B-k+1} \right)$$

In our case, the number of available offline nodes in each block is between  $\tilde{t} - \tilde{t}^{2/3}$  and  $\tilde{t} + \tilde{t}^{2/3}$ , w.h.p. So the amount of weight assigned to the last available node after block  $k+1$  is at least

$$\ln \left( \frac{B+1}{B-k+1} \right) \left( \frac{1}{\delta} \right) \left( \frac{t}{\tilde{t} + \tilde{t}^{2/3}} \right) \geq \ln \left( \frac{B+1}{B-k+1} \right) \left( \frac{1}{\delta} \right) \left( \frac{1}{(1 + \tilde{t}^{-1/3})} \right)$$

Note that once we have given a total weight of 1 to the last node, the water-filling algorithm will not be able to distribute any more weight. Hence, the water-filling algorithm stops after  $k$  blocks, with  $k$  being at most the smallest integer satisfying

$$\ln \left( \frac{B+1}{B-k+1} \right) \left( \frac{1}{\delta} \right) \left( \frac{1}{(1 + \tilde{t}^{-1/3})} \right) \geq 1$$

In this case,

$$k = (B+1)(1 - e^{-\delta(1 + \tilde{t}^{-1/3})}) = (B+1)(1 - e^{-\delta(1+o(1))})$$

Since each block allocates a total weight of  $\frac{t}{\delta}$ , the total weight of the fractional matching obtained by the water-filling algorithm is at most

$$\begin{aligned} \left(\frac{t}{\delta}\right) (B+1) \left(1 - e^{-\tilde{\delta}(1+o(1))}\right) &= \left(\frac{t}{\delta}\right) \left(\frac{\delta^2 n}{t} + 1\right) \left(1 - e^{-\tilde{\delta}(1+o(1))}\right) \\ &= \delta n \left(1 - e^{-\tilde{\delta}(1+o(1))}\right) \left(1 + \frac{t}{\delta^2 n}\right) \end{aligned}$$

Since, by construction, we have  $t = o(d)$ , this is  $\delta n \left(1 - e^{-\tilde{\delta}(1+o(1))} + o(1)\right)$  as desired. ◀

► **Theorem 14.** *No (randomized) algorithm for the semi-online bipartite matching problem can achieve a competitive ratio better than  $1 - \delta e^{-\delta}$ .*

**Proof.** Lemma 13 shows that after matching  $n - \tilde{d}$  predicted vertices, the best randomized algorithm can match at most  $\delta n \left(1 - e^{-\tilde{\delta}(1+o(1))} + o(1)\right)$  of the adversarial vertices. Let  $M$  be the matching found by any randomized algorithm on the graph  $G$ . Hence, we have

$$\begin{aligned} \mathbb{E}[|M|] &\leq n - \tilde{d} + \delta n \left(1 - e^{-\tilde{\delta}(1+o(1))} + o(1)\right) \leq n - \delta n + \delta n \left(1 - e^{-\tilde{\delta}(1+o(1))} + o(1)\right) \\ &= n - \delta n e^{-\tilde{\delta}(1+o(1))} + \delta n o(1) \\ &= n \left(1 - \delta e^{-\tilde{\delta}(1+o(1))} + \delta o(1)\right) \end{aligned}$$

Since  $G$  has a perfect matching of size  $n$ , the competitive ratio is upper bounded by  $(1 - \delta e^{-\delta})$  as  $n \rightarrow \infty$ . ◀

## 7 Extensions - Imperfect Predictions and Agnosticism

In this section, we consider a more general model where we allow the predicted graph to have small random errors. We define the  $(d, \epsilon)$  semi-online model as follows - We are given a predicted graph  $H = (U, V, E_H)$ , where  $|U| = |V| = n$ . As before,  $U$  are the offline nodes and  $V$  are the online<sup>5</sup> nodes. However, we do not explicitly separate  $V$  into predicted and adversarial nodes; all nodes are seen by the offline preprocessing stage, but some subset of these nodes will be altered adversarially.

An adversary selects up to  $d$  online nodes and may arbitrarily change their neighborhoods. In addition, we allow the realized graph  $G$  to introduce small random changes to the remaining predicted graph after the adversary has made its choices. Specifically, each edge in  $H$  not controlled by the adversary is removed independently with probability  $\epsilon$ . Further, for each  $u \in U, v \in V$ , we add edge  $(u, v)$  (if it does not already exist in the graph) independently with probability  $\epsilon|M|/n^2$ , where  $M$  is a maximum matching in  $H$ . Note that in expectation, we will add fewer than  $\epsilon|M|$  edges; simply adding edges with probability  $\epsilon$  (instead of  $\epsilon|M|/n^2$ ) would overwhelm the embedded matching. We call an algorithm *agnostic* if it does not know the  $d$  nodes chosen by the adversary during the preprocessing (offline) phase. There are two variants - either the algorithm knows the value of  $d$  or it does not. We show a hardness result in the former case and consider algorithms in the latter case.

We first consider agnostic algorithms to find integral matchings in this  $(d, \epsilon)$  semi-online model and give a hardness result and a corresponding tight algorithm for the case when  $\epsilon = 0$ .

<sup>5</sup> The algorithm does not know the arrival order of nodes in  $V$ .

■ **Figure 4** Hard instance for Agnostic algorithms.

► **Theorem 15.** *In the  $(d, \epsilon)$  semi-online model with  $d < n/4$ , no (randomized) agnostic algorithm can find a matching of size more than  $n - d - \epsilon(n - 3d) + O(\epsilon^2 n)$  in expectation, taken over the randomness of the algorithm and the randomness of the realized graph. This holds even if  $d$  is known in advance by the algorithm.*

**Proof.** Assume  $n$  is even. Our hard instance consists of the following predicted graph  $H$ : For each integer  $i \in [0, \frac{n}{2})$ , add edges  $(v_{2i+1}, u_{2i+1})$ ,  $(v_{2i+1}, u_{2i+2})$ , and  $(v_{2i+2}, u_{2i+2})$ . This creates  $n/2$  connected components. See Figure 4 for an illustration.

The adversary chooses  $d$  components uniformly at random. Let  $\mathcal{A} = \{i_1, i_2, \dots, i_d\} \subset [0, \frac{n}{2})$  denote the indices of the  $d$  components selected by the adversary. For each index  $i \in \mathcal{A}$ , the adversary then selects  $v_{2i+2}$  and changes its neighborhood so it only connects with  $u_{2i+1}$  (instead of  $u_{2i+2}$ ).

For simplicity, let's first consider the case when  $\epsilon = 0$ . The algorithm can do no better than picking some  $p \in [0, 1]$ , and matching  $v_{2i+1}$  to  $u_{2i+1}$  with probability  $p$ , and matching  $v_{2i+1}$  to  $u_{2i+2}$  otherwise, for all  $i$ . The algorithm then matches  $v_{2i+2}$  to its neighbor, if possible. Now, for all  $i \in \mathcal{A}$  (components selected by the adversary), this gets an expected matching of size  $p + 2(1 - p) = 2 - p$ . On the other hand, for all  $i \notin \mathcal{A}$ , the expected matching is size  $2p + (1 - p) = 1 + p$ . Since there are  $d$  components with an adversary and  $n/2 - d$  components without, this gives a total matching of size  $(2 - p)d + (1 + p)(n/2 - d) = n/2 + d + p(\frac{n}{2} - 2d)$ . This is maximized when  $p = 1$  (since  $d < n/4$ ) to yield a matching of size  $n - d$ .

When  $\epsilon > 0$ , the algorithm still should set  $p = 1$ ; if the desired edge is removed, then the algorithm will match with whatever node is available. Components with an adversarial node *gain* an edge in the matching when the edge  $(v_{2i+1}, u_{2i+1})$  is removed since the algorithm is forced into the right choice; if both edges  $(v_{2i+1}, u_{2i+1})$  and  $(v_{2i+1}, u_{2i+2})$  are removed, we neither gain nor lose. The expected gain is  $\epsilon - \epsilon^2$ . Components without an adversarial node lose an edge in the matching whenever either edge  $(v_{2i+1}, u_{2i+1})$  or edge  $(v_{2i+2}, u_{2i+2})$  is removed, and they lose an additional edge if all three edges of the component are removed. So the expected loss is  $2\epsilon - \epsilon^2 + \epsilon^3$ . Since there are  $d$  components with adversarial nodes and  $n/2 - d$  without, this is a total of loss of

$$-d(\epsilon - \epsilon^2) + (n/2 - d)(2\epsilon - \epsilon^2 + \epsilon^3) = \epsilon(n - 3d) - O(\epsilon^2 n)$$

Hence, the total matching is size  $n - \epsilon(n - 3d) + O(\epsilon^2 n)$ , as claimed. ◀

► **Theorem 16.** *Given a predicted graph  $H$  with a perfect matching, suppose there are  $d$  adversarial nodes and  $\epsilon = 0$  as described above in the  $(d, \epsilon)$  semi-online model. Then there is an agnostic algorithm that does not know  $d$  that finds a matching of expected size  $n - d$ .*

**Proof.** Before any online nodes arrive, find a perfect matching  $M$  in  $H$ . In the online stage, as each node  $v$  arrives, we attempt to identify  $v$  with an online node in the predicted graph with the same neighborhood, and match  $v$  according to  $M$ . If no node in the predicted graph has neighborhood identical to  $v$ , we know that  $v$  is adversarial and we can simply leave it unmatched. (Note that adversarial nodes can mimic non-adversarial nodes, but it doesn't actually hurt us since they are isomorphic.) The predicted matching had size  $n$ , and we lose one edge for each adversarial node, so the obtained matching has size  $n - d$ . ◀

## 7.1 Fractional matchings for predictions with errors

In this section, we show that we can find an almost optimal *fractional* matching for the  $(d, \epsilon)$  semi-online matching problem.

We use a result from [22], which gives a method of reconstructing a fractional matching using only the local structure of the graph and a single stored value for each offline node. They provide the notion of a *reconstruction function*. Their results extend to a variety of linear constraints and convex objectives, but here we need only a simple reconstruction function. For any positive integer  $k$ , define  $g^k : (\mathbb{R}_0^+)^k \rightarrow (\mathbb{R}_0^+)^k$  by

$$g^k(\alpha_1, \alpha_2, \dots, \alpha_k) = (\alpha_1 - \max(0, z), \alpha_2 - \max(0, z), \dots, \alpha_k - \max(0, z))$$

where  $z$  is a solution to  $\sum_j \min(\max(0, \alpha_j - z), 1) = 1$ .

The reconstruction function  $g$  is this family of functions. Note that this is well-defined: there is always a solution  $z$  between  $-1$  and the largest  $\alpha_j$ , and the solution is unique unless  $z \leq 0$ .

The result of [22] assigns a value  $\alpha_u$  to each  $u$  in the set of offline nodes, and reconstructs a matching on the fly as each online node arrives, using only the neighborhood of the online node and the stored  $\alpha$  values. Crucially, the reconstruction assigns reasonable values even when the neighborhood is different than predicted. In this way, it is robust to small changes in the graph structure.

► **Lemma 17** (Restated from [22]). *Let  $g_i^k$  be defined as above, and let  $H = (U, V, E_H)$  be a bipartite graph with a perfect matching of size  $n = |U| = |V|$ . Then there exist values  $\alpha_u$  for each  $u \in U$  (which can be found in polynomial time) such that the following holds: For all  $v \in V$ , define  $x_{u_i, v} = g_i(\alpha_{u_1}, \alpha_{u_2}, \dots, \alpha_{u_k})$ , where  $u_1, u_2, \dots, u_k$  is the neighborhood of  $v$ . Then  $x$  defines a fractional matching on  $H$  with weight  $n$ .*

Interested readers can find the proof in the full version. Given this reconstruction technique, we can now describe the algorithm:

- In the preprocessing phase, find the  $\alpha_u$  values for all  $u \in U$  using Lemma 17.
- In the online phase, for each online node  $v$ , compute  $\tilde{x}_{u_i, v} = g_i(\alpha_{u_1}, \dots, \alpha_{u_k})$ , where  $u_1, \dots, u_k \in \Gamma_G(v)$ , as described above. Assign weight  $\tilde{x}_{u_i, v}$  to the edge from  $u_i$  to  $v$ ; if that would cause node  $u_i$  to have more than a total weight 1 assigned to it, just assign as much as possible.

Note that we make the online computation based on the neighborhood in  $G$ , the realized graph, although the  $\alpha_u$  values were computed based on  $H$ , the predicted graph. We have the following.

► **Theorem 18.** *In the  $(d, \epsilon)$  semi-online matching problem in which the predicted graph has a perfect matching, there is a deterministic agnostic algorithm that gives a fractional matching of size  $n(1 - 2\epsilon - \delta)$  in expectation, taken over the randomized realization of the graph. The algorithm does not know the value of  $d$  or the value of  $\epsilon$  in advance.*

**Proof.** If the realized graph were exactly as predicted, we would give the fractional assignment  $x$  guaranteed in Lemma 17, which has weight  $n$ . However, the fractional matching that is actually realized is somewhat different. For each online node that arrives, we treat it the same whether it is adversarial or not. But we have a few cases to consider for analysis:

- Case 1: The online node  $v$  is adversarial. In this case, we forfeit the entire weight of 1 in the matching. We may assign some fractional matching to incident edges. However, we count this as ‘excess’ and do not credit it towards our total. In this way, we lose at most  $\delta n$  total weight.
- Case 2: The online node  $v$  is not adversarial, but it has extra edges added through a random process. There are at most  $\epsilon n$  such nodes in expectation. In this case, we treat them the same as adversarial. We forfeit the entire weight of 1, and ignore the ‘excess’ assignment. This loses at most  $\epsilon n$  total weight in expectation.
- Case 3: The online node  $v$  is as exactly as predicted. In this case, we correctly calculate  $x_{uv}$  for each  $u \in \Gamma(v)$ . Further, we assign  $x_{uv}$  to each edge, unless there was already ‘excess’ there. Since we never took credit for this excess, we will take  $x_{uv}$  credit now. So we do not lose anything in this case.
- Case 4: The online node  $v$  is as predicted, except each edge is removed with probability  $\epsilon$  (and no edges are added). In this case, when we solve for  $z$ , we find a value that is bounded above by the true  $z$ . The reason is that in the predicted graph, we solved  $\sum_{u \in \Gamma(v)} \min(\max(0, \alpha_u - z), 1) = 1$  for  $z$  when computing  $g$ . In the realized graph, this same sum has had some of its summands removed, meaning the solution in  $z$  is at most what it was before. So the value of  $\tilde{x}_{uv}$  that we calculate is at least  $x_{uv}$  for all  $u$  in the realized neighborhood. We take a credit of  $x_{uv}$  for each of these, leaving the rest as excess. Note that we have assigned 0 to each edge that was in the predicted graph but missing in the realized graph. Since each edge goes missing with probability  $\epsilon$ , this is a total of at most  $\epsilon n$  in expectation.

So, the total amount we lose in expectation is  $2\epsilon n + \delta n$ . Since the matching in the predicted graph has weight  $n$ , the claim follows. ◀

## 7.2 Semi-Online Algorithms For Ski Rental

In this section, we consider the semi-online ski rental problem. In the classical ski rental problem, a skier needs to ski for an unknown number of days and on each day needs to decide whether to rent skis for the day at a cost of 1 unit, or whether to buy skis for a higher cost of  $b$  units and ski for free thereafter. We consider a model where the skier has perfect predictions about whether or not she will ski on a given day for a few days in the time horizon. In addition, she may or may not ski on the other days. For instance, say the skier knows whether or not she’s skiing for all weekends in the season, but is uncertain of the other days. The goal is to design an algorithm for buying skis so that the total cost of skiing is competitive with respect to the optimal solution for adversarial choices for all the days for which we have no predictions.

Let  $x$  denote the number of days that the predictions guarantee the skier would ski. Further, it is more convenient to work with the fractional version of the problem so that it costs 1 unit to buy skis and renting for  $z$  (fractional) days costs  $z$  units. In this setting, we

know in advance that the skier will ski for at least  $x$  days. There is a randomized algorithm that guarantees a competitive ratio of  $1/(1 - (1 - x)e^{-(1-x)})$ . Our analysis is a minor extension of an elegant result of [11].

► **Theorem 19.** *There is a  $\frac{e}{e - (1 - x)e^x}$  competitive randomized algorithm for the semi-online ski-rental problem where  $x$  is a lower bound of the number of days the skier will ski.*

**Proof.** Without loss of generality, we can assume that all the days with a prediction occur before any of the adversarial days arrive. Otherwise, the algorithm can always pretend as if the predictions have already occurred, since only the number of skiing days is important and not their order. Recall that  $x$  denotes the number of days that the predictions guarantee the skier would ski. Let  $u \geq x$  be the actual number of days (chosen by the adversary) that she will ski. Since buying skis costs 1, the optimal solution has a cost of  $\min(u, 1)$ . Clearly, if  $x \geq 1$ , we must always buy the skis immediately and hence we assume that  $0 \leq x < 1$  in the rest of the section. Further, even the optimal deterministic algorithm buys skis once  $z = 1$ , so we may assume that  $u \leq 1$ .

Let  $p_x(z)$  denote the probability that we buy the skis on day  $z$ , and let  $q(x)$  denote the probability that we buy skis immediately. Recall that  $p_x$  is implicitly a function of the prediction  $x$ . Given a fixed number of days to ski  $u$ , we can now compute the expected cost of the algorithm as

$$\text{Cost}(x, u) = q(x) + \int_0^u (1 + z) \cdot p_x(z) dz + \int_u^1 u \cdot p_x(z) dz$$

Our goal is to choose a probability distribution  $p$  so as to minimize  $\text{Cost}(x, u)/\min(u, 1)$  while the adversary's goal is to choose  $u$  to maximize the same quantity. We will choose  $p_x$  and  $q$  so that  $\text{Cost}(x, u)/\min(u, 1)$  is constant with respect to  $u$ . As we noted,  $u \leq 1$ , so  $\min(u, 1) = u$ . Setting the  $\text{Cost}(x, u) = c \cdot u$  for constant  $c$  and taking the derivative with respect to  $u$  twice gives us

$$0 = \frac{\partial}{\partial u} p_x(u) - p_x(u)$$

Of course,  $p_x$  must also be a valid probability distribution. Thus, we set  $p_x(z) = (1 - q(x)) \cdot \frac{e^z}{e - e^x}$  for  $z \geq x$ . For  $z < x$ , we set  $p_x(z) = 0$  since there is no reason to buy skis while  $z < x$  if we did not already buy it immediately.

Recalling that we set  $\text{Cost}(x, u) = c \cdot u$ , we can substitute  $p_x(z)$  and solve for  $q(x)$ , finding

$$q(x) = \frac{xe^x}{e - (1 - x)e^x}$$

Hence, the competitive ratio is thus given by

$$\frac{\text{Cost}(x, u)}{u} = \frac{1}{u} \left( q(x) + \frac{1 - q(x)}{e - e^x} \int_x^u (1 + z)e^z dz + \frac{1 - q(x)}{e - e^x} \int_u^1 u \cdot e^z dz \right)$$

Substitute  $q(x)$ , and after some manipulation, this becomes

$$\frac{\text{Cost}(x, u)}{u} = \frac{e}{e - (1 - x)e^x}$$

Note that when  $x = 0$ , this becomes the classic ski rental problem, and the above bound is  $e/(e - 1)$ , as expected. ◀

### Abstract

---

We initiate the study of *quantum races*, games where two or more quantum computers compete to solve a computational problem. While the problem of dueling algorithms has been studied for classical deterministic algorithms [12], the quantum case presents additional sources of uncertainty for the players. The foremost among these is that players do not know if they have solved the problem until they measure their quantum state. This question of “when to measure?” presents a very interesting strategic problem. We develop a game-theoretic model of a multi-player quantum race, and find an approximate Nash equilibrium where all players play the same strategy. In the two-party case, we further show that this strategy is nearly optimal in terms of payoff among all symmetric Nash equilibria. A key role in our analysis of quantum races is played by a more tractable version of the game where there is no payout on a tie; for such races we completely characterize the Nash equilibria in the two-party case.

One application of our results is to the stability of the Bitcoin protocol when mining is done by quantum computers. Bitcoin mining is a race to solve a computational search problem, with the winner gaining the right to create a new block. Our results inform the strategies that eventual quantum miners should use, and also indicate that the collision probability – the probability that two miners find a new block at the same time – would not be too high in the case of quantum miners. Such collisions are undesirable as they lead to forking of the Bitcoin blockchain.

## 1 Introduction

We study the scenario of two or more quantum computers competing to solve a computational task, which we call a *quantum race*. This setting presents a different problem to finding the fastest algorithm for a task, as the only goal is to solve the task before the competitors. For example, imagine a search race where Alice and Bob, each armed with identical quantum computers, compete to find a marked item in a database. The first person to find the marked item wins \$1, with the payout being split in the case of a tie. The first natural idea is for Alice to run Grover’s algorithm [11], which can find a marked item in a database of size  $N$  with high probability in time  $O(\sqrt{N})$ . However, if Alice’s strategy is to run Grover’s algorithm and measure after the specified number of steps to maximize her success probability, Bob will have an advantage by measuring after running Grover’s algorithm for a few less steps. Although this way Bob has a slightly lower success probability, he gains a huge advantage in always answering first. This simple example shows that the optimal algorithm to solve a problem can be different from the optimal strategy to employ when the goal is to solve the problem before an opponent.

The scenario of competing algorithms has been studied before in the classical deterministic setting [12]. In a classical game, the uncertainty is provided by an unknown probability distribution over the inputs: depending on what the input is, one algorithm may perform better than another. The quantum setting inherently has additional sources of uncertainty, most interestingly that players do not know if they have solved the problem until they *measure* their quantum state. Going back to the search game, in the classical version the players know at every instant if they have found the marked item or not. This is not the case in the quantum setting, where a player can only tell if she has found the desired item by measuring her quantum state. Furthermore, if she measures her state and does not find the marked item, then she must begin the search again from scratch. In the quantum case there is a natural tension between waiting to measure, and thereby building up the probability of success upon measuring, and measuring sooner, to answer before one’s competitors. We study this game theoretic problem to develop strategies for players to use in quantum races.

One of our main motivations for studying quantum races is to model quantum computers mining the decentralized currency Bitcoin [16]. Mining is the process by which new blocks of transactions are added to the history of Bitcoin transactions, called the blockchain. The winner of a race to solve a computational search problem gains the right to add a new block of transactions to the blockchain, and participants in this race are called miners. Quantum miners could use Grover’s algorithm to solve the search problem with quadratically fewer search queries than needed classically. But what should the strategy of quantum miners be when competing against each other?

► **Question 1.** *What is the optimal strategy for quantum miners?*

Figuring out the optimal strategy for quantum miners is important to analyze the impact of quantum mining on the stability of the Bitcoin protocol. When two miners solve the computational search problem at (nearly) the same time, the blockchain can fork as it is unclear which new block is the “correct” history of Bitcoin transactions. Forking is bad for the security of Bitcoin as it can decrease the cost of attacks [10], increase the gain from

deviating from the intended mining protocol [9], and generally decreases chain growth and wastes resources. In the classical case, each search query has the same probability of success. In the quantum case, however, because of Grover’s algorithm the success probability grows roughly quadratically with the number of search queries. Does this lead to many quantum miners finding blocks at the same time?

► **Question 2.** *What is the probability that two or more quantum miners playing the optimal strategy find a block at the same time?*

In the next subsections, we describe our model and results in more detail and the impact it has on these questions.

## 1.1 The model and results

In a *symmetric* game all players have the same payoff function. In his original paper defining a Nash equilibrium, Nash showed that every symmetric multiparty finite game has a symmetric equilibrium, i.e. one where all players play the same strategy [17]. When all players have identical quantum computers, a quantum race is naturally a symmetric race, and we describe this scenario first.

We model a symmetric multiplayer quantum race in the following way. The pure strategies available to a player are the possible times at which she can measure  $1, 2, 3, \dots, K$ . For each time  $t$ , a player has an algorithm that she can run for  $t$  steps and for which the success probability is  $p_t$ . Without loss of generality, we assume that these probabilities form an increasing sequence  $0 < p_1 < p_2 < \dots < p_K \leq 1$ . A general strategy is a probability distribution over the possible times to measure. The player who succeeds first receives a payoff of 1. In the case of a tie, the payoff is split amongst all players who succeed first at the same time. Our model can be thought of as a “one-shot” race, as if a player measures and does not succeed, she does not get a chance to restart and try again. While a race where players are allowed to repeatedly restart until someone wins would be more realistic, it becomes much more difficult to analyze due to the proliferation of possible strategies, and we leave this for future work.

### Two-player case

We begin explaining our model and results in more detail in the two-player case. In this case, a game defined by the probabilities  $p_1, \dots, p_K$  can be represented by the payoff matrix for Alice, given by the  $K$ -by- $K$  matrix  $A$ , and the payoff matrix for Bob  $B$ . The  $(s, t)$  entry of  $A$  gives Alice’s payoff when she runs an algorithm for time  $s$  and Bob plays time  $t$ . In the case of a quantum race, this is defined as

$$A(s, t) = \begin{cases} p_s & \text{if } s < t \\ p_s(1 - p_s) + \frac{1}{2}p_s^2 & \text{if } s = t \\ p_s(1 - p_t) & \text{if } s > t \end{cases} \quad (1)$$

As the game is symmetric, Bob’s payoff matrix is  $B = A^T$ .

Our analysis of quantum races begins in Section 3 by analyzing a more tractable variant of the game we call a *stingy* quantum race. In a stingy quantum race, there is no payout in the case of a tie (the game organizer is stingy). A Nash equilibrium of a two-party stingy quantum race has very strong constraints on its support structure (see Corollary 16). In particular, if  $(x, y)$  is a Nash equilibrium in a two-party stingy quantum race, then the union

of the supports of  $x$  and  $y$  must be an interval  $\{T, T + 1, \dots, K\}$  that contains the maximum running time  $K$ . There are 3 possible types of Nash equilibria in a two-party stingy quantum race, and we characterize all of them (see Theorem 22, and Appendix of [14]).

One particularly nice type of equilibrium is what we call a *coinciding* equilibrium. In a coinciding equilibrium, the support of all player's strategies is the same, but the strategies do not have to be identical. This is a more general notion than a symmetric equilibrium where all strategies are the same. In a coinciding equilibrium for a stingy quantum race, the support of each player's strategy is an interval  $\{T, T + 1, \dots, K\}$ . This leaves the problem of determining the starting point  $T$  of this interval in a Nash equilibrium. We are able to show that there is always exactly one  $T$  such that there is a Nash equilibrium with support  $\{T, T + 1, \dots, K\}$ .

► **Theorem 3** (Informal, see Theorem 22). *In a two-party stingy quantum race defined by probabilities  $p_1, \dots, p_K$ , there is a unique coinciding Nash equilibrium. In this equilibrium all players play the same strategy, and the support of the strategies is an interval  $\{T^*, T^* + 1, \dots, K\}$ .*

We also explicitly find this Nash equilibrium.

This result begs the question: what is this value of  $T^*$ ? At what success probability does it become worthwhile to start measuring? By putting an additional restriction on the probabilities  $p_1, \dots, p_K$ , we can give quite a precise answer to this question. We say  $p_1, \dots, p_K$  is an  $\ell$ -dense sequence (see Definition 13) if  $p_1 \leq \frac{\ell}{K}, p_K \geq 1 - \frac{\ell}{K}$ , and  $p_{i+1} - p_i \leq \frac{\ell}{K}$  for  $i = 2, \dots, K - 1$ . This is quite a natural restriction that is satisfied for many races. In the quantum search race, where the  $p_i$  are the Grover success probabilities, and therefore also in the application to Bitcoin, the  $\ell$ -density condition is satisfied with  $\ell = \pi/2$ . In the  $\ell$ -dense case, we can give the following bound on  $T^*$ .

► **Theorem 4** (Informal, see Corollary 25 and Corollary 28). *Let  $p_1, \dots, p_K$  be an  $\ell$ -dense sequence with  $K \geq 6\ell$ . Then the starting point  $T^*$  of the unique coinciding Nash equilibrium in the stingy quantum race defined by these probabilities is such that  $p_{T^*} = \sqrt{2} - 1 + \Theta\left(\frac{\ell}{K}\right)$ .*

Thus it is worthwhile to start measuring once the success probability becomes around  $\sqrt{2} - 1$ , and this is largely independent of the actual values of  $p_1, \dots, p_K$ .

In Section 4, we apply our analysis of two-player stingy quantum races to the case of general quantum races. As the only difference between a stingy quantum race and a quantum race is the payout on ties, intuitively strategies in these two kinds of races should have similar payoffs when the probability of ties is small. We follow this intuition and show that when  $p_1, \dots, p_K$  form an  $\ell$ -dense sequence the probability of a tie is  $O\left(\frac{\ell}{K}\right)$  (see Theorem 27) when players use the unique coinciding equilibrium from the stingy race, and this strategy is an  $O\left(\frac{\ell}{K}\right)$ -approximate Nash equilibrium of the corresponding quantum race.

Approximate Nash equilibria are naturally an imperfect lens into true Nash equilibria. The approximate Nash equilibrium we give would not be a reasonable suggestion for the actual strategies of quantum players if there were other equilibria with much higher payoff, for example. We show that this is not the case, and the approximate Nash equilibrium we give is nearly optimal in terms of payoff amongst all symmetric equilibria.

► **Theorem 5** (Informal, see Theorem 31 and Theorem 33). *Let  $p_1, \dots, p_k$  be an  $\ell$ -dense sequence with  $K \geq 6\ell$ . Then the unique coinciding equilibrium of the two-player stingy quantum race defined by these probabilities is an  $O\left(\frac{\ell}{K}\right)$ -approximate Nash equilibrium in the corresponding quantum race. Moreover, the payoff achieved by this strategy is within  $O\left(\sqrt{\frac{\ell}{K}}\right)$  of the largest payoff achievable by any symmetric Nash equilibrium.*

To show that the approximate Nash equilibrium we give is nearly optimal in terms of payoff (Theorem 33), we use the bilinear programming formulation of Nash equilibria due to Mangasarian and Stone [15]. We exploit the properties of the sum of Alice's and Bob's payoff matrices  $A + A^T$  (from Eq. (1)). More specifically, It turns out that over a probability simplex  $x$ , the quadratic form  $x^T(A + A^T)x$  is a negative-definite plus linear function. When optimizing over symmetric strategies this makes the Mangasarian and Stone bilinear program (which is a maximization problem) into a convex quadratic program. We then use Dorn's [8] equivalent dual formulation of a convex quadratic program (see Eq. (17)), which is a minimization problem. We explicitly construct a feasible solution to this dual minimization problem to upper bound the payoff of any symmetric Nash equilibrium. Our construction of this dual solution again makes use of our analysis of stingy quantum races.

### Multiplayer case

The case of many players is what we are interested in for the application to Bitcoin. Luckily, we are able to recover analogs of many of the results from the two-player case in the multiplayer case as well. We start in Section 5 by analyzing  $n$ -player stingy quantum races, and show the following.

► **Theorem 6** (Informal, see Theorem 41). *Let  $p_1, \dots, p_K$  define an  $n$ -player stingy quantum race. This race has a unique coinciding Nash equilibrium, and in this equilibrium all players play the same strategy. The support of each strategy is an interval  $\{T^*, T^* + 1, \dots, K\}$ .*

To show that an  $n$ -player stingy quantum race has a unique coinciding Nash equilibrium, our proof proceeds through a 2-player *asymmetric* stingy quantum race. In a 2-player asymmetric race, Alice has probabilities  $p_1, \dots, p_K$  of succeeding after  $t$  steps and Bob has a (potentially different) sequence of probabilities  $P_1, \dots, P_K$ . An asymmetric race models the case where Alice and Bob have quantum computers of potentially different speeds. We relate the payoff for Alice in a  $n$ -player stingy quantum race to the payoff for Alice in a 2-player quantum race against a more powerful opponent (see Lemma 40). We can then refer to Theorem 21 in Section 3 which completely characterizes coinciding equilibria in asymmetric 2-player stingy quantum races. This gives Theorem 6.

When the sequence  $p_1, \dots, p_K$  is  $\ell$ -dense, we can also say something about the starting point  $T^*$  of the  $n$ -player coinciding equilibrium, though not as precisely as in the two-party case.

► **Theorem 7** (Informal, see Theorem 44). *Let  $p_1, \dots, p_K$  be an  $\ell$ -dense sequence defining a stingy  $n$ -player quantum race with  $n \geq 2$ . If  $K \geq 4e\ell n$  then the starting point  $T^*$  of the unique coinciding equilibrium is such that  $p_{T^*} = \Theta(\frac{1}{n})$ .*

This means that the more players there are in a game, the earlier one starts to measure in the unique coinciding equilibrium.

In light of Question 2 we also want to see what the probability of more than one player succeeding at the same time in this unique coinciding equilibrium. We show the following.

► **Theorem 8.** *Let  $P_1, \dots, P_K$  define an  $\ell$ -dense stingy  $n$ -player quantum race such that  $4e\ell n \leq K$ . When the players play the coinciding equilibrium of the stingy race, the probability that two or more players succeed at the same time is at most  $\frac{8e\ell n}{K}$ .*

Finally, as in the two-party case, we show that the unique coinciding equilibrium of a stingy race is also an approximate Nash equilibrium in the corresponding quantum race, provided the sequence of probabilities is  $\ell$ -dense.

► **Theorem 9.** *Let  $P_1, \dots, P_K$  define an  $\ell$ -dense stingy  $n$ -player quantum race,  $n \geq 2$ , with  $4en\ell \leq K$ . If  $x = (x_1, \dots, x_n)$  is the coinciding Nash equilibrium for this stingy race, then  $x$  is an  $\frac{8e\ell}{K}$ -approximate Nash equilibrium of the corresponding quantum race.*

## 1.2 Application to Bitcoin

One application of our study of quantum races is to the decentralized digital currency Bitcoin, developed in 2008 by Satoshi Nakamoto [16]. Bitcoin transactions are packaged into blocks and stored in a public ledger called the blockchain. A major obstacle in creating a decentralized currency is to find a way for all parties to agree on the history of transactions. In Bitcoin, this is done through *Nakamoto consensus*: the right to create a new block is decided through proof-of-work, a contest to solve a computational problem. The winner of this contest has the right to make a new block of transactions, is given a reward in bitcoin, and then the process repeats itself. The players competing in this process are called miners. Nakamoto consensus remains the primary means of achieving consensus across all cryptocurrencies, although there are coins using other consensus mechanisms such as proof-of-stake [13] or Byzantine agreement [6].

The proof-of-work task used in Bitcoin (originally developed in a system called Hashcash [2]) is essentially a search problem. The problem is to find a value  $x$  (called a nonce) such that  $h(H \parallel x) \leq t$ , where  $h$  is a hash function (doubly iterated SHA-256 in the case of Bitcoin),  $H$  is the header of the block of transactions to be processed, and  $t$  is a hardness parameter that can be varied so that the entire network takes 10 minutes to solve this task, on average.

Several works have studied the impact that quantum computers would have on the Bitcoin protocol [5, 1, 18], both on the mining process we have described above and on the digital signatures used in Bitcoin to authenticate ownership of coins. We will focus here on the impact of quantum computers on Bitcoin mining.

As the Bitcoin proof-of-work is a search task, quantum miners could use Grover's algorithm to find a nonce  $x$  satisfying  $h(H \parallel x) \leq t$  with quadratically fewer evaluations of the hash function  $h$  than is needed by a classical computer<sup>1</sup>. The use of Grover's algorithm creates new issues for proof-of-work that do not exist in the classical case. Desirable properties of a proof-of-work task have been studied from an axiomatic point of view by Biryukov and Khovratovich [3]. One property they give is *progress-freeness*: the probability of a miner solving the proof-of-work task in any moment is independent of previous events. This is achieved for a classical miner in the Bitcoin proof of work, as every call to the hash function is equally likely to find a good nonce  $x$ . Progress-freeness is not achieved for a quantum miner running Grover's algorithm, as the success probability grows roughly quadratically with the amount of time the algorithm is run.

Sattath [18] points out that this gives a way for quantum miners to deviate from the prescribed protocol in order to increase their chance of winning a block. To explain this deviation, imagine a simplified case where the proof-of-work is to find a unique marked item in a database of size  $N$ . Say that Alice, a quantum miner, receives a new block from the network which was found by Bob. When Alice receives this block she will be in the middle of running Grover's algorithm to find the marked item herself. The prescribed protocol says that she should immediately halt this run of Grover's algorithm and begin working

<sup>1</sup> While this seems to give quantum computers a huge advantage for Bitcoin mining, specialized classical Bitcoin mining hardware currently can perform 14 trillion hashes per second [4] and would outperform a near-term quantum computer with gate speeds of 100MHz [1]

on a new search problem by mining on top of Bob's new block. However, if Alice has run Grover algorithm for  $c\sqrt{N}$  steps, for a constant  $c$ , she will have already built up a constant probability of finding the marked item upon measuring. From the point of view of maximizing her payoff, there is no harm in just measuring to see if she finds the marked item. If Alice gets lucky and indeed finds the marked item, then she can broadcast her new block to the network. Depending on her connectivity to the network, some other miners may receive Alice's block before Bob's, and there is some probability that Alice's new block eventually becomes the block accepted by the network rather than Bob's, meaning that Alice will receive the bitcoin reward. Note that this does not happen in the classical case, where after Alice receives Bob's block she would still just have probability  $1/N$  to find the marked item with each additional search query. In this case it makes sense to immediately start mining on top of the new block.

Luckily, Sattath also provides an easy fix for the Bitcoin protocol to remedy this problem. Without going into the technical details, this fix essentially forces miners to commit to how long they will run Grover's algorithm *before they begin*. Thus if Alice commits to running Grover's algorithm for time  $\sqrt{N}/100$ , yet receives Bob's block after time  $\sqrt{N}/200$ , if she tries to immediately measure and publish her own block, the network will reject it because of the timing discrepancy. This fix fits in very well with our model of quantum races, as a strategy is exactly a probability distribution over choices of times to measure.

The quantum race that captures the case of Bitcoin mining is what we call the *Grover race* (see Definition 12). In this race, the success probability  $p_t$  is given by the success probability of  $t$ -iterations of Grover's algorithm<sup>2</sup>. This race is an  $\ell$ -dense race for  $\ell = \pi/2$ . The size of the search space, and thus the maximum number of iterations  $K$  to run Grover's algorithm, is determined by the *difficulty* setting of the Bitcoin protocol. Currently the difficulty (as of September 7, 2018) is approximately  $7 \cdot 10^{12}$ , which, by Bitcoin's definition of difficulty, means that the network has to do roughly  $2^{32} \cdot 7 \cdot 10^{12}$  many hashes to succeed, in expectation. This leads to a value of  $K$  of approximately  $10^{11}$ . Thus for this application  $\frac{\ell}{K}$  is very small, and Theorem 9 implies that the unique coinciding equilibrium for the stingy Grover race is an  $\epsilon$ -approximate Nash equilibrium in the Grover race for  $\epsilon \leq 3 \cdot 10^{-10}$ . This gives a reasonable answer to Question 1 for what a good strategy would be for quantum miners, and moreover has the desirable property that all miners run the same algorithm. By Theorem 8, when there are  $n$  miners running this strategy the probability of a tie is at most  $3n \cdot 10^{-10}$ . This gives an answer to Question 2, that quantum mining is not likely to produce a high forking rate and thereby destabilize the Bitcoin protocol.

## 2 Preliminaries

We use  $e \approx 2.71828$  for Euler's number. For a probability  $0 \leq p \leq 1$ , we set  $\bar{p} = 1 - p$ . For a natural number  $n$ , we let  $[n] = \{1, \dots, n\}$ . We let  $\Delta_n = \{x \in \mathbb{R}^n : x \geq 0, \sum_{i=1}^n x_i = 1\}$  be the probability simplex. For  $x \in \Delta_n$  we let  $\text{supp}(x) = \{i \in [n] : x_i > 0\}$  be the support of  $x$ .

► **Definition 10** (quantum race). A 2-player quantum race is specified by two sequences of increasing probabilities  $0 < p_1 < p_2 < \dots < p_K \leq 1$ , and  $0 < P_1 < P_2 < \dots < P_K \leq 1$  for some integer  $K \geq 2$ . The set of pure strategies of both players is  $[K]$ . The  $K \times K$  payoff

<sup>2</sup> It is known that  $t$  queries of Grover's algorithm maximizes the probability of success in a search problem over all  $t$ -query quantum algorithms [7].

matrix  $A$  of Alice and  $B$  of Bob are defined as

$$A(i, j) = \begin{cases} p_i & \text{if } i < j, \\ p_i \bar{P}_j + \frac{1}{2} p_i P_i & \text{if } i = j, \\ p_i \bar{P}_j & \text{otherwise.} \end{cases} \quad B(i, j) = \begin{cases} P_j & \text{if } j < i, \\ P_j \bar{p}_i + \frac{1}{2} p_i P_i & \text{if } i = j, \\ P_j \bar{p}_i & \text{otherwise.} \end{cases}$$

If  $p_i = P_i$  for all  $i = 1, \dots, K$  then we call the game a *symmetric* quantum race. Note that in this case  $B = A^T$ .

In our study of quantum races, a key role will be played by an auxiliary game that is easier to analyze called a stingy quantum race. A stingy quantum race differs from a quantum race only in that no payout is given in the case of a tie.

► **Definition 11** (stingy quantum race). A 2-player stingy quantum race is specified by two sequences of increasing probabilities  $0 < p_1 < p_2 < \dots < p_K \leq 1$ , and  $0 < P_1 < P_2 < \dots < P_K \leq 1$  for some integer  $K \geq 2$ . The set of pure strategies of both players is  $[K]$ . The  $K \times K$  payoff matrix  $A_0$  of Alice is defined as

$$A_0(i, j) = \begin{cases} p_i & \text{if } i < j, \\ p_i \bar{P}_j & \text{otherwise.} \end{cases}$$

The payoff matrix of Bob  $B_0$  is defined as

$$B_0(i, j) = \begin{cases} P_j & \text{if } j < i, \\ P_j \bar{p}_i & \text{otherwise.} \end{cases}$$

If  $p_i = P_i$  for all  $i = 1, \dots, K$  then we call the game a *symmetric* stingy quantum race. Note that in this case  $B_0 = A_0^T$ .

The main specific quantum race we will be interested in is the *Grover race*. This results from two players competing to find a marked item in a database and playing by running Grover's algorithm for a certain amount of time and then measuring. Formally, the race is defined as follows.

► **Definition 12** (Grover race). We define the (stingy) Grover race on  $N$  items as the symmetric (stingy) quantum race with  $K = \lceil \frac{\pi}{4} \sqrt{N} - 3/2 \rceil$  and  $p_t = \sin^2 \left( 2(t + 1/2) \arcsin \left( \frac{1}{\sqrt{N}} \right) \right)$ , for  $1 \leq t \leq K$ .

Here  $p_t$  is the success probability of Grover's algorithm of finding a unique marked item in a database of  $N$  items. It is known that  $p_t$  is the highest success probability for finding a marked item for any quantum algorithm making  $t$  many calls to the database [7].

The Grover race has many nice properties, and we will abstract out one of them here. This allows us to show results for a general class of quantum races, rather than just the Grover race.

► **Definition 13** (dense race). Let  $p_1 < p_2 < \dots < p_K \leq 1$ . We call the sequence  $(p_1, \dots, p_K)$   $\ell$ -dense if  $p_1 \leq \frac{\ell}{K}$ ,  $p_K \geq 1 - \frac{\ell}{K}$ , and  $p_{i+1} - p_i \leq \frac{\ell}{K}$  for all  $i = 1, \dots, K - 1$ . For a dense sequence  $(p_1, \dots, p_K)$  will similarly call the symmetric (stingy) quantum race defined by this sequence a symmetric (stingy)  $\ell$ -dense quantum race.

The (stingy) Grover race is an  $\ell$ -dense race with  $\ell = \pi/2$ .

### 3 Two-player stingy quantum races

We will first analyze Nash equilibria in stingy quantum races. We can show several structural properties about the support of Nash equilibria in stingy quantum races that make them easier to analyze than quantum races. After our analysis in this section, we will bootstrap our knowledge of Nash equilibria in stingy quantum races to find an approximate Nash equilibrium for quantum races.

Consider a stingy quantum race given by the probabilities  $0 < p_1 < p_2 < \dots < p_K \leq 1$  and  $0 < P_1 < P_2 < \dots < P_K$ , and let  $y$  be a mixed strategy of Bob. For  $t \leq K$ , we let  $\text{sup}_{\leq t}(y) = \{j \in \text{sup}(y) : j \leq t\}$  be the set of times played by Bob that are at most  $t$ , and similarly, we let  $\text{sup}_{> t}(y) = \{j \in \text{sup}(y) : j > t\}$  be the set of times played by Bob that are greater than  $t$ . Observe that when Alice plays the pure strategy  $t$  against  $y$ , her payoff is

$$e_t^T A y = p_t \left( \sum_{j \in \text{sup}_{\leq t}(y)} y_j \bar{P}_j + \sum_{j \in \text{sup}_{> t}(y)} y_j \right).$$

► **Claim 14.** *Let  $(x, y)$  be a Nash equilibrium of a 2-player stingy quantum race. If  $t_1 \in \text{sup}(x)$  then there does not exist  $t_2 > t_1$  with  $\text{sup}_{\leq t_1}(y) = \text{sup}_{\leq t_2}(y)$ .*

**Proof.** Say that the game is defined by probabilities  $0 < p_1 < p_2 < \dots < p_K \leq 1$  and  $0 < P_1 < P_2 < \dots < P_K$ . If  $\text{sup}_{\leq t_1}(y) = \text{sup}_{\leq t_2}(y)$  then

$$e_{t_2}^T A y = \frac{p_{t_2}}{p_{t_1}} e_{t_1}^T A y.$$

As  $p_{t_1} < p_{t_2}$ , the payoff for playing  $t_2$  is strictly larger than that for playing  $t_1$ . Therefore  $t_1$  is not a best response for  $y$ , in contradiction with the definition of a Nash equilibrium. ◀

This claim implies that the support structure of Nash equilibria in stingy quantum races is relatively simple. We first make the following definition.

► **Definition 15.** A pair of strategies  $(x, y)$  is called *coinciding* if  $\text{sup}(x) = \text{sup}(y)$ . A pair of strategies  $(x, y)$  is called *alternating* if there exists  $1 \leq t_1 < t_2 \leq K$  such that the support of one player is  $\{t_1, t_1 + 2, \dots, t_2 - 1\}$  and the support of the other is  $\text{sup}(y) = \{t_1 + 1, t_1 + 3, \dots, t_2\}$ . A pair of strategies  $(x, y)$  is called  $(t_1, c, t_2)$ -*alternating-coinciding* if there are natural numbers  $1 \leq t_1 < t_2 \leq K$  and  $t_1 + 2 \leq c \leq t_2$  such that the support of one player is  $\{t_1, t_1 + 2, \dots, c - 2, c, c + 1, c + 2, \dots, t_2\}$  and the support of the other is  $\text{sup}(y) = \{t_1 + 1, t_1 + 3, \dots, c - 3, c - 1, c, c + 1, c + 2, \dots, t_2\}$ .

► **Corollary 16.** *Let  $(x, y)$  be a Nash equilibrium of a stingy quantum race specified by probabilities  $0 < p_1 < p_2 < \dots < p_K \leq 1$  and  $0 < P_1 < P_2 < \dots < P_K$ . Then there is some  $1 \leq T \leq K$  such that*

- $\text{sup}(x) \cup \text{sup}(y) = [T, K]$  ,
- $(x, y)$  is either coinciding, alternating, or alternating-coinciding.

**Proof.** From Claim 14 we can easily derive the following two statements:

- $\text{sup}(x) \cup \text{sup}(y)$  is an interval containing the time with maximum success probability,
- For every  $t_1, t_2 \in \text{sup}(x)$  there must be  $t \in \text{sup}(y)$  with  $t_1 < t \leq t_2$ .

These statements immediately imply the claim. ◀

We now study the particularly simple coinciding equilibria. Due to space constraints we do not discuss the other types of equilibria here. However, we give a full characterization of all Nash equilibria in a symmetric stingy quantum race in the full version of the paper [14].

### 3.1 Unique coinciding equilibrium

We first look for Nash equilibria where the mixed strategies of Alice and Bob have the same support. If the number of strategies is  $K$ , we know by Corollary 16 that this support must be a set  $\{T, T+1, \dots, K\}$ , for some  $1 \leq T \leq K$ .

► **Lemma 17.** *Consider a stingy quantum race defined by  $0 < p_1 < \dots < p_K \leq 1$  and  $0 < P_1 < P_2 < \dots < P_K$ . Let  $x, y \in \mathbb{R}^K$ . Then  $(x, y)$  is a Nash equilibrium for this game with support  $\{T, T+1, \dots, K\}$ , for some  $1 \leq T \leq K$ , if and only if  $x$  and  $y$  satisfy the following system of equations and inequalities.*

$$e_t^\top Ay = e_T^\top Ay, \quad \text{for } T < t \leq K, \quad (2)$$

$$e_{T-1}^\top Ay \leq e_T^\top Ay, \quad (3)$$

$$y_t = 0 \quad \text{for } 0 < t < T, \quad (4)$$

$$y_t > 0 \quad \text{for } T \leq t \leq K, \quad (5)$$

$$\sum_{t=T}^K y_t = 1 \quad (6)$$

$$x^\top Be_t = x^\top Be_T, \quad \text{for } T < t \leq K, \quad (7)$$

$$x^\top Be_{T-1} \leq x^\top Be_T, \quad (8)$$

$$x_t = 0 \quad \text{for } 0 < t < T, \quad (9)$$

$$x_t > 0 \quad \text{for } T \leq t \leq K, \quad (10)$$

$$\sum_{t=T}^K x_t = 1. \quad (11)$$

**Proof.** Eq. (4)–(6) and (9)–(11) express that  $x$  and  $y$  are probability distributions with support  $\{T, T+1, \dots, K\}$ . The other conditions for a Nash equilibrium are that all strategies in the support of  $x$  are best responses against  $y$  and vice versa. That all strategies in the support of  $x$  are best responses against  $y$  means

$$e_t^\top Ay = e_T^\top Ay, \quad \text{for } T < t \leq K,$$

$$e_{t-1}^\top Ay \leq e_t^\top Ay, \quad \text{for } 1 \leq t < T.$$

The first equation here is exactly Eq. (2). The inequality here is implied by Eq. (3). This is because for  $t < T-1$ ,  $e_t^\top Ay = \frac{p_t}{p_{T-1}} e_{T-1}^\top Ay$ , as  $\sup_{\leq T-1}(y) = \sup_{\leq t}(y)$ . A similar argument show that Eq. (7)–(8) show that all strategies in the support of  $y$  are best responses against  $x$ . ◀

When  $P_K = 1$ , then Alice has zero payoff on playing time  $K$ . Thus as long as  $K \geq 2$ , when  $P_K = 1$  there is no coinciding Nash equilibrium  $(x, y)$  where  $\text{sup}(x) = \text{sup}(y) = \{K\}$ . A similar argument applies when  $p_K = 1$ . We will therefore exclude the case  $T = K$  and either  $p_K = 1$  or  $P_K = 1$  for the next definition and Lemma 19.

► **Definition 18.** We define the values  $q_T^A, q_T^B$ , for  $T = 2, \dots, K$ , and  $r_T^A, r_T^B, z_T^A, z_T^B$ , for  $T = 1, \dots, K-1$ . The values  $z_K^A, r_K^A$  are not defined when  $T = K, p_K = 1$  and  $z_K^B, r_K^B$  are

not defined when  $T = K, P_K = 1$ .

$$\begin{aligned} q_i^A &= \frac{1}{p_i} \left( \frac{1}{P_{i-1}} - \frac{1}{P_i} \right), & q_i^B &= \frac{1}{\bar{P}_i} \left( \frac{1}{p_{i-1}} - \frac{1}{p_i} \right), \\ r_T^A &= \frac{1}{\bar{P}_T} \left( \frac{1}{P_K} - \sum_{i=T+1}^K \bar{p}_i q_i^A \right), & r_T^B &= \frac{1}{\bar{P}_T} \left( \frac{1}{p_K} - \sum_{i=T+1}^K \bar{P}_i q_i^B \right), \\ z_T^A &= r_T^A + \sum_{i=T+1}^K q_i^A, & z_T^B &= r_T^B + \sum_{i=T+1}^K q_i^B. \end{aligned}$$

► **Lemma 19.** *For every  $1 \leq T \leq K - 1$ , and the case  $T = K$  and  $P_K \neq 1$ , the system of linear equations composed of the Eq. (2), (4) and (6) of Lemma 17 has a unique solution given by*

$$y_t = \begin{cases} r_T^B / z_T^B & \text{if } t = T, \\ q_t^B / z_T^B & \text{if } T < t \leq K, \\ 0 & \text{otherwise.} \end{cases}$$

**Proof.** For convenience, we drop the normalization condition  $\sum_{t=T}^K y_t = 1$  and instead scale  $y$  such that the expected payoff of a best response is 1. That is, we replace Eq. (6) by Eq. (12):

$$e_T^T A y = 1. \quad (12)$$

Clearly the solutions of Eq. (2),(4),(6) and the solutions of Eq. (2),(4),(12) differ only by a constant multiplicative factor, and from a solution of the latter system a solution of the former one can be obtained by dividing it coordinate-wise by  $\sum_{t=T}^K y_t$ .

We first want to find the solutions of Eq. (2) and (12). Together, they can be expressed in matrix form as:

$$\begin{bmatrix} p_T \bar{P}_T & p_T & p_T & \cdots & p_T \\ p_{T+1} \bar{P}_T & p_{T+1} \bar{P}_{T+1} & p_{T+1} & \cdots & p_{T+1} \\ p_{T+2} \bar{P}_T & p_{T+2} \bar{P}_{T+1} & p_{T+2} \bar{P}_{T+2} & \cdots & p_{T+2} \\ \vdots & & & \ddots & \vdots \\ p_K \bar{P}_T & p_K \bar{P}_{T+1} & p_K \bar{P}_{T+2} & \cdots & p_K \bar{P}_K \end{bmatrix} \begin{bmatrix} y_T \\ y_{T+1} \\ y_{T+2} \\ \vdots \\ y_K \end{bmatrix} = \begin{bmatrix} 1 \\ 1 \\ 1 \\ \vdots \\ 1 \end{bmatrix}. \quad (13)$$

We can simplify the above system of linear equations as follows:

$$\begin{bmatrix} 0 & P_{T+1} & 0 & \cdots & 0 \\ 0 & 0 & P_{T+2} & \cdots & 0 \\ 0 & 0 & 0 & \cdots & 0 \\ \vdots & & & \ddots & \vdots \\ \bar{P}_T & \bar{P}_{T+1} & \bar{P}_{T+2} & \cdots & \bar{P}_K \end{bmatrix} \begin{bmatrix} y_T \\ y_{T+1} \\ y_{T+2} \\ \vdots \\ y_K \end{bmatrix} = \begin{bmatrix} 1/p_T - 1/p_{T+1} \\ 1/p_{T+1} - 1/p_{T+2} \\ 1/p_{T+2} - 1/p_{T+3} \\ \vdots \\ 1/p_K \end{bmatrix}.$$

From this we can see that, for every  $1 \leq T \leq K$ , Eq. (13) has a unique solution, given by  $y_T = r_T^B$ , and  $y_t = q_t^B$ , for  $T < t \leq K$ . ◀

► **Definition 20.** Define  $T_A^*$  (respectively  $T_B^*$ ) as the smallest integer  $1 \leq T \leq K$  such that  $r_T^A > 0$  (respectively  $r_T^B > 0$ ). When  $T_A^* = T_B^*$  we denote their common value as  $T^*$ .

This definition makes sense as in the case  $p_K = 1$  (when  $r_K^A$  is not defined) we see that  $r_{K-1}^A > 0$  and otherwise  $r_K^A = \frac{1}{p_K P_K} > 0$ . A similar argument applies for  $r_K^B$ .

► **Lemma 21.** Eq. (2)–(6) have a solution if and only if  $T = T_B^*$ . In the case  $T = T_B^*$ , the solution is unique and is given by

$$y_t = \begin{cases} r_{T_B^*}^B / z_{T_B^*}^B & \text{if } t = T_B^*, \\ q_t^B / z_{T_B^*}^B & \text{if } T_B^* < t \leq K. \end{cases}$$

**Proof.** Refer [14]. ◀

The following theorem characterizes the coinciding Nash equilibria in a stingy quantum race.

► **Theorem 22.** A stingy quantum race defined by probabilities  $0 < p_1 < \dots < p_K \leq 1$  and  $0 < P_1 < \dots < P_K \leq 1$  has a coinciding Nash equilibrium if and only if  $T_A^* = T_B^*$ . In this case, letting  $T^* = T_A^* = T_B^*$  there is a unique coinciding equilibrium given by

$$x_t = \begin{cases} r_{T^*}^A / z_{T^*}^A & \text{if } t = T^*, \\ q_t^A / z_{T^*}^A & \text{if } T^* < t \leq K, \end{cases}, \quad y_t = \begin{cases} r_{T^*}^B / z_{T^*}^B & \text{if } t = T^*, \\ q_t^B / z_{T^*}^B & \text{if } T^* < t \leq K. \end{cases}$$

In particular, when  $p_i = P_i$  for all  $1 \leq i \leq K$  then  $(x, x)$  is the unique coinciding Nash equilibrium.

**Proof.** By Lemma 17 a coinciding Nash equilibrium  $(x, y)$  supported on  $\{T, T+1, \dots, K\}$  must satisfy Eq. (2)–(11). By Theorem 21, Eq. (2)–(6) are satisfied if and only if  $T = T_B^*$  and  $y$  is given as in the Lemma. We can also apply Theorem 21 to (the transpose of) Eq. (7)–(11) to see that they have a solution if and only if  $T = T_A^*$  and  $x$  is given by

$$x_t = \begin{cases} r_{T_A^*}^A / z_{T_A^*}^A & \text{if } t = T_A^*, \\ q_t^A / z_{T_A^*}^A & \text{if } T_A^* < t \leq K, \\ 0 & \text{otherwise.} \end{cases}$$

As  $x$  and  $y$  must have the same support in a coinciding Nash equilibrium, there can only exist a coinciding Nash equilibrium if  $T_A^* = T_B^*$ .

When  $p_i = P_i$  for all  $1 \leq i \leq K$  then clearly  $r_T^A = r_T^B$  and  $q_i^A = q_i^B$  and it will always be the case that  $T_A^* = T_B^*$ . Thus there will always exist a Nash equilibrium in this case, given by the unique solution to Eq. (2)–(11). ◀

### 3.2 Payoff and collision probability

In this section we will explore the consequences of the coinciding Nash equilibrium we have found for the payoff of the game and for the probability that the two players win at the same time, the collision probability. For these results, we will only consider the symmetric case when there is always a unique symmetric equilibrium whose support begins at  $T^* = T_A^* = T_B^*$ . Note that the payoff for each player with this strategy is  $\frac{1}{z_{T^*}}$ . Since a player receives payoff 1 upon winning,  $\frac{1}{z_{T^*}}$  is also exactly the each player's winning probability.

To investigate the collision probability, we will also make the following definitions.

► **Definition 23** (Unnormalized collision probability). Define

$$\sigma(T) = p_T^2 r_T^2 + \sum_{i=T+1}^K p_i^2 q_i^2.$$

With this definition,  $\frac{1}{z_{T^*}^2}\sigma(T^*)$  is the collision probability we are interested in. First we analyze the payoff in a symmetric stingy quantum race.

► **Theorem 24.** *Let  $p_1 < p_2 < \dots < p_K$  define a stingy symmetric quantum race. Then  $z_{T^*} = 1 + \sqrt{1 + \frac{1}{p_K^2} + \sigma(T^*)}$ . In particular,  $\frac{1}{z_{T^*}} \leq \sqrt{2} - 1$ .*

**Proof.** Refer [14]. ◀

► **Corollary 25.** *If  $T^* \geq 2$  then*

$$p_{T^*-1} \leq \sqrt{2} - 1 .$$

**Proof.** As can be seen from Bob playing time  $T^* - 1$ , we have  $p_{T^*-1}z_{T^*} \leq 1$ , thus  $p_{T^*-1} \leq \sqrt{2} - 1$  by Theorem 24. ◀

Although Theorem 24 gives an exact expression for the payoff, we would like to get a general lower bound on the payoff. This requires showing an upper bound on the collision probability. Showing an upper bound on the collision probability is also important for the application to Bitcoin, to estimate the forking probability amongst quantum miners.

The first step to upper bounding the collision probability is to get a rough lower bound on  $p_{T^*}$ . This is our initial bootstrap, which will then let us upper bound the collision probability and then in turn get a sharper lower bound on  $p_{T^*}$  in Corollary 28. For these results we restrict to  $\ell$ -dense stingy quantum races.

► **Lemma 26.** *Let  $p_1, \dots, p_K$  define an  $\ell$ -dense symmetric stingy quantum race. If  $K \geq 6\ell$  then  $p_{T^*} > \frac{5}{21}$ . In particular,  $T^* \geq 2$ .*

**Proof.** Refer [14]. ◀

► **Theorem 27.** *Let  $p_1, \dots, p_K$  define an  $\ell$ -dense symmetric stingy quantum race. If  $K \geq 6\ell$  then*

$$\frac{\sigma(T^*)}{z_{T^*}^2} \leq \frac{6\ell}{K} \quad \text{and} \quad \sigma(T^*) \leq \frac{196\ell}{K} .$$

**Proof.** Refer [14]. ◀

Now that we have an upper bound on the collision probability, we obtain the following corollary to Theorem 24.

► **Corollary 28.** *Let  $p_1, \dots, p_K$  define an  $\ell$ -dense symmetric stingy quantum race. Let  $\tau = \frac{50\sqrt{2}\ell}{K}$ . If  $K \geq 6\ell$  then*

$$z_{T^*} \leq \sqrt{2} + 1 + \tau, \quad \frac{1}{z_{T^*}} \geq \sqrt{2} - 1 - \tau(\sqrt{2} - 1)^2, \quad p_{T^*} \geq \sqrt{2} - 1 - \tau(\sqrt{2} - 1)^2 .$$

**Proof.** Refer [14]. ◀

## 4 Two-player quantum races

In this section, we bootstrap our results about symmetric stingy quantum races to analyze symmetric quantum races. Our main results are two-fold.

1. The unique coinciding Nash equilibrium in an  $\ell$ -dense symmetric stingy quantum race is an approximate Nash equilibrium in the corresponding quantum race.
2. The approximate Nash equilibrium from (1) achieves a payoff which is nearly optimal among all symmetric Nash equilibria in a symmetric quantum race.

The intuition for item (1) is clear. The only difference between a stingy quantum race and a quantum race is the payoff on ties. For the unique coinciding Nash equilibrium we have shown that the collision probability is  $O(\ell/K)$ , thus the change in payoff on ties will make only a small change to the payoffs under this strategy.

For item (2), we use the quadratic programming characterization of Nash equilibria [15]. Consider a game  $(A, B)$  where  $A, B$  are  $m$ -by- $n$  matrices. The program

$$\begin{aligned} & \underset{x \in \Delta^m, y \in \Delta^n, \alpha, \beta \in \mathbb{R}}{\text{maximize}} && x^T(A + B)y - \alpha - \beta \\ & \text{subject to} && Ay \leq \alpha \mathbf{1}, \\ & && B^T x \leq \beta \mathbf{1}, \end{aligned} \tag{14}$$

has an optimal value of 0, and any  $(x, y)$  attaining the value 0 is a Nash equilibrium. In the case of a symmetric quantum race  $(A, A^T)$ , when we restrict to symmetric strategies  $(x, x)$  the objective function in Eq. (14) becomes negative definite plus linear, making this a standard quadratic program. We then use the tight dual formulation of a quadratic program [8] to give an upper bound on the payoff of any symmetric Nash equilibrium, by explicitly constructing solutions to the dual problem. This allows us to show that the payoff of the unique coinciding equilibrium in a stingy race achieves a payoff which is within  $O(\sqrt{\ell/K})$  of optimal amongst all symmetric equilibria in the corresponding quantum race.

We now proceed to show these two results.

### 4.1 Approximate Nash equilibrium

► **Definition 29.** A two-player game described by payoff matrices  $(A, B)$  is said to have an  $\epsilon$ -approximate Nash equilibrium  $(p, q)$ , for  $\epsilon \geq 0$ , if the following two conditions hold

$$p^T Aq \geq v^T Aq - \epsilon \text{ for all } v \in \Delta_m \tag{15}$$

$$p^T Bq \geq p^T Bu - \epsilon \text{ for all } u \in \Delta_n . \tag{16}$$

► **Definition 30.** A two-player game described by payoff matrices  $(A, B)$  is said to have an  $\epsilon$ -well supported Nash equilibrium  $(p, q)$ , for  $\epsilon \geq 0$  if

$$e_i^T Aq \geq e_j^T Aq - \epsilon \text{ for all } i \in \text{sup}(p) \text{ and } j \in [m]$$

$$p^T B e_i \geq p^T B e_j - \epsilon \text{ for all } i \in \text{sup}(q) \text{ and } j \in [n] .$$

Note that an  $\epsilon$ -well supported Nash equilibrium is also an  $\epsilon$ -approximate Nash equilibrium, but the reverse does not hold.

► **Theorem 31.** Let  $p_1, \dots, p_K$  be an  $\ell$ -dense sequence defining the symmetric stingy quantum race  $(A_0, A_0^T)$  and the symmetric quantum race  $(A, A^T)$ . Let  $(x, x)$  be the unique coinciding Nash equilibrium for the stingy quantum race  $(A_0, A_0^T)$  given by Theorem 22. Then  $(x, x)$  is a  $\frac{7(\sqrt{2}-1)\ell}{K}$ -well supported Nash equilibrium in the quantum race  $(A, A^T)$ .

**Proof.** To show that  $(x, x)$  is an  $\epsilon$ -well supported Nash equilibrium in the quantum race  $(A, A^T)$  it suffices to show that  $e_i^T Ax \geq e_j^T Ax - \epsilon$  for all  $T^* \leq i \leq K$  and  $j \in [K]$ . We omit the details of the proof here and refer the readers to [14]. ◀

## 4.2 Upper bound on payoff

Let  $(x, x)$  be the unique coinciding Nash equilibrium in an  $\ell$ -dense symmetric stingy quantum race  $(A_0, A_0^T)$ . We have just shown that  $(x, x)$  is a  $\frac{7(\sqrt{2}-1)\ell}{K}$ -well supported Nash equilibrium in the corresponding quantum race  $(A, A^T)$ . By Corollary 28,  $(x, x)$  achieves payoff at least  $\sqrt{2} - 1 - 50\sqrt{2}(\sqrt{2} - 1)^2 \frac{\ell}{K}$  in the game  $(A, A^T)$ . In this section, we show that this payoff is within  $O(\sqrt{\ell/K})$  of optimal among all symmetric strategies  $(y, y)$  for the game  $(A, A^T)$ .

Our starting point is to use the program in Eq. (14) to provide a means to upper bound the value of any symmetric equilibrium.

► **Lemma 32.** *Let  $(A, A^T)$  be a symmetric game and define for  $c \geq 0$*

$$\begin{aligned} \gamma_A(c) = \underset{x}{\text{maximize}} \quad & \frac{1}{2}x^T(A + A^T)x \\ \text{subject to} \quad & Ax \leq c\mathbf{1}, \\ & \mathbf{1}^T x = 1, x \geq \mathbf{0}. \end{aligned}$$

*For all  $c_0$ , such that  $\gamma_A(c) < c$  for all  $c \geq c_0$ , the payoff of any symmetric Nash equilibrium in the game  $(A, A^T)$  is less than  $c_0$ .*

**Proof.** We show the contrapositive. Suppose there is a symmetric Nash equilibrium  $(x, x)$  with payoff  $c \geq c_0$ . Then  $(x, x, c, c)$  is a feasible solution to the program in Eq. (14) with objective value 0. Thus  $Ax \leq c$  and  $\frac{1}{2}x^T(A + A^T)x = c$ . ◀

This is the approach we take to upper bounding the payoff of symmetric Nash equilibria in a quantum race.

► **Theorem 33.** *Let  $p_1, \dots, p_K$  be an  $\ell$ -dense sequence with  $K \geq 6\ell$ . Then any symmetric Nash equilibrium  $(x, x)$  in the two-player quantum race defined by  $p_1, \dots, p_K$  has payoff at most  $\sqrt{2} - 1 + 5\sqrt{\frac{\ell}{K}}$ .*

**Proof.** Let  $(A, A^T)$  be the payoff matrices of a two-player quantum race defined by  $p_1, \dots, p_K$ . We will show that  $\gamma_A(c) < c$  for all  $c > \sqrt{2} - 1 + 5\sqrt{\frac{\ell}{K}}$ . By Lemma 32 this proves the theorem.

In the case of a quantum race  $A + A^T = p\mathbf{1}^T + 1p^T - pp^T$ . This means that over the probability simplex, the quadratic form  $x^T(A + A^T)x = -x^T(pp^T)x + 2p^T x$  is a negative-definite plus linear function. In this case,  $\gamma_A(c)$  is in the standard form of a quadratic program and has a dual program with matching value [8].

$$\begin{aligned} \gamma_A(c) = \underset{v \in \mathbb{R}^K, \lambda, d \in \mathbb{R}}{\text{minimize}} \quad & \frac{1}{2}\lambda^2 + c \cdot \mathbf{1}^T v + d \\ \text{subject to} \quad & A^T v \geq (1 - \lambda)p - d\mathbf{1}, \\ & v \geq \mathbf{0}. \end{aligned} \tag{17}$$

Our approach will be to construct a feasible solution to Eq. (17) to demonstrate that  $\gamma_A(c) < c$  for all  $c > \sqrt{2} - 1 + 5\sqrt{\frac{\ell}{K}}$ .

## 51:16 Strategies for Quantum Races

First note that for  $c > \frac{1}{2}$  there is a trivial solution where  $\lambda = 1, d = 0$  and  $v$  is the all-zero vector which shows that  $\gamma(c) < c$ . We now focus on the case  $c \leq \frac{1}{2}$ . Let  $\sqrt{2} - 1 \leq c \leq \frac{1}{2}$ . We will develop a lower bound on  $c$  which implies  $\gamma_A(c) < c$ .

Let  $S$  be the smallest index  $i$  such that  $p_i \geq c$ . Note that as  $A$  is an  $\ell$ -dense quantum race we have  $p_S \leq c + \frac{\ell}{K}$ . We let

$$d = (1 - \lambda) \left( 1 + p_K - \frac{p_K}{p_S} \right)$$

and

$$v(i) = \begin{cases} 0 & \text{if } 1 \leq i < S \\ (1 - \lambda - d) \frac{p_S}{\bar{p}_S} \frac{1}{p_i} \left( \frac{1}{p_i} - \frac{1}{p_{i+1}} \right) & \text{if } S \leq i < K \\ (1 - \lambda - d) \frac{p_S}{p_K^2 \bar{p}_S} - \frac{(1-\lambda)}{p_K} & \text{if } i = K \end{cases} .$$

The choice of  $v$  comes from solving the system of linear equations  $(A_0^T v)_i = (1 - \lambda)p_i - d$  for  $S \leq i \leq K$ . The parameter  $\lambda$  will be chosen later.

Let us see that  $v$  satisfies the constraints of Eq. (17). Note that  $1 - \lambda - d = (1 - \lambda)p_K \frac{\bar{p}_S}{p_S}$ . Thus  $v(K) = 0$  and  $v \geq 0$  so long as  $\lambda \leq 1$ .

As mentioned, by construction  $v$  satisfies  $(A_0^T v)_i = (1 - \lambda)p_i - d$  for  $S \leq i \leq K$ . Thus as  $A = A_0 + \frac{1}{2} \text{diag}(p)^2$  and  $v \geq 0$  we also have  $(A^T v)_i \geq (1 - \lambda)p_i - d$  for  $S \leq i \leq K$ .

For  $i < S$  we have that

$$(A^T v)_i \geq (A_0^T v)_i = \bar{p}_i p^T v \geq \bar{p}_S p^T v = (1 - \lambda)p_S - d \geq (1 - \lambda)p_i - d .$$

Thus the constraint  $A_0^T v \geq (1 - \lambda)p - d\mathbf{1}$  is satisfied. We have shown that  $v$  is a feasible solution for any choice of  $\lambda \leq 1$ . We now choose  $\lambda$  to minimize the objective value. Substituting our choices of  $v, d$  into the objective value we have

$$\begin{aligned} \gamma_A(c) &\leq \frac{1}{2} \lambda^2 + (1 - \lambda) \left( 1 + p_K - \frac{p_K}{p_S} \right) + c(1 - \lambda) p_K \sum_{i=S}^{K-1} \frac{1}{p_i} \left( \frac{1}{p_i} - \frac{1}{p_{i+1}} \right) \\ &= \frac{1}{2} \lambda^2 + (1 - \lambda) \left( 1 + p_K \left( -\frac{\bar{p}_S}{p_S} + c \cdot \sum_{i=S}^{K-1} \frac{1}{p_i} \left( \frac{1}{p_i} - \frac{1}{p_{i+1}} \right) \right) \right) \end{aligned}$$

Define

$$\beta(c) = 1 + p_K \left( -\frac{\bar{p}_S}{p_S} + c \cdot \sum_{i=S}^{K-1} \frac{1}{p_i} \left( \frac{1}{p_i} - \frac{1}{p_{i+1}} \right) \right) .$$

The objective value  $\frac{1}{2} \lambda^2 + (1 - \lambda)\beta(c)$  is minimized over  $\lambda$  by taking  $\lambda = \beta(c)$ . This makes the objective value  $\beta(c) - \beta(c)^2/2$ . We have now reduced the problem to showing  $\beta(c) - \beta(c)^2/2 - c < 0$ . The roots of the corresponding quadratic equation are  $1 \pm \sqrt{1 - 2c}$ . Note that  $c \leq 1/2$ , thus the square root term will be real. Thus we will simultaneously have  $\beta(c) \leq 1$  and  $\beta(c) - \beta(c)^2/2 < c$  when  $\beta(c) < 1 - \sqrt{1 - 2c}$ . In Lemma 34, we show that  $\beta(c) < 1 - \sqrt{1 - 2c}$  when  $\sqrt{2} - 1 + 5\sqrt{\frac{\ell}{K}} \leq c \leq \frac{1}{2}$ . This will conclude the proof.  $\blacktriangleleft$

**► Lemma 34.**  $\beta(c) < 1 - \sqrt{1 - 2c}$  for any  $\sqrt{2} - 1 + 5\sqrt{\frac{\ell}{K}} \leq c \leq \frac{1}{2}$ .

**Proof.** Refer [14].  $\blacktriangleleft$

## 5 Multiplayer quantum races

### 5.1 Basic properties

For an integer  $n \geq 2$ , an  $n$ -player game is specified by a set of *pure strategies*  $S_i$ , and *payoff* functions  $u_i : S \rightarrow \mathbb{R}$ , for each player  $i \in [n]$ , where by definition  $S = S_1 \times \cdots \times S_n$  is the set of *pure strategy profiles*. For  $s \in S$ , the value  $u_i(s)$  is the payoff of player  $i$  for pure strategy profile  $s$ . Let  $S_{-i} = S_1 \times \cdots \times S_{i-1} \times S_{i+1} \times \cdots \times S_n$  be the set of all pure strategy profiles of players other than  $i$ . For  $s \in S$  and  $i \in [n]$ , we set the *partial* pure strategy profile  $s_{-i} \in S_{-i}$  to be  $(s_1, \dots, s_{i-1}, s_{i+1}, \dots, s_n)$ . For  $s'$  in  $S_{-i}$ , and  $s_i \in S_i$ , we denote by  $(s', s_i)$  the *combined* pure strategy profile  $(s'_1, \dots, s'_{i-1}, s_i, s'_{i+1}, \dots, s'_n) \in S$ . We will suppose that each player has  $m$  pure strategies and that  $S_i = \{e_1, \dots, e_m\}$ , the canonical basis of the vector space  $\mathbb{R}^m$ , for all  $i \in [n]$ , and therefore  $S = \{e_1, \dots, e_m\}^n$ . For simplicity, instead of  $e_j$  we often say strategy  $j$ .

A *mixed strategy* for player  $i$  is a probability distribution over  $S_i$  that we identify with a vector  $x_i = (x_i^1, \dots, x_i^m)$  such that  $x_i^j \geq 0$ , for all  $j \in [m]$ , and  $\sum_{j \in [m]} x_i^j = 1$ . We denote by  $\Delta_i$  the set of mixed strategies for  $i$ , and we call  $\Delta = \Delta_1 \times \cdots \times \Delta_n$  the set of *mixed strategy profiles*. For a mixed strategy profile  $x = (x_1, \dots, x_n)$  and pure strategy profile  $s \in S$ , the product  $x^s = x_1^{s_1} x_2^{s_2} \cdots x_n^{s_n}$  is the probability of  $s$  in  $x$ . We will consider the multilinear extension of the payoff functions from  $S$  to  $\Delta$  defined by  $u_i(x) = \sum_{s \in S} x^s u_i(s)$ . The set  $\Delta_{-i}$ , the partial mixed strategy profile  $x_{-i}$ , for  $x \in \Delta$  and  $i \in [n]$ , and the combined mixed strategy profile  $(x', x_i)$  for  $x' \in \Delta_{-i}$  and  $x_i \in \Delta_i$  are defined analogously to the pure case.

The pure strategy  $s_i$  is a *best response* for player  $i$  against the partial mixed strategy profile  $x' \in \Delta_{-i}$  if it maximizes  $u_i(x', \cdot)$ . For  $x \in \Delta$  and  $i \in [n]$ , we will denote by  $\text{br}(x_{-i})$  the set of best responses of player  $i$  against  $x_{-i}$ . A *Nash equilibrium* is a mixed strategy profile  $x = (x_1, \dots, x_n)$  such that  $\text{sup}(x_i) \subseteq \text{br}(x_{-i})$ , for all  $i \in [n]$ .

► **Definition 35** ( $n$ -party stingy quantum race). Let  $n \geq 2$  be a positive integer. An  $n$ -party stingy quantum race is defined by a sequence of increasing probabilities  $0 < P_1 < P_2 < \dots < P_K \leq 1$ , for some positive integer  $K$ . The set of pure strategies of all players is  $[K]$ . For every  $i$ , the utility function of the  $i^{\text{th}}$  player is defined as

$$u_i(s_1, \dots, s_n) = P_{s_i} \prod_{k \neq i, s_k \leq s_i} \bar{P}_{s_k}.$$

Consider an  $n$ -party stingy quantum race given by the probabilities  $0 < P_1 < \dots < P_K \leq 1$ , and let  $x_{-i} \in \Delta_{-i}$  for some  $i \in [n]$ . If player  $i$  plays the pure strategy  $s$  against  $x_{-i}$ , her payoff is

$$u_i(x_{-i}, s) = P_s \prod_{k \neq i} \left( \sum_{s_k \in \text{sup}_{\leq s}(x_k)} x_k^{s_k} \bar{P}_{s_k} + \sum_{s_k \in \text{sup}_{> s}(x_k)} x_k^{s_k} \right). \quad (18)$$

The following is the multiparty analog of Claim 14.

► **Claim 36.** Let  $x = (x_1, \dots, x_n)$  be a Nash equilibrium of an  $n$ -party stingy quantum race defined by probabilities  $P_1 < \dots < P_K$ . If  $s_1 \in \text{sup}(x_i)$ , for some  $i \in [n]$ , then for all  $s_2 > s_1$  there exists  $k \neq i$  such that  $\text{sup}_{\leq s_1}(x_k) \neq \text{sup}_{\leq s_2}(x_k)$ .

**Proof.** If  $\text{sup}_{\leq s_1}(x_k) = \text{sup}_{\leq s_2}(x_k)$ , for all  $k \neq i$  then

$$u_i(x_{-i}, s_2) = \frac{P_{s_2}}{P_{s_1}} u_i(x_{-i}, s_1).$$

As  $p_{s_1} < p_{s_2}$ , the payoff for playing  $s_2$  is strictly larger than that for playing  $s_1$ . Therefore  $s_1$  is not a best response for  $x_{-i}$ , in contradiction with the definition of a Nash equilibrium. ◀

This claim implies the following properties for the supports of Nash equilibria in a multiplayer stingy quantum race.

► **Corollary 37.** *Let  $x$  be a Nash equilibrium of an  $n$ -party stingy quantum race defined by probabilities  $0 < P_1 < P_2 < \dots < P_K \leq 1$ . Then we have:*

- $\bigcup_{i=1}^n \text{sup}(x_i)$  is an interval containing  $K$ ,
- for every  $i \in [n]$ , for every  $s_1, s_2 \in \text{sup}(x_i)$  there exists  $s \in \bigcup_{k \neq i} \text{sup}(x_k)$  with  $s_1 < s \leq s_2$ .

Let  $x$  be a Nash equilibrium of an  $n$ -party stingy quantum race. We say that  $x$  is *coinciding* if  $\text{sup}(x_i) = \text{sup}(x_k)$ , for all  $i, k \in [n]$ . We call this common support in a coinciding Nash equilibrium the *support* of the equilibrium. In the multiparty case we will only study coinciding Nash equilibria.

## 5.2 Coinciding Nash equilibria of stingy multiplayer races

By Corollary 37 we know that in a coinciding Nash equilibrium of an  $n$ -party stingy quantum race the support of the equilibrium is of the form  $\{T, T+1, \dots, K\}$ , for some  $1 \leq T \leq K$ . We would like to characterize these coinciding equilibria.

► **Lemma 38.** *Let  $x = (x_1, \dots, x_n)$ , where  $x_i$  is a  $K$ -dimensional real vector for every  $i \in [n]$ , and let  $1 \leq T \leq K$ . Then  $x$  is a Nash equilibrium of support  $\{T, T+1, \dots, K\}$  in an  $n$ -party stingy quantum race defined by  $0 < P_1 < \dots < P_K \leq 1$  if and only if  $x$  satisfies the following system, for all  $i \in [n]$ :*

$$u_i(x_{-i}, t) = u_i(x_{-i}, T) \quad \text{for } T < t \leq K, \quad (19)$$

$$u_i(x_{-i}, T-1) \leq u_i(x_{-i}, T), \quad (20)$$

$$x_i^t = 0 \quad \text{for } 0 < t < T, \quad (21)$$

$$x_i^t > 0 \quad \text{for } T \leq t \leq K, \quad (22)$$

$$\sum_{t=T}^K x_i^t = 1. \quad (23)$$

**Proof.** For every  $i \in [n]$ , Eq. (21)–(23) express that  $x_i$  is a probability distribution of support  $\{T, T+1, \dots, K\}$ . For  $T \geq 2$ , when playing a strategy  $t < T$  against the partial mixed strategy profile  $x_{-i}$ , the  $i$ th player's payoff is maximized if she plays  $T-1$ . Therefore Eq. (19) and (20) express that the strategies in her support are all best responses against  $x_{-i}$ . ◀

► **Definition 39.** For an  $n$ -party stingy quantum race defined by  $0 < P_1 < \dots < P_K \leq 1$  we define its *reduced game* as the 2-party stingy quantum race defined by the two sequences of probabilities  $p_1 < \dots < p_K$ , and  $P_1 < \dots < P_K$  where  $p_j = P_j^{1/(n-1)}$ , for  $1 \leq j \leq K$ .

We denote by  $A$  the payoff matrix of the first player in the reduced game

► **Lemma 40.** *Let an  $n$ -party stingy quantum race be defined by  $0 < P_1 < \dots < P_K \leq 1$ , let  $x = (x_1, \dots, x_n)$ , where  $x_i$  is a  $K$ -dimensional vector, and let  $1 \leq T \leq K$ . Then Eq. (19)–(23) are satisfied by  $x$ , for every  $i \in [n]$  if and only if Eq. (2)–(6) for the reduced game are satisfied by  $x_i$ , for every  $i \in [n]$ .*

**Proof.** Refer [14]. ◀

The following theorem characterizes the coinciding Nash equilibria in an  $n$ -party stingy quantum race.

► **Theorem 41.** *An  $n$ -party stingy quantum race always has a unique coinciding Nash equilibrium  $x = (x_1, \dots, x_n)$ , where  $x_1 = \dots = x_n$ . If the game is defined by the probabilities  $0 < P_1 < P_2 < \dots < P_K$  then the coinciding equilibrium has support  $\{T^*, T^* + 1, \dots, K\}$ , where  $T^* = T_B^*$  of the reduced game, and for all  $i \in [n]$ , the distribution  $x_i$  is defined on its support as*

$$x_i^t = \begin{cases} r_{T^*}^B / z_{T^*}^B & \text{if } t = T^*, \\ q_t^B / z_{T^*}^B & \text{if } T^* < t \leq K. \end{cases}$$

**Proof.** Combining Lemma 38 and Lemma 40, we get that  $x$  is a coinciding Nash equilibrium of support  $\{T, T + 1, \dots, K\}$  if and only if  $x_i$  satisfies Eq. (2)–(6) for the reduced game, for all  $i \in [n]$ . By Theorem 21 this happens if and only if  $T = T_B^*$  of the reduced game, and the unique solution for  $x_i$ , for  $i \in [n]$ , is the one stated by the Theorem. ◀

### 5.3 Collision probability of the stingy coinciding equilibrium

Our main objective in this section is to upper bound the collision probability – the probability that two or more players succeed at the same time – in the coinciding equilibrium found in the last section for an  $\ell$ -dense stingy  $n$ -player quantum race. To help with this, we make the following definition.

► **Definition 42.** For a joint probability distribution  $y = (y_1, \dots, y_n) \in \Delta$ , let  $\text{cp}_i^m(y)$  denote the probability that player  $i$  succeeds first and that exactly  $m$  players (including  $i$ ) succeed at the same time under the joint strategy  $y$ . Let  $\text{cp}_i(y) = \sum_{m=2}^n \text{cp}_i^m(y)$  denote the probability that player  $i$  succeeds first and at least one other player succeeds at the same time.

Let us also set up notation to describe the coinciding equilibrium in a stingy multiplayer race. Define the following quantities

$$q_i = \frac{1}{\bar{P}_i} \left( \frac{1}{P_{i-1}^{1/(n-1)}} - \frac{1}{P_i^{1/(n-1)}} \right), r_T = \frac{1}{\bar{P}_T} \left( \frac{1}{P_K^{1/(n-1)}} - \sum_{i=T+1}^K \bar{P}_i q_i \right), z_T = r_T + \sum_{i=T+1}^K q_i .$$

Let  $T^*$  be the starting point of the support of the coinciding equilibrium. Then by Theorem 41, the strategy of player  $i$  in the coinciding equilibrium is given by

$$x_i^t = \begin{cases} r_{T^*} / z_{T^*} & \text{if } t = T^*, \\ q_t / z_{T^*} & \text{if } T^* < t \leq K, \\ 0 & \text{if } t < T^* . \end{cases} \quad (24)$$

To obtain concrete bounds on the collision probability, we will need bounds on  $z_{T^*}$  and  $P_{T^*-1}$ .

► **Lemma 43.** *In any stingy multiplayer quantum race with  $n$  players  $(1/z_{T^*})^{n-1} < 1/n$ .*

**Proof.** Refer [14]. ◀

► **Theorem 44.** *Let  $P_1, \dots, P_K$  define a stingy  $n$ -player quantum race with  $n \geq 2$ . Then  $P_{T^*-1} < \frac{1}{n}$ . If in addition  $P_1, \dots, P_K$  form an  $\ell$ -dense sequence and  $4e\ell n \leq K$  then  $P_{T^*-1} \geq \frac{1}{2en}$ , where  $e$  is Euler's number.*

**Proof.** Refer [14]. ◀

The next lemma bounds the collision probability for player  $i$  when all players but player  $i$  play according to the coinciding equilibrium, and player  $i$  plays an arbitrary strategy  $v$ . We will use this lemma to bound the total collision probability and also in Section 5.4 to show that the stingy coinciding equilibrium is an approximate equilibrium in a multiparty race.

► **Lemma 45.** *Let  $P_1, \dots, P_K$  define an  $\ell$ -dense stingy  $n$ -player quantum race,  $n \geq 2$ , with  $4en\ell \leq K$ , and let  $x$  be the unique coinciding equilibrium given by Eq. (24). Then  $\text{cp}_i(x_{-i}, v) \leq \frac{8e\ell}{K}$  for any  $i \in [n]$  and  $v \in \Delta_i$ .*

**Proof.** Refer [14]. ◀

► **Theorem 8.** *Let  $P_1, \dots, P_K$  define an  $\ell$ -dense stingy  $n$ -player quantum race such that  $4en\ell \leq K$ . When the players play the coinciding equilibrium of the stingy race, the probability that two or more players succeed at the same time is at most  $\frac{8en\ell}{K}$ .*

**Proof.** By Lemma 45, the probability that two or more players succeed at the same time is at most

$$\sum_{i=1}^n \text{cp}_i(x) \leq \frac{8en\ell}{K} . \quad \blacktriangleleft$$

## 5.4 Multiplayer quantum races

In this section we use our results about the stingy multiplayer quantum race to analyse the multiplayer quantum race. Namely, we show that the coinciding equilibrium in a stingy multiplayer quantum race is an approximate equilibrium in a multiplayer race. The difference between a stingy multiplayer race and a multiplayer race is that in a multiplayer race, the payoff is equally divided amongst all players who succeed first at the same time.

► **Definition 46** (Multiplayer quantum race). Let  $u_i$  be the payoff function for player  $i \in [n]$  in the  $n$ -player stingy race defined by  $P_1 < \dots < P_k$ , as given by Eq. (18). The payoff function  $u'_i$  in the  $n$ -player quantum race defined by  $P_1, \dots, P_k$  is

$$u'_i(x) = u_i(x) + \sum_{m=2}^n \frac{\text{cp}_i^m(x)}{m} .$$

While the tie-splitting payoff in Definition 46 is quite natural, one could imagine other definitions in-between stingy multiplayer races and the definition of multiplayer races we have given. Our results in this section depend very weakly on the exact definition of how ties are split in a multiplayer race. In fact, the only property we use is  $u'_i(x) \leq u_i(x) + \text{cp}_i(x)$ . This property holds under any reasonable definition of tie-splitting.

Now we show Theorem 9 from the introduction that the coinciding Nash equilibrium in a multiplayer stingy quantum race is an approximate Nash equilibrium in a multiplayer quantum race.

► **Theorem 9.** *Let  $P_1, \dots, P_K$  define an  $\ell$ -dense stingy  $n$ -player quantum race,  $n \geq 2$ , with  $4en\ell \leq K$ . If  $x = (x_1, \dots, x_n)$  is the coinciding Nash equilibrium for this stingy race, then  $x$  is an  $\frac{8e\ell}{K}$ -approximate Nash equilibrium of the corresponding quantum race.*

## Abstract

We introduce a new model for testing graph properties which we call the *rejection sampling model*. We show that testing bipartiteness of  $n$ -nodes graphs using rejection sampling queries requires complexity  $\tilde{\Omega}(n^2)$ . Via reductions from the rejection sampling model, we give three new lower bounds for tolerant testing of Boolean functions of the form  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ :

- Tolerant  $k$ -junta testing with *non-adaptive* queries requires  $\tilde{\Omega}(k^2)$  queries.
- Tolerant unateness testing requires  $\tilde{\Omega}(n)$  queries.
- Tolerant unateness testing with *non-adaptive* queries requires  $\tilde{\Omega}(n^{3/2})$  queries.

Given the  $\tilde{O}(k^{3/2})$ -query non-adaptive junta tester of Blais [7], we conclude that non-adaptive tolerant junta testing requires more queries than non-tolerant junta testing. In addition, given the  $\tilde{O}(n^{3/4})$ -query unateness tester of Chen, Waingarten, and Xie [19] and the  $\tilde{O}(n)$ -query non-adaptive unateness tester of Baleshzar, Chakrabarty, Pallavoor, Raskhodnikova, and Seshadhri [3], we conclude that tolerant unateness testing requires more queries than non-tolerant unateness testing, in both adaptive and non-adaptive settings. These lower bounds provide the first separation between tolerant and non-tolerant testing for a natural property of Boolean functions.

## 1 Introduction

Over the past decades, property testing has emerged as an important line of research in sublinear time algorithms. The goal is to understand randomized algorithms for approximate decision making, where the algorithm needs to decide (with high probability) whether a huge object has some property by making a few queries to the object. Many different types of objects and properties have been studied from this property testing perspective (see the surveys by Ron [35, 36] and the recent textbook by Goldreich [26] for overviews of contemporary property testing research). This paper deals with property testing of Boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  and property testing of graphs with vertex set  $[n]$ .

<sup>2</sup> This work is supported in part by the NSF Graduate Research Fellowship under Grant No. DGE-16-44869, CCF-1703925, CCF-1563155, and CCF-1420349.

In this paper we describe a new model of graph property testing, which we call the *rejection sampling model*. For  $n \in \mathbb{N}$  and a subset  $\mathcal{P}$  of graphs on the vertex set  $[n]$ , we say a graph  $G$  on vertex set  $[n]$  has property  $\mathcal{P}$  if  $G \in \mathcal{P}$  and say  $G$  is  $\varepsilon$ -far from having property  $\mathcal{P}$  if all graphs  $H \in \mathcal{P}$  differ on at least  $\varepsilon n^2$  edges<sup>3</sup>. The problem of  $\varepsilon$ -testing  $\mathcal{P}$  with *rejection sampling queries* is the following task:

Given some  $\varepsilon > 0$  and access to an unknown graph  $G = ([n], E)$ , output “accept” with probability at least  $\frac{2}{3}$  if  $G$  has property  $\mathcal{P}$ , and output “reject” with probability at least  $\frac{2}{3}$  if  $G$  is  $\varepsilon$ -far from having property  $\mathcal{P}$ . The access to  $G$  is given by the following oracle queries: given a query set  $L \subseteq [n]$ , the oracle samples an edge  $(i, j) \sim E$  uniformly at random and returns  $\{i, j\} \cap L$ .

We measure the complexity of algorithms with rejection sampling queries by considering the sizes of the queries. The complexity of an algorithm making queries  $L_1, \dots, L_t \subseteq [n]$  is  $\sum_{i=1}^t |L_i|$ .

The rejection sampling model allows us to study testers which rely on random sampling of edges, while providing the flexibility of making lower-cost queries. This type of query access strikes a delicate balance between simplicity and generality: queries are constrained enough for us to show high lower bounds, and at the same time, the flexibility of making queries allows us to reduce the rejection sampling model to Boolean function testing problems. Specifically, we reduce to tolerant junta testing and tolerant unateness testing (see Subsection 1.1).

Our main result in the rejection sampling model is regarding *non-adaptive* algorithms. These algorithms need to fix their queries in advance and are not allowed to depend on answers to previous queries (in the latter case we say that the algorithm is *adaptive*). We show a lower bound on the complexity of testing whether an unknown graph  $G$  is bipartite using non-adaptive queries.

► **Theorem 1.** *There exists a constant  $\varepsilon > 0$  such that any non-adaptive  $\varepsilon$ -tester for bipartiteness in the rejection sampling model has cost  $\tilde{\Omega}(n^2)$ .*<sup>4</sup>

More specifically, Theorem 1 follows from applying Yao’s principle to the following lemma.

► **Lemma 2.** *Let  $\mathcal{G}_1$  be the uniform distribution over the union of two disjoint cliques of size  $n/2$ , and let  $\mathcal{G}_2$  be the uniform distribution over complete bipartite graphs with each part of size  $n/2$ . Any deterministic non-adaptive algorithm that can distinguish between  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with constant probability using rejection sampling queries, must have complexity  $\tilde{\Omega}(n^2)$ .*

We discuss a number of applications of the rejection sampling model (specifically, of Lemma 2) in the next subsection. In particular, we obtain new lower bounds in the *tolerant testing framework* introduced by Parnas, Ron, and Rubinfeld in [34] for two well-studied properties of Boolean functions (specifically,  $k$ -juntas and unateness; see the next subsection for definitions of these properties). These lower bounds are obtained by a reduction from the rejection sampling model; we show that too-good-to-be-true Boolean function testers for these properties imply the existence of rejection sampling algorithms which distinguish  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with  $\tilde{o}(n^2)$  complexity. Therefore, we may view the rejection sampling model as a useful abstraction in studying the hard instances of tolerant testing  $k$ -juntas and unateness.

<sup>3</sup> The distance definition can be modified accordingly when one considers bounded degree or sparse graphs.

<sup>4</sup> We use the notations  $\tilde{O}, \tilde{\Omega}$  to hide polylogarithmic dependencies on the argument, i.e. for expressions of the form  $O(f \log^c f)$  and  $\Omega(f / \log^c f)$  respectively (for some absolute constant  $c$ ).

## 1.1 Applications to Tolerant Testing: Juntas and Unateness

Given  $n \in \mathbb{N}$  and a subset  $\mathcal{P}$  of  $n$ -variable Boolean functions, a Boolean function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  has property  $\mathcal{P}$  if  $f \in \mathcal{P}$ . The distance between Boolean functions  $f, g: \{0, 1\}^n \rightarrow \{0, 1\}$  is  $\text{dist}(f, g) = \Pr_{x \sim \{0, 1\}^n}[f(x) \neq g(x)]$ . The distance of  $f$  to the property  $\mathcal{P}$  is  $\text{dist}(f, \mathcal{P}) = \min_{g \in \mathcal{P}} \text{dist}(f, g)$ . We say that  $f$  is  $\varepsilon$ -close to  $\mathcal{P}$  if  $\text{dist}(f, \mathcal{P}) \leq \varepsilon$  and  $f$  is  $\varepsilon$ -far from  $\mathcal{P}$  if  $\text{dist}(f, \mathcal{P}) > \varepsilon$ . The problem of *tolerant property testing* [34] of  $\mathcal{P}$  asks for query-efficient randomized algorithms for the following task:

Given parameters  $0 \leq \varepsilon_0 < \varepsilon_1 < 1$  and black-box query access to a Boolean function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ , accept with probability at least  $\frac{2}{3}$  if  $f$  is  $\varepsilon_0$ -close to  $\mathcal{P}$  and reject with probability at least  $\frac{2}{3}$  if  $f$  is  $\varepsilon_1$ -far from  $\mathcal{P}$ .

An algorithm which performs the above task is an  $(\varepsilon_0, \varepsilon_1)$ -tolerant tester for  $\mathcal{P}$ . A  $(0, \varepsilon_1)$ -tolerant tester is a *standard* property tester or a *non-tolerant* tester. As noted in [34], tolerant testing is not only a natural generalization, but is also very often the desirable attribute of testing algorithms. This motivates the high level question: how does the requirement of being tolerant affect the complexity of testing the properties studied? We make progress on this question by showing query-complexity separations for two well-studied properties of Boolean functions:  $k$ -juntas, and unate functions.

- ( $k$ -junta) A function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  is a  $k$ -junta if it depends on at most  $k$  of its variables, i.e., there exists  $k$  distinct indices  $i_1, \dots, i_k \in [n]$  and a  $k$ -variable function  $g: \{0, 1\}^k \rightarrow \{0, 1\}$  where  $f(x) = g(x_{i_1}, \dots, x_{i_k})$  for all  $x \in \{0, 1\}^n$ .
- (unateness) A function  $f: \{0, 1\}^n \rightarrow \{0, 1\}$  is *unate* if  $f$  is either non-increasing or non-decreasing in every variable. Namely, there exists a string  $r \in \{0, 1\}^n$  such that the function  $f(x \oplus r)$  is monotone with respect to the bit-wise partial order on  $\{0, 1\}^n$ .

While separations between tolerant and non-tolerant testing of Boolean function properties were known for an (artificial) property (see Subsection 1.2), these results are the first to give such lower bounds for a natural class of well-studied properties of Boolean functions. The first such theorem we state concerns non-adaptive tolerant testers for  $k$ -juntas.

► **Theorem 3.** *For any  $\alpha < 1$ , there exists constants  $0 < \varepsilon_0 < \varepsilon_1 < 1$  such that for any  $k = k(n) \leq \alpha n$ , any non-adaptive  $(\varepsilon_0, \varepsilon_1)$ -tolerant  $k$ -junta tester must make  $\tilde{\Omega}(k^2)$  queries.*

We give a noteworthy consequences of the Theorem 3. In [7], Blais gave a non-adaptive  $\tilde{O}(k^{3/2})$ -query tester for (non-tolerant) testing of  $k$ -juntas, which was shown to be optimal for non-adaptive algorithms by Chen, Servedio, Tan, Waingarten and Xie in [17]. Combined with Theorem 3, this shows a polynomial separation in the query complexity of non-adaptive tolerant junta testing and non-adaptive junta testing.

The next two theorems concern tolerant testers for unateness.

► **Theorem 4.** *There exists constants  $0 < \varepsilon_0 < \varepsilon_1 < 1$  such that any (possibly adaptive)  $(\varepsilon_0, \varepsilon_1)$ -tolerant unateness tester must make  $\tilde{\Omega}(n)$  queries.*

► **Theorem 5.** *There exists constant  $0 < \varepsilon_0 < \varepsilon_1 < 1$  such that any non-adaptive  $(\varepsilon_0, \varepsilon_1)$ -tolerant unateness tester must make  $\tilde{\Omega}(n^{3/2})$  queries.*

A similar separation in tolerant and non-tolerant testing occurs for the property of unateness as a consequence of Theorem 4 and Theorem 5. Recently, in [3], Baleshzar, Chakrabarty, Pallavoor, Raskhodnikova, and Seshadhri gave a non-adaptive  $\tilde{O}(n)$ -query tester for (non-tolerant) unateness testing, and Chen, Waingarten and Xie [18] gave an

(adaptive)  $\tilde{O}(n^{3/4})$ -query tester for (non-tolerant) unateness testing. We thus, conclude that by Theorem 4 and Theorem 5, tolerant unateness testing is polynomially harder than (non-tolerant) unateness testing, in both adaptive and non-adaptive settings.

## 1.2 Related Work

The properties of  $k$ -juntas and unateness have received much attention in property testing research ([24, 20, 7, 8, 10, 37, 17, 9] study  $k$ -juntas, and [27, 31, 14, 3, 18, 19] study unateness). We briefly review the current state of affairs in (non-tolerant)  $k$ -junta testing and unateness testing, and then discuss tolerant testing of Boolean functions and the rejection sampling model.

**Testing  $k$ -juntas.** The problem of testing  $k$ -juntas, introduced by Fischer, Kindler, Ron, Safra, and Samorodnitsky [24], is now well understood up to poly-logarithmic factors. Chockler and Gutfreund [20] show that any tester for  $k$ -juntas requires  $\Omega(k)$  queries (for a constant  $\varepsilon_1$ ). Blais [8] gave a junta tester that uses  $O(k \log k + k/\varepsilon_1)$  queries, matching the bound of [20] up to a factor of  $O(\log k)$  for constant  $\varepsilon_1$ . When restricted to non-adaptive algorithms, [24] gave a non-adaptive tester making  $\tilde{O}(k^2/\varepsilon_1)$  queries, which was subsequently improved in [7] to  $\tilde{O}(k^{3/2})/\varepsilon_1$ . In terms of lower bounds, Buhrman, Garcia-Soriano, Matsliah, and de Wolf [10] gave a  $\Omega(k \log k)$  lower bound for  $\varepsilon = \Omega(1)$ , and Servedio, Tan, and Wright [37] gave a lower bound which showed a separation between adaptive and non-adaptive algorithms for  $\varepsilon_1 = \frac{1}{\log k}$ . These results were recently improved in [17] to  $\tilde{\Omega}(k^{3/2}/\varepsilon_1)$ , settling the non-adaptive query complexity of the problem up to poly-logarithmic factors.

**Testing unateness.** The problem of testing unateness was introduced alongside the problem of testing monotonicity in Goldreich, Goldwasser, Lehman, Ron, and Samorodnitsky [27], where they gave the first  $O(n^{3/2}/\varepsilon_1)$ -query non-adaptive tester. Khot and Shinkar [31] gave the first improvement by giving a  $\tilde{O}(n/\varepsilon_1)$ -query adaptive algorithm. A non-adaptive algorithm with  $\tilde{O}(n/\varepsilon_1)$  queries was given in [13, 3]. Recently, [18, 2] show that  $\tilde{\Omega}(n)$  queries are necessary for non-adaptive one-sided testers. Subsequently, [19] gave an adaptive algorithm testing unateness with query complexity  $\tilde{O}(n^{3/4}/\varepsilon_1^2)$ . The current best lower bound for general adaptive testers appears in [18], where it was shown that any adaptive two-sided tester must use  $\tilde{\Omega}(n^{2/3})$  queries.

**Tolerant testing.** Once we consider tolerant testing, i.e., the case  $\varepsilon_0 > 0$ , the picture is not as clear. In the paper introducing tolerant testing, [34] observed that standard algorithms whose queries are uniform (but not necessarily independent) are inherently tolerant to some extent. Nevertheless, achieving  $(\varepsilon_0, \varepsilon_1)$ -tolerant testers for constants  $0 < \varepsilon_0 < \varepsilon_1$ , can require applying different methods and techniques (see e.g, [30, 34, 25, 1, 32, 33, 22, 11, 6, 5, 38]).

By applying the observation from [34] to the unateness tester in [3], the tester accepts functions which are  $O(\varepsilon_1/n)$ -close to unate with constant probability. We similarly obtain weak guarantees for tolerant testing of  $k$ -juntas. Diakonikolas, Lee, Matulef, Onak, Rubinfeld, Servedio, and Wan [21] observed that one of the (non-adaptive) junta testers from [24] accepts functions that are  $\text{poly}(\varepsilon_1, 1/k)$ -close to  $k$ -juntas. Chakraborty, Fischer, Garcia-Soriano, and Matsliah [15] noted that the analysis of the junta tester of Blais [8] implicitly implies an  $\exp(k/\varepsilon_1)$ -query complexity tolerant tester which accepts functions that are  $\varepsilon_1/c$ -close to some  $k$ -junta (for some constant  $c > 1$ ) and rejects functions that are  $\varepsilon_1$ -far from every  $k$ -junta. Recently, Blais, Canonne, Eden, Levi and Ron [9] showed that when required to distinguish between the cases that  $f$  is  $\varepsilon_1/10$ -close to a  $k$ -junta, or is  $\varepsilon_1$ -far from a  $2k$ -junta,  $\text{poly}(k, 1/\varepsilon_1)$  queries suffice.

For general properties of Boolean functions, tolerant testing could be much harder than standard testing. Fischer and Fortnow [23] used PCPs in order to construct a property of Boolean functions  $\mathcal{P}$  which is  $(0, \varepsilon_1)$ -testable with a constant number of queries (depending on  $\varepsilon_1$ ), but any  $(1/4, \varepsilon_1)$ -tolerant test for  $\mathcal{P}$  requires  $n^c$  queries for some  $c > 0$ . While [23] presents a strong separation between tolerant and non-tolerant testing, the complexity of tolerant testing of many natural properties remains open. We currently neither have a  $\text{poly}(k, \frac{1}{\varepsilon_1})$ -query tester which  $(\varepsilon_0, \varepsilon_1)$ -tests  $k$ -juntas, nor a  $\text{poly}(n, \frac{1}{\varepsilon_1})$ -query tester that  $(\varepsilon_0, \varepsilon_1)$ -tests unateness or monotonicity when  $\varepsilon_0 = \Theta(\varepsilon_1)$ .

**Testing graphs with rejection sampling queries.** Even though the problem of testing graphs with rejection sampling queries has not been previously studied, the model shares characteristics with previous studied frameworks. These include sample-based testing studied by Goldreich, Goldwasser, and Ron in [28, 29], where the oracle receives random samples from the input. One crucial difference between rejection sampling algorithms (which always query  $[n]$ ) and sample-based testers is the fact that rejection sampling algorithms only receive *positive* examples (in the form of edges), as opposed to random positions in the adjacency matrix (which may be a *negative* example indicated the non-existence of an edge).

The rejection sampling model for graph testing also bears some resemblance to the conditional sampling framework for distribution testing introduced in Canonne, Ron, and Servedio, as well as Chakraborty, Fischer, Goldhirsh, and Matsliah [12, 16], where the algorithm specifies a query set and receives a sample conditioned on it lying in the query set.

### 1.3 Techniques and High Level Overview

We first give an overview of how the lower bound in the rejection sampling model (Lemma 2) implies lower bounds for tolerant testing of  $k$ -juntas and unateness, and then we give an overview of how Lemma 2 is proved.

**Reducing Boolean Function Testing from Rejection Sampling.** This work should be considered alongside some recent works showing lower bounds for testing the properties of monotonicity, unateness, and juntas in the standard property testing model [4, 18, 17]. At a high level, the lower bounds for Boolean function testing proceed in three steps:

1. First, design a randomized indexing function  $\Gamma: \{0, 1\}^n \rightarrow [N]$  that partitions the Boolean cube  $\{0, 1\}^n$  into roughly equal parts in a way compatible with the property (either junta, or unateness). We want to ensure that algorithms that make few queries cannot learn too much about  $\Gamma$ , and that queries falling in the same part are close in Hamming distance.
2. Second, define two distributions over functions  $\mathbf{h}_i: \{0, 1\}^n \rightarrow \{0, 1\}$  for each  $i \in [N]$ . The hard functions are defined by  $\mathbf{f}(x) = \mathbf{h}_{\Gamma(x)}(x)$ , so that one distribution corresponds to functions with the property, and the other distribution corresponds to functions far from the property.
3. Third, show that any testing algorithm for the property is actually solving some algorithmic task (determined by the distributions of  $\mathbf{h}_i$ ) which is hard when queries are close in Hamming distance.

The first step in the above-mentioned plan is standard (given familiarity with [18] and [17]). We will use a construction from [17] for the junta lower bound and a Talagrand-based construction (similar to [18], but somewhat simpler) for the unateness lower bounds. The novelty in this work lies in steps 2 and 3. We will define the distributions over sub-functions  $\mathbf{h}_i$  such that the resulting Boolean functions  $\mathbf{f}(x) = \mathbf{h}_{\Gamma(x)}(x)$  either is  $\varepsilon_0$ -close to desired

property ( $k$ -juntas and unateness), or is  $\varepsilon_1$ -far from having the desired property ( $k$ -juntas and unateness). Then, we will show that any algorithm for tolerant testing of  $k$ -juntas or unateness must be able to solve a hard instance of bipartiteness testing in the rejection sampling model.

At a very high level, our reductions will follow by associating to each distribution of Boolean functions  $\mathbf{f}: \{0, 1\}^n \rightarrow \{0, 1\}$  a distribution over graphs  $\mathbf{G}$  defined on a subset of  $[n]$  (these will be  $\mathcal{G}_1$  and  $\mathcal{G}_2$ ). The edges of a graph  $\mathbf{G}$  sampled from  $\mathcal{G}_1$  or  $\mathcal{G}_2$  will encode how the variables of  $\mathbf{f}$  interact with one another, and the distance of  $\mathbf{f}$  to  $k$ -junta (or unateness) will depend on a global parameter of the  $\mathbf{G}$ .<sup>5</sup> In addition, Boolean function queries on  $\mathbf{f}$  will be interpreted as rejection sampling queries to  $\mathbf{G}$ , so that tests distinguishing the distributions of Boolean functions will give rise to rejection sampling algorithms which distinguish between  $\mathcal{G}_1$  and  $\mathcal{G}_2$ . Since we will show a lower bound in the rejection sampling model, we will obtain a lower bound for tolerant testing of  $k$ -juntas and unateness.

For a more detailed discussion of the distributions and the reductions see Sections 3 and 4.

**Distinguishing  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with Rejection Sampling Queries.** In order to prove Lemma 2, one needs to rule out any deterministic non-adaptive algorithm which distinguishes between  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with rejection sampling queries of complexity  $\tilde{o}(n^2)$ . In order to keep the discussion at a high level, we identify three possible “strategies” for determining whether an underlying graph is a complete bipartite graph, or a union of two disjoint cliques:

1. One approach is for the algorithm to sample edges and consider the subgraph obtained from edges returned by the oracle. For instance, the algorithm may make all rejection sampling queries to be  $[n]$ . These queries are expensive in the rejection sampling model, but they guarantee that an edge from the graph will be observed. If the algorithm is lucky, and there exists a triangle in the subgraph observed, the graph must not be bipartite, so it must come from  $\mathcal{G}_2$ .
2. Another sensible approach is for the algorithm to forget about the structure of the graph, and simply view the distribution on the edges generated by the randomness in the rejection sampling oracle as a distribution testing problem. Suppose for simplicity that the algorithm makes rejection sampling queries  $[n]$ . Then, the corresponding distributions supported on edges from  $\mathcal{G}_1$  and  $\mathcal{G}_2$  will be  $\Omega(1)$ -far from each other, so a distribution testing algorithm can be used.
3. A third, more subtle, approach is for the algorithm to use the fact that  $\mathcal{G}_1$  and  $\mathcal{G}_2$  correspond to the union of two cliques and a complete bipartite graph, and extract knowledge about the non-existence of edges when making queries which return either  $\emptyset$  or a single vertex. More specifically, suppose that by having observed some edges, the algorithm observes two connected components  $L_1$  and  $L_2$ . If when querying  $L_1 \cup L_2$  multiple times, we do not observe an edge, it is more likely the underlying graph comes from  $\mathcal{G}_1$  than  $\mathcal{G}_2$ . Specifically, if  $\mathbf{G} \sim \mathcal{G}_1$  and  $L_1$  lies in one clique and  $L_2$  lies in the other clique, there would be no edges with edges from  $L_1$  and  $L_2$ ; on the other hand, if  $\mathbf{G} \sim \mathcal{G}_2$ , then  $L_1$  and  $L_2$  would always have some edges between them.

---

<sup>5</sup> The relevant graph parameter in  $k$ -juntas and unateness will be different. Luckily, both graph parameters will have gaps in their value depending on the distribution the graphs were drawn from (either  $\mathcal{G}_1$  or  $\mathcal{G}_2$ ). This allows us to reuse the work of proving Lemma 2 to obtain Theorem 3, Theorem 4, and Theorem 5.

The three strategies mentioned above all fail to give  $\tilde{O}(n^2)$  rejection sampling algorithms. The first approach fails because with a budget of  $\tilde{O}(n^2)$ , rejection sampling algorithms will observe subgraphs which consist of various trees of size at most  $\log n$ , thus we will not observe cycles. The second approach fails since the distributions are supported on  $\Omega(n^2)$  edges, so distribution testing algorithms will require  $\Omega(n)$  edges (which costs  $\Omega(n^2)$ ) to distinguish between  $\mathcal{G}_1$  and  $\mathcal{G}_2$ . Finally, the third approach fails since algorithms will only observe  $o(n)$  responses from the oracle corresponding to lone vertices which will be split roughly evenly among the unknown parts of the graph, so these observations will not be enough to distinguish between  $\mathcal{G}_1$  and  $\mathcal{G}_2$ .

Our lower bound rules out the three strategies sketched above when the complexity is  $\tilde{O}(n^2)$ , and shows that if the above three strategies do not work (in any possible combination with each other as well), then no non-adaptive algorithm of complexity  $\tilde{O}(n^2)$  will work. The main technical challenge is to show that the above strategies are the *only* possible strategies to distinguish  $\mathcal{G}_1$  and  $\mathcal{G}_2$ . In Section 5, we give a more detailed, yet still high-level discussion of the proof of Lemma 2.

Finally, the analysis of Lemma 2 is tight; there is a non-adaptive rejection sampling algorithm which distinguishes  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with complexity  $\tilde{O}(n^2)$ . The algorithm (based on the first approach mentioned above) is simple: make  $\tilde{O}(n)$  queries  $L = [n]$ , and if we observe an odd-length cycle, we output “ $\mathcal{G}_1$ ”, otherwise, output “ $\mathcal{G}_2$ ”.

## 1.4 Preliminaries

We use boldfaced letters such as  $\mathbf{A}, \mathbf{M}$  to denote random variables. Given a string  $x \in \{0, 1\}^n$  and  $j \in [n]$ , we write  $x^{(j)}$  to denote the string obtained from  $x$  by flipping the  $j$ -th coordinate. An edge along the  $j$ -th direction in  $\{0, 1\}^n$  is a pair  $(x, y)$  of strings with  $y = x^{(j)}$ . In addition, for  $\alpha \in \{0, 1\}$  we use the notation  $x^{(j \rightarrow \alpha)}$  to denote the string  $x$  where the  $j$ th coordinate is set to  $\alpha$ . Given  $x \in \{0, 1\}^n$  and  $S \subseteq [n]$ , we use  $x|_S \in \{0, 1\}^S$  to denote the projection of  $x$  on  $S$ . For a distribution  $\mathcal{D}$  we write  $\mathbf{d} \sim \mathcal{D}$  to denote an element  $d$  drawn according to the distribution. We sometimes write  $a \approx b \pm c$  to denote  $b - c \leq a \leq b + c$ .

## 2 The Rejection Sampling Model

In this section, we define the rejection sampling model and the distributions over graphs we will use throughout this work. We define the rejection sampling model tailored to our specific application of proving Lemma 2.

► **Definition 6.** Consider two distributions,  $\mathcal{G}_1$  and  $\mathcal{G}_2$  supported on graphs with vertex set  $[n]$ . The problem of distinguishing  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with a rejection sampling oracle aims to distinguish between the following two cases with a specific kind of query:

- Cases: We have an unknown graph  $\mathbf{G} \sim \mathcal{G}_1$  or  $\mathbf{G} \sim \mathcal{G}_2$ .
- Rejection Sampling Oracle: Each query is a subset  $L \subseteq [n]$ ; an oracle samples an edge  $(j_1, j_2)$  from  $\mathbf{G}$  uniformly at random, and the oracle returns  $\mathbf{v} = \{j_1, j_2\} \cap L$ . The complexity of a query  $L$  is given by  $|L|$ .

We say a non-adaptive algorithm Alg for this problem is a sequence of query sets  $L_1, \dots, L_q \subseteq [n]$ , as well as a function Alg:  $([n] \cup ([n] \times [n]) \cup \{\emptyset\})^q \rightarrow \{\text{“}\mathcal{G}_1\text{”}, \text{“}\mathcal{G}_2\text{”}\}$ . The algorithm sends each query to the oracle, and for each query  $L_i$ , the oracle responds  $\mathbf{v}_i \in [n] \cup ([n] \times [n]) \cup \{\emptyset\}$ , which is either a single element of  $[n]$ , an edge in  $\mathbf{G}$ , or  $\emptyset$ . The algorithm succeeds if:

$$\Pr_{\substack{\mathbf{G} \sim \mathcal{G}_1, \\ \mathbf{v}_1, \dots, \mathbf{v}_q}} [\text{Alg}(\mathbf{v}_1, \dots, \mathbf{v}_q) \text{ outputs “}\mathcal{G}_1\text{”}] - \Pr_{\substack{\mathbf{G} \sim \mathcal{G}_2, \\ \mathbf{v}_1, \dots, \mathbf{v}_q}} [\text{Alg}(\mathbf{v}_1, \dots, \mathbf{v}_q) \text{ outputs “}\mathcal{G}_1\text{”}] \geq \frac{1}{3}.$$

The complexity of Alg is measured by the sum of the complexity of the queries, so we let  $\text{cost}(\text{Alg}) = \sum_{i=1}^q |L_i|$ .

While our interest in this work is primarily on lower bounds for the rejection sampling model, an interesting direction is to explore upper bounds of various natural graph properties with rejection sampling queries. Our specific applications only require ruling out non-adaptive algorithms, but one may define adaptive algorithms in the rejection sampling model and study the power of adaptivity in this setting as well.

## 2.1 The Distributions $\mathcal{G}_1$ and $\mathcal{G}_2$

Let  $\mathcal{G}_1$  and  $\mathcal{G}_2$  be two distributions supported on graphs with vertex set  $[n]$  defined as follows. Let  $\mathbf{A} \subseteq [n]$  be a uniform random subset of size  $\frac{n}{2}$ .

$$\mathcal{G}_1 = \left\{ K_{\mathbf{A}} \cup K_{\overline{\mathbf{A}}} : \mathbf{A} \subseteq [n] \text{ random subset size } \frac{n}{2} \right\}$$

$$\mathcal{G}_2 = \left\{ K_{\mathbf{A}, \overline{\mathbf{A}}} : \mathbf{A} \subseteq [n] \text{ random subset size } \frac{n}{2} \right\},$$

where for a subset  $A$ ,  $K_A$  is the complete graph on vertices in  $A$  and  $K_{A, \overline{A}}$  is the complete bipartite graph whose sides are  $A$  and  $\overline{A}$ .

## 3 Tolerant Junta Testing

In this section, we will prove that distinguishing the two distributions  $\mathcal{G}_1$  and  $\mathcal{G}_2$  using a rejection sampling oracle reduces to distinguishing two distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  over Boolean functions, where  $\mathcal{D}_{\text{yes}}$  is supported on functions that are close to  $k$ -juntas and  $\mathcal{D}_{\text{no}}$  is supported on functions that are far from any  $k$ -junta with high probability.

### 3.1 High Level Overview

We start by providing some intuition of how our constructions and reduction implement the plan set forth in Subsection 1.3 for the property of being a  $k$ -junta. We define two distributions supported on Boolean functions,  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$ , so that functions in  $\mathcal{D}_{\text{yes}}$  are  $\varepsilon_0$ -close to being  $k$ -juntas and functions in  $\mathcal{D}_{\text{no}}$  are  $\varepsilon_1$ -far from being  $k$ -juntas (where  $\varepsilon_0$  and  $\varepsilon_1$  are appropriately defined constants and  $k = \frac{3n}{4}$ ).

As mentioned in the introduction, our distributions are based on the indexing function used in [17]. We draw a uniform random subset  $\mathbf{M} \subseteq [n]$  of size  $n/2$  and our function  $\Gamma = \Gamma_{\mathbf{M}}: \{0, 1\}^n \rightarrow \{0, 1\}^{[2^{n/2}]}$  projects the points onto the variables in  $\mathbf{M}$ . Thus, it remains to define the sequence of functions  $\mathbf{H} = (\mathbf{h}_i: \{0, 1\}^n \rightarrow \{0, 1\} : i \in [2^{n/2}])$ .

We will sample a graph  $\mathbf{G} \sim \mathcal{G}_1$  (in the case of  $\mathcal{D}_{\text{yes}}$ ), and a graph  $\mathbf{G} \sim \mathcal{G}_2$  (in the case of  $\mathcal{D}_{\text{no}}$ ) supported on vertices in  $\overline{\mathbf{M}}$ . Each function  $\mathbf{h}_i: \{0, 1\}^n \rightarrow \{0, 1\}$  is given by first sampling an edge  $(j_1, j_2) \sim \mathbf{G}$  and letting  $\mathbf{h}_i$  be a parity (or a negated parity) of the variables  $x_{j_1}$  and  $x_{j_2}$ . Thus, a function  $\mathbf{f}$  from  $\mathcal{D}_{\text{yes}}$  or  $\mathcal{D}_{\text{no}}$  will have all variables being relevant, however, we will see that functions in  $\mathcal{D}_{\text{yes}}$  have a group of  $\frac{n}{4}$  variables which can be eliminated efficiently<sup>6</sup>.

We think of the sub-functions  $\mathbf{h}_i$  defined with respect to edges from  $\mathbf{G}$  as implementing a sort of *gadget*: the gadget defined with respect to an edge  $(j_1, j_2)$  will have the property that if  $\mathbf{f}$  eliminates the variable  $j_1$ , it will be “encouraged” to eliminate variable  $j_2$  as well.

<sup>6</sup> We say that a variable is eliminated if we change the function to remove the dependence of the variable.

In fact, each time an edge  $(j_1, j_2) \sim \mathbf{G}$  is used to define a sub-function  $h_i$ , any  $k$ -junta  $g: \{0, 1\}^n \rightarrow \{0, 1\}$  where variable  $j_1$  or  $j_2$  is irrelevant will have to change half of the corresponding part indexed by  $\Gamma$ . Intuitively, a function  $f \sim \mathcal{D}_{\text{yes}}$  or  $\mathcal{D}_{\text{no}}$  (which originally depends on all  $n$  variables) wants to eliminate its dependence of  $n - k$  variables in order to become a  $k$ -junta. When  $f$  picks a variable  $j \in \overline{\mathbf{M}}$  to eliminate (since variables in  $\mathbf{M}$  are too expensive), it must change points in parts where the edge sampled is incident on  $j$ . The key observation is that when  $f$  needs to eliminate multiple variables, if  $f$  picks the variables  $j_1$  and  $j_2$  to eliminate, whenever a part samples the edge  $(j_1, j_2)$ , the function changes the points in one part and eliminates two variables. Thus,  $f$  eliminates two variables by changing the same number of points when there are edges between  $j_1$  and  $j_2$ .

At a high level, the gadgets encourage the function  $f$  to remove the dependence of variables within a group of edges, i.e., the closest  $k$ -junta will correspond to a function  $g$  which eliminates groups of variables with edges within each other and few outgoing edges. More specifically, if we want to eliminate  $\frac{n}{4}$  variables from  $f$ , we must find a bisection of the graph  $\mathbf{G}$  whose cut value is small; in the case of  $\mathcal{G}_1$ , one of the cliques will have cut value 0, whereas any bisection of a graph from  $\mathcal{G}_2$  will have a high cut value, which makes functions in  $\mathcal{D}_{\text{yes}}$  closer to  $\frac{3n}{4}$ -juntas than functions in  $\mathcal{D}_{\text{no}}$ .

The reduction from rejection sampling is straight-forward. We consider all queries which are indexed to the same part, and if two queries indexed to the same part differ on a variable  $j$ , then the algorithm “explores” direction  $j$ . Each part  $i \in [2^{n/2}]$  where some query falls in has a corresponding rejection sampling query  $L_i$ , which queries the variables explored by the Boolean function testing algorithm.

### 3.2 The Distributions $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$

The goal of this subsection is to define the two distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$ , supported over Boolean functions with  $n$  variables. Functions  $f \in \mathcal{D}_{\text{yes}}$  will be *close* to being a  $k$ -junta with high probability, and functions  $f \sim \mathcal{D}_{\text{no}}$  will be *far* from any  $k$ -junta with high probability. We note that it suffices to consider  $k = \frac{3n}{4}$  to obtain Theorem 3. We refer the reader to the full version of the paper for the reduction from arbitrary  $k$  to  $k = \frac{3n}{4}$ .

**Distribution  $\mathcal{D}_{\text{yes}}$ .** A function  $f$  from  $\mathcal{D}_{\text{yes}}$  is generated from a tuple of three random variables,  $(\mathbf{M}, \mathbf{A}, \mathbf{H})$ , and we set  $f = f_{\mathbf{M}, \mathbf{A}, \mathbf{H}}$ . The tuple is drawn according to the following randomized procedure:

1. Sample a uniformly random subset  $\mathbf{M} \subseteq [n]$  of size  $m \stackrel{\text{def}}{=} \frac{n}{2}$ . Let  $N = 2^m$  and  $\Gamma_{\mathbf{M}}: \{0, 1\}^n \rightarrow [N]$  be the function that maps  $x \in \{0, 1\}^n$  to a number encoded by  $x|_{\mathbf{M}} \in [N]$ .
2. Sample  $\mathbf{A} \subseteq \overline{\mathbf{M}}$  of size  $\frac{n}{4}$  uniformly at random, and consider the graph  $\mathbf{G}$  defined on vertices  $[\overline{\mathbf{M}}]$  with  $\mathbf{G} = K_{\mathbf{A}} \cup K_{\overline{\mathbf{A}}}$ , i.e.,  $\mathbf{G}$  is a uniformly random graph drawn according to  $\mathcal{G}_1$ .
3. Define a sequence of  $N$  functions  $\mathbf{H} = \{h_i: \{0, 1\}^n \rightarrow \{0, 1\} : i \in [N]\}$  drawn from a distribution  $\mathcal{E}(\mathbf{G})$ . For each  $i \in \{1, \dots, N/2\}$ , we let  $h_i(x) = \bigoplus_{\ell \in \mathbf{M}} x_{\ell}$ . For each  $i \in \{N/2 + 1, \dots, N\}$ , we will generate  $h_i$  independently by sampling an edge  $(j_1, j_2) \sim \mathbf{G}$  uniformly at random, as well as a uniform random bit  $r \sim \{0, 1\}$ . We let

$$h_i(x) = x_{j_1} \oplus x_{j_2} \oplus r.$$

4. Using  $\mathbf{M}, \mathbf{A}$  and  $\mathbf{H}$ , define  $f_{\mathbf{M}, \mathbf{A}, \mathbf{H}} = h_{\Gamma_{\mathbf{M}}(x)}(x)$  for each  $x \in \{0, 1\}^n$ .

**Figure 1** Example of graphs  $\mathbf{G}$  from  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$ . On the left, the graph  $\mathbf{G}$  is the union of two cliques of size  $\frac{n}{4}$ , corresponding to  $\mathcal{D}_{\text{yes}}$ . We note that  $\chi(G) = \frac{1}{2}$ , since if we let  $S = \mathbf{A}$  (pictured as the blue set), we see that  $S$  contains half of the edges. On the right, the graph  $\mathbf{G}$  is the complete bipartite graph with side sizes  $\frac{n}{4}$ , corresponding to  $\mathcal{D}_{\text{no}}$ . We note that  $\chi(G) = \frac{3}{4}$ : consider any set  $S \subseteq \overline{M}$  of size at least  $\frac{n}{4}$  pictured in the blue region, and let  $\alpha = |S \cap A|$  and  $\beta = |S \cap \overline{A}|$ , where  $\alpha + \beta \geq \frac{n}{4}$ , so  $E(S, S) + E(S, \overline{S}) \geq \binom{n}{4}^2 - \alpha\beta \geq \binom{n}{4}^2(1 - \frac{1}{4})$ .

**Distribution  $\mathcal{D}_{\text{no}}$ .** A function  $f$  drawn from  $\mathcal{D}_{\text{no}}$  is also generated by first drawing the tuple  $(\mathbf{M}, \mathbf{A}, \mathbf{H})$  and setting  $f = f_{\mathbf{M}, \mathbf{A}, \mathbf{H}}$ . Both  $\mathbf{M}$  and  $\mathbf{A}$  are drawn using the same procedure; the only difference is that the graph  $\mathbf{G} = K_{\mathbf{A}, \overline{\mathbf{A}}}$ , i.e.,  $\mathbf{G}$  is a uniformly random graph drawn according to  $\mathcal{G}_2$ . Then  $\mathbf{H} \sim \mathcal{E}(\mathbf{G})$  is sampled from the modified graph  $\mathbf{G}$ .

We let  $k \stackrel{\text{def}}{=} \frac{3n}{4}$ ,  $\varepsilon_0 \stackrel{\text{def}}{=} \frac{1}{8}$ , and  $\varepsilon_1 \stackrel{\text{def}}{=} \frac{3}{16}$ . Consider a fixed subset  $M \subseteq [n]$  which satisfies  $|M| = \frac{n}{2}$ , and a fixed subset  $A \subseteq \overline{M}$  which satisfies  $|A| = \frac{n}{4}$ . Let  $G$  be a graph defined over vertices in  $\overline{M}$ , and for any subsets  $S_1, S_2 \subseteq \overline{M}$ , let  $E_G(S_1, S_2) = |\{(j_1, j_2) \in G : j_1 \in S_1, j_2 \in S_2\}|$ , be the number of edges between sets  $S_1$  and  $S_2$ . Additionally, we let

$$\chi(G) = \min \left\{ \frac{E_G(S, S) + E_G(S, \overline{S})}{E_G(\overline{M}, \overline{M})} : S \subseteq \overline{M}, |S| \geq \frac{n}{4} \right\} \quad (1)$$

be the minimum fraction of edges adjacent to a set  $S$  of size at least  $\frac{n}{4}$ . The following lemma relates the distance of a function  $\mathbf{f} = f_{M, \mathbf{A}, \mathbf{H}}$  where  $\mathbf{H} \sim \mathcal{E}(G)$  to being a  $k$ -junta to  $\chi(G)$ . We then apply this lemma to the graph in  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  to show that functions in  $\mathcal{D}_{\text{yes}}$  are  $\varepsilon_0$ -close to being  $k$ -juntas, and functions in  $\mathcal{D}_{\text{no}}$  are  $\varepsilon_1$ -far from being  $k$ -juntas.

**► Lemma 7.** *Let  $G$  be any graph defined over vertices in  $A$ . If  $\mathbf{f} = f_{M, \mathbf{A}, \mathbf{H}}$ , where  $\mathbf{H} \sim \mathcal{E}(G)$ , then with probability at least  $1 - o(1)$ ,*

$$\frac{1}{4} \cdot \chi(G) - o(1) \leq \text{dist}(\mathbf{f}, k\text{-Junta}) \leq \frac{1}{4} \cdot \chi(G) + o(1).$$

**► Corollary 8.** *We have that  $\mathbf{f} \sim \mathcal{D}_{\text{yes}}$  has  $\text{dist}(\mathbf{f}, k\text{-Junta}) \leq \varepsilon_0 + o(1)$  with probability  $1 - o(1)$ , and that  $\mathbf{f} \sim \mathcal{D}_{\text{no}}$  has  $\text{dist}(\mathbf{f}, k\text{-Junta}) \geq \varepsilon_1 - o(1)$  with probability  $1 - o(1)$ .*

The proof shows that distinguishing the two distributions  $\mathcal{G}_1$  and  $\mathcal{G}_2$  using rejection sampling oracle reduces to distinguishing the two distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$ .

► **Lemma 9.** *Suppose there exists a deterministic non-adaptive algorithm Alg making  $q$  queries to Boolean functions  $f: \{0, 1\}^{2n} \rightarrow \{0, 1\}$ . Then, there exists a deterministic non-adaptive algorithm Alg' making rejection sampling queries to an  $n$ -vertex graph such that:*

$$\Pr_{f \sim \mathcal{D}_{\text{yes}}} [\text{Alg}(f) \text{ “accepts”}] = \Pr_{\mathbf{G} \sim \mathcal{G}_1} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_1\text{”}], \quad \text{and}$$

$$\Pr_{f \sim \mathcal{D}_{\text{no}}} [\text{Alg}(f) \text{ “accepts”}] = \Pr_{\mathbf{G} \sim \mathcal{G}_2} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_1\text{”}].$$

and has  $\text{cost}(\text{Alg}') = O(q \log n)$  with probability  $1 - o(1)$  over the randomness in Alg'.

## 4 Tolerant Unateness Testing

In this section, we show how to reduce distinguishing distributions  $\mathcal{G}_1$  and  $\mathcal{G}_2$  to distinguishing between Boolean functions which are close to unate and Boolean functions which are far from unate. We start with a high level overview of the constructions and reduction, and then proceed to give formal definitions and the reductions for adaptive and non-adaptive tolerant testing.

### 4.1 High Level Overview

We now describe how our constructions and reduction implement the plan set forth in Subsection 1.3 for the property of unateness. Similarly to Section 3, we define two distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  supported on Boolean functions, so that functions in  $\mathcal{D}_{\text{yes}}$  are  $\varepsilon_0$ -close to being unate, and functions in  $\mathcal{D}_{\text{no}}$  are  $\varepsilon_1$ -far from being unate (where  $\varepsilon_0$  and  $\varepsilon_1$  are appropriately defined constants).

We will use a randomized indexing function  $\Gamma: \{0, 1\}^n \rightarrow [N] \cup \{0^*, 1^*\}$  based on the Talagrand-style constructions from [4, 18] to partition  $\{0, 1\}^n$  in a unate fashion, specifically,  $\Gamma$  will satisfy that for all  $i \neq j \in [N]$ , if  $x, y \in \{0, 1\}^n$  have  $\Gamma(x) = i$  and  $\Gamma(y) = j$ , then  $x$  and  $y$  are *incomparable*,  $x \not\prec y$  and  $y \not\prec x$ . Again, we will then use a graph  $\mathbf{G} \sim \mathcal{G}_1$  or  $\mathcal{G}_2$  to define the sequence of sub-function  $\mathbf{H} = (\mathbf{h}_i: \{0, 1\}^n \rightarrow \{0, 1\} : i \in [N])$ . The sub-functions  $\mathbf{h}_i$  will be given by a parity (or negated parity) of three variables: two variables will correspond to the end points of an edge sampled  $(j_1, j_2) \sim \mathcal{G}$ , the third variable will be one of two pre-specified variables, which we call  $m_1$  and  $m_2$ . Consider for simplicity the case when  $\mathbf{h}_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$ , and assume that we require that variable  $m_1$  is non-decreasing.

Similarly to Section 3, the functions  $\mathbf{h}_i$  are thought of as gadgets. We will have that if  $\mathbf{h}_i$  is defined with respect to an edge  $(j_1, j_2)$  and  $m_1$ , then the function  $\mathbf{f}$  will be “encouraged” to make variables  $j_1$  and  $j_2$  have opposite directions, i.e., either  $j_1$  is non-increasing and  $j_2$  is non-decreasing, or  $j_1$  is non-decreasing and  $j_2$  is non-increasing. In order to see why the three variable parity implements this gadget, we turn our attention to Figure 2 and Figure 3.

Intuitively, the function  $\mathbf{f}$  needs to change some of its inputs to be unate, and it must choose whether the variables  $j_1$  and  $j_2$  will be monotone (non-decreasing) or anti-monotone (non-increasing). Suppose  $\mathbf{f}$  decides that the variable  $j_1$  should be monotone and  $j_2$  be anti-monotone, and  $m_1$  will always be monotone (since it will be too expensive to make it anti-monotone). Then, when  $\mathbf{h}_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$ ,  $\mathbf{h}_i$  will have some *violating edges*, i.e., edges in direction  $j_1$  which are decreasing, or edges in direction  $j_2$  which are increasing, or edges in direction  $m_1$  which are decreasing (see Figure 2, where these violating edges are marked in red). In this case, there exists a way that  $\mathbf{f}$  may change  $\frac{1}{4}$ -th fraction of the points and remove all violating edges (again, this procedure is shown in Figure 2).

■ **Figure 2** Example of a function  $h_i: \{0, 1\}^n \rightarrow \{0, 1\}$  with  $h_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$  with variable  $j_1$  (which ought to be monotone),  $j_2$  (which ought to be anti-monotone), and  $m_1$  (which is always monotone). The image on the left-hand side represents  $h_i$ , and the red edges correspond to violating edges for variables  $j_1, j_2$  and  $m_1$ . In other words, the red edges correspond to anti-monotone edges in variables  $j_1$ , monotone edges in variables  $j_2$ , and anti-monotone edges in direction  $m_1$ . On the right-hand side, we show how such a function can be “fixed” into a function  $h'_i: \{0, 1\}^n \rightarrow \{0, 1\}$  by changing  $\frac{1}{4}$ -fraction of the points.

In contrast, suppose that  $f$  decides that the variables  $j_1$  and  $j_2$  both should be monotone. Then, when  $h_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$ , the violating edges (shown in Figure 3) form vertex-disjoint cycles of length 6 in  $\{0, 1\}^n$ , thus, the function  $f$  will have to change  $\frac{3}{8}$ -th fraction of the points in order to remove all violating edges. In other words, when there is an edge  $(j_1, j_2)$  sampled in  $h_i$ , the function  $f$  is “encouraged” to make  $j_1$  and  $j_2$  have opposite directions, and “discouraged” to make  $j_1$  and  $j_2$  have the same direction. The other cases are presented in Figures 4, 5, and 6.

In order for  $f$  to become unate, it must first choose whether each variable will be monotone or anti-monotone.  $f$  will choose all variables in  $\mathbf{M}$  to be monotone, the variable  $m_1$  to be monotone, and  $m_2$  to be anti-monotone, but will have to make a choice for each variable in  $\overline{\mathbf{M}}$ , corresponding to each vertex of the graph  $\mathbf{G}$ . As discussed above, for each edge  $(j_1, j_2)$  in the graph,  $f$  is encouraged to make these orientations opposite from each other, so  $f$  will want to look for the maximum cut on the graph, whose value will be different in  $\mathcal{G}_1$  and  $\mathcal{G}_2$ .

Similarly to the case in Section 3, the reduction will follow by defining the rejection sampling queries  $L_i$  corresponding to variables explored in sub-function  $h_i$ . The unate indexing functions  $\Gamma$  are not as strong as the indexing functions from the Section 3, so for each query in the Boolean function testing algorithm, our reduction will lose some cost in the rejection sampling algorithm. In particular, the adaptive reduction loses  $n$  cost for each Boolean function query, since adaptive algorithms can efficiently explore variables with a binary search; this gives the  $\tilde{\Omega}(n)$  lower bound for tolerant unateness testing. The non-adaptive reduction loses  $O(\sqrt{n} \log n)$  cost for each Boolean function query since queries falling in the same part may be  $\Omega(\sqrt{n})$  away from each other (the same scenario occurs in the non-adaptive monotonicity lower bound of [18]). The non-adaptive reduction is more complicated than the adaptive reduction since it is not exactly a black-box reduction (we require a lemma from Section 5). This gives the  $\tilde{\Omega}(n^{3/2})$  lower bound for non-adaptive tolerant unateness testing.

■ **Figure 3** Example of a function  $h_i: \{0, 1\}^n \rightarrow \{0, 1\}$  with  $h_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$  with variables  $j_1$  and  $j_2$  (which ought to be monotone), and  $m_1$  (which ought to be monotone). On the left side, we indicate the violating edges with red arrows, and note that the functions in the left and right differ by  $\frac{3}{8}$ -fraction of the points. We also note that any function  $h'_i: \{0, 1\}^n \rightarrow \{0, 1\}$  which has  $j_1$ ,  $j_2$  and  $m_1$  monotone must differ from  $h_i$  on at least  $\frac{3}{8}$ -fraction of the points because the violating edges of  $h_i$  form a cycle of length 6.

## 4.2 The Distributions $\mathcal{D}_{\text{yes}}$ and $\mathcal{D}_{\text{no}}$

We now turn to describing a pair of distributions  $\mathcal{D}_{\text{yes}}$  and  $\mathcal{D}_{\text{no}}$  supported on Boolean functions  $f: \{0, 1\}^n \rightarrow \{0, 1\}$ . These distributions will have the property that for some constants  $\varepsilon_0$  and  $\varepsilon_1$  with  $0 < \varepsilon_0 < \varepsilon_1$ ,

$$\Pr_{f \sim \mathcal{D}_{\text{yes}}} [\text{dist}(f, \text{Unate}) \leq \varepsilon_0] = 1 - o(1) \quad \text{and} \quad \Pr_{f \sim \mathcal{D}_{\text{no}}} [\text{dist}(f, \text{Unate}) \geq \varepsilon_1] = 1 - o(1).$$

We first define a function  $f \sim \mathcal{D}_{\text{no}}$ , where we fix the parameter  $N = 2^{\sqrt{n}}$ .

1. Sample some set  $\mathbf{M} \subseteq [n]$  of size  $|\mathbf{M}| = \frac{n}{2}$  uniformly at random and let  $m_1, m_2 \sim \mathbf{M}$  be two distinct indices.
2. We let  $\mathbf{T} \sim \mathcal{E}(\mathbf{M} \setminus \{m_1, m_2\})$  (which we describe next).  $\mathbf{T}$  is a sequence of terms  $(\mathbf{T}_i : i \in [N])$  which is used to define a multiplexer map  $\Gamma_{\mathbf{T}}: \{0, 1\}^n \rightarrow [N] \cup \{0^*, 1^*\}$ .
3. We sample  $\mathbf{A} \subseteq \overline{\mathbf{M}}$  of size  $|\mathbf{A}| = \frac{n}{2}$  and define a graph as  $\mathbf{G} = K_{\mathbf{A}} \cup K_{\overline{\mathbf{A}}}$ .
4. We now define the distribution over sub-functions  $\mathbf{H} = (h_i : i \in [N]) \sim \mathcal{H}(m_1, m_2, \mathbf{G})$ . For each function  $h_i: \{0, 1\}^n \rightarrow \{0, 1\}$ , we generate  $h_i$  independently:
  - When  $i \leq 3N/4$ , we sample  $j \sim \{m_1, m_2\}$  and we let:

$$h_i(x) = \begin{cases} x_j & j = m_1 \\ \neg x_j & j = m_2 \end{cases}.$$

- Otherwise, if  $i > 3N/4$ , we sample an edge  $(j_1, j_2) \sim \mathbf{G}$  and an index  $j_3 \sim \{m_1, m_2\}$  we let:

$$h_i(x) = \begin{cases} x_{j_1} \oplus x_{j_2} \oplus x_{j_3} & j_3 = m_1 \\ \neg x_{j_1} \oplus x_{j_2} \oplus x_{j_3} & j_3 = m_2 \end{cases}.$$

52:14 Lower Bounds for Tolerant Junta and Unateness Testing

The function  $\mathbf{f}: \{0, 1\}^n \rightarrow \{0, 1\}$  is given by  $\mathbf{f}(x) = f_{\mathbf{T}, \mathbf{A}, \mathbf{H}}(x)$  where:

$$f_{\mathbf{T}, \mathbf{A}, \mathbf{H}}(x) = \begin{cases} 1 & |x|_{\mathbf{M}} > \frac{n}{4} + \sqrt{n} \\ 0 & |x|_{\mathbf{M}} < \frac{n}{4} - \sqrt{n} \\ 1 & \Gamma_{\mathbf{T}}(x) = 1^* \\ 0 & \Gamma_{\mathbf{T}}(x) = 0^* \\ \mathbf{h}_{\Gamma_{\mathbf{T}}(x)}(x) & \text{otherwise} \end{cases}. \quad (2)$$

We now turn to define the distribution  $\mathcal{E}(M)$  supported on terms  $\mathbf{T}$ , as well as the multiplexer map  $\Gamma_{\mathbf{T}}: \{0, 1\}^n \rightarrow [N]$ . As mentioned above,  $\mathbf{T} \sim \mathcal{E}(M)$  will be a sequence of  $N$  terms  $(\mathbf{T}_i : i \in [N])$ , where each  $\mathbf{T}_i$  is given by a DNF term:  $\mathbf{T}_i(x) = \bigwedge_{j \in \mathbf{T}_i} x_j$ , where the set  $\mathbf{T}_i \subseteq M$  is a uniformly random  $\sqrt{n}$ -element subset. Given the sequence of terms  $\mathbf{T}$ , we let:

$$\Gamma_{\mathbf{T}}(x) = \begin{cases} 0^* & \forall i \in [N], \mathbf{T}_i(x) = 0 \\ 1^* & \exists i_1 \neq i_2 \in [N], \mathbf{T}_{i_1}(x) = \mathbf{T}_{i_2}(x) = 1 \\ i & \mathbf{T}_i(x) = 1 \text{ for a unique } i \in [N] \end{cases}.$$

It remains to define the distribution  $\mathcal{D}_{\text{yes}}$  supported on Boolean functions. The function  $\mathbf{f} \sim \mathcal{D}_{\text{yes}}$  will be defined almost exactly the same. We still have  $\mathbf{f} = f_{\mathbf{T}, \mathbf{A}, \mathbf{H}}$  as defined above, however, the graph  $\mathbf{G}$  will be different. In particular, we will let  $\mathbf{G} = K_{\mathbf{A}, \overline{\mathbf{A}}}$ .

Fix any set  $M \subseteq [n]$  of size  $\frac{n}{2}$  and let  $m_1, m_2 \in M$  be two distinct indices and  $M' = M \setminus \{m_1, m_2\}$ . For any  $\mathbf{T} \sim \mathcal{E}(M')$ , let  $\mathbf{X} \subseteq \{0, 1\}^n$  be the subset of points indexed to some subfunction  $\mathbf{h}_i$ :

$$\mathbf{X} \stackrel{\text{def}}{=} \{x \in \{0, 1\}^n : |x|_M \in [n/4 - \sqrt{n}, n/4 + \sqrt{n}] \text{ and } \Gamma_{\mathbf{T}}(x) \in [N]\},$$

and define  $\gamma \in (0, 1)$  be the parameter:  $\gamma \stackrel{\text{def}}{=} \mathbb{E}_{\mathbf{T} \sim \mathcal{E}(M')} \left[ \frac{|\mathbf{X}|}{2^n} \right]$ .

In addition, let  $X_i \subseteq X$  be the subset of points  $x \in X$  with  $\Gamma_{\mathbf{T}}(x) = i$ , and note that the subsets  $X_1, \dots, X_N$  partition  $X$ , where each  $|X_i| \leq 2^{n-\sqrt{n}}$ . With probability  $1 - o(1)$  over the draw of  $\mathbf{T} \sim \mathcal{E}(M)$ , we have:

$$\sum_{i=1}^{3N/4} |X_i| = 2^n \cdot \frac{3\gamma}{4} \left( 1 \pm \frac{1}{n} \right) \quad \text{and} \quad \sum_{i=3N/4+1}^N |X_i| = 2^n \cdot \frac{\gamma}{4} \left( 1 \pm \frac{1}{n} \right). \quad (3)$$

Thus, we only consider functions  $\mathbf{f} \sim \mathcal{D}_{\text{yes}}$  (or  $\sim \mathcal{D}_{\text{no}}$ ) where the sets  $M$ , and  $T$  satisfy (3).

We consider any set  $A \subseteq \overline{M}$  of size  $\frac{n}{4}$ . Now, consider any graph  $G$  defined over vertices in  $\overline{M}$ , and we let:

$$\chi(G) = \min \left\{ \frac{E_G(S, S) + E_G(\overline{S}, \overline{S})}{E_G(\overline{M}, \overline{M})} : S \subseteq \overline{M} \right\}.$$

In other words, we note that  $\chi(G)$  is one minus the fractional value of the maximum cut, and the value of  $\chi(G)$  is minimized for the set  $S$  achieving the maximum cut of  $G$ . The following lemma relates the distance to unateness of a function  $\mathbf{f} = f_{T, A, \mathbf{H}}$  with  $\mathbf{H} \sim \mathcal{H}(m_1, m_2, G)$ , where  $G$  is an underlying graph defined on vertices in  $\overline{M}$ .

► **Lemma 10.** *Let  $G$  be any graph defined over vertices in  $\overline{M}$ . If  $\mathbf{f} = f_{T, A, \mathbf{H}}$  where  $\mathbf{H} \sim \mathcal{H}(m_1, m_2, G)$ , then with probability at least  $1 - o(1)$ ,*

$$\frac{\gamma}{16} \left( 1 + \frac{1}{2} \cdot \chi(G) \right) - o(1) \leq \text{dist}(\mathbf{f}, \text{Unate}) \leq \frac{\gamma}{16} \left( 1 + \frac{1}{2} \cdot \chi(G) \right) + o(1).$$

We consider the constants  $\varepsilon_0 = \frac{\gamma}{16}$  and  $\varepsilon_1 = \frac{5\gamma}{64}$ .

► **Corollary 11.** *We have that  $\mathbf{f} \sim \mathcal{D}_{\text{yes}}$  has  $\text{dist}(\mathbf{f}, \text{Unate}) \leq \varepsilon_0 + o(1)$  with high probability, and  $\mathbf{f} \sim \mathcal{D}_{\text{no}}$  has  $\text{dist}(\mathbf{f}, \text{Unate}) \geq \varepsilon_1 - o(1)$  with high probability.*

■ **Figure 4** Similarly to Figure 2, this is an example of a function  $h_i: \{0,1\}^n \rightarrow \{0,1\}$  with  $h_i(x) = x_{j_1} \oplus x_{j_2} \oplus x_{m_1}$  variables  $j_1$  (which ought to be anti-monotone),  $j_2$  (which ought to be monotone), and  $m_1$  (which is always monotone) being “fixed” into a function  $h'_i: \{0,1\}^n \rightarrow \{0,1\}$  defined on the right-hand side.

### 4.3 Reducing from Rejection Sampling

In order to reduce from rejection sampling, we need the following two lemmas.

► **Lemma 12.** *Suppose there exists a deterministic algorithm Alg making  $q$  queries to Boolean functions  $f: \{0,1\}^{2n} \rightarrow \{0,1\}$ . Then, there exists a deterministic non-adaptive algorithm Alg' making rejection sampling queries to an  $n$ -vertex graph with  $\text{cost}(\text{Alg}') = qn$  such that:*

$$\begin{aligned} \Pr_{f \sim \mathcal{D}_{\text{yes}}} [\text{Alg}(f) \text{ “accepts”}] &= \Pr_{\mathbf{G} \sim \mathcal{G}_2} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_2\text{”}], \quad \text{and} \\ \Pr_{f \sim \mathcal{D}_{\text{no}}} [\text{Alg}(f) \text{ “accepts”}] &= \Pr_{\mathbf{G} \sim \mathcal{G}_1} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_2\text{”}]. \end{aligned}$$

► **Lemma 13.** *Suppose there exists a deterministic non-adaptive algorithm Alg making  $q$  queries to Boolean functions  $f: \{0,1\}^{2n} \rightarrow \{0,1\}$  where  $q \leq \frac{n^{3/2}}{\log^8 n}$ . Then, there exists a deterministic non-adaptive algorithm Alg' making rejection sampling queries to an  $n$ -vertex graph such that:*

$$\begin{aligned} \Pr_{f \sim \mathcal{D}_{\text{yes}}} [\text{Alg}(f) \text{ “accepts”}] &\approx \Pr_{\mathbf{G} \sim \mathcal{G}_2} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_2\text{”}] \pm o(1), \quad \text{and} \\ \Pr_{f \sim \mathcal{D}_{\text{no}}} [\text{Alg}(f) \text{ “accepts”}] &\approx \Pr_{\mathbf{G} \sim \mathcal{G}_1} [\text{Alg}'(\mathbf{G}) \text{ outputs “}\mathcal{G}_2\text{”}] \pm o(1). \end{aligned}$$

and has  $\text{cost}(\text{Alg}') \leq q\sqrt{n} \log n$  with probability  $1 - o(1)$  over the randomness in Alg'.

Combining Lemma 12 with Theorem 1, we conclude Theorem 4, and combining Lemma 13 with Theorem 1, we conclude Theorem 5.

## 5 A lower bound for distinguishing $\mathcal{G}_1$ and $\mathcal{G}_2$ with rejection samples

In this section, we derive a lower bound for distinguishing  $\mathcal{G}_1$  and  $\mathcal{G}_2$  with rejection samples.

► **Lemma 14.** *Any deterministic non-adaptive algorithm Alg with  $\text{cost}(\text{Alg}) \leq \frac{n^2}{\log^6 n}$ , has:*

$$\Pr_{\mathbf{G} \sim \mathcal{G}_1} [\text{Alg outputs “}\mathcal{G}_1\text{”}] \leq (1 + o(1)) \Pr_{\mathbf{G} \sim \mathcal{G}_2} [\text{Alg outputs “}\mathcal{G}_1\text{”}] + o(1).$$

■ **Figure 5** Similarly to Figure 2, this is an example of a function  $h_i: \{0, 1\}^n \rightarrow \{0, 1\}$  with  $h_i(x) = \neg x_{j_1} \oplus x_{j_2} \oplus x_{m_2}$  variables  $j_1$  (which ought to be anti-monotone),  $j_2$  (which ought to be monotone), and  $m_2$  (which is always anti-monotone) being “fixed” into a function  $h'_i: \{0, 1\}^n \rightarrow \{0, 1\}$  defined on the right-hand side.

We assume Alg is a deterministic non-adaptive algorithm with  $\text{cost}(\text{Alg}) \leq \frac{n^2}{\log^6 n}$ . Alg makes queries  $L_1, \dots, L_t \subseteq [n]$  and the oracle returns  $\mathbf{v}_1, \dots, \mathbf{v}_t$ , some of which are edges, some are lone vertices, and some are  $\emptyset$ . Let  $\mathbf{G}_o \subseteq \mathbf{G}$  be the graph observed by the algorithm by considering all edges in  $\mathbf{v}_1, \dots, \mathbf{v}_t$ . We let  $|\mathbf{G}_o|$  be the number of edges.

Before going on to prove the lower bound, we use the following simplification. First, we assume that any algorithm Alg has all its queries  $L_1, \dots, L_t$  satisfying that either  $|L_i| \leq \frac{n}{\log n}$ , or  $L_i = [n]$ . Thus, it suffices to show for this restricted class of algorithms, the cost must be at least  $\frac{n^2}{\log^5 n}$ .

### 5.1 High Level Overview

We will argue outcome-by-outcome; i.e., we consider the possible ways the algorithm can act, which depends on the responses to the queries the algorithm gets. Consider some responses  $v_1, \dots, v_t \in [n] \cup ([n] \times [n]) \cup \{\emptyset\}$ , where each  $v_i$  may be either a lone vertex, an edge, or  $\emptyset$ . Suppose that upon observing this outcome, the algorithm outputs “ $\mathcal{G}_1$ ”. There will be two cases:

- The first case is when the probability of observing this outcome from  $\mathcal{G}_2$  is not too much lower than the probability of observing this outcome from  $\mathcal{G}_1$ . In these outcomes, we will not get too much advantage in distinguishing  $\mathcal{G}_1$  and  $\mathcal{G}_2$ .
- The other case is when the probability of observing this outcome from  $\mathcal{G}_2$  is substantially lower than the probability of observing this outcome from  $\mathcal{G}_1$ . These cases do help us distinguish between  $\mathcal{G}_1$  and  $\mathcal{G}_2$ ; thus, we will want to show that collectively, the probability that we observe these outcomes from  $\mathcal{G}_1$  is  $o(1)$ .

We will be able to characterize the outcomes which fall into the first case and the second case by considering a sequence of events. In particular we define five events which depend on  $v_1, \dots, v_t$ , as well as the random choice of  $\mathbf{A}$ . Consider the outcome  $v_1, \dots, v_t$  which together form components  $C_1, \dots, C_\alpha$ . The events are the following<sup>7</sup>:

<sup>7</sup> We note that the first two event are not random and depends on the values  $v_1, \dots, v_t$ , and the rest are random variables depending on the partition  $\mathbf{A}$  and the oracle responses  $v_1, \dots, v_t$ .

■ **Figure 6** Examples of functions  $h_i: \{0, 1\}^n \rightarrow \{0, 1\}$  with orientations on the variables and violating edges. On the left-hand side,  $h_i(x) = \neg x_{j_1} \oplus x_{j_2} \oplus x_{m_2}$  with variables  $j_1$  and  $j_2$  (which ought to be monotone), and  $m_2$  (which is always anti-monotone). On the right-hand side,  $h_i(x) = \neg x_{j_1} \oplus x_{j_2} \oplus x_{m_2}$  with variables  $j_1$  and  $j_2$  (which ought to be anti-monotone), and  $m_2$  (which is always anti-monotone). We note that the violating edges form a cycle of length 6, so any unate function whose orientations on  $j_1$  and  $j_2$  are as indicated (both monotone on the left-hand side, and both anti-monotone on the right-hand side) must disagree on a  $\frac{3}{8}$ -fraction of the points.

1.  $\mathcal{E}_T$  (Observe small trees): this is the event where the values of  $v_1, \dots, v_t$  form components  $C_1, \dots, C_\alpha$  which are all trees of size at most  $\log n$ .
2.  $\mathcal{E}_F$  (Observe few non-empty responses): this is the event where the values of  $v_1, \dots, v_t$  have at most  $\frac{n}{\log^4 n}$  non- $\emptyset$  responses. This event implies that the total number of vertices in the responses  $v_1, \dots, v_t$  is at most  $\frac{n}{\log^4 n}$ .
3.  $\mathcal{E}_{C,\text{yes}}$  and  $\mathcal{E}_{C,\text{no}}$  (Consistency condition of the components observed): these are the events where  $\mathbf{A} \subseteq [n]$  partitions the components  $C_1, \dots, C_\alpha$  in a manner consistent with  $\mathcal{G}_1$  in  $\mathcal{E}_{C,\text{yes}}$  or  $\mathcal{G}_2$  in  $\mathcal{E}_{C,\text{no}}$ , i.e., either every  $C_i$  is contained within  $\mathbf{A}$  or  $\overline{\mathbf{A}}$  (in the case of  $\mathcal{G}_1$ , or edges in every  $C_i$  cross the partition on vertices induced by  $\mathbf{A}$  (in the case of  $\mathcal{G}_2$ ). These events are random variables that depend only on  $\mathbf{A}$ . It will become clear that in order to observe the outcome  $v_1, \dots, v_t$  in  $\mathcal{G}_1$ , event  $\mathcal{E}_{C,\text{yes}}$  must be triggered, and in  $\mathcal{G}_2$ , event  $\mathcal{E}_{C,\text{no}}$  must be triggered. See Figure 7 for an illustration.
4.  $\mathcal{E}_O$  (Observe specific responses): this event is over the randomness in  $\mathbf{A}$ , as well as the randomness in the responses of the oracle  $v_1, \dots, v_t$ . The event is triggered when the responses of the oracle are exactly those dictated by  $v_1, \dots, v_t$ ; i.e., for all  $i \in [t]$ ,  $v_i = v_i$ .
5.  $\mathcal{E}_B$  (Balanced lone vertices condition): this event is over the randomness in  $\mathbf{A}$ , as well as the responses  $v_1, \dots, v_t$ . The event occurs when the queries  $L_i$  corresponding to lone vertices  $v_i$  have  $|L_i \cap \mathbf{A}|$  and  $|L_i \cap \overline{\mathbf{A}}|$  roughly equal, and roughly half of  $v_i$  fall in  $\mathbf{A}$ .

Having defined these events, the lower bound follows by the following three lemmas. The first lemma says that for any outcomes satisfying  $\mathcal{E}_T$  and  $\mathcal{E}_F$ , the probability over  $\mathbf{A}$  of being consistent in  $\mathcal{G}_1$  cannot be much higher than in  $\mathcal{G}_2$ . The second lemma says that the outcomes satisfying the events described above do not help in distinguishing  $\mathcal{G}_1$  and  $\mathcal{G}_2$ . The third lemma says that good outcomes occur with high probability over  $\mathcal{G}_1$ .

► **Lemma 15 (Consistency Lemma).** *Consider a fixed  $v_1, \dots, v_t \in [n] \cup ([n] \times [n]) \cup \{\emptyset\}$  forming components  $C_1, \dots, C_\alpha$  where events  $\mathcal{E}_T$  and  $\mathcal{E}_F$  are satisfied. Then, we have:*

$$\Pr_{\substack{\mathbf{G} \sim \mathcal{G}_1 \\ v_1, \dots, v_t}} [\mathcal{E}_{C,\text{yes}}] \leq (1 + o(1)) \Pr_{\substack{\mathbf{G} \sim \mathcal{G}_2 \\ v_1, \dots, v_t}} [\mathcal{E}_{C,\text{no}}].$$

■ **Figure 7**  $A$  consistently partition of the components  $C_1, C_2, C_3$  and  $C_4$  according to  $\mathcal{G}_1$  (on the left) and  $\mathcal{G}_2$  (on the right).

► **Lemma 16** (Good Outcomes Lemma). Consider a fixed  $v_1, \dots, v_t \in [n] \cup ([n] \times [n]) \cup \{\emptyset\}$  forming components  $C_1, \dots, C_\alpha$  where events  $\mathcal{E}_T$  and  $\mathcal{E}_F$  are satisfied. Then, we have:

$$\Pr_{\substack{\mathbf{G} \sim \mathcal{G}_1 \\ v_1, \dots, v_t}} [\mathcal{E}_O \wedge \mathcal{E}_B \mid \mathcal{E}_{C, \text{yes}}] \leq (1 + o(1)) \Pr_{\substack{\mathbf{G} \sim \mathcal{G}_2 \\ v_1, \dots, v_t}} [\mathcal{E}_O \mid \mathcal{E}_{C, \text{no}}].$$

► **Lemma 17** (Bad Outcomes Lemma). We have that:

$$\Pr_{\substack{\mathbf{G} \sim \mathcal{G}_1 \\ v_1, \dots, v_t}} [\neg \mathcal{E}_T \vee \neg \mathcal{E}_F \vee \neg \mathcal{E}_B] = o(1).$$

Assuming the above three lemmas, we may prove Lemma 14.

## Abstract

Shamir's celebrated secret sharing scheme provides an efficient method for encoding a secret of arbitrary length  $\ell$  among any  $N \leq 2^\ell$  players such that for a threshold parameter  $t$ , (i) the knowledge of any  $t$  shares does not reveal any information about the secret and, (ii) any choice of  $t + 1$  shares fully reveals the secret. It is known that any such threshold secret sharing scheme necessarily requires shares of length  $\ell$ , and in this sense Shamir's scheme is optimal. The more general notion of ramp schemes requires the reconstruction of secret from any  $t + g$  shares, for a positive integer gap parameter  $g$ . Ramp secret sharing scheme necessarily requires shares of length  $\ell/g$ . Other than the bound related to secret length  $\ell$ , the share lengths of ramp schemes can not go below a quantity that depends only on the gap ratio  $g/N$ .

In this work, we study secret sharing in the extremal case of bit-long shares and arbitrarily small gap ratio  $g/N$ , where standard ramp secret sharing becomes impossible. We show, however, that a slightly relaxed but equally effective notion of semantic security for the secret, and negligible reconstruction error probability, eliminate the impossibility. Moreover, we provide explicit constructions of such schemes. One of the consequences of our relaxation is that, unlike standard ramp schemes with perfect secrecy, adaptive and non-adaptive adversaries need different analysis and construction. For non-adaptive adversaries, we explicitly construct secret sharing schemes that provide secrecy against any  $\tau$  fraction of observed shares, and reconstruction from any  $\rho$  fraction of shares, for any choices of  $0 \leq \tau < \rho \leq 1$ . Our construction achieves secret length  $N(\rho - \tau - o(1))$ , which we show to be optimal. For adaptive adversaries, we construct explicit schemes attaining a secret length  $\Omega(N(\rho - \tau))$ . We discuss our results and open questions.

## 1 Introduction

Secret sharing, introduced independently by Blakley [3] and Shamir [20], is one of the most fundamental cryptographic primitives with far-reaching applications, such as being a major tool in secure multiparty computation (cf. [12]). The general goal in secret sharing is to encode a secret  $s$  into a number of *shares*  $X_1, \dots, X_N$  that are distributed among  $N$  players such that only certain *authorized subsets* of the players can reconstruct the secret. An *authorized* subset of players is a set  $A \subseteq [N]$  such that the set of shares with indices in  $A$  can collectively be used to reconstruct the secret  $s$  (*perfect reconstructibility*). On the other hand,  $A$  is an *unauthorized* subset if the knowledge of the shares with indices in  $A$  reveals no information about the secret (*perfect privacy*). The set of authorized and unauthorized sets define an access structure, of which the most widely used is the so-called *threshold structure*. A secret sharing scheme with *threshold* access structure, is defined with respect to an integer parameter  $t$  and satisfies the following properties. Any set  $A \subseteq [N]$  with  $|A| \leq t$  is an unauthorized set. That is, the knowledge of any  $t$  shares, or fewer, does not reveal any information about the secret. On the other hand, any set  $A$  with  $|A| > t$  is an authorized set. That is, the knowledge of any  $t + 1$  or more shares completely reveals the secret.

Shamir's secret sharing scheme [20] gives an elegant construction for the threshold access structure that can be interpreted as the use of Reed-Solomon codes for encoding the secret. Suppose the secret  $s$  is an  $\ell$ -bit string and  $N \leq 2^\ell$ . Then, Shamir's scheme treats the secret as an element of the finite field  $\mathbb{F}_q$ , where  $q = 2^\ell$ , padded with  $t$  uniformly random and independent elements from the same field. The resulting vector over  $\mathbb{F}_q^{t+1}$  is then encoded using a Reed-Solomon code of length  $N$ , providing  $N$  shares of length  $\ell$  bits each. The fact that a Reed-Solomon code is Maximum Distance Separable (MDS) can then be used to show that the threshold guarantee for privacy and reconstruction is satisfied.

Remarkably, Shamir's scheme is optimal for threshold secret sharing in the following sense: Any threshold secret sharing scheme sharing  $\ell$ -bit secrets necessarily requires shares of length at least  $\ell$ , and Shamir's scheme attains this lower bound [23]. It is natural to ask whether secret sharing is possible at share lengths below the secret length  $\log q < \ell$ , where  $\log$  is to base 2 throughout this work. Of course, in this case, the threshold guarantee that requires all subsets of participants be either authorized, or unauthorized, can no longer be attained. Instead, the notion can be relaxed to *ramp* secret sharing which allows some subset of participants to learn some information about the secret. A ramp scheme is defined with respect to two threshold parameters,  $t$  and  $r > t + 1$ . As in threshold scheme, the knowledge of any  $t$  shares or fewer does not reveal any information about the secret. On the other hand, any  $r$  shares can be used to reconstruct the secret. The subsets of size between  $t + 1$  and  $r - 1$ , may learn some information about the secret. The information-theoretic bound (see e.g. [17]) now becomes

$$\ell \leq (r - t) \log q. \tag{1}$$

Ideally, one would like to obtain equality in (1) for as general parameter settings as possible.

Let  $g := r - t$  denote the *gap* between the privacy and reconstructibility parameters. Let the secret length  $\ell$  and the number of players  $N$  be unconstrained integer parameters. It is known that, using Reed-Solomon code interpretation of Shamir's approach applied to a random linear code, for every fixed *relative gap*  $\gamma := g/N$ , there is a constant  $q$  only depending on  $\gamma$  such that a ramp secret sharing scheme with share size  $q$  exists. Such schemes can actually be constructed by using explicit algebraic geometry codes instead of random linear codes. In fact, this dependence of share size  $q$  on relative gap  $g/N$  is inherent for threshold and more generally ramp schemes. It is shown in an unpublished work of Kilian and Nisan<sup>1</sup> for threshold schemes, and later more generally in [8], that for ramp schemes with share size  $q$ , threshold gap  $g$ , privacy threshold  $t$  and unconstrained number of players  $N$ , the following always holds:  $q \geq (N - t + 1)/g$ . Very recently in [4], a new bound with respect to the reconstruction parameter  $r$  is proved through connecting secret sharing for one bit secret to game theory:  $q \geq (r + 1)/g$ . These two bounds together yield

$$q \geq (N + g + 2)/(2g). \quad (2)$$

Note that the bound (2) is very different from the bound (1) in nature. The bound (1) is the fundamental limitation of information-theoretic security, bearing the same flavour as the One-Time-Pad. The bound (2) is independent of the secret length and holds even when the secret is one bit.

We ask the following question: *For a fixed constant share size  $q$  (in particular,  $q = 2$ ), is it possible to construct (relaxed but equally effective) ramp secret sharing schemes with arbitrarily small relative gap  $\gamma > 0$  that asymptotically achieve equality in (1)?*

Our results in this work show that the restriction (2) can be overcome if we allow a negligible privacy error in statistical distance (semantic security) and a negligible reconstruction error probability.

## 1.1 Related work

Secret sharing with binary shares is recently selectively studied in [5] with the focus on the tradeoff between the privacy parameter  $t$  and the computational complexity of the reconstruction function. The concern of this line of works is to construct secret sharing schemes whose sharing and reconstructing algorithms are both in the complexity class  $AC^0$  (i.e., constant depth circuits).

The model of secret sharing considered in [5] has perfect privacy, namely, the distributions of any  $t$  shares from a pair of distinct secrets are identical, while reconstruction is not necessarily with probability 1. In a followup work [6], the privacy is further relaxed to semantic security with an error parameter  $\varepsilon > 0$ . The relaxation is shown to be useful in allowing more choices of  $t$  while keeping the computational complexity of the reconstruction algorithm within  $AC^0$ .

In [5, 6], the secret is one bit. In [9], secrets of length equal to a fraction of  $N$  (number of players) is considered. This time binary secret sharing with adaptive and non-adaptive adversaries similar to the model we consider in this work is defined. However the paper considers only a privacy threshold  $t$ , and reconstruction is from the full share set ( $r = N$  always). Their goal is to achieve large secrets  $\ell = \Omega(N)$  over binary shares with large privacy parameter  $t = \Omega(N)$ , which is also similar to ours. They have an additional goal of keeping

<sup>1</sup> Their result is unpublished, and is independently obtained and generalised by [8] (see [8, Appendix A]).

the computational complexity of the reconstruction algorithm within  $AC^0$ , which we do not consider in this work. Their large privacy parameter  $t = \tau N$  is with a  $\tau$  much smaller than 1, which means that the relative threshold gap  $\gamma = 1 - \tau$  can not be arbitrarily small.

In the literature, perhaps the closest notion to secret sharing with binary shares is that of *wiretap codes*, first studied in information theory. In the basic wiretap channel model of Wyner and its extension to *broadcast channel with confidential messages* [25, 13], there is a point-to-point *main* channel between a sender and a receiver that has partial leakage to the adversary, and the leakage of information is modelled by a second point-to-point *wiretapper* channel between the sender and the adversary. The goal of the sender is to encode messages in such a way that the receiver can decode them, while the adversary does not learn much about them [25]. The highest information rate achievable for a wiretap channel is called the *secrecy capacity*. A Binary Erasure Channel with erasure probability  $p$  ( $BEC_p$ ) is a probabilistic transformation that maps inputs 0 and 1 to a symbol  $?$ , which denotes erasure, with probability  $p$  and to the inputs themselves with probability  $1 - p$ . The erasure channel scenario of wiretap model is closely related to secret sharing with fixed share size. For a pair ( $BEC_{p_m}, BEC_{p_w}$ ) of  $BEC$ 's, such that  $p_m < p_w$ , it is known that the secrecy capacity is the difference of the respective channel capacities:  $(1 - p_m) - (1 - p_w) = p_w - p_m$ .

It is important to note the distinctions between the erasure wiretap model above, and binary secret sharing. First, the guarantees of wiretap codes are required to only hold for random messages, whereas in secret sharing, the cryptographic convention of security for worst-case messages is required. Second, in the standard wiretap model, the notion of secrecy is information-theoretic and is typically measured in terms of the mutual information. Namely, for a random  $\ell$ -bit message  $M$ , and letting  $W$  denote the information delivered to the adversary, secrecy is satisfied in the weak (resp., strong) sense if  $I(M; W) \leq \varepsilon \ell$  (resp.,  $I(M; W) \leq \varepsilon$ ) for an arbitrarily small constant  $\varepsilon$ . The randomness of the random variable  $W$  depends on the randomness of  $M$ , the two channels, as well as the internal randomness of the encoder. For secret sharing, on the other hand, either perfect secrecy or semantic secrecy (negligible leakage with respect to statistical distance) is a requirement.

The notion of secrecy in wiretap codes has evolved over years. More recently the notion of semantic security for wiretap model has been introduced [2], which allows arbitrary message distribution and is shown to be equivalent to negligible leakage with respect to statistical distance.

There remains one last distinction between *semantically secure* wiretap model and secret sharing with fixed share size. That is the nature of the main and wiretapper channels are typically stochastic (e.g., the erasure channel with random i.i.d. erasures), whereas for secret sharing a worst-case guarantee for the erasure patterns is required. Namely, in secret sharing, reconstruction with overwhelming probability is required for every choice of  $r$  or more shares, and privacy of the secret is required for every (adaptive or non-adaptive) choice of the  $t$  shares observed by the adversary.

On the other hand, Ozarow and Wyner proposed the *wiretap channel II*, where an adversary observes arbitrary  $t$  out of the total  $N$  bits of the communication [18]. The wiretapper channel of the wiretap channel II is the adversarial analogue of a  $BEC_{p_w}$  with erasure probability  $p_w = (N - t)/N$ . This is exactly the same as the privacy requirement of the binary secret sharing. But in the wiretap channel II model, the main channel is a clear channel. This is corresponding to the special case of binary secret sharing where the reconstruction is only required when all shares are available. The adversarial analogue of the erasure scenario Wyner wiretap channel should have a main channel that erases  $Np_m$  components out of the total  $N$  components, which is the same as the reconstruction

requirement of binary secret sharing. Moreover, same as the Wyner wiretap channel model, the secrecy of the wiretap channel II is only required for uniform message and satisfies the weak (resp., strong) secrecy mentioned above.

## 1.2 Our contributions

We motivate the study of secret sharing scheme with fixed share size  $q$ , and study the extremal case of binary shares. Our goal is to show that even in this extremely restrictive case, a slight relaxation of the privacy and reconstruction notions of ramp secret sharing guarantees explicit construction of families of ramp schemes<sup>2</sup> with any constant relative privacy and reconstruction thresholds  $0 \leq \tau < \rho \leq 1$ , in particular, the relative threshold gap  $\gamma = \rho - \tau$  can be an arbitrarily small constant. Namely, for any constants  $0 \leq \tau < \rho \leq 1$ , it can be guaranteed that any  $\tau N$  or fewer shares reveal essentially no information about the secret, whereas any  $\rho N$  or more shares can reconstruct the exact secret with a negligible failure probability. While we only focus on the extremal special case  $q = 2$  in this presentation, all our results can be extended to any constant  $q$  (see Section 6).

We consider binary sharing of a large  $\ell$ -bit secret and for this work focus on the asymptotic case where the secret length  $\ell$ , and consequently the number of players  $N$ , are sufficiently large. We replace perfect privacy with semantic security, the strongest cryptographic notion of privacy second only to perfect privacy. That is, for any two secrets (possibly chosen by the adversary), we require the adversary's view to be statistically indistinguishable. The view of the adversary is a random variable with randomness coming solely from the internal randomness of the sharing algorithm. The notion of indistinguishability that we use is statistical (total variation) distance bounded by a leakage error parameter  $\varepsilon$  that is negligible in  $N$ . Using non-perfect privacy creates a distinction between non-adaptive and adaptive secrecy. A non-adaptive adversary chooses any  $\tau$  fraction of the  $N$  players at once, and receives their corresponding shares. An adaptive adversary however, selects share holders one by one, receives their shares and uses its available information to make its next choice. When  $\varepsilon = 0$ , i.e., when perfect privacy holds, non-adaptive secrecy automatically implies adaptive secrecy as well. However, this is not necessarily the case when  $\varepsilon > 0$  and we thus study the two cases separately. Similarly, we replace the perfect reconstruction with probabilistic reconstruction allowing a failure probability  $\delta$  that is negligible in  $N$ . The special case of  $\delta = 0$  means perfect reconstruction.

Note that secret sharing with fixed share size necessarily imposes certain restrictions that are not common in standard secret sharing. Unlike secret sharing with share length dependent on the secret length (for threshold schemes) or secret length and threshold gap (for ramp schemes), binary sharing of an  $\ell$ -bit secret obviously requires at least  $\ell$  shares to accommodate the secret information. For a family of ramp secret sharing schemes with fixed share size  $q$  and fixed relative thresholds  $0 \leq \tau < \rho \leq 1$ , as  $N$  grows the absolute gap length  $(\rho - \tau)N$  grows, and the accommodatable length of the secret is expected to grow and so the ratio  $\ell/N \in (0, 1]$  becomes a key parameter of interest for the family, referred to as the *coding rate*. As is customary in coding theory, it is desired to characterize the maximum possible ratio  $\ell/N \in (0, 1]$  for binary secret sharing. We use the relation (a similar relation was used in [10] for robust secret sharing) between a binary secret sharing family with relative threshold  $(\tau, \rho)$  and codes for a Wyner wiretap channel with two BEC's to derive a coding rate upper bound of  $\rho - \tau$  for binary secret sharing (see Lemma 11).

<sup>2</sup> We abuse the notion and will continue calling these relaxed schemes ramp schemes.

Our main technical contributions are explicit constructions of binary secret sharing schemes in both the non-adaptive and adaptive models, and proving optimality of non-adaptive construction. Namely, we prove the following:

► **Theorem 1** (informal summary of Lemma 11, Corollary 17, and Corollary 21). *For any choice of  $0 \leq \tau < \rho \leq 1$ , and large enough  $N$ , there is an explicit construction of a binary secret sharing scheme with  $N$  players that provides (adaptive or non-adaptive) privacy against leakage of any  $\tau N$  or fewer shares, as well as reconstruction from any  $\rho N$  or more of the shares (achieving semantic secrecy with negligible error and imperfect reconstruction with negligible failure probability). For non-adaptive secrecy, the scheme shares a secret of length  $\ell = (\rho - \tau - o(1))N$ , which is asymptotically optimal. For adaptive secrecy, the scheme shares a secret of length  $\ell = \Omega((\rho - \tau)N)$ .*

As a side contribution, our findings unify the Wyner wiretap model and its adversarial analogue. Our capacity-achieving construction of binary secret sharing for non-adaptive adversaries implies that the secrecy capacity of the adversarial analogue of the erasure scenario Wyner wiretap channel is similarly characterized by the erasure ratios of the two channels. Moreover, the secrecy can be strengthened to semantic security.

This answers an open question posted in [1]. The authors studied a generalisation of the wiretap II model, where the adversary chooses  $t$  bits to observe and erases them. They showed that the rate  $1 - \tau - h_2(\tau)$ , where  $h_2(\cdot)$  is the binary entropy function, can be achieved and left open the question of whether a higher rate is achievable. Our result specialized to their setting shows that, the rate  $1 - 2\tau$  can be explicitly achieved.

### 1.3 Our approach and techniques

Our explicit constructions follow the paradigm of invertible randomness extractors formalized in [11]. Invertible extractors were used in [11] for explicit construction of optimal wiretap coding schemes in the Wiretap channel II [18]. This, in particular, is corresponding to the  $\rho = 1$  special case of secret sharing where reconstruction is only required when all shares are available. Moreover, the secrecy there is an information-theoretic notion, and only required to hold for uniform messages. The consequence of the latter is that the construction in [11] does not directly give us binary secret sharing, not even for the  $\rho = 1$  special case. The exposition below is first focused on how semantic security is achieved.

As in [11], we rely on *invertible affine extractors* as our primary technical tool. Such an extractor is an explicit function  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^\ell$  such that, for any random variable  $X$  uniformly distributed over an unknown  $k$ -dimensional affine subspace of  $\mathbb{F}_2^n$ , the distribution of  $\text{AExt}(X)$  is close to the uniform distribution over  $\mathbb{F}_2^\ell$  in statistical distance. Furthermore, the invertibility guarantee provides an efficient algorithm for sampling a uniform element from the set  $\text{AExt}^{-1}(s)$  of pre-images for any given output  $s \in \mathbb{F}_2^\ell$ .

It is then natural to consider the affine extractor's uniform inverter as a candidate building block for the sharing algorithm of a secret sharing scheme. Intuitively, if the secret  $s$  is chosen uniformly at random, we have the guarantee that for any choice of a bounded number of the bits of its random pre-image revealed to the adversary, the distribution of the random pre-image conditioned on the revealed value satisfies that of an affine source. Now according to the definition of an affine extractor, the extractor's output (i.e., the secret  $s$ ) remains uniform (and thus unaffected in distribution) given the information revealed to the adversary. Consequently, secrecy should at least hold in an information-theoretic sense, i.e. the mutual information between the secret and the revealed vector components is zero. This is what was formalized and used in [11] for the construction of Wiretap channel II codes.

For non-adaptive adversaries, in fact it is possible to use *invertible seeded extractors* rather than invertible affine extractors described in the above construction. A (strong) seeded extractor assumes, in addition to the main input, an independent seed as an auxiliary input and ensures uniformity of the output for most fixings of the seed. The secret sharing encoder appends a randomly chosen seed to the encoding and inverts the extractor with respect to the chosen seed. Then, the above argument would still hold even if the seed is completely revealed to the adversary.

The interest in the use of seeded, as opposed to seedless affine, extractors is twofold. First, nearly optimal and very efficient constructions of seeded extractors are known in the literature that extract nearly the entire source entropy with only a short seed. This allows us to attain nearly optimal rates for the non-adaptive case. Furthermore, and crucially, such nearly optimal extractor constructions (in particular, Trevisan's extractor [24, 19]) can in fact be linear functions for every fixed choice of the seed (in contrast, seedless affine extractors can never be linear functions). We take advantage of the linearity of the extractor in a crucial way and use a rather delicate analysis to show that in fact the linearity of the extractor can be utilized to prove that the resulting secret sharing scheme provides the stringent worst-case secret guarantee which is a key requirement distinguishing secret sharing schemes (a cryptographic primitive) from wiretap codes (an information-theoretic notion).

Using a seeded extractor instead of a seedless extractor, however, introduces a new challenge. In order for the seeded extractor to work, the seed has to be independent of the main input, which is a distribution induced by the adversary's choice of reading positions. The independence of the seed and the main input can be directly argued when the adversary is non-adaptive. An adaptive adversary, however, may choose its reading positions to learn about the seed first, and then choose the rest of the reading positions according to the value of the seed. In this case, we can not prove the independence of the seed and the main input.

For adaptive adversaries, we go back to using an invertible affine extractor. We prove that both security for worst-case messages and against adaptive adversaries are guaranteed if the affine extractor provides the strong guarantee of having a nearly uniform output with respect to the  $\ell_\infty$  measure rather than  $\ell_1$ . However, this comes at the cost of the extractor not being able to extract the entire entropy of the source, leading to ramp secret sharing schemes with slightly sub-optimal rates, albeit still achieving rates within a constant factor of the optimum. As a proof of concept, we utilize a simple padding and truncation technique to convert any off-the-shelf seedless affine extractor (such as those of Bourgain [7] or Li [16]) to one that satisfies the stronger uniformity condition that we require.

We now turn to reconstruction from an incomplete set of shares. In order to provide reconstructibility from a subset of size  $r$  of the shares, we naturally compose the encoding obtained from the extractor's inversion routine with a linear erasure-correcting code. The linearity of the code ensures that the extractor's input subject to the adversary's observation (which now can consist of linear combinations of the original encoding) remains uniform on some affine space, thus preserving the privacy guarantee.

However, since by the known rate-distance trade-offs of binary error-correcting codes, no deterministic coding scheme can correct more than a  $1/2$  fraction of erasures (a constraint that would limit the choice of  $\rho$ ), the relaxed notion of *stochastic coding schemes* is necessary for us to allow reconstruction for all choices of  $\rho \in (\tau, 1]$ . Intuitively, a stochastic code is a randomized encoder with a deterministic decoder, that allows the required fraction of errors to be corrected. We utilize what we call a *stochastic affine* code. Such codes are equipped with encoders that are affine functions of the message for every fixing of the encoder's internal randomness. We show that such codes are as suitable as deterministic linear codes for providing the linearity properties that our construction needs.

In fact, we need capacity-achieving stochastic erasure codes, i.e., those that correct every  $1 - \rho$  fraction of erasures at asymptotic rate  $\rho$ , to be able to construct binary secret sharing schemes with arbitrarily small relative gap  $\gamma = \rho - \tau$ . To construct capacity-achieving stochastic affine erasure codes, we utilize a construction of stochastic codes due to Guruswami and Smith [15] for bit-flip errors. We observe that this construction can be modified to yield capacity-achieving erasure codes. Roughly speaking, this is achieved by taking an explicit capacity-achieving linear code for BEC and pseudo-randomly shuffling the codeword positions. Combined with a delicate encoding of hidden “control information” to communicate the choice of the permutation to the decoder in a robust manner, the construction transforms robustness against random erasures to worst-case erasures at the cost of making the encoder randomized.

## 1.4 Organization of the paper

Section 2 contains a brief introduction to the two building blocks for our constructions: randomness extractors and stochastic codes. In Section 3, we formally define the binary secret sharing model and prove a coding rate upper bound. Section 4 contains a capacity-achieving construction with privacy against non-adaptive adversaries. Section 5 contains a constant rate construction with privacy against adaptive adversaries. Finally, we conclude the paper and discuss open problems in Section 6.

## 2 Preliminaries and definitions

In this section, we review the necessary facts and results about randomness extractors, both the seeded and seedless affine variants, as well as the stochastic erasure correcting codes.

Randomness extractors extract close to uniform bits from input sequences that are not uniform but have some guaranteed entropy. The closeness to uniform of the extractor output is measured by the statistical distance (half the  $\ell_1$ -norm). For a set  $\mathcal{X}$ , we use  $X \leftarrow \mathcal{X}$  to denote that  $X$  is distributed over the set  $\mathcal{X}$ . For two random variables  $X, Y \leftarrow \mathcal{X}$ , the statistical distance between  $X$  and  $Y$  is defined as,

$$\text{SD}(X; Y) = \frac{1}{2} \sum_{x \in \mathcal{X}} |\Pr[X = x] - \Pr[Y = x]|.$$

We say  $X$  and  $Y$  are  $\varepsilon$ -close if  $\text{SD}(X, Y) \leq \varepsilon$ . A *randomness source* is a random variable with lower bound on its min-entropy, which is defined by  $H_\infty(X) = -\log \max_x \{\Pr[X = x]\}$ . We say a random variable  $X \leftarrow \{0, 1\}^n$  is a  $(n, k)$ -source if  $H_\infty(X) \geq k$ .

For well structured sources, there exist deterministic functions that can extract close to uniform bits. The *support* of  $X \leftarrow \mathcal{X}$  is the set of  $x \in \mathcal{X}$  such that  $\Pr[X = x] > 0$ . An *affine*  $(n, k)$ -source is an  $(n, k)$ -source whose support is an affine sub-space of  $\{0, 1\}^n$  and each vector in the support occurs with the same probability. Let  $U_m$  denote the random variable uniformly distributed over  $\{0, 1\}^m$ .

► **Definition 2.** A function  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^m$  is an affine  $(k, \varepsilon)$ -extractor if for any affine  $(n, k)$ -source  $X$ , we have

$$\text{SD}(\text{AExt}(X); U_m) \leq \varepsilon.$$

An affine extractor can not be a linear function.

For general  $(n, k)$ -sources, there does not exist a deterministic function that can extract close to uniform bits from all of them simultaneously. A family of deterministic functions are needed.

► **Definition 3.** A function  $\text{Ext}: \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^m$  is a strong seeded  $(k, \varepsilon)$ -extractor if for any  $(n, k)$ -source  $X$ , we have

$$\text{SD}(S, \text{Ext}(S, X); S, U_m) \leq \varepsilon,$$

where  $S$  is chosen uniformly from  $\{0, 1\}^d$ . A seeded extractor  $\text{Ext}(\cdot, \cdot)$  is called linear if for any fixed seed  $S = s$ , the function  $\text{Ext}(s, \cdot)$  is a linear function.

We will use Trevisan's extractor [24] in our first construction. In particular, we use the following improvement of this extractor due to Raz, Reingold and Vadhan [19].

► **Lemma 4** ([19]). *There is an explicit linear strong seeded  $(k, \varepsilon)$ -extractor  $\text{Ext}: \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^\ell$  with  $d = O(\log^3(n/\varepsilon))$  and  $\ell = k - O(d)$ .*

We will use Bourgain's affine extractor in our second construction. We note, however, that we could have used other explicit extractors for this purpose, such as [16].

► **Lemma 5** ([7]). *For every constant  $0 < \mu \leq 1$ , there is an explicit affine  $(\mu n, \varepsilon)$ -extractor  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^m$  with output length  $m = \Omega(n)$  and error  $\varepsilon = 2^{-\Omega(n)}$ .*

Explicit constructions of randomness extractors have efficient forward direction of extraction. In some applications, we usually need to efficiently invert the process: Given an extractor output, sample a random pre-image.

► **Definition 6** ([11]). Let  $f$  be a mapping from  $\{0, 1\}^n$  to  $\{0, 1\}^m$ . For  $0 \leq v < 1$ , a function  $\text{Inv}: \{0, 1\}^m \times \{0, 1\}^r \rightarrow \{0, 1\}^n$  is called a  $v$ -inverter for  $f$  if the following conditions hold:

- (Inversion) Given  $y \in \{0, 1\}^m$  such that its pre-image  $f^{-1}(y)$  is nonempty, for every  $r \in \{0, 1\}^r$  we have  $f(\text{Inv}(y, r)) = y$ .
- (Uniformity)  $\text{Inv}(U_m, U_r)$  is  $v$ -close to  $U_n$ .

A  $v$ -inverter is called efficient if there is a randomized algorithm that runs in worst-case polynomial time and, given  $y \in \{0, 1\}^m$  and  $r$  as a random seed, computes  $\text{Inv}(y, r)$ . We call a mapping  $v$ -invertible if it has an efficient  $v$ -inverter, and drop the prefix  $v$  from the notation when it is zero. We abuse the notation and denote the inverter of  $f$  by  $f^{-1}$ .

A *stochastic code* has a randomised encoder and a deterministic decoder. The encoder  $\text{Enc}: \{0, 1\}^m \times \mathcal{R} \rightarrow \{0, 1\}^n$  uses local randomness  $R \leftarrow \mathcal{R}$  to encode a message  $m \in \{0, 1\}^m$ . The decoder is a deterministic function  $\text{Dec}: \{0, 1\}^n \rightarrow \{0, 1\}^m \cup \{\perp\}$ . The decoding probability is defined over the encoding randomness  $R \leftarrow \mathcal{R}$ . Stochastic codes are known to explicitly achieve the capacity of some adversarial channels [15].

Affine sources play an important role in our constructions. We define a general requirement for the stochastic code used in our constructions.

► **Definition 7** (Stochastic Affine codes). Let  $\text{Enc}: \{0, 1\}^m \times \mathcal{R} \rightarrow \{0, 1\}^n$  be the encoder of a stochastic code. We say it is a stochastic affine code if for any  $r \in \mathcal{R}$ , the encoding function  $\text{Enc}(\cdot, r)$  specified by  $r$  is an affine function of the message. That is we have

$$\text{Enc}(m, r) = mG_r + \Delta_r,$$

where  $G_r \in \{0, 1\}^{m \times n}$  and  $\Delta_r \in \{0, 1\}^n$  are specified by the randomness  $r$ .

We then adapt a construction in [15] to obtain the following capacity-achieving Stochastic Affine-Erasure Correcting Code (SA-ECC). In particular, we show for any  $p \in [0, 1)$ , there is an explicit stochastic affine code that corrects  $p$  fraction of adversarial erasures and achieves the rate  $1 - p$ .

► **Lemma 8** (Adapted from [15]). *For every  $p \in [0, 1)$ , and every  $\xi > 0$ , there is an efficiently encodable and decodable stochastic affine code  $(\text{Enc}, \text{Dec})$  with rate  $R = 1 - p - \xi$  such that for every  $\mathbf{m} \in \{0, 1\}^{NR}$  and erasure pattern of at most  $p$  fraction, we have  $\Pr[\text{Dec}(\widetilde{\text{Enc}}(\mathbf{m})) = \mathbf{m}] \geq 1 - \exp(-\Omega(\xi^2 N / \log^2 N))$ , where  $\widetilde{\text{Enc}}(\mathbf{m})$  denotes the partially erased random codeword and  $N$  denotes the length of the codeword.*

**Proof Sketch.** We defer the details of the construction to the full version of this paper. For now we refer to [15, Theorem 6.1] and point out the adaptations needed. There are six building blocks involved in the construction: SC, RS, Samp, KNR, POLY<sub>*t*</sub> and REC. We replace the first and last building blocks.

The first building block is a *Stochastic Code* (SC). We need two properties from this building block: detect when the codeword is masked by a random offset and correct from erasures of no more than  $1 - \rho + \xi$  fraction. Since the correction is with respect to erasure, as opposed to flips in [15, Theorem 6.1], we then use an erasure list-decodable code [14] instead of an error list-decodable code. This is necessary when  $\rho < \frac{1}{2}$ , since the latter can not correct errors beyond one half.

The last building block is a *Random Error Code* (REC). We need two properties from this building block: correct from random erasures of  $1 - \rho$  fraction and the encoder is a linear function. The linearity was not required in [15, Theorem 6.1]. Explicit linear codes at rate  $1 - p$  that correct  $p$  fraction of random erasures are known. We can use any explicit construction of capacity achieving linear codes for BEC <sub>$1-\rho$</sub>  to obtain REC and use a similar argument of [22]. ◀

### 3 Binary secret sharing schemes

In this section, we define our model of nearly-threshold binary secret sharing schemes. We begin with a description of the two models of non-adaptive and adaptive adversaries which can access up to  $t$  of the  $N$  shares.

A *leakage oracle* is a machine  $\mathcal{O}(\cdot)$  that takes as input an  $N$ -bit string  $\mathbf{c} \in \{0, 1\}^N$  and then answers the *leakage queries* of the type  $I_j$ , for  $I_j \subset [N]$ ,  $j = 1, 2, \dots, q$ . Each query  $I_j$  is answered with  $\mathbf{c}_{I_j}$ . An interactive machine  $\mathcal{A}$  that issues the leakage queries is called a *leakage adversary*. Let  $A_{\mathbf{c}} = \cup_{j=1}^q I_j$  denote the union of all the index sets chosen by  $\mathcal{A}$  when the oracle input is  $\mathbf{c}$ . The oracle is called  $t$ -bounded, denoted by  $\mathcal{O}_t(\cdot)$ , if it rejects leakage queries from  $\mathcal{A}$  if there exists some  $\mathbf{c} \in \{0, 1\}^N$  such that  $|A_{\mathbf{c}}| > t$ . An adaptive leakage adversary decides the index set  $I_{j+1}$  according to the oracle's answers to all previous queries  $I_1, \dots, I_j$ . A non-adaptive leakage adversary has to decide the index set  $A_{\mathbf{c}}$  before any information about  $\mathbf{c}$  is given. This means that for a non-adaptive adversary, given any oracle input  $\mathbf{c} \in \{0, 1\}^N$ , we always have  $A_{\mathbf{c}} = A$  for some  $A \subset [N]$ . Let  $\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\cdot)}$  denote the view of the leakage adversary  $\mathcal{A}$  interacting with a  $t$ -bounded leakage oracle. When  $\mathcal{A}$  is non-adaptive, we use the shorthand  $\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\cdot)} = (\cdot)_A$ , for some  $A \subset [N]$  of size  $|A| \leq t$ .

A function  $\varepsilon: \mathbb{N} \rightarrow \mathbb{R}$  is called *negligible* if for every positive integer  $k$ , there exists an  $N_k \in \mathbb{N}$  such that  $|\varepsilon(N)| < \frac{1}{N^k}$  for all  $N > N_k$ . The following definition of ramp Secret Sharing Scheme (SSS) allows imperfect privacy and reconstruction with errors bounded by negligible functions  $\varepsilon(\cdot)$  and  $\delta(\cdot)$ , respectively.

► **Definition 9.** For any  $0 \leq \tau < \rho \leq 1$ , an  $(\varepsilon(N), \delta(N))$ -SSS with relative threshold pair  $(\tau, \rho)$  is a pair of polynomial-time algorithms (Share, Recst),

$$\text{Share}: \{0, 1\}^{\ell(N)} \times \mathcal{R} \rightarrow \{0, 1\}^N,$$

where  $\mathcal{R}$  denote the randomness set, and

$$\text{Recst}: \widetilde{\{0, 1\}^N} \rightarrow \{0, 1\}^{\ell(N)} \cup \{\perp\},$$

where  $\widetilde{\{0, 1\}}^N$  denotes the subset of  $(\{0, 1\} \cup \{?\})^N$  with at least  $N\rho$  components not equal to the erasure symbol “?”, that satisfy the following properties.

- Reconstruction: Given  $r(N) = N\rho$  correct shares of a share vector  $\text{Share}(\mathbf{s})$ , the reconstruction algorithm  $\text{Recst}$  reconstructs the secret  $\mathbf{s}$  with probability at least  $1 - \delta(N)$ .

When  $\delta(N) = 0$ , we say the SSS has perfect reconstruction.

- Privacy (non-adaptive/adaptive):

- Non-adaptive: for any  $\mathbf{s}_0, \mathbf{s}_1 \in \{0, 1\}^{\ell(N)}$ , any  $A \subset [N]$  of size  $|A| \leq t(N) = N\tau$ ,

$$\text{SD}(\text{Share}(\mathbf{s}_0)_A; \text{Share}(\mathbf{s}_1)_A) \leq \varepsilon(N). \quad (3)$$

- Adaptive: for any  $\mathbf{s}_0, \mathbf{s}_1 \in \{0, 1\}^{\ell(N)}$  and any adaptive adversary  $\mathcal{A}$  interacting with a  $t(N)$ -bounded leakage oracle  $\mathcal{O}_{t(N)}(\cdot)$  for  $t(N) = N\tau$ ,

$$\text{SD}\left(\text{View}_{\mathcal{A}}^{\mathcal{O}_{t(N)}(\text{Share}(\mathbf{s}_0))}; \text{View}_{\mathcal{A}}^{\mathcal{O}_{t(N)}(\text{Share}(\mathbf{s}_1))}\right) \leq \varepsilon(N). \quad (4)$$

When  $\varepsilon(N) = 0$ , we say the SSS has perfect privacy.

The difference  $\gamma = \rho - \tau$  is called the relative gap, since  $N\gamma = r(N) - t(N)$  is the threshold gap of the scheme. When clear from context, we write  $\varepsilon, \delta, t, k, \ell$  instead of  $\varepsilon(N), \delta(N), t(N), r(N), \ell(N)$ . When the parameters are not specified, we call a  $(\varepsilon, \delta)$ -SSS simply a binary SSS.

In the above definition, a binary SSS has a pair of designed relative thresholds  $(\tau, \rho)$ . In this work, we are concerned with constructing nearly-threshold binary SSS, namely, binary SSS with arbitrarily small relative gap  $\gamma = \rho - \tau$ . We also want our binary SSS to share a large secret  $\ell = \Omega(N)$ .

► **Definition 10.** For any  $0 \leq \tau < \rho \leq 1$ , a coding rate  $R \in [0, 1]$  is achievable if there exists a family of  $(\varepsilon, \delta)$ -SSS with relative threshold pair  $(\tau, \rho)$  such that  $\varepsilon$  and  $\delta$  are both negligible in  $N$  and  $\frac{\ell}{N} \rightarrow R$ . The highest achievable coding rate of binary SSS for a pair  $(\tau, \rho)$  is called its capacity.

By relating binary SSS to Wyner wiretap codes with a pair of BEC’s, we obtain the following coding rate upper bound for binary SSS.

► **Lemma 11.** For  $0 \leq \tau < \rho \leq 1$ , the coding rate capacity of binary SSS with relative threshold pair  $(\tau, \rho)$  is asymptotically upper-bounded by  $\rho - \tau$ .

Due to the space constraint, details of the proof are given in the full version of this paper.

**Proof Sketch.** Let  $(\text{Share}, \text{Recst})$  be a non-adaptive binary SSS with relative threshold pair  $(\tau, \rho)$ . We use  $\text{Share}$  as the encoder and  $\text{Recst}$  as the decoder, and verify that we obtain a Wyner wiretap code with a  $\text{BEC}_{p_m}$  main channel and a  $\text{BEC}_{p_w}$  wiretapper channel, where  $p_m = 1 - \rho - \xi$  and  $p_w = 1 - \tau + \xi$ , respectively, for arbitrarily small  $\xi > 0$ . Erasures in binary SSS are worst-case, while they are probabilistic in the Wyner wiretap model. We however note that asymptotically, the number of random erasures of  $\text{BEC}_{p_m}$  and  $\text{BEC}_{p_w}$  approaches  $Np_m$  and  $Np_w$ , respectively, with overwhelming probability, and so a code that protects against worst-case erasure can be used as a code with probabilistic erasure. We also take into account the difference in the secrecy notion in binary SSS and Wyner wiretap code. ◀

In the rest of the paper, we give two constant rate constructions of nearly-threshold binary SSS against non-adaptive adversary and adaptive adversary, respectively. The non-adaptive adversary construction is optimal in the sense that the coding rate achieves the upper bound in Lemma 11.

#### 4 Secret sharing against non-adaptive adversaries

We first present our construction of capacity-achieving binary SSS against non-adaptive adversaries, using linear strong seeded extractors and optimal rate stochastic erasure correcting codes. The following theorem describes the construction using these components.

► **Theorem 12.** *Let  $\text{Ext}: \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^\ell$  be a linear strong seeded  $(n - t, \frac{\varepsilon}{8})$ -extractor and  $\text{Ext}^{-1}(\mathbf{z}, \cdot): \{0, 1\}^\ell \times \mathcal{R}_1 \rightarrow \{0, 1\}^n$  be the inverter of the function  $\text{Ext}(\mathbf{z}, \cdot)$  that maps an  $\mathbf{s} \in \{0, 1\}^\ell$  to one of its pre-images chosen uniformly at random. Let  $(\text{SA-ECCenc}, \text{SA-ECCdec})$  be a stochastic affine-erasure correcting code with the encoder  $\text{SA-ECCenc}: \{0, 1\}^{d+n} \times \mathcal{R}_2 \rightarrow \{0, 1\}^N$  that tolerates  $N - r$  erasures and decodes with success probability at least  $1 - \delta$ . Then the following coding scheme  $(\text{Share}, \text{Recst})$  is a non-adaptive  $(\varepsilon, \delta)$ -SSS with threshold pair  $(t, r)$ .*

$$\begin{cases} \text{Share}(\mathbf{s}) &= \text{SA-ECCenc}(\mathbf{Z} \parallel \text{Ext}^{-1}(\mathbf{Z}, \mathbf{s})), \text{ where } \mathbf{Z} \stackrel{\$}{\leftarrow} \{0, 1\}^d; \\ \text{Recst}(\tilde{\mathbf{v}}) &= \text{Ext}(\mathbf{z}, \mathbf{x}), \text{ where } (\mathbf{z} \parallel \mathbf{x}) = \text{SA-ECCdec}(\tilde{\mathbf{v}}). \end{cases}$$

Here  $\tilde{\mathbf{v}}$  denotes an incomplete version of a share vector  $\mathbf{v} \in \{0, 1\}^N$  with some of its components replaced by erasure symbols.

The proof of Theorem 12 will follow naturally from Lemma 13. We first state and prove this general property of a linear strong extractor, which is of independent interest. For the property to hold, we in fact only need the extractor to be able to extract from affine sources. The proof of Lemma 13 is a bit long. We then break it into a claim and two propositions.

► **Lemma 13.** *Let  $\text{Ext}: \{0, 1\}^d \times \{0, 1\}^n \rightarrow \{0, 1\}^m$  be a linear strong  $(k, \varepsilon)$ -extractor. Let  $f_A: \{0, 1\}^{d+n} \rightarrow \{0, 1\}^t$  be any affine function with output length  $t \leq n - k$ . For any  $\mathbf{m}, \mathbf{m}' \in \{0, 1\}^m$ , let  $(\mathbf{Z}, \mathbf{X}) = (\mathbf{U}_d, \mathbf{U}_n) \mid (\text{Ext}(\mathbf{U}_d, \mathbf{U}_n) = \mathbf{m})$  and  $(\mathbf{Z}', \mathbf{X}') = (\mathbf{U}_d, \mathbf{U}_n) \mid (\text{Ext}(\mathbf{U}_d, \mathbf{U}_n) = \mathbf{m}')$ . We have*

$$\text{SD}(f_A(\mathbf{Z}, \mathbf{X}); f_A(\mathbf{Z}', \mathbf{X}')) \leq 8\varepsilon. \quad (5)$$

**Proof.** For the above pairwise guarantee (5) to hold, it suffices to show that for every fixed choice of  $\mathbf{m} \in \{0, 1\}^m$ , the distribution of  $f_A(\mathbf{Z}, \mathbf{X})$  is  $(4\varepsilon)$ -close to  $\mathbf{U}_d \times \mathcal{D}$ , where  $\mathbf{U}_d$  is the uniform distribution on  $\{0, 1\}^d$ .

Without loss of generality, we assume that the linear function  $\text{Ext}(\mathbf{z}, \cdot): \{0, 1\}^n \rightarrow \{0, 1\}^m$ , for every seed  $\mathbf{z}$ , has the entire  $\{0, 1\}^m$  as its image<sup>3</sup>. Without loss of generality, it suffices to assume that  $f_A$  is of the form  $f_A(\mathbf{Z}, \mathbf{X}) = (\mathbf{Z}, W(\mathbf{X}))$  for some affine function  $W: \{0, 1\}^n \rightarrow \{0, 1\}^t$ . This is because for any arbitrary  $f_A$ , the information contained in  $f_A(\mathbf{Z}, \mathbf{X})$  can be obtained from  $(\mathbf{Z}, W(\mathbf{X}))$  for a suitable choice of  $W$ . Let  $\mathcal{D}$  be the uniform distribution on the image of  $W$ .

Let  $\mathbf{K} \leftarrow \{0, 1\}^n$  be a random variable uniformly distributed over the kernel of the linear transformation defined by  $W$ , and note that it has entropy at least  $n - t \geq k$ . The extractor  $\text{Ext}$  thus guarantees that  $\text{Ext}(\mathbf{Z}, \mathbf{K})$ , for a uniform and independent seed  $\mathbf{Z}$ , is  $\varepsilon$ -close to uniform. By averaging, it follows that for at least  $1 - 4\varepsilon$  fraction of the choices of the seed  $\mathbf{z} \in \{0, 1\}^d$ , the distribution of  $\text{Ext}(\mathbf{z}, \mathbf{K})$  is  $(1/4)$ -close to uniform.

<sup>3</sup> If this condition is not satisfied for some choice  $\mathbf{z}$  of the seed, there must be linear dependencies between the  $m$  output bits of  $\text{Ext}(\mathbf{z}, \cdot)$ . Therefore, for this choice  $\text{Ext}(\mathbf{z}, \cdot)$  can never be an extractor and arbitrarily changing  $\text{Ext}(\cdot, \mathbf{z})$  to be an arbitrary full rank linear function will not change the overall performance of the extractor.

► **Claim 14.** *Let  $U$  be uniformly distributed on  $\{0, 1\}^m$  and  $U'$  be any affine source that is not uniform on  $\{0, 1\}^m$ . Then, the statistical distance between  $U$  and  $U'$  is at least  $1/2$ .*

Claim 14 follows from the observation that any affine source  $U'$  that is not uniform on  $\{0, 1\}^m$  will have a support (the set of vectors  $u$  such that  $\Pr[U' = u] > 0$ ) that is an affine subspace of  $\{0, 1\}^m$  with dimension at most  $m - 1$ .

Continuing with the previous argument, since  $\text{Ext}$  is a linear function for every seed, the distribution of  $\text{Ext}(z, K)$  for any seed  $z$  is an affine source. Therefore, the above claim allows us to conclude that for at least  $1 - 4\varepsilon$  fraction of the choices of  $z$ , the distribution of  $\text{Ext}(z, K)$  is *exactly* uniform. Let  $\mathcal{G} \subseteq \{0, 1\}^d$  be the set of such choices of the seed. Observe that if  $\text{Ext}(z, K)$  is uniform for some seed  $z$ , then for any affine translation of  $K$ , namely,  $K + v$  for any  $v \in \{0, 1\}^n$ , we have that  $\text{Ext}(z, K + v)$  is uniform as well. This is due to the linearity of the extractor.

Recall that our goal is to show that  $f_A(Z, X) = (Z, W(X))$  is  $(4\varepsilon)$ -close to  $U_d \times \mathcal{D}$ . The distribution  $(Z, W(X))$  is obtained as  $(U_d, W(U_n)) | (\text{Ext}(U_d, U_n) = m)$ . For the rest of the proof, we first find out the distribution  $(U_d, W(U_n)) | (\text{Ext}(U_d, U_n) = m, U_d = z)$  for a seed  $z \in \mathcal{G}$  (Proposition 15) and then take the convex combination over the uniform seed to obtain  $(Z, W(X))$  (Proposition 16). The argument starts with a uniform message  $M \stackrel{\$}{\leftarrow} \{0, 1\}^m$  instead of a particular message  $m \in \{0, 1\}^m$ . We define a new set of simplified notations. Let  $Z \stackrel{\$}{\leftarrow} \{0, 1\}^d$  be an independent and uniform seed. Let  $(Z, Y)$  be the pre-image of  $M$  and  $(Z, W) := f_A(Z, Y)$ . Proposition 15 and 16 are stated in terms of the triple  $(M, Z, W)$ .

► **Proposition 15.** *Let  $z \in \mathcal{G}$  and consider any  $m \in \{0, 1\}^m$ . Then, the conditional distribution of  $W | (Z = z, M = m)$  is exactly  $\mathcal{D}$ .*

To prove Proposition 15, note that the distribution of  $(Z, Y)$  is uniform on  $\{0, 1\}^{d+n}$ . Now, fix any  $z \in \mathcal{G}$  and let  $w \in \{0, 1\}^t$  be any element in the image of  $W(\cdot)$ . Since the conditional distribution  $Y | (Z = z)$  is uniform over  $\{0, 1\}^n$ , further conditioning on  $W(Y) = w$  yields that  $Y | (Z = z, W = w)$  is uniform over a translation of the kernel of  $W(\cdot)$ . By the assumption  $z \in \mathcal{G}$  and recalling  $M = \text{Ext}(Z, Y)$ , we therefore know that the extractor output is exactly uniform over  $\{0, 1\}^m$ . That is,  $M | (Z = z, W = w)$  is exactly uniform over  $\{0, 1\}^m$  and hence in this case  $M$  and  $W$  are independent. On the other hand, the distribution of  $(Z, W)$  is exactly  $U_d \times \mathcal{D}$ , since the map  $W(\cdot)$  is linear. In particular, for any  $z \in \{0, 1\}^d$ , the conditional distribution  $W | (Z = z)$  is exactly  $\mathcal{D}$ . This together with the fact that  $M$  and  $W$  are independent yield that the conditional distribution of  $(M, W) | (Z = z)$  is exactly  $U_m \times \mathcal{D}$ . We have therefore proved Proposition 15.

► **Proposition 16.** *For any  $m \in \{0, 1\}^m$ , the conditional distribution of  $(Z, W) | (M = m)$  is  $(4\varepsilon)$ -close to  $U_d \times \mathcal{D}$ .*

To prove Proposition 16, it suffices to note that the distribution of  $(Z, W) | (M = m)$  is a convex combination of the distributions  $(Z, W) | (M = m, Z = z)$  and then use the result of Proposition 15 along with the fact that  $\Pr[Z \notin \mathcal{G}] \leq 4\varepsilon$ . A detailed derivation follows.

Recall that for any  $z \in \{0, 1\}^d$ , the conditional distribution of  $W | (Z = z)$  is exactly  $\mathcal{D}$  (since  $Y | (Z = z)$  is uniform over  $\{0, 1\}^n$ ). Consider any event  $\mathcal{E} \subseteq \{0, 1\}^{d+t}$  and let  $p := \Pr[(Z, W) \in \mathcal{E}]$ . Since  $Z$  and  $W$  are independent, we have that

$$p = 2^{-d} \sum_{(z, w) \in \mathcal{E}} \mathcal{D}(w),$$

where  $\mathcal{D}(w)$  denotes the probability assigned to the outcome  $w$  by  $\mathcal{D}$ . On the other hand, we shall write down the same probability in the conditional probability space  $M = m$  and show

53:14 Secret Sharing with Binary Shares

that it is different from  $p$  by at most  $4\varepsilon$ , concluding the claim on the statistical distance. We have

$$\begin{aligned} \Pr[(Z, W) \in \mathcal{E} | M = m] &= \sum_{(z,w) \in \mathcal{E}} \Pr[Z = z, W = w | M = m] \\ &= \sum_{(z,w) \in \mathcal{E}, z \in \mathcal{G}} \Pr[Z = z, W = w | M = m] \\ &\quad + \sum_{(z,w) \in \mathcal{E}, z \notin \mathcal{G}} \Pr[Z = z, W = w | M = m]. \end{aligned}$$

Note that

$$\eta := \sum_{(z,w) \in \mathcal{E}, z \notin \mathcal{G}} \Pr[Z = z, W = w | M = m] \leq \Pr[Z \notin \mathcal{G} | M = m] \leq 4\varepsilon,$$

since  $M$  and  $Z$  are independent. Therefore,

$$\begin{aligned} \Pr[(Z, W) \in \mathcal{E} | M = m] &= \sum_{(z,w) \in \mathcal{E}, z \in \mathcal{G}} \Pr[Z = z, W = w | M = m] + \eta \\ &= 2^{-d} \sum_{(z,w) \in \mathcal{E}, z \in \mathcal{G}} \Pr[W = w | M = m, Z = z] + \eta \end{aligned} \tag{6}$$

$$= 2^{-d} \sum_{(z,w) \in \mathcal{E}, z \in \mathcal{G}} \mathcal{D}(w) + \eta \tag{7}$$

$$= 2^{-d} \left( \sum_{(z,w) \in \mathcal{E}} \mathcal{D}(w) - \sum_{(z,w) \in \mathcal{E}, z \notin \mathcal{G}} \mathcal{D}(w) \right) + \eta$$

where (6) uses the independence of  $W$  and  $Z$  and (7) follows from Proposition 15. Observe that

$$\eta' := 2^{-d} \sum_{(z,w) \in \mathcal{E}, z \notin \mathcal{G}} \mathcal{D}(w) = 2^{-d} \sum_{z \notin \mathcal{G}} \sum_{\substack{w: \\ (z,w) \in \mathcal{E}}} \mathcal{D}(w) \leq 2^{-d} (2^d - |\mathcal{G}|) \leq 4\varepsilon.$$

Therefore,

$$\Pr[(Z, W) \in \mathcal{E} | M = m] = p + \eta - \eta' = p \pm 4\varepsilon = \Pr[(Z, W) \in \mathcal{E}] \pm 4\varepsilon,$$

since  $0 \leq \eta \leq 4\varepsilon$  and  $0 \leq \eta' \leq 4\varepsilon$ . We have therefore proved Proposition 16.  $\blacktriangleleft$

With Lemma 13 at hand, we are now at a good position to prove Theorem 12.

**Proof of Theorem 12.** The reconstruction from  $r$  shares follows trivially from the definition of stochastic erasure correcting code. We now prove the privacy.

The sharing algorithm of the SSS (before applying the stochastic affine code) takes a secret, which is a particular extractor output  $\mathbf{s} \in \{0, 1\}^\ell$ , and uniformly samples a seed  $\mathbf{z} \in \{0, 1\}^d$  of  $\text{Ext}$  before uniformly finds an  $\mathbf{x} \in \{0, 1\}^n$  such that  $\text{Ext}(\mathbf{z}, \mathbf{x}) = \mathbf{s}$ . This process of obtaining  $(\mathbf{z}, \mathbf{x})$  is the same as sampling  $(U_d, U_n) \stackrel{\$}{\leftarrow} \{0, 1\}^{d+n}$  and then restrict to  $\text{Ext}(U_d, U_n) = \mathbf{s}$ . We define the random variable tuple

$$(Z, X) := (U_d, U_n) | (\text{Ext}(U_d, U_n) = \mathbf{s}) \tag{8}$$

and refer to it as the pre-image of  $\mathbf{s}$ .

Let  $\Pi_A : \{0, 1\}^N \rightarrow \{0, 1\}^t$  be the projection function that maps a share vector to the  $t$  shares with index set  $A \subset [N]$  chosen by the non-adaptive adversary. Observe that the combination  $(\Pi_A \circ \text{SA-ECCenc}) : \{0, 1\}^{d+n} \rightarrow \{0, 1\}^t$  (for any fixed randomness  $r$  of SA-ECCenc) is an affine function. So the view of the adversary is simply the output of the affine function  $f_A = (\Pi_A \circ \text{SA-ECCenc})$  applied to the random variable tuple  $(Z, X)$  defined in (8).

We can now formulate the privacy of the SSS in this context. We want to prove that the statistical distance of the views of the adversary for a pair of secrets  $s$  and  $s'$  can be made arbitrarily small. The views of the adversary are the outputs of the affine function  $f_A$  with inputs  $(Z, X)$  and  $(Z', X')$  for the secret  $s$  and  $s'$ , respectively. According to Lemma 13, we then have that the privacy error is  $8 \times \frac{\varepsilon}{8} = \varepsilon$ .  $\blacktriangleleft$

We now analyze the coding rate of the  $(\varepsilon, \delta)$ -SSS with relative threshold pair  $(\frac{t}{N}, \frac{r}{N})$  constructed in Theorem 12 when instantiated with the SA-ECC from Lemma 8 and the Ext from Lemma 4. The secret length is  $\ell = n - t - O(d)$ , where the seed length is  $d = O(\log^3(2n/\varepsilon))$ . The SA-ECC encodes  $d + n$  bits to  $N$  bits and with coding rate  $R_{ECC} = \rho - \xi$  for a small  $\xi$  determined by  $\delta$  (satisfying the relation  $\delta = \exp(-\Omega(\xi^2 N / \log^2 N))$  according to Lemma 8). We then have  $n = N(\rho - \xi) - d$ , resulting in the coding rate

$$R = \frac{\ell}{N} = \frac{n - t - O(d)}{N} = \frac{N(\rho - \xi) - t - O(d)}{N} = \rho - \tau - \left(\xi + \frac{O(d)}{N}\right) = \rho - \tau - o(1).$$

► **Corollary 17.** *For any  $0 \leq \tau < \rho \leq 1$ , there is an explicit construction of non-adaptive  $(\varepsilon, \delta)$ -SSS with relative threshold pair  $(\tau, \rho)$  achieving coding rate  $\rho - \tau - o(1)$ , where  $\varepsilon$  and  $\delta$  are both negligible.*

The binary SSS obtained in Corollary 17 is asymptotically optimal as it achieves the upper bound in Lemma 11.

## 5 Secret sharing against adaptive adversaries

In this section, we will describe our construction which achieves privacy against adaptive adversaries, using seedless affine extractors. We start with the specific extraction property needed from our affine extractors.

► **Definition 18.** An affine extractor  $\text{AExt} : \{0, 1\}^n \rightarrow \{0, 1\}^m$  is called  $(k, \varepsilon)$ -almost perfect if for any affine  $(n, k)$ -source  $X$ ,

$$\left| \Pr[\text{AExt}(X) = y] - \frac{1}{2^m} \right| \leq 2^{-m} \cdot \varepsilon, \text{ for any } y \in \{0, 1\}^m.$$

Almost perfect property can be trivially achieved by requiring an exponentially (in  $m$ ) small error in statistical distance, using the relation between  $\ell_\infty$ -norm and  $\ell_1$ -norm.

► **Theorem 19.** *Let  $\text{AExt} : \{0, 1\}^n \rightarrow \{0, 1\}^\ell$  be an invertible  $(n - t, \frac{\varepsilon}{2})$ -almost perfect affine extractor and  $\text{AExt}^{-1} : \{0, 1\}^\ell \times \mathcal{R}_1 \rightarrow \{0, 1\}^n$  be its  $v$ -inverter that maps an  $s \in \{0, 1\}^\ell$  to one of its pre-images chosen uniformly at random. Let  $(\text{SA-ECCenc}, \text{SA-ECCdec})$  be a stochastic affine-erasure correcting code with encoder  $\text{SA-ECCenc} : \{0, 1\}^n \times \mathcal{R}_2 \rightarrow \{0, 1\}^N$  that tolerates  $N - r$  erasures and decodes with success probability at least  $1 - \delta$ . Then the  $(\text{Share}, \text{Recst})$  defined as follows is an adaptive  $(\varepsilon + v, \delta)$ -SSS with threshold pair  $(t, r)$ .*

$$\begin{cases} \text{Share}(s) &= \text{SA-ECCenc}(\text{AExt}^{-1}(s)); \\ \text{Recst}(\tilde{v}) &= \text{AExt}(\text{SA-ECCdec}(\tilde{v})), \end{cases}$$

where  $\tilde{v}$  denotes an incomplete version of a share vector  $v \in \{0, 1\}^N$  with some of its components replaced by erasure symbols.

**Proof.** The  $(r, \delta)$ -reconstructability follows directly from the erasure correcting capability of the SA-ECC. For any  $\tilde{\mathbf{v}}$  with at most  $N - r$  erasure symbols and the rest of its components consistent with a valid codeword  $\mathbf{v} \in \{0, 1\}^N$ , the SA-ECC decoder identifies the unique codeword  $\mathbf{v}$  with probability  $1 - \delta$  over the encoder randomness. The corresponding SA-ECC message of  $\mathbf{v}$  is then inputted to AExt and the original secret  $\mathbf{s}$  is reconstructed with the same probability.

We next prove the  $(t, \varepsilon)$ -privacy. Without loss of generality, we first assume the inverter of the affine extractor is perfect, namely,  $v = 0$ . When  $v$  is negligible but not equal to zero, the overall privacy error will increase slightly, but still remain negligible. For any  $r \in \mathcal{R}_2$ , the affine encoder of SA-ECC is characterised by a matrix  $G_r \in \{0, 1\}^{n \times N}$  and an offset  $\Delta_r$ . For  $n$  unknowns  $\mathbf{x} = (x_1, \dots, x_n)$ , we have

$$\text{SA-ECCenc}(\mathbf{x}) = \mathbf{x}G_r + \Delta_r = (\mathbf{x}G_1, \dots, \mathbf{x}G_N) + \Delta_r,$$

where  $G_i = (g_{1,i}, \dots, g_{n,i})^T$  (here the subscript “ $r$ ” is omitted to avoid double subscripts) denotes the  $i$ th column of  $G_r$ ,  $i = 1, \dots, N$ . This means that knowing a component  $c_i$  of the SA-ECC codeword is equivalent to obtaining a linear equation  $c_i \oplus \Delta_i = \mathbf{x}G_i = g_{1,i}x_1 + \dots + g_{n,i}x_n$  about the  $n$  unknowns  $x_1, \dots, x_n$ , where  $\Delta_i$  (again, the subscript “ $r$ ” is omitted) denotes the  $i$ th component of  $\Delta_r$ . Now, we investigate the distribution of  $\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}))}$  for any secret  $\mathbf{s} \in \{0, 1\}^\ell$  by finding the probability  $\Pr[\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}))} = \mathbf{w}]$  for arbitrary  $\mathbf{w}$ . We then have

$$\begin{aligned} \Pr[\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}))} = \mathbf{w}] &= \Pr[\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{SA-ECCenc}(\mathbf{X}))} = \mathbf{w} | \text{AExt}(\mathbf{X}) = \mathbf{s}] \\ &= \frac{\Pr[\text{AExt}(\mathbf{X}) = \mathbf{s} | \text{View}_{\mathcal{A}}^{\text{SA-ECCenc}(\mathbf{X})} = \mathbf{w}] \cdot \Pr[\text{View}_{\mathcal{A}}^{\text{SA-ECCenc}(\mathbf{X})} = \mathbf{w}]}{\Pr[\text{AExt}(\mathbf{X}) = \mathbf{s}]} \\ &\stackrel{(i)}{=} \frac{(1 \pm \frac{\varepsilon}{2})2^{-\ell} \cdot \Pr[\text{View}_{\mathcal{A}}^{\text{SA-ECCenc}(\mathbf{X})} = \mathbf{w}]}{\Pr[\text{AExt}(\mathbf{X}) = \mathbf{s}]} \\ &\stackrel{(ii)}{=} \frac{(1 \pm \frac{\varepsilon}{2})2^{-\ell} \cdot \frac{2^{n - \text{rank}(\mathcal{A})}}{2^n}}{2^{-\ell}} \\ &= (1 \pm \frac{\varepsilon}{2}) \cdot 2^{-\text{rank}(\mathcal{A})}, \end{aligned}$$

where notations  $\mathbf{X}$ ,  $\pm$ ,  $\text{rank}(\mathcal{A})$  and  $(i)$ ,  $(ii)$  are explained as follows. In above, we first use the fact that  $\Pr[\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}))} = \mathbf{w}]$  can be seen as the probability of uniformly selecting  $\mathbf{X}$  from  $\{0, 1\}^n$ , with the condition that  $\text{AExt}(\mathbf{X}) = \mathbf{s}$ . This is true because the sets  $\text{AExt}^{-1}(\mathbf{s})$  for all  $\mathbf{s}$ , partition  $\{0, 1\}^n$  and the rest follows from Definition 6. The shorthand “ $y = 1 \pm \frac{\varepsilon}{2}$ ” denotes “ $1 - \frac{\varepsilon}{2} \leq y \leq 1 + \frac{\varepsilon}{2}$ ”. The shorthand “ $\text{rank}(\mathcal{A})$ ” denotes the rank of the up to  $t$  columns of  $G$  corresponding to the index set  $\mathcal{A}$  adaptively chosen by  $\mathcal{A}$ . The equality  $(i)$  follows from the fact that AExt is an  $(n - t, 2^{-(\ell+1)}\varepsilon)$ -affine extractor and the uniform  $\mathbf{X}$  conditioned on at most  $t$  linear equations is an affine source with at least  $n - t$  bits entropy. The equality  $(ii)$  holds if and only if  $\mathbf{w}$  is in the set  $\{\text{SA-ECCenc}(\mathbf{x})_{\mathcal{A}} : \mathbf{x} \in \{0, 1\}^n\}$ . Indeed, consider  $\mathbf{X}$  as unknowns for equations, the number of solutions to the linear system  $\text{SA-ECCenc}(\mathbf{X})_{\mathcal{A}} = \mathbf{w}$  is either 0 or equal to  $2^{n - \text{rank}(\mathcal{A})}$ .

The distribution of  $\text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}))}$  for any secret  $\mathbf{s}$  is determined by the quantity  $\text{rank}(\mathcal{A})$ , which is independent of the secret  $\mathbf{s}$ . Let  $\mathbf{W}$  be the uniform distribution over the set  $\{\text{SA-ECCenc}(\mathbf{x})_{\mathcal{A}} : \mathbf{x} \in \{0, 1\}^n\}$ . Then by the triangular inequality, we have

$$\begin{aligned} &\text{SD} \left( \text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}_0))}; \text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}_1))} \right) \\ &\leq \text{SD} \left( \text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}_0))}; \mathbf{W} \right) + \text{SD} \left( \mathbf{W}; \text{View}_{\mathcal{A}}^{\mathcal{O}_t(\text{Share}(\mathbf{s}_1))} \right) \\ &\leq \frac{\varepsilon}{2} + \frac{\varepsilon}{2} = \varepsilon. \end{aligned}$$

When the inverter of the affine extractor is not perfect, the privacy error is upper bounded by  $\varepsilon + v$ . This concludes the privacy proof. ◀

There are explicit constructions of binary affine extractors that, given a constant fraction of entropy, outputs a constant fraction of random bits with exponentially small error (see Lemma 5). There are known methods for constructing an invertible affine extractor  $\text{AExt}'$  from any affine extractor  $\text{AExt}$  such that the constant fraction output size and exponentially small error properties are preserved. A simple method is to let  $\text{AExt}'(U_n||M) := \text{AExt}(U_n) \oplus M$  (see Appendix A for a discussion). This is summarized in the lemma below.

► **Lemma 20.** *For any  $\delta \in (0, 1]$ , there is an explicit seedless  $(\delta n, \varepsilon)$ -almost perfect affine extractor  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^m$  where  $m = \Omega(n)$  and  $\varepsilon = \exp(-\Omega(n))$ . Moreover, there is an efficiently computable  $\varepsilon$ -inverter for the extractor.*

**Proof.** Let  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^m$  be Bourgain’s affine extractor (Lemma 5) for entropy rate  $\mu$ , output length  $m = \Omega(n)$ , and achieving exponentially small error  $\varepsilon = \exp(-\Omega(n))$ . Using the one-time pad trick (Appendix A), we construct an invertible variant achieving output length  $m' = \Omega(m) = \Omega(n)$  and exponentially small error. Finally, we simply truncate the output length of the resulting extractor to  $m'' = \Omega(m') = \Omega(n)$  bits so that the closeness to uniformity measured by  $\ell_\infty$  norm required for almost-perfect extraction is satisfied. The truncated extractor is still invertible since the inverter can simply pad the given input with random bits and invoke the original inverter function. ◀

It now suffices to instantiate Theorem 19 with the explicit construction of SA-ECC and the invertible affine extractor  $\text{AExt}$  of Lemma 20. Let  $R_{ECC}$  denote the rate of the SA-ECC. Then we have  $R_{ECC} = \frac{n}{N}$ , where  $n$  is the input length of the affine extractor  $\text{AExt}$  and  $N$  is the number of players. The intuition of the construction in Theorem 19 is that if a uniform secret is shared and conditioning on the revealed shares the secret still has a uniform distribution (being the output of a randomness extractor), then no information is leaked. In fact, the proof of Theorem 19 above is this intuition made exact, with special care on handling the imperfectness of the affine extractor. So as long as the “source” of the affine extractor  $\text{AExt}$  has enough entropy, privacy is guaranteed. Here the “source” is the distribution  $U_n$  conditioned on the adversary’s view, which is the output of a  $t$ -bit affine function. The “source” then is affine and has at least  $n - \tau N = n(1 - \frac{\tau}{R_{ECC}})$  bits of entropy. Now as long as  $\tau < R_{ECC}$ , using the  $\text{AExt}$  from Lemma 5 (more precisely, an invertible affine extractor  $\text{AExt}' : \{0, 1\}^{n'} \rightarrow \{0, 1\}^\ell$  constructed from  $\text{AExt}$ ) with  $\mu = 1 - \frac{\tau}{R_{ECC}}$ , a constant fraction of random bits can be extracted with exponentially small error. This says that privacy is guaranteed for  $\tau \in [0, R_{ECC})$ . The stochastic affine ECC in Lemma 8 asymptotically achieves the rate  $1 - (1 - \rho) = \rho$ . We then have the following corollary.

► **Corollary 21.** *For any  $0 \leq \tau < \rho \leq 1$ , there is an explicit constant coding rate adaptive  $(\varepsilon, \delta)$ -SSS with relative threshold pair  $(\tau, \rho)$ , where  $\varepsilon$  and  $\delta$  are both negligible.*

The construction above achieves a constant coding rate for any  $(\tau, \rho)$  pair satisfying  $0 \leq \tau < \rho \leq 1$ . However, since the binary affine extractor in Lemma 5 does not extract all the entropy from the source and moreover the step that transforms an affine extractor into an invertible affine extractor incurs non-negligible overhead, the coding rate of the above construction does not approach  $\rho - \tau$ . We leave explicit constructions of binary SSS against adaptive adversary with better coding rate as an interesting technical open question.

## 6 Conclusion

We studied the problem of sharing *arbitrary long secrets* using constant length shares and required a nearly-threshold access structure. By nearly-threshold we mean a ramp scheme with arbitrarily small gap to number of players ratio. We show that by replacing perfect privacy and reconstructibility with slightly relaxed notions and inline with similar strong cryptographic notions, one can explicitly construct such nearly-threshold schemes. We gave two constructions with security against non-adaptive and adaptive adversaries, respectively, and proved optimality of the former. Our work also make a new connection between secret sharing and wiretap coding.

We presented our model and constructions for the extremal case of binary shares. However, we point out that the model and our constructions can be extended to shares over any desired alphabet size  $q$ . Using straightforward observations (such as assigning multiple shares to each player), this task reduces to extending the constructions over any prime  $q$ . In this case, the building blocks that we use; namely, the stochastic error-correcting code, seeded and seedless affine extractors need to be extended to the  $q$ -ary alphabet. The constructions [24, 19, 15] that we use, however, can be extended to general alphabets with straightforward modifications. The only exception is Bourgain's seedless affine extractor [7]. The extension of [7] to arbitrary alphabets is not straightforward and has been accomplished in a work by Yehudayoff [26].

Our constructions are not linear: even the explicit non-adaptive construction that uses an affine function for every fixing of the encoder's randomness does not result in a linear secret sharing. Linearity is an essential property in applications such as multiparty computation and so explicit constructions of *linear* secret sharing schemes in our model will be an important achievement. Yet another important direction for future work is deriving bounds and constructing optimal codes for finite length ( $N$ ) case. Such result will also be of high interest for wiretap coding.

### A One-Time-Pad trick of inverting extractors

The following trick to transform an efficient function into one that is also efficiently invertible has appeared in different form before (see for example [21]). We prove it here for the case of affine extractors, for completeness.

► **Lemma 22.** *Let  $\text{AExt}: \{0, 1\}^n \rightarrow \{0, 1\}^m$  be an affine  $(n, k)$ -extractor with error  $\varepsilon$ . Then  $\text{AExt}' : \{0, 1\}^{n+m} \rightarrow \{0, 1\}^m$  defined as follows is a  $\varepsilon$ -invertible affine  $(n+m, k+m)$ -extractor with error  $\varepsilon$ .*

$$\text{AExt}'(z) = \text{AExt}'(x||y) = \text{AExt}(x) + y,$$

where the input  $z \in \{0, 1\}^{n+m}$  is separated into two parts:  $x \in \{0, 1\}^n$  and  $y \in \{0, 1\}^m$ .

**Proof.** Let  $Z$  be a random variable with flat distribution supported on an affine subspace of  $\{0, 1\}^{n+m}$  of dimension at least  $k+m$ . Separate  $Z$  into two parts  $Z = (X||Y)$ , where  $X \in \{0, 1\}^n$  and  $Y \in \{0, 1\}^m$ . Then conditioned on any  $Y = y$ ,  $X$  has a distribution supported on an affine subspace of  $\{0, 1\}^n$  of dimension at least  $k$ . This asserts that conditioned on any  $Y = y$ ,

$$\text{SD}(\text{AExt}(X) + y; U_{\{0,1\}^m}) \leq \varepsilon.$$

Averaging over the distribution of  $Y$  concludes the extractor proof.

We next show an efficient inverter  $\text{AExt}'^{-1}$  for  $\text{AExt}'$ . For any  $s \in \{0, 1\}^m$ , define

$$\text{AExt}'^{-1}(s) = (U_n || \text{AExt}(U_n) + s).$$

The randomised function  $\text{AExt}'^{-1}$  is efficient and  $\text{AExt}'^{-1}(U_m) \stackrel{\varepsilon}{\sim} U_{n+m}$ . ◀

## Abstract

We study the multiparty communication complexity of high dimensional permutations in the Number On the Forehead (NOF) model. This model is due to Chandra, Furst and Lipton (CFL) who also gave a nontrivial protocol for the Exactly- $n$  problem where three players receive integer inputs and need to decide if their inputs sum to a given integer  $n$ . There is a considerable body of literature dealing with the same problem, where  $(\mathbb{N}, +)$  is replaced by some other abelian group. Our work can be viewed as a far-reaching extension of this line of research. We show that the known lower bounds for that group-theoretic problem apply to all high dimensional permutations. We introduce new proof techniques that reveal new and unexpected connections between NOF communication complexity of permutations and a variety of well-known problems in combinatorics. We also give a direct *algorithmic* protocol for Exactly- $n$ . In contrast, all previous constructions relied on large sets of integers without a 3-term arithmetic progression.

## 1 Introduction

The multiplayer Number On the Forehead (NOF) model of communication complexity was first introduced by Chandra, Furst and Lipton [13]. Here  $k$  players need to evaluate a given function  $f : [n]^k \rightarrow \{0, 1\}$ , where we think of  $f$  as having  $k$  arguments  $x_1, \dots, x_k$ , each comprised of  $\log n$  bits. The  $i$ -th input vector  $x_i$  is placed metaphorically on player  $i$ 's forehead, so that every player sees the whole input but one argument. Players communicate by writing bits on a shared blackboard in order to compute  $f$ .

The NOF communication model has turned out to be a fascinating, though exceedingly difficult object of study. Indeed, good lower bounds in the NOF model would resolve several longstanding open problems in complexity theory, such as lower bounds on the size of  $ACC^0$

---

<sup>1</sup> Supported in part by ERC grant 339096, High-dimensional combinatorics.

circuits for a natural function in  $P$  [40, 23]. They also imply lower bounds for branching programs, time-space tradeoffs for Turing machines [26], and proof complexity lower bounds [8]. The implications of good NOF lower bounds go in other, less expected directions as well. E.g., knowing the communication complexity of specific natural functions, even for  $k = 3$ , would have profound implications in graph theory and combinatorics. Finally, the search for nontrivial protocols in this area is a wonderful challenge for algorithms designers. There is a short list of such beautiful examples [13, 22] which begs to be extended.

Furthermore, our understanding of NOF communication complexity, even for  $k = 3$  players, lags well behind our understanding of the standard model ( $k = 2$  players). This gap is usually attributed to the dearth of proof techniques in the NOF setting. In the 2-party setting, many measures of complexity allow us to prove both upper and lower bounds. Such measures include matrix rank, various matrix norms, nonnegative rank, discrepancy, corruption bounds and information complexity. Most of these measures are computationally simple and admit dual characterizations which are very helpful in proving both upper and lower bounds. On the other hand, in the NOF setting for  $k \geq 3$ , the key combinatorial objects are cylinder intersections (rather than combinatorial rectangles) and tensor norms. These are much more complex, and thus far have resisted a workable characterization.

A case in point is the separation of randomized from deterministic communication complexity. The 2-party *equality function* has a randomized protocol of bounded cost, whereas a simple rank argument shows that every deterministic protocol must incur linear cost. This provides an optimal separation of deterministic and randomized communication complexity [26]. On the other hand, for  $k \geq 3$ , the best *explicit* separation between nondeterministic and randomized NOF complexity is logarithmic, even though counting arguments yield linear separations [7]. The Exactly- $n$  function is defined as follows: Input  $x_1, \dots, x_k \in [n]$  is accepted iff  $\sum_i x_i = n$ . In their seminal paper, Chandra, Furst and Lipton [13] conjectured that Exactly- $n$  achieves a strong separation, and also connected the communication complexity of this function to well-known problems in additive combinatorics. But thus far, despite considerable research effort, the lower bounds for Exactly- $n$  are much weaker even than the best (logarithmic) explicit separations.

The main goal of our work is to further investigate the connections between NOF complexity of functions and questions in additive combinatorics, with the hope of stimulating further research to make progress in both directions. A large and rapidly growing body of work establishes interesting relationships between problems in additive combinatorics and complexity theory. For example, the study of expander graphs and extractors, pseudorandomness, and property testing is closely related, some time even synonymous with similar notions in additive combinatorics. Moreover, techniques from complexity theory have been useful in additive combinatorics and vice versa. Some recent examples include the proof of the cap-set conjecture [14, 17] and Dvir's resolution [15] of the finite field Kakeya problem, as well as the beautiful interplay between dense model theorems in additive combinatorics and the notions of boosting and hardcore sets from complexity theory [11, 38, 29].

Here we consider a broad class of functions called high dimensional permutations. We uncover strong connections between the NOF communication complexity of these functions and several fundamental problems in additive combinatorics. Originally defined in [27], a  $(k - 1)$ -dimensional permutation is a function  $f : [n]^k \rightarrow \{0, 1\}$  such that for every index  $k \geq i \geq 1$  and for every choice of  $x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_k \in [n]$ , there is exactly one value of  $x_i \in [n]$  for which  $f(x_1, \dots, x_{i-1}, x_i, x_{i+1}, \dots, x_k) = 1$ . This class of functions generalizes many well-studied functions in communication complexity. It is also closely related to many other functions such as the Exactly- $n$  function mentioned above.

We will show that many well-studied problems in NOF complexity are not just related, but are in fact identical or nearly identical to central problems in additive combinatorics. We feel that this mutual relation deserves much more attention, and that progress in this area is likely to greatly advance both domains. Specifically we believe that the study of the communication complexity of high dimensional permutations and related graph functions (defined in [7]) is a worthwhile undertaking that will help us develop new lower bounds proof techniques for the notoriously difficult NOF model. Using these connections, we make modest progress on several upper and lower bounds in NOF communication complexity.

## 1.1 Our Contributions

As mentioned above, our main goal and contribution is to unveil the strong relationships between the NOF complexity of high dimensional permutation problems and central problems in additive combinatorics and Ramsey theory. Already the founding paper of Chandra, Furst and Lipton [13] makes a connection between the NOF complexity of Exactly- $n$  and the areas of Ramsey theory and additive combinatorics. A more general framework was introduced in [10]: Given an abelian group  $G$  and  $T \in G$ , the function  $f_{k,T}^G$  evaluates to 1 on input  $x_1, \dots, x_k \in G$  iff  $\sum_i x_i = T$  (this expression is well-defined since  $G$  is abelian). The functions  $f_{k,T}^G$  are high dimensional permutations. (Note that this holds as well for non-abelian  $G$ , though we need to specify the order at which  $\prod_i x_i$  is evaluated). Another strong connection is that the Hales-Jewett theorem, a cornerstone of Ramsey theory, can be interpreted in terms of communication complexity [35].

We establish a new and close connection between the NOF communication complexity of high dimensional permutations and dense Ruzsa-Szemerédi graphs. These graphs appear in various contexts in Combinatorics, Computer Science and Information Theory, thus highlighting new connections between communication complexity and these various problems. For example, an efficient deterministic communication protocol for any permutation yields an efficient wiring scheme for shared directional multi-channels. For more on this, see e.g., [12] and [4]. In the classical,  $k = 2$  case, monochromatic submatrices play a key role in the theory. For higher  $k$  this is replaced by the much more poorly understood monochromatic *cylinder intersection*. Naturally, much of our work here revolves around these complicated objects. However, in certain simple cases we are able to get a grip on the largest size of a cylinder intersection that contains only 1-inputs of  $f$ . As we show, in this case knowledge of this quantity essentially determines the NOF communication complexity of  $f$  (see more on this in the next section). The case in question is  $k = 3$  and the group  $G = \mathbb{Z}_2^n$ . As we show, the size of the largest cylinder intersection containing only 1-inputs of  $f$  is the largest cardinality of a subset  $W \subseteq \mathbb{Z}_4^n$  such that for every three distinct members  $\mathbf{x}, \mathbf{y}, \mathbf{z} \in W$  there is an index  $1 \leq i \leq n$  for which  $(x_i, y_i, z_i) \notin X$ , where

$$X = \{(0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3), (0, 1, 2), (1, 0, 3), (2, 3, 0), (3, 2, 1)\}.$$

This parameter may seem artificial, but in fact, this framework includes several important problems in combinatorics, for different choices of  $X$ . Thus, if we take  $X := \{(0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3), (0, 1, 2)\}$ , then this becomes precisely the density Hales-Jewett problem, solved in [19]. Also, if  $X$  is comprised of all triplets  $(a, b, c) \in \mathbb{Z}_4^3$  with  $a + c = 2b$ , we arrive at the cap-set problem for  $\mathbb{Z}_4^n$  which was recently settled in breakthrough papers by Croot, Lev, and Pach, and by Ellenberg and Gijswijt [14, 17]. In the next subsection we list our new results that stem from these connections.

### 1.1.1 Upper Bounds

We give a new algorithm for Exactly- $n$  as well as several other instances of  $f_{k,T}^G$ . All previous upper bounds for these functions crucially depend on Behrend's famous construction [9] of a large set of integers with no 3-term arithmetic progressions. This yields a large monochromatic cylinder intersection, and a simple probabilistic translation lemma then shows how to cover the whole space by monochromatic cylinder intersections, thus providing an efficient protocol. To show that this indeed yields a large monochromatic cylinder intersection, we appeal to the notion of *corner-free* sets [2, 36] which here, too, plays a key role. We cannot realistically hope to improve the bounds by finding a construction better than Behrend's, in view of the many such failed attempts throughout the past 70 years (but note [16]). However, Behrend's construction is actually more than we need. The solution of  $f_{k,T}^G$  only requires corner-free sets. That is, 3-term AP freeness implies corner-freeness, but we do not expect that the two concepts are equivalent. We take a first step in this direction and give a new algorithm which is not dependent on 3-term AP freeness. We hope that this indicates a viable approach to improved protocols for the Exactly- $n$  function. We also describe a nontrivial protocol for the  $f_{3,T}^G$  problem for  $G = \mathbb{Z}_2^n$ .

### 1.1.2 Lower Bounds

We give a counting argument which shows that almost every  $k$ -dimensional permutation has communication complexity  $\Omega(\frac{\log n}{k})$ . Clearly, up to the  $\frac{1}{k}$  factor, this is as high as this quantity can get. Our proof relies on a recent lower bound of Keevash [25] on the number of high-dimensional permutations. This method resembles the counting argument for graph functions of [7], which does not apply, though, to permutations.

Regarding bounds on explicit functions, we prove a weak upper bound on the size of a 1-monochromatic cylinder intersection for any permutation (in fact our result holds for a wider family of functions that we call linjections). This bound uses a graph theoretic characterization of the communication complexity of permutations, connecting it also to Ruzsa-Szemerédi graphs. Not unexpectedly, our proof mirrors a similar result for Ruzsa-Szemerédi graphs: Solymosi [36] showed that the multidimensional Szemerédi theorem follows from the triangle removal lemma. We adapt Solymosi's proof to our context. The main tools in the proof are thus the graph and the hypergraph removal lemmas.

We note that previous results were limited to the  $f_{k,T}^G$  function for abelian groups with many factors, whereas ours works for general permutations. To emphasize the significance of the last point, consider the NOF complexity of following three classes of functions: (i) Permutations that come from Abelian groups, (ii) Those that come from general groups, (iii) Latin squares. We consider each such function up to an arbitrary renaming of rows and columns. The sizes of these three classes differ very substantially. For a given order  $n$  the size of the relevant class is (i)  $\exp(O(\sqrt{\log n}))$ , (ii) At most  $\exp((\frac{2}{27} + o(1)) \log^3 n)$ , and (iii)  $((1 + o(1)) \frac{n}{e^2})^{n^2}$ .

For  $k = 3$  we can say more: The communication complexity of every 2-dimensional permutation  $[n]^3 \rightarrow \{0, 1\}$  is  $\Omega(\log \log \log n)$ . This extends the lower bound of [10] from the realm of abelian groups to all permutations. The proof of the this lower bound uses only elementary counting arguments, and is closely related to the result of [20] on monochromatic corners on the integer grid.

The above lower bound also implies a result of Meshulam that was derived toward the study of shared directional multi-channels. Meshulam's result appears as Proposition 4.3 in [4], where further background can be found.

## 1.2 Related Work

The NOF model was introduced by Chandra, Furst and Lipton in [13]. One of the functions they consider is Exactly- $n : [n]^3 \rightarrow \{0, 1\}$ . For  $x, y, z \in [n]$ , we let Exactly- $n(x, y, z) = 1$  if and only if  $x + y + z = n$ . Surprisingly, they proved that the communication complexity of this function is only  $O(\sqrt{\log n})$ , but their proof yields no explicit protocol. Although this function is not a permutation, the proofs go through as well for the mod  $n$  permutation [10], and thus far this is the most efficient protocol found for any permutation. The protocol of [13] is based on Behrend's famous construction [9] of a large subset of  $[n]$  with no three-term arithmetic progression. In addition, they prove an inexplicit lower bound of  $\omega_n(1)$  on the complexity of Exactly- $n$ . This is based on Gallai's result [21, p. 38] that every finite coloring of a Euclidean space contains a monochromatic homothet of every finite set in that space.

Beigel, Gasarch and Glenn [10] considered the more general  $f_{k,T}^G$  problem, where  $G$  is an abelian group,  $T$  is an element of  $G$  and  $k \geq 2$  an integer. In this scenario  $k$  players need to decide whether  $x_1 + x_2 + \dots + x_k = T$ . They show that the communication complexity of  $f_{3,T}^G$  is at least  $\Omega(\log \log \log n)$  for every abelian group  $G$  and any  $T \in G$ . For the case  $G = \mathbb{Z}_n$ , this follows as well from [20] and a recent result of Shkerdov [34] also yields a similar lower bound for every abelian group  $G$ . For general  $k \geq 3$  and for an abelian group  $G$  that is the product of  $t$  cyclic groups, it is shown in [10] that the deterministic NOF complexity of  $f_{k,T}^G$  is  $\omega_t(1)$ . The proof is by reduction to a lower bound from [37], that is based on the Hales-Jewett Theorem (see [21]).

Note that  $f_{k,T}^G$  can be defined as well in non-abelian groups  $G$ . Namely,  $f_{k,T}^G(x_1, \dots, x_k) = 1$  iff  $x_1 \cdot x_2 \cdot \dots \cdot x_k = T$ , where now the order of multiplication matters. Note also that the function  $f_{k,T}^G$  is a permutation for every group  $G$ , every  $T \in G$  and  $k \geq 2$ .

As mentioned above, [7] studies graph functions and give a nonexplicit strong separation between randomized and deterministic NOF complexity. To be precise, this counting argument shows that most graph functions  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  with  $N \cong \sqrt{\frac{n}{k}}$  have deterministic communication complexity  $\Omega(\log \frac{n}{k})$ . Still, even for  $k = 3$  it remains open to find *explicit* graph functions with high deterministic communication complexity. Currently, the best lower bound on the deterministic communication complexity of a graph function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  for  $k \geq 3$  is  $\Omega(\log \log n)$  proved in [7] (using also results from [5]). We note that the discrepancy method, used to establish NOF lower bounds (e.g., [6]), cannot be utilized here since it also applies to randomized communication complexity.

Lastly, we comment on the Hales-Jewett theorem, a pillar of Ramsey theory. It was previously applied in the study of the combinatorial problems mentioned above. It turns out that this theorem has an equivalent formulation in the language of communication complexity [35], and is tightly coupled with the NOF multiparty communication complexity of high dimensional permutations.

## 2 Basics

### 2.1 NOF Communication Complexity

In the Number On the Forehead (NOF) multiparty communication complexity game,  $k$  players collaborate to compute a function  $f : X_1 \times \dots \times X_k \rightarrow \{0, 1\}$ . Usually,  $X_i = [n]$  for all  $i \in [k]$ , but we also consider occasionally a variation where the last player is exceptional and  $X_k = [N]$  for some integer  $N$  that is not necessarily equal to  $n$ .

For  $(x_1, \dots, x_k) \in X_1 \times \dots \times X_k$ , and for each  $i \in [k]$ , player  $i$  receives  $x^{-i} \in X_1 \times \dots \times X_{i-1} \times X_{i+1} \times \dots \times X_k$ ; that is, all but  $x_i$ . The players exchange bits according to

an agreed-upon protocol, by writing them on a publicly visible blackboard. The protocol specifies, for every possible blackboard contents, whether or not the communication is ongoing. It shows the final output when the communication is over, and shows the next player to speak if the communication is still ongoing. The protocol also specifies what each player writes as a function of the blackboard contents and of the inputs seen by that player. The *cost* of the protocol is the maximum number of bits written on the blackboard.

The *deterministic communication complexity* of  $f$ ,  $D_k(f)$ , is the minimum cost of a deterministic protocol for  $f$  that always outputs the correct answer. A randomized protocol of cost  $c$  is just a distribution over deterministic protocols each of cost at most  $c$ . For  $0 \leq \epsilon < 1/2$ , the *randomized communication complexity* of  $f$ ,  $R_{k,\epsilon}(f)$ , is the minimum cost over randomized protocols such that for every input, err with probability at most  $\epsilon$  (over the distribution of deterministic protocols).

In the  $k = 2$  players case, the key combinatorial objects of study are combinatorial rectangles: Every cost- $c$  communication protocol for  $f : X_1 \times X_2 \rightarrow \{0, 1\}$  partitions  $X_1 \times X_2$  into  $2^c$  monochromatic combinatorial rectangles. For  $k$ -party NOF communication, a cost- $c$  protocol induces a partition of  $X_1 \times \dots \times X_k$  into  $2^c$  *monochromatic cylinder intersections*:

► **Definition 1.** A *cylinder in dimension  $i$*  is a subset  $S \subseteq \prod X_i$  such that if  $(x_1, \dots, x_k) \in S$ , then  $(x_1, \dots, x_{i-1}, x'_i, x_{i+1}, \dots, x_k) \in S$  for all  $x'_i$ . A *cylinder intersection* is a set of the form  $\bigcap_{i=1}^k T_i$ , where  $T_i$  is a cylinder in dimension  $i$ .

## 2.2 Graph Functions, Permutations and Linjections

► **Definition 2.** The line  $L \subseteq [n]^k$ , defined by a pair  $(a, i)$ , where  $a \in [n]^{k-1}$ ,  $i \in [k]$ , is the set of vectors  $v \in [n]^k$  such that  $v^{-i} = a$  and  $v_i$  is an arbitrary element in  $[n]$ .

► **Definition 3.** A function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  is a *graph function* if for every  $(x_1, \dots, x_{k-1})$  there is a unique  $b \in [N]$  such that  $f(x_1, \dots, x_{k-1}, b) = 1$ . In other words, every line in the  $k^{\text{th}}$  dimension,  $L = (a, k)$ , intersects  $f^{-1}(1)$  in exactly one point.

Associated with every graph function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  is a map  $A(f) : [n]^{k-1} \rightarrow [N]$ , where  $A(f)(x_1, \dots, x_{k-1}) = y$  if and only if  $f(x_1, \dots, x_{k-1}, y) = 1$ . We consider the two as one and the same object and freely switch back and forth between the two descriptions.

► **Definition 4.** Let  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  be a graph function. We denote by  $\alpha_k(f)$  the largest size of a cylinder intersection that is contained in  $f^{-1}(1)$ . In other words, the largest cardinality of 1-monochromatic cylinder intersection with respect to  $f$ . Also, let  $\chi_k(f)$  be the least number of 1-monochromatic cylinder intersections whose union is  $f^{-1}(1)$ . We omit the subscript  $k$  when it is clear from context.

Given a graph function  $f$ , the measure  $\chi(f)$  corresponds to the nondeterministic NOF communication complexity of  $f$ , since it is a covering of the 1's of  $f$  by cylinder intersections [26]. In general, the nondeterministic NOF communication complexity of a Boolean function can be much smaller than the deterministic complexity – in fact, for the set disjointness function, nondeterministic complexity is logarithmic in the deterministic complexity (for constant  $k$ ). However, graph functions are special; the following lemma shows that for graph functions, the two notions basically coincide. The proof is an adaptation of a proof from [13]; see also [10, 7] for similar arguments.

► **Theorem 5.** For every graph function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$ ,  $\log \chi_k(f) \leq D_k(f) \leq \lceil \log \chi_k(f) \rceil + k - 1$ .

A communication protocol in which players write only one message on the board, of arbitrary length is called a *one-way* protocol. This applies to the protocol in the proof of Theorem 5. The restriction to a single message per player may make one-way protocols much weaker than standard protocols [30, 5]. However for graph functions, one-way protocols and regular protocols are equally powerful:

► **Corollary 6.** *For every graph function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$ ,  $D_k(f) \leq D_k^1(f) \leq D_k(f) + k$  where  $D_k^1(f)$  is the one-way communication complexity of  $f$ .*

Implicit in the proofs of the above statements is the fact that for graph functions, monochromatic cylinder intersections can be nicely characterized by forbidden (dual) objects called *stars*, which we define next. We will see in the next section that stars are very closely connected to corners (and higher dimensional generalizations) in Ramsey theory.

► **Definition 7.** A *star*  $Star(\mathbf{x}, \mathbf{x}')$  is a subset of  $[n]^{k-1} \times [N]$  of the form

$$\{(x'_1, x_2, \dots, x_k), (x_1, x'_2, \dots, x_k), \dots, (x_1, x_2, \dots, x'_k)\},$$

where  $x_i \neq x'_i$  for each  $i$ . We refer to  $\mathbf{x} = (x_1, x_2, \dots, x_k)$  as the star's *center*, and note that the center does *not* belong to the star.

► **Lemma 8.** *Let  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  be a graph function, and let  $S \subseteq f^{-1}(1)$ . Then  $S$  is a (1-monochromatic) cylinder intersection with respect to  $f$  if and only if it does not contain a star.*

Next we define high dimensional permutations and linjections.

► **Definition 9.** A  $(k-1)$ -dimensional permutation of order- $n$  is a map  $f : [n]^k \rightarrow \{0, 1\}$  with the property that for every line  $L = (a, i)$  in  $[n]^k$ ,  $|L \cap f^{-1}(1)| = 1$ .

In other words,  $f$  is a permutation function if and only if every line contains a unique 1 entry. This property is easily seen to be equivalent to the property that for every choice of  $x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_k \in [n]$ , there is exactly one value,  $A_i(x^{-i})$  for  $x_i \in [n]$  such that  $f(x_1, \dots, x_{i-1}, A_i(x^{-i}), x_{i+1}, \dots, x_k) = 1$ .

► **Example 10.** For the sake of gaining better intuition we often consider the important special case  $k = 3$ . This is insightful, since 2-dimensional permutations  $f : [n]^3 \rightarrow \{0, 1\}$  are synonymous with Latin squares. In this case  $A(f)$  is an  $n \times n$  matrix with entries in  $[n]$  where every row and column contains each element in  $[n]$  exactly once. Here we see an elementary but important connection with additive combinatorics; stars coincide with the well-studied notion of *corners* [2, 36]. A star is a triplet of entries in  $f^{-1}(1)$ ,  $(x, y, z')$ ,  $(x', y, z)$ ,  $(x, y', z)$ , which corresponds to the “corner” or “ $A$ -star”,  $(x, y)$ ,  $(x', y)$ ,  $(x, y')$ , where  $A(x', y)$  and  $A(x, y')$  have the same value ( $z$ ), but  $A(x, y)$  has a different value  $z'$ .

► **Example 11.** High dimensional permutations generalize the family of functions  $f_{k,T}^G$  for abelian groups  $G$ . For this communication problem, each player receives (on his/her forehead) an element  $x_i \in G$ , and they want to decide whether or not  $x_1 + \dots + x_k = T$ , that is, whether the sum of the elements is exactly  $T$ .

We can further generalize the notion of a permutation function as follows.

► **Definition 12.** A *linjection* is a graph function  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  with  $N \geq n$  such that  $|f^{-1}(1)| = n^{k-1}$  and every line contains **at most** one point at which  $f = 1$ . A function  $f$  is a linjection if and only if the restriction of  $A(f)$  to any line is an injection.

Linjections are graph functions where  $N \geq n$ , (with permutation functions corresponding to  $n = N$ ), but not vice versa. Determining the least possible communication complexity of a linjection in certain dimensions is an interesting and challenging problem. Henceforth, we use and study the following two notions.

► **Definition 13.** Define  $\alpha_k(n, N) = \max_f \alpha_k(f)$ , and  $\chi_k(n, N) = \min_f \chi_k(f)$ , both taken over all linjections  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$ .

Note that  $\chi_k(n, N) \geq n^{k-1}/\alpha_k(n, N)$ .

### 3 High Dimensional Permutations and Additive Combinatorics

#### 3.1 A Graph-theoretic Characterization

In this section we give a new characterization of  $\alpha_k$  which will turn out to be a variant of the maximum density of Ruzsa-Szemerédi graphs. We start with the case  $k = 3$ .

Recall that we can view a linjection  $f : [n]^2 \times [N] \rightarrow \{0, 1\}$  as an  $n \times n$  matrix,  $A = A(f)$  with entries from  $[N]$ . Alternatively we view it as a tripartite graph  $G(A)$  with parts  $R = [n]$ ,  $C = [n]$  and  $W \subseteq [N]$ . Its edge set is defined as follows: for every triple  $(x, y, b) \in f^{-1}(1)$ , we add the triangle  $(x, y), (y, b), (x, b)$ ,  $x \in R, y \in C, b \in W$  to  $G(A)$ . In particular,  $R \cup C$  span a complete bipartite subgraph of  $G(A)$  and  $(i, b), i \in R, b \in W$  is an edge iff there is a  $b$  entry in row  $i$  of  $A$ , likewise for columns.

Let us consider the triangles  $\langle x, y, b \rangle$ ,  $x \in R, y \in C, b \in W$ , in  $G(A)$ . A triangle  $\langle x, y, b \rangle$  in  $G$  is *trivial* if  $A(x, y) = b$ . However, there can also be nontrivial (induced) triangles in  $G$ , which correspond to centers of stars. We define a *G-star* to be a triple of triangles in  $G$  of the form  $\langle x, y, b' \rangle, \langle x', y, b \rangle, \langle x, y', b \rangle$ . The point is that while these (trivial) triangles are edge-disjoint, their union contains the additional induced triangle  $\langle x, y, b \rangle$ . Define  $\bar{\alpha}(G)$  to be the largest cardinality of a family of edge-disjoint triangles that contains no *G-star*. In other words, a family of edge-disjoint triangles the union of which contains no additional triangle.

Let  $\bar{\alpha}(n, N) = \max_G \bar{\alpha}(G)$  where the maximum is over subgraphs of  $K_{n,n,N}$ . Then:

► **Theorem 14.** For every two integers  $n, N > 0$ , if  $n \leq N$  then  $\alpha_3(n, N) \leq \bar{\alpha}(n, N)$ . If  $N \geq 2n - 1$ , then  $\alpha_3(n, N) = \bar{\alpha}(n, N)$ .

**Proof.** We show first that  $\alpha_3(n, N) \leq \bar{\alpha}(n, N)$ . Let  $f : [n] \times [n] \times [N] \rightarrow \{0, 1\}$  be a linjection and let  $S \subseteq [n] \times [n] \times [N]$  be a star-free subset of  $f^{-1}(1)$ . We prove the claim by constructing a *G-star-free* family  $T$  of  $|S|$  edge-disjoint triangles in  $G = G(A(f))$ . Let

$$T = \{\langle x, y, b \rangle \mid (x, y, b) \in S\}.$$

The claim follows, since stars  $\{(x', y, b), (x, y', b), (x, y, b)\}$  correspond to *G-stars* in  $T$ . Next we prove the reverse inequality  $\alpha_3(n, N) \geq \bar{\alpha}(n, N)$  when  $N \geq 2n - 1$ .

Given a *G-star-free* family  $T$  of edge-disjoint triangles in a subgraph  $G$  of  $K_{n,n,N}$ , we find a linjection  $A : [n] \times [n] \rightarrow [N]$  that contains an *A-star-free* subset  $S \subset [n]^2$  of size  $|T|$ . In the proof we actually first construct  $S$  and only then proceed to define  $A$  in full.

We define  $S$  to be the projection of  $T$  to its first two coordinates. Namely,

$$S = \{(x, y) \mid \langle x, y, b \rangle \in T \text{ for some } b\}.$$

To define  $A$ , we first let  $A(x, y) = b$  for every  $\langle x, y, b \rangle \in T$ .

Since  $T$  is  $G$ -star-free, it follows that  $S$  is  $A$ -star-free. What is missing is that  $A$  is only partially defined. We show that when  $N \geq 2n - 1$  this partial definition can be extended to a linjection. Since the triangles in  $T$  are edge-disjoint it follows that in the partially defined  $A$ , no value appears more than once in any row or column. It remains to define  $A$  on all the entries outside of  $S$  and maintain this property. Indeed this can be done entry by entry. At worst there are  $2n - 2$  values that are forbidden for the entry of  $A$  that we attempt to define next, and therefore there is always an acceptable choice. ◀

**General  $k$ .** The construction for general  $k$  is a natural extension of the case  $k = 3$ . We associate with every linjection  $A : [n]^{k-1} \rightarrow [N]$  a  $k$ -partite  $(k-1)$ -uniform hypergraph  $H(A)$ . The parts of the vertex set are denoted  $Q_1, \dots, Q_{k-1}$  and  $W$ . Each  $Q_i$  is a copy of  $[n]$  and, as above,  $W$  is the range of  $A$ . There is a complete  $(k-1)$ -partite hypergraph on the  $k-1$  parts  $Q_1, \dots, Q_{k-1}$ . Given  $x_1 \in Q_1, \dots, x_{i-1} \in Q_{i-1}, x_{i+1} \in Q_{i+1}, \dots, x_{k-1} \in Q_{k-1}$  and  $w \in W$ , we put the hyperedge  $x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_{k-1}, w$  in  $H(A)$  iff there is a (necessarily unique)  $x_i^* \in [n]$  for which  $A(x_1, \dots, x_{i-1}, x_i^*, x_{i+1}, \dots, x_{k-1}) = w$ .

We proceed to investigate *cliques* in  $H(A)$ , i.e., sets of  $k$  vertices, every  $k-1$  of which form an edge. For  $k = 3$ , we distinguished between those triangles in  $G(A)$  that correspond to an entry in  $[n]^2$  and those that form a star, and a similar distinction applies for general  $k$ .

It is easy to see that if  $A(x_1, \dots, x_{k-1}) = w$ , then  $x_1, \dots, x_{k-1}, w$  form a clique. Such a clique is considered *trivial*. In contrast,  $x_1, \dots, x_{k-1}, w$  is a nontrivial clique iff for every  $i$  there exists an  $x'_i \neq x_i$  such that  $A(x_1, \dots, x_{i-1}, x'_i, x_{i+1}, \dots, x_{k-1}) = w$ .

As above, we define for  $H = H(A)$  the parameter  $\bar{\alpha}_k(H)$ . It is the largest size of a family  $K$  of cliques in  $H$  such that: (i) No two share a hyperedge, and (ii) The hypergraph comprised of all cliques in  $K$  contains no additional cliques. Let  $\bar{\alpha}_k(n, N) = \max_H \bar{\alpha}_k(H)$  over all  $k$ -partite  $(k-1)$ -uniform hypergraphs  $H$ . Then

▶ **Theorem 15.** *For every two integers  $n \leq N$ ,  $\alpha_k(n, N) \leq \bar{\alpha}_k(n, N)$ , and if  $N > (k-1)(n-1)$  then  $\alpha_k(n, N) = \bar{\alpha}_k(n, N)$ .*

The proof is similar to the proof of Theorem 14 and appears in the full paper.

As the proofs show,  $\bar{\alpha}_k(n, N)$  is the largest cardinality of a star-free subset of  $[n]^{k-1} \times [N]$  that meets every line in  $[n]^{k-1} \times [N]$  at most once. To qualify for  $\alpha_k(n, N)$  this subset must, in addition, be extendable to a linjection, so clearly  $\bar{\alpha}_k(n, N) \geq \alpha_k(n, N)$ . We wonder whether this additional requirement creates a substantial difference between the two parameters. Specifically, how are  $\bar{\alpha}_k(n, N)$  and  $\alpha_k(n, N)$  related in the range  $n \leq N \leq (k-1)(n-1)$ ? These two parameters need not be equal in this range, since  $\alpha_3(4, 4) = 8$  and  $\bar{\alpha}_3(4, 4) = 9$ , as we show in Section 4.3.

**Connection to Ruzsa-Szemerédi Graphs.** A graph is called an  $(r, t)$ -Ruzsa-Szemerédi graph if its edge set can be partitioned into  $t$  edge-disjoint induced matchings, each of size  $r$ . These graphs were introduced in 1978 and have been extensively studied since then. Of particular interest are dense Ruzsa-Szemerédi graphs, with  $r$  and  $t$  large, in terms of  $n$ , the number of vertices. Such graphs have applications in Combinatorics, Complexity theory and Information theory. Also, there are several known interesting constructions, relying on different techniques.

Let  $G$  be a tripartite graph with parts  $R, C, W$  of cardinalities  $n, n, N$  respectively. Let  $T$  be a  $G$ -star-free family of edge disjoint triangles in  $G$ . Let  $F$  be the bipartite graph with parts  $R$  and  $C$  where there is an edge between  $r \in R$  and  $c \in C$  iff there is some  $b \in W$  such that  $(r, c, b) \in T$ . Then  $F$  is the union of at most  $N$  edge-disjoint induced matchings, since all the edges that correspond to a given  $b \in W$  form an induced matching.

This construction can easily be reversed: Let  $F$  be a subgraph of  $K_{n,n}$  that is the union of  $N$  edge disjoint induced matchings, with a total of  $\bar{\alpha}$  edges. We can construct a tripartite  $G$  (a subgraph of  $K_{n,n,N}$ ) that contains a family of  $\bar{\alpha}$  pairwise disjoint triangles, and has no  $G$ -stars. We conclude that

► **Observation 16.** *Let  $n \leq N$  be positive integers, then  $\bar{\alpha}_3(n, N)$  is the largest number of edges in a union of  $N$  edge-disjoint induced matchings in  $K_{n,n}$ .*

This observation exhibits a strong connection between (i) The problem of constructing dense  $(r, t)$ -Ruzsa-Szemerédi graphs, and (ii) The construction of a large star-free subset  $S \subseteq [n] \times [n] \times [t]$  that meets every line at most once. The two problems differ only slightly. In one, the underlying graph is bipartite and in the other all induced matching must have the same cardinality. But these differences can be bridged quite easily, as observed in the following lemma.

► **Lemma 17.** **1.**  *$(r, t)$ -Ruzsa-Szemerédi graphs on  $n$  vertices imply  $\bar{\alpha}_3(\frac{n}{2}, t) \geq \frac{rt}{2}$ .*  
**2.**  *$\bar{\alpha}_3(n, t) \geq rt$  implies that there exists a  $(\frac{r}{2}, t)$ -Ruzsa-Szemerédi graph on  $n$  vertices.*

**Proof.** For the first claim, let  $G = (V, E)$  be a  $(r, t)$ -Ruzsa-Szemerédi graph on  $n$  vertices, and let  $E_1, E_2, \dots, E_t$  be the partition of  $E$  into induced matchings. We can find (e.g., by a random choice) a subset  $A \subset V$  of  $\lfloor \frac{n}{2} \rfloor$  vertices, so that at least  $|E|/2$  edges are in the cut  $C = (A, \bar{A})$ . Also,  $C \cap E_1, C \cap E_2, \dots, C \cap E_t$  is a partition of the edges of the bipartite graph  $(A, \bar{A}, C)$  into  $t$  disjoint induced matchings. Therefore,  $\bar{\alpha}_3(\frac{n}{2}, t) \geq \frac{rt}{2}$ .

For the second part, suppose that  $\bar{\alpha}_3(n, t) \geq rt$ . Namely, there is a collection of disjoint induced matchings  $M_1, \dots, M_t \subseteq E(K_{n,n})$  with  $\sum_1^t |M_i| \geq rt$ . We split each  $M_i$  into  $\lfloor \frac{2|M_i|}{r} \rfloor$  sets of  $\geq r/2$  edges each. Note that  $\sum_1^t a_i \geq rt$  implies that  $\sum_1^t \lfloor \frac{2a_i}{r} \rfloor \geq t$  and a subset of an induced matching is an induced matching, so we finally have a family of at least  $t$  disjoint induced matchings each of size  $\frac{r}{2}$ . ◀

### 3.1.1 Application to Shared Directional Multi-channels

Ruzsa-Szemerédi graphs have various applications in several fields [36, 4, 33, 3, 24, 12]. In [12] they are applied to Information Theory, and the study of *shared directional multi-channels*, a subject that is strongly related to communication complexity. Such a channel is comprised of a set of inputs and a set of outputs, to which are connected transmitters and receivers respectively. Associated with each input is a set of outputs, that receive any signal placed at that input. A message is received successfully at an output of the channel if and only if it is addressed to the receiver connected to that output and no other signals concurrently reach that output. Therefore, when communicating over a shared channel, we want the edges (corresponding to messages sent in one round) to form an induced matching. The challenge is to partition  $K_{n,n}$  into families of pairwise disjoint induced matchings. The number of parts correspond to the number of receivers allowed at each output, and the number of matchings in each partition corresponds to the number of rounds.

The relation to communication complexity is as follows: A  $c$ -bit communication protocol for any injection  $A : [n] \times [n] \rightarrow [N]$  induces a partition of  $K_{n,n}$  into  $c$  such families of disjoint induced matchings. Thus, such a communication protocol, gives an  $N$  round protocol for the shared directional multi-channel, with  $c$  receivers per station, and vice-versa.

In constructing a shared directional multi-channel, we seek to minimize the number of rounds required for a given number of transmitters. Alon, Moitra, and Sudakov [4] showed that for any  $\epsilon > 0$  there is partition of  $K_{n,n}$  into at most  $2^{O(\frac{1}{\epsilon})}$  graphs each of which is a family of at most  $O(n^{1+\epsilon})$  induced matchings. This gives an  $O(n^{1+\epsilon})$  round protocol for shared directional multi-channel with  $2^{O(\frac{1}{\epsilon})}$  receivers.

Translated to the language of NOF protocols and combining with Corollary 34 (see Section 5.3 in the sequel), we conclude:

► **Theorem 18.** *For all  $\epsilon > 0$  and all large enough  $n$ ,  $2^{O(\frac{1}{\epsilon})} \geq \chi_3(n, n^{1+\epsilon}) \geq \Omega(\log \frac{1}{\epsilon})$ .*

### 3.2 A Characterization of $\alpha_k(f_{k,T}^{\mathbb{Z}_2^n})$

In this section we focus on the problem  $f_{k,T}^G$  for the abelian group  $\mathbb{Z}_2^n$ . In other words, we study the permutation  $f_{k,T}^{\mathbb{Z}_2^n}$ . We give an alternative characterization of  $\alpha_3(f_{3,T}^{\mathbb{Z}_2^n})$  which brings forth the relation between this problem and several known combinatorial objects. The complexity of  $f_{k,T}^{\mathbb{Z}_2^n}$  is independent of  $T$ , so we will omit the subscript  $T$  in this section. Also, throughout this section we let  $A_k^G = A(f_k^G)$ .

Let  $X \subset \mathbb{Z}_4^3$ . We call a subset of  $W \subseteq \mathbb{Z}_4^n$  *X-free* if for every three distinct members  $x, y, z \in W$  there is an index  $1 \leq i \leq n$  for which  $(x_i, y_i, z_i) \notin X$ .

► **Theorem 19.** *Let*

$$X = \{(0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3), (0, 1, 2), (1, 0, 3), (2, 3, 0), (3, 2, 1)\} \subset \mathbb{Z}_4^3,$$

*then  $\alpha_3(A_3^{\mathbb{Z}_2^n})$  is the largest cardinality of an X-free subset of  $\mathbb{Z}_4^n$ .*

**Proof.** Recall that  $\alpha_3(A_3^{\mathbb{Z}_2^n})$  is the largest cardinality of an  $A_n$ -star free subset of  $(\mathbb{Z}_2^n)^2$ , where  $A_n = A_3^{\mathbb{Z}_2^n}$ . So it suffices to find a bijection  $\psi$  from  $(\mathbb{Z}_2^n)^2$  to  $\mathbb{Z}_4^n$  such that  $S \subseteq (\mathbb{Z}_2^n)^2$  is mapped to an X-free set if and only if  $S$  is  $A_n$ -star free.

We define  $\psi$  for  $n = 1$  and extend it entry-wise to a mapping from  $(\mathbb{Z}_2^n)^2$  to  $\mathbb{Z}_4^n$ . The definition for  $n = 1$  is as follows:  $\psi(0, 0) = 0$ ,  $\psi(0, 1) = 1$ ,  $\psi(1, 0) = 2$  and  $\psi(1, 1) = 3$ .

We need to show that if  $(x_1, y_1), (x_2, y_2), (x_3, y_3) \in (\mathbb{Z}_2^n)^2$  is a  $A_n$ -star, then every coordinate in  $(\psi(x_1, y_1), \psi(x_2, y_2), \psi(x_3, y_3))$  belongs to  $X$ , and vice versa. Since the map  $\psi$  is defined coordinate-wise it suffices to check this for  $n = 1$ . A triple  $(x_1, y_1), (x_1 + d, y_1), (x_1 + d', y_1)$  is a (trivial or non-trivial) star in  $A_1$  iff  $x_1 + (y_1 + d) = (x_1 + d') + y_1$ , i.e.,  $d = d'$ , and thus an  $A_1$ -star is a triple of the form  $(x_1, y_1), (x_1, y_1 + d), (x_1 + d, y_1)$ . If  $d = 0$  then obviously  $(\psi(x_1, y_1), \psi(x_1, y_1 + d), \psi(x_1 + d, y_1)) \in \{(0, 0, 0), (1, 1, 1), (2, 2, 2), (3, 3, 3)\} \subset X$ . When  $d = 1$  there are four cases to check:

1.  $x_1 = 0$  and  $y_1 = 0$  then  $(\psi(x_1, y_1), \psi(x_1, y_1 + d), \psi(x_1 + d, y_1)) = (0, 1, 2) \in X$ .
2.  $x_1 = 0$  and  $y_1 = 1$  then  $(\psi(x_1, y_1), \psi(x_1, y_1 + d), \psi(x_1 + d, y_1)) = (1, 0, 3) \in X$ .
3.  $x_1 = 1$  and  $y_1 = 0$  then  $(\psi(x_1, y_1), \psi(x_1, y_1 + d), \psi(x_1 + d, y_1)) = (2, 3, 0) \in X$ .
4.  $x_1 = 1$  and  $y_1 = 1$  then  $(\psi(x_1, y_1), \psi(x_1, y_1 + d), \psi(x_1 + d, y_1)) = (3, 2, 1) \in X$ .

On the other hand it is not hard to check that for each  $(a, b, c) \in X$  the triplet  $\psi^{-1}(a), \psi^{-1}(b), \psi^{-1}(c)$  is a star in  $A_1$  or  $a = b = c$ . This proves the claim. ◀

Fix an integer  $s \geq 2$  and let  $HJ(n, s)$  denote the largest size of a  $Y_s$ -free subset of  $[s]^n$ , where  $Y_s$  is the following set of  $s$ -tuples:  $\{(1, \dots, s)\} \cup \{(i, i, \dots, i) \mid i = 1, 2, \dots, s\}$ . The density Hales-Jewett theorem states that  $HJ(n, s) = o(s^n)$  for every fixed  $s$  [19, 31]. Theorem 19, and the observation that the first three coordinates of the 4-tuples in  $Y_4$  all belong to  $X$ , imply that  $\alpha_3(A_3^{\mathbb{Z}_2^n}) \leq HJ(n, 4)$ .

The cap-set problem for  $\mathbb{Z}_4^n$  also belongs to the same circle of problems. It concerns the largest size of an arithmetic-triple-free set in  $\mathbb{Z}_4^n$ . We mention in passing the recent breakthrough [14, 17] in this area which showed that this size is at most  $4^{(\gamma+o(1))n}$  with  $\gamma \approx 0.926$ . Let  $Z \subset \mathbb{Z}_4^3$  be the set of all ordered triplets  $(a, b, c) \in \mathbb{Z}_4^3$  satisfying  $a + c = 2b$ . The cap set problems concerns exactly the largest possible cardinality of a  $Z$ -free subset of  $\mathbb{Z}_4^n$ . Since  $X \subset Z$  it follows that this size is bounded by  $\alpha_3(A_3^{\mathbb{Z}_2^n})$ .

The proof of Theorem 19 extends verbatim to general  $k \geq 3$ . It yields a subset  $X \subset \mathbb{Z}_{2^{k-1}}^k$  such that  $\alpha_k(A_k^{\mathbb{Z}_k^n})$  is the largest cardinality of an  $X$ -free subset of  $\mathbb{Z}_{2^{k-1}}^n$ .

By taking  $X$  that includes all vectors  $(a, a, \dots, a) \in \mathbb{Z}_{2^{k-1}}^k$  for  $a \in \mathbb{Z}_{2^{k-1}}$  and the vector  $(0, 1, 2, 4, \dots, 2^{k-2})$  we can maintain the relation between  $\alpha_k(A_k^{\mathbb{Z}_k^n})$  and the density Hales-Jewett theorem for every  $k$ .

## 4 Upper Bounds

### 4.1 An Algorithmic Protocol for Exact- $T$ over $\mathbb{Z}^d$

The aim of this section is to give the first algorithmic protocol for Exactly- $n$  as well as other Exact- $T$  functions. Our protocol is explicit, and does not rely on a construction of a large set without a 3-term AP. We only appeal to the elementary fact that no sphere can contain three equally spaced colinear points. The algorithm has two main steps. We first provide a very efficient protocol for Exact- $T$  over  $\mathbb{Z}^d$ , whose cost grows only logarithmically with  $d$ .

Let  $f : ([m]^d)^3 \rightarrow \{0, 1\}$  be defined via  $f(x, y, z) = 1$  if and only if  $x + y + z = T$ , where  $T \in \mathbb{Z}^d$  is some fixed vector. We provide an explicit NOF protocol for  $f$  whose cost is only  $O(\log md)$ . In words, players try to compute the vector  $x + 2y + 3z$  “to the best of their knowledge” and then they compare notes.

1. Player 1 computes  $v_x = T - y - z + 2y + 3z$ .
2. Player 2 computes  $v_y = x + 2(T - x - z) + 3z$ .
3. Player 3 computes  $v_z = x + 2y + 3(T - x - y)$ .
4. Player 1 writes  $\|v_x\|_2^2$  on the blackboard.
5. Player 2 writes 1 or 0 on the blackboard depending on whether  $\|v_y\|_2^2 = \|v_x\|_2^2$ .
6. Player 3 writes 1 or 0 on the blackboard depending on whether  $\|v_z\|_2^2 = \|v_x\|_2^2$ .
7. The protocol outputs 1 if the last two bits were both equal to 1, and 0 otherwise.

The cost of the above protocol is essentially determined by the largest possible value of  $\|v_x\|_2^2$  in step 4 which is at most  $O(m^2d)$ . Therefore, this cost does not exceed  $O(\log md)$ . We turn to prove correctness.

► **Lemma 20.** *The above protocol is correct.*

**Proof.** First note that the protocol outputs 1 if and only if  $\|v_x\|_2^2 = \|v_y\|_2^2 = \|v_z\|_2^2$ . Also,  $v_x + v_z = 2v_y$ , so that this condition holds only if all three vectors are equal, in which case  $T - x - y - z = 0$ . ◀

► **Remark (More general protocols).** Several variations on the above theme suggest themselves. Fix integers  $a, b, c \in \mathbb{Z}$  and a  $d \times d$  positive definite matrix  $D$  with integer entries. The players compute  $a(T - y - z) + by + cz$ ,  $ax + b(T - x - z) + cz$  and  $ax + by + c(T - x - y)$ , and rather than comparing the values of  $\|v\|_2$ , they consider the values of  $vDv^t$ . We wonder if these, or similar variations can together improve the complexity of the protocol.

### 4.2 Algorithmic Protocols for Exactly- $N$ and $f_{k,T}^G$ over $\mathbb{Z}_m^n$

We seek algorithmically explicit protocols for Exactly- $N$ <sup>2</sup>, namely for the function  $f : [N]^3 \rightarrow \{0, 1\}$  such that  $f(x, y, z) = 1$  if and only if  $x + y + z = N$ , i.e., the exact-T problem over  $\mathbb{Z}$

<sup>2</sup> Since  $n$  is used as an exponent in this section we use  $N$  for the size of input in Exactly- $N$ .

or equivalently over  $\mathbb{Z}_N$ . We can give an efficient protocol to this problem by reduction to the protocol in the previous section, even though when applied directly to  $\mathbb{Z}_N$  they give no improvement over the trivial protocol.

First fix a base  $m$  and let  $n = 1 + \lceil \log_m N \rceil$ . Consider the base- $m$  representation on the elements of  $[N]$ . Given a representation  $x \in \{0, 1, \dots, m-1\}^n$  of a number base  $m$ , for convenience we consider  $x_1$  as the least significant digit. Note that all representations are of length  $n$ , if a number is small its representation is padded with zeros. The following protocol solves the Exactly- $N$  problem in these settings. Let  $T$  be the base- $m$  representation of  $N$ .

1. Player 1 computes the vector  $C \in \{0, 1, 2\}^m$  defined as follows: the  $i$ -th entry of  $C$  is equal to  $k \in \{0, 1, 2\}$  satisfying

$$T_i + (k-1)m < y_i + z_i + C_{i-1} \leq T_i + km,$$

where addition is over  $\mathbb{Z}$ , and we define  $C_0 = 0$ .

2. Denote by  $C_x$  the carry vector computed by Player 1 in step 1. Player 2 and 3 compute corresponding vectors  $C_y$  and  $C_z$ , in a similar way.
3. Player 1 writes  $C = C_x$  on the board.
4. Player 2 and 3, in turn, write 1 on the board if and only if their vector  $C_y$  ( $C_z$ ) is equal to  $C_x$ .
5. If the last two bits written on the board are equal to 1, continue. Otherwise output 0 and terminate.
6. All players compute (in private) the vector  $T'_i = T_i + mC_i - C_{i-1}$ , for  $i = 1, \dots, n$ .
7. The players run a protocol for the exact-T problem over  $\mathbb{Z}^n$  with  $x, y, z$  and  $T'$ .

The cost of the above protocol is  $O(n+2)$  for steps 1-5, plus the cost of the protocol used in step 7. The cost is thus  $O(n + \log mn)$  if the players use the protocol from Section 4.1 in the last step. We prove next that this protocol is correct.

► **Lemma 21.** *The above protocol is correct.*

**Proof.** First assume  $N = x + y + z$  over  $\mathbb{Z}$ . It is easy to verify the correctness of the protocol in this case, except maybe step 5. The correctness of step 5 follows from the following simple observation: assume  $x_i + y_i + z_i + C_{i-1} = T_i + km$  (over  $\mathbb{Z}$ ) for  $k \in \{0, 1, 2\}$ , then it must be that the sum of any pair of  $x_i, y_i, z_i$  and  $C_{i-1}$  is larger than  $T_i + (k-1)m$  and at most  $T_i + km$ . Now consider the case  $T \neq x + y + z$ . If the protocol rejects on step 5 then obviously this is correct. If it does not reject then all players compute the same vector  $T'$ , and  $x + y + z = N$  over  $\mathbb{Z}$  if and only if  $x + y + z = T'$  over  $\mathbb{Z}^n$ . The correctness now follows from the correctness of the protocol over  $\mathbb{Z}^n$ . ◀

The above protocol for Exactly- $N$  is correct for any choice of base  $m$ . To get an efficient protocol we optimize the choice of  $m$ . The running time of the protocol is  $O(n + \log mn) = O(n + \log m)$ . Since  $m^n = N$ , we get that  $\log N = n \log m$ , and thus the optimal choice is roughly  $m = 2^{\sqrt{\log N}}$  which gives a running time of  $O(\sqrt{\log N})$ .

► **Remark (The group  $\mathbb{Z}_m^n$ ).** The above protocol can also be adapted for  $\mathbb{Z}_m^n$  (with addition modulo  $m$ ). The idea is very similar, the only difference is that in the first steps Player 1 computes the vector  $I_x \in \{0, 1, 2\}^n$  defined as follows: the  $i$ -th entry of  $I_x$  is equal to  $k \in \{0, 1, 2\}$  satisfying

$$T_i + (k-1)m < y_i + z_i \leq T_i + km,$$

where addition is over  $\mathbb{Z}$ . The other two players compute analogous vectors.

### 4.3 A Protocol for $f_{k,T}^G$ over $\mathbb{Z}_2^n$

In this section we focus on the exact- $T$  problem for the abelian group  $\mathbb{Z}_2^n$ . In other words, we study the permutation  $f_{k,T}^{\mathbb{Z}_2^n}$ . First we prove a lower bound on  $\alpha_3(f_{3,T}^{\mathbb{Z}_2^n})$ , and then show that this lower bound implies the existence of an efficient protocol for  $f_{3,T}^{\mathbb{Z}_2^n}$ . The complexity of  $f_{k,T}^{\mathbb{Z}_2^n}$  is independent of  $T$ , so we can and will omit the subscript  $T$  in this section. Throughout this subsection we let  $A_k^G = A(f_k^G)$ .

First we prove that  $A_k^{\mathbb{Z}_2^n}$ -star freeness is preserved under tensor product. Let  $S \subset (\mathbb{Z}_2^n)^{k-1}$ , denote by  $S \otimes S$  the subset of  $(\mathbb{Z}_2^{2n})^{k-1}$  comprised of all vectors  $(x_1, y_1, \dots, x_{k-1}, y_{k-1})$  such that  $x_i, y_i \in S$  for  $i = 1, \dots, k-1$ .

► **Lemma 22.** *If  $S$  is  $A_k^{\mathbb{Z}_2^n}$ -star free then  $S \otimes S$  is  $A_k^{\mathbb{Z}_2^{2n}}$ -star free.*

**Proof.** Let  $A = A_k^{\mathbb{Z}_2^{2n}}$  and let

$$(z_1, \dots, z_{k-1}), (z_1 + d, \dots, z_{k-1}), \dots, (z_1, \dots, z_{k-1} + d)$$

be an  $A$ -star in  $S \times S$ , where for each  $1 \leq i \leq k-1$ ,  $z_i = (x_i, y_i)$  with  $x_i, y_i \in S$ . Denote also  $d = (d^1, d^2)$  where  $d^1, d^2 \in \mathbb{Z}_2^n$ . Then either

$$(x_1, \dots, x_{k-1}), (x_1 + d^1, \dots, x_{k-1}), \dots, (x_1, \dots, x_{k-1} + d^1)$$

is an  $A_k^{\mathbb{Z}_2^n}$ -star in  $S$ , or

$$(y_1, \dots, y_{k-1}), (y_1 + d^2, \dots, y_{k-1}), \dots, (y_1, \dots, y_{k-1} + d^2)$$

is an  $A_k^{\mathbb{Z}_2^n}$ -star in  $S$ , since either  $d^1 \neq 0$  or  $d^2 \neq 0$ . ◀

It follows that if, for some fixed  $m$ , we can find a large  $A_k^{\mathbb{Z}_2^m}$ -star free subset  $S$ , then tensor powers of  $S$  are large  $A_k^{\mathbb{Z}_2^n}$ -star free sets. We show:

► **Lemma 23.**  $\alpha_3(A_3^{\mathbb{Z}_3^2}) = \alpha_3(n, n) = 8$ .

Together with Lemma 22 this yields:

► **Corollary 24.** *For every integer  $n \geq 2$ , there holds  $\alpha_3(A_3^{\mathbb{Z}_3^{2n}}) \geq 2^{3n/2}$ .*

**Proof.** Let  $S$  be a star-free subset in  $A_3^{\mathbb{Z}_3^2}$  of cardinality  $8 = 4^{3/2}$  as in Lemma 23. The claim follows by taking the tensor powers of  $S$  as in Lemma 22. ◀

**Proof of Lemma 23.** We denote the elements of  $\mathbb{Z}_3^2$  as follows  $(0, 0) = 0$ ,  $(0, 1) = 1$ ,  $(1, 0) = 2$  and  $(1, 1) = 3$ . The matrix associated with  $A_3^{\mathbb{Z}_3^2}$  is:

$$\begin{matrix} \mathbf{0} & \mathbf{1} & \mathbf{2} & \mathbf{3} \\ 1 & 0 & \mathbf{3} & \mathbf{2} \\ \mathbf{2} & \mathbf{3} & 0 & 1 \\ 3 & 2 & \mathbf{1} & \mathbf{0} \end{matrix}$$

The 8 entries in bold form a star-free set, so that  $\alpha_3(A_3^{\mathbb{Z}_3^2}) \geq 8$ , and consequently  $\alpha_3(4, 4) \geq 8$ . One can verify that in fact  $\alpha_3(4, 4) = \alpha_3(A_3^{\mathbb{Z}_3^2}) = 8$ . To see this first notice that if there is a star-free subset of cardinality 9 then one of the values must appear three times which already determines 10 out of the 16 entries. One can now rule out the existence of a size 9 star-free subset by exhaustive search. ◀

It is interesting to determine  $\alpha_k(n, n)$  for some small values of  $n$ . For example:

- Determine  $\alpha_3(8, 8)$ , in particular compute  $\alpha_3(A_3^{\mathbb{Z}_3^8})$ .
- Determine  $\alpha_k(4, 4)$ , in particular compute  $\alpha_k(A_k^{\mathbb{Z}_k^4})$ , for  $k > 3$ .

It is interesting to note that, while as shown,  $\alpha_3(4, 4) = 8$ , there holds  $\bar{\alpha}_3(4, 4) = 9$ . The fact that  $\bar{\alpha}_3(4, 4) \leq 9$  is easy to verify, and the following example shows the equality:

1	*	*	3
*	1	*	4
*	*	1	2
2	3	4	*

Thus, continuing the discussion at the end of Section 3.1,  $\bar{\alpha}_3(n, N)$  and  $\alpha_3(n, N)$  need not be equal when  $N < 2n - 1$ .

The following theorem shows that for groups,  $\alpha_k$  (the size of the largest 1-monochromatic cylinder intersection) completely characterizes  $\chi_k$  (the minimum number of cylinder intersections that partition the 1's). The proof is a simple generalization of Theorem 4.3 in [13].

► **Theorem 25.** *If  $G$  is a group of order  $n$ , then*

$$\chi_k(f_k^G) \leq O\left(\frac{kn^{k-1} \log n}{\alpha_k(f_k^G)}\right).$$

**Proof.** The proof is in two steps:

**Step I:**  $A$ -star freeness is preserved under translation, where  $A = A_k^G$ . Indeed, let  $S \subset G^{k-1}$  and let  $\mathbf{a} = (a_1, \dots, a_{k-1}) \in G^{k-1}$ . If

$$(x_1, \dots, x_{k-1}), (x_1 + d, \dots, x_{k-1}), \dots, (x_1, \dots, x_{k-1} + d)$$

is an  $A$ -star in  $S + \mathbf{a}$ , then

$$(x_1, \dots, x_{k-1}) - \mathbf{a}, (x_1 + d, \dots, x_{k-1}) - \mathbf{a}, \dots, (x_1, \dots, x_{k-1} + d) - \mathbf{a}$$

is an  $A$ -star in  $S$ .

**Step II:** Every  $S \subset G^{k-1}$  has  $O(\frac{kn^{k-1} \log n}{|S|})$  translates whose union covers all of  $G^{k-1}$ . This follows from the integrality gap for covering [28], but for completeness here is a proof. Pick at random  $t$  translates  $\mathbf{a}_1, \dots, \mathbf{a}_t \in [n]^{k-1}$  of  $S$ . The probability that a given element  $\mathbf{x} \in [n]^{k-1}$  is covered by a random translate of  $S$  is exactly  $\frac{|S|}{n^{k-1}}$ . Therefore, and since the translates are picked independently uniformly at random, the expected number of uncovered elements of  $G^{k-1}$  is

$$n^{k-1} \cdot \left(1 - \frac{|S|}{n^{k-1}}\right)^t.$$

Taking  $t = O(\frac{kn^{k-1} \log n}{|S|})$  makes the expectation less than 1, which proves the lemma. ◀

► **Corollary 26.**  $\chi_3(f_3^{\mathbb{Z}_3^m}) \leq O(m \cdot 2^{m/2})$ .

The bound in Corollary 26 is similar to the bound of Ada, Chattopadhyay, Fawzi and Nguyen [1] for the case  $k = 3$ , with slight improvement in the log factors. Ada et al. proved  $\chi_3(f_3^{\mathbb{Z}_3^m}) \leq O(m^{k+1} 2^{m/2^{k-2}})$ , by observing that this function is a composed function of the form  $NOR \circ XOR$  and giving non trivial protocols for such cases.

Note that the proof of Theorem 25 yields a cover of  $[n]^{k-1}$  by  $A$ -star free sets, but this is easily turned into a partition, since a subset of an  $A$ -star free set is also  $A$ -star free. Therefore, any lower bound on  $\alpha_k(f_k^G)$  can be translated into an upper bound on  $\chi_k(f_k^G)$  which in turn implies an efficient (non-explicit) protocol for  $f_k^G$  (By Theorem 5). Another interesting consequence of Theorem 25 is that any lower bound on  $\chi_k(f_k^G)$  significantly larger than  $\log n$  improves the known bounds for the size of a corner-free subset of  $G$ . This clearly boosts our interest in the multiparty communication complexity of  $f_k^G$ .

We wonder whether there are analogs of Theorem 25 for every permutation.

► **Question 27.** *How large can  $\chi_k(A) \cdot \alpha_k(A)/n^{k-1}$  be for an arbitrary permutation  $A$ ?*

## 5 Lower Bounds

### 5.1 Nonconstructive Lower Bounds

We first prove a nearly tight but nonconstructive lower bound on the communication complexity of random high-dimensional permutations.

► **Theorem 28.** *For every integer  $k \geq 3$ , and for most  $(k - 1)$ -dimensional permutations  $f : [n]^k \rightarrow \{0, 1\}$ ,*

$$\log \chi_k(f) \geq \Omega\left(\frac{\log n}{k}\right).$$

**Proof.** The lower bound on the number of high-dimensional permutations was recently improved by Keevash [25] who showed that there are at least  $2^{\Omega(n^d \log n)}$   $d$ -dimensional permutations. If we view a permutation as a map  $[n]^k \rightarrow \{0, 1\}$ , this means at least  $2^{\Omega(n^{k-1} \log n)}$  permutations. In the spirit of the proof of Lemma 3.5 in [7], we now estimate the number of such permutation for which  $\chi_k(f)$  is bounded. Note that we cannot simply use the estimate from [7] since it only works for functions  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  with  $N$  that is much smaller than  $n$ , roughly  $N \leq \sqrt{\frac{n}{k}}$ .

Let  $f : [n]^k \rightarrow \{0, 1\}$  be a  $(k - 1)$ -dimensional permutation, and let  $\{C_1, \dots, C_\chi\}$  be a partition of  $f^{-1}(1)$  into  $\chi = \chi_k(f)$  cylinder intersections. For  $i \in [k]$  define a function  $A_i : [n]^{k-1} \rightarrow [\chi]$  as follows: For  $a = (a_1, \dots, a_{k-1}) \in [n]^{k-1}$ , let  $L = (a, i)$  be a line in  $[n]^{k-1}$ . There is a unique 1 entry in  $L$  and this entry is in exactly one of the cylinder intersections  $\{C_1, \dots, C_\chi\}$ , say  $C_j$ . In this case we define  $A_i(a_1, \dots, a_{k-1}) = j$ .

As seen in the proof of Theorem 5, it is possible to recover  $f$  from knowledge of the functions  $A_1, \dots, A_k$ . Namely,  $f(x_1, \dots, x_k) = 1$  if and only if all the values  $A_i(x_1, \dots, x_{i-1}, x_{i+1}, \dots, x_{k-1})$  for  $i = 1, \dots, k$  are equal. But for every  $i \in [k]$  there are  $\chi^{n^{k-1}}$  possible functions  $A_i : [n]^{k-1} \rightarrow [\chi]$ . Thus, the number of  $(k - 1)$ -dimensional permutations  $f : [n]^k \rightarrow \{0, 1\}$  with  $\chi_k(f) \leq \chi$  is at most  $(\chi^{n^{k-1}})^k = 2^{kn^{k-1} \cdot \log \chi}$ . Combining this with Keevash's lower bound achieves our result. ◀

A simple corollary of Theorem 28, and Theorem 5 is:

► **Corollary 29.** *For every integer  $k \geq 2$ , almost all  $(k - 1)$ -dimensional permutations  $f : [n]^k \rightarrow \{0, 1\}$  satisfy  $D_k(f) \geq \Omega\left(\frac{\log n}{k}\right)$ .*

Theorem 28 proves the lower bound  $\chi_k(f) \geq 2^{\Omega\left(\frac{\log n}{k}\right)}$  for a random permutation  $f : [n]^k \rightarrow \{0, 1\}$ . It is interesting to find out how this extends for a random linjection  $f : [n]^{k-1} \times [N] \rightarrow \{0, 1\}$  with  $n < N$ . It is also interesting to see whether the dependency on  $k$  can be removed.

Finally we turn to the case  $k = 3$ . The number of 2-dimensional permutations (aka Latin squares) is known to be  $((1 + o(1)) \frac{n}{\epsilon^2})^{n^2}$  (see [39]). It follows that for most 2-dimensional permutations  $f$  there holds  $\log \chi_3(f) \geq \frac{1}{3} \log n - \Theta(1)$ .

## 5.2 Lower Bounds for $\chi_k(n, N)$

We prove an upper bound on  $\alpha_k(n, N)$ , using its graph theoretic interpretation from Section 3.1, which implies the corresponding lower bound on  $\chi_k$ . We start with  $k = 3$ :

► **Theorem 30.** *Let  $A : [n] \times [n] \rightarrow [N]$  be a linjection, where  $N \leq n \cdot 2^{c \log^*(n)}$ . Then there exists  $c > 0$  such that  $\alpha_3(A) \leq O\left(\frac{n^2}{2^{c \log^*(n)}}\right)$ .*

The proof of Theorem 30 is an adaptation of Solymosi's [36] simplification of Ajtai and Szemerédi's [2] Corners Theorem. We will use the improved version of the triangle removal lemma [33] due to Fox [18]:

► **Lemma 31** (Triangle removal lemma). *For every  $\epsilon > 0$  there is a  $\delta > 0$  such that every  $n$ -vertex graph with at most  $\delta n^3$  triangles can be made triangle-free by removing  $\epsilon n^2$  edges. Specifically  $\delta^{-1}$  can be taken as a tower of twos of height  $405 \log \epsilon^{-1}$ .*

**Proof of Theorem 30.** Let  $G = G(A)$ ,  $V = V(G)$ . Notice that  $|V| = 2n + N$ . Let  $S \subset [n]^2$  be an  $A$ -star free subset of size  $\alpha_3(A)$ . As in the proof of Theorem 14 we let  $T = \{ \langle x, y, A(x, y) \rangle \mid (x, y) \in S \}$  be the family of triangles in  $G$  that corresponds to  $S$ . Let  $F$  be that subgraph of  $G$  whose edge set is the union of all triangles in  $T$ . This graph contains the  $|S|$  edge-disjoint triangles in  $T$ , and no additional triangles.

Thus, if we denote  $\delta = |S|/|V|^3$  and  $\epsilon = |S|/|V|^2$ , then  $F$  contains exactly  $\delta|V|^3$  triangles and it cannot be made triangle free by removing fewer than  $\epsilon|V|^2$  edges. Lemma 31 yields  $\log^*(\delta^{-1}) \leq 405 \log(\epsilon^{-1})$ , and since  $\delta < \frac{n^2}{(2n+N)^3} < \frac{1}{N}$  we conclude that

$$\epsilon \leq 2^{\frac{1}{405} \log^*(N)}.$$

But  $|S| = \epsilon|V|^2 \leq 9\epsilon N^2$ , so that for  $N \leq 2^{c \log^*(n)} n$ , with  $c = (3 \cdot 405)^{-1}$ ,  $|S| \leq O\left(\frac{n^2}{2^{c \log^*(n)}}\right)$ . ◀

We now state the case of general  $k$ , proved in the full version.

► **Theorem 32.** *For every natural numbers  $k \geq 3$ ,  $n$  and  $N$  it holds that*

$$\alpha_k(n, N) \leq O\left(\frac{kn^{k-2}N}{\log^*(n)}\right).$$

## 5.3 A Lower Bound on $\chi_3(n, N)$

In this section we state our better lower bound for the case  $k = 3$ . The proofs appears in the full version of our paper.

► **Lemma 33.** *Let  $L = \chi_3(n, N)$  for some integers  $N \geq n$ , then  $\log n < (2^{L+1} - 1) \cdot \log(4NL/n)$ . In particular for  $k = 3$ , we have  $\chi_3(n, n) \geq \log \log n - O(\log \log \log n)$ .*

Another simple corollary of Lemma 33 is due to Meshulam and is reproduced in [4].

► **Corollary 34.** *If  $\chi_3(n, N) \leq L$  for some integers  $N \geq n$ , then  $N \geq \frac{1}{4L} \cdot n^{1+1/(2^L-1)}$ .*

**A note on the case  $k > 3$ .** As we have just seen  $\chi_3(A) \geq \Omega(\log \log n)$  for every 2-dimensional permutation  $A$ . It is conceivable that a similar bound holds for higher dimensions as well. This was previously conjectured in [10] for the Exact- $T$  problem. If we try to adapt the proof of Lemma 33 to higher  $k$ , exactly one difficulty arises which we formulate as a question.

► **Question 35.** Let  $S \subseteq [n]^k$  be a set of cardinality  $m$  that meets every line at most once. Determine, or estimate  $\phi_k(n, m)$ , the least possible cardinality  $|\bar{S}|$  of its closure. We use the shorthand  $\phi_k(m)$  when appropriate.

For  $k = 2$  the answer is easy:  $\phi_2(m) = m^2$ , since  $|\bar{S}| = |S|^2$ . But for  $k > 2$  the problem becomes very hard and no lower bound is known. In fact, for  $k \geq 3$ , and for large enough  $m$  there holds  $\phi_k(m) = m$ . In other words, unlike the case  $k = 2$  it may happen that  $\bar{S} = S$  for large  $S$ . For example, as shown in [13],  $\phi_3(m) = m$  when  $m = n^2/2^{\Omega(\sqrt{\log n})}$ , whereas it is shown in [34] that  $\phi_3(m) > m$  when  $m \geq n^2/(\log \log n)^{\frac{1}{22}}$ . For  $k > 3$  the situation is even worse, and all we have are the very weak lower bounds from Section 5.2. Namely, it follows from Theorem 32 that  $\phi_k(m)$  must be larger than  $m$  when  $m \geq \Omega\left(\frac{kn^{k-1}}{\log^r(n)}\right)$ . Proving any non-trivial bounds on  $\phi_k(m)$  is a very interesting challenge. We raise the following conjecture in an attempt to improve the lower bounds on  $\chi_3(n, n)$ :

► **Conjecture 36.** There are constants  $c_1, c_2 > 0$  such that if  $S \subseteq [n]^3$  meets every line at most once, and if  $|S| \geq n^2/(\log \log n)^{c_1}$ , then  $|\bar{S}| \geq n^3/(\log \log n)^{c_2}$ .

## 6 Conclusion and Open Problems

This paper raises numerous open problems. Below we collect some of the major ones and explain some implications that would follow from progress on these questions.

► **Question 37.** Improve the lower bound  $\chi_3(n, n) \geq \Omega(\log \log n)$ .

Any lower bound  $\chi_3(n, n) \geq \omega(\log \log n)$  yields an improvement to the best known bound on the number of colors required to color the  $n \times n$  grid with no monochromatic equilateral right triangles. This subject goes back to Ajtai and Szemerédi's corners theorem [2] and its implications in additive combinatorics due to Solymosi [36]. A lower bound  $\chi_3(n, n) \geq \omega(\log n)$  would improve the best known gap between randomized and deterministic communication complexity in the 3-players NOF model. A lower bound  $\chi_3(n, n) \geq \Omega(\log n \cdot \log \log n)$  will improve the best known upper bound on the size of corner-free subsets of  $G^2$  for any abelian group  $G$ . And finally, a lower bound  $\chi_3(n, n) \geq \Omega(\log^2 n)$  will improve the best bounds on the size of a subset of  $\mathbb{Z}_n$  with no three-term arithmetic progression. This is a classic problem that goes back at least to the 1950's [32].

► **Question 38.** Improve the upper bound  $\chi_3(n, n) \leq 2^{O(\sqrt{\log n})}$ .

The construction of denser Ruzsa-Szemerédi graphs than currently known. Namely,  $n$ -vertex graphs which are the disjoint union of  $n$  induced matchings, all of the same size  $r$ . This, in turn, reflects on the many applications of these. This would also improve our understanding regarding the limits of the triangle removal lemma; note that the current gaps between the bound in this lemma are huge.

► **Question 39.** Improve the bounds on  $\chi_k(n, n)$  for  $k > 3$ .

► **Question 40.** Improve the bounds on  $\alpha_k(n, n)$  for  $k > 3$ .

That would improve our state of knowledge regarding the bounds for the hypergraph removal lemma. It is also interesting to determine  $\alpha_k(n, n)$  for some small values of  $n$ . For example: Determine  $\alpha_3(8, 8)$ , and in particular compute  $\alpha_3(A_3^{\mathbb{Z}_3^2})$ , or Determine  $\alpha_k(4, 4)$ , and in particular compute  $\alpha_k(A_k^{\mathbb{Z}_2^2})$  for  $k > 3$ .

► **Question 41.** *What is the relationship between  $\bar{\alpha}_k(n, N)$  and  $\alpha_k(n, N)$  in the whole range  $n \leq N \leq (k - 1)(n - 1)$ ?*

## Abstract

The Ising model originated in statistical physics as a means of studying phase transitions in magnets, and has been the object of intensive study for almost a century. Combinatorially, it can be viewed as a natural distribution over cuts in a graph, and it has also been widely studied in computer science, especially in the context of approximate counting and sampling. In this paper, we study the complex zeros of the partition function of the Ising model, viewed as a polynomial in the “interaction parameter”; these are known as *Fisher zeros* in light of their introduction by Fisher in 1965. While the zeros of the partition function as a polynomial in the “field” parameter have been extensively studied since the classical work of Lee and Yang, comparatively little is known about Fisher zeros. Our main result shows that the zero-field Ising model has no Fisher zeros in a complex neighborhood of the entire region of parameters where the model exhibits correlation decay. In addition to shedding light on Fisher zeros themselves, this result also establishes a formal connection between two distinct notions of phase transition for the Ising model: the absence of complex zeros (analyticity of the free energy, or the logarithm of the partition function) and decay of correlations with distance. We also discuss the consequences of our result for efficient deterministic approximation of the partition function. Our proof relies heavily on algorithmic techniques, notably Weitz’s self-avoiding walk tree, and as such belongs to a growing body of work that uses algorithmic methods to resolve classical questions in statistical physics.

## 1 Introduction

In combinatorial terms, the Ising model is a probability distribution over the cuts of a graph. Given a graph  $G = (V, E)$ , the configurations of the model are assignments  $\sigma$  of “+” or “−” spins to the vertices of  $G$ ;  $\sigma$  corresponds to the cut between spin-“+” and spin-“−” vertices. The model assigns to configuration  $\sigma$  the weight  $w_{G,\beta}(\sigma) = \beta^{|\{e=(u,v) \in E : \sigma(u) \neq \sigma(v)\}|}$ , where  $\beta > 0$  is a parameter. The associated probability distribution, known as the *Gibbs measure*, is then defined by assigning probability  $\mu_{G,\beta}(\sigma) := \frac{1}{Z_G(\beta)} w_{G,\beta}(\sigma)$  to each configuration  $\sigma$ . The normalizing factor here is the *partition function*, defined as

$$Z_G(\beta) := \sum_{\sigma: V \rightarrow \{+, -\}} w_{G,\beta}(\sigma) = \sum_{k=0}^{|E|} \gamma_k \beta^k, \quad (1)$$

where  $\gamma_k$  is the number of  $k$ -edge cuts in  $G$ . Note that  $Z_G(\beta)$  is a polynomial in  $\beta$  with positive coefficients. We also sometimes consider graphs in which certain vertices are *pinned* to “+” or “−” spins. For such a graph, we restrict the sum in the definition of  $Z_G$  to those configurations  $\sigma$  in which these vertices have the spin determined by their pinning.

The origins of the Ising model lie in the qualitative modeling of phase transitions in magnets [11]; indeed, it was the first model among the wide class of *spin systems* to be studied extensively in statistical physics. The parameter  $\beta$  above is a proxy for the “temperature” or “interaction strength”, while the graph is a proxy for the physical structure of the magnet. In this parameterization,  $\beta > 1$  corresponds to so-called anti-ferromagnetic interactions (where neighbors prefer to have different spins),  $\beta < 1$  to ferromagnetic interactions (where neighbors prefer to have the same spins), and  $\beta = 1$  to infinite temperature (where the neighbors behave independently of each other). We will restrict our attention throughout to graphs of fixed (but arbitrary) maximum degree  $\Delta$ .

Historically, there have been two distinct (though closely related) mechanisms for defining and understanding phase transitions in statistical physics. The first is decay of long-range correlations in the Gibbs measure, which is familiar in theoretical computer science due to its extensive use in approximation algorithms and the analysis of spin systems and graphical models. The second, which is more classical and less familiar in computer science, is analyticity of the “free energy”  $\log Z$  (where  $Z$  is the partition function). This second notion connects naturally to stability theory of polynomials, and in particular to the study of the location of *complex* roots of the partition function  $Z$ , even when only real values of the parameters make physical sense in the model. The seminal work of Lee and Yang [12, 28] was one of the first, and certainly the best known, to use this notion. We note in passing that stability theory has seen a surge of recent interest in theoretical computer science, in contexts ranging from approximation algorithms to the construction of Ramanujan graphs (see, e.g., [17, 18, 1, 2, 26]).

We now briefly describe the connection between the analyticity of the free energy and the location of complex zeros of the partition function. The first ingredient is that natural observables of the model (e.g., the *magnetization*) can be written as derivatives of the free energy with respect to an appropriate parameter of the model. Thus, analyticity of the free energy for a given range  $S$  of parameters implies that all such observables vary continuously (and have continuous derivatives) when the parameter value lies in  $S$ , which in turn implies that there is no phase transition in  $S$ . However, it is not hard to see that for any finite graph, the free energy is always analytic as a function of  $\beta$  when  $\beta$  lies on the positive real axis, suggesting a complete absence of phase transitions. Indeed, it turns out (see, e.g., [23, Chapter 1]) that in order to see phase transitions one has to consider *infinite* graphs.

For concreteness, we consider the case of the Ising model on the infinite 2-dimensional integer lattice  $\mathbb{Z}^2$  [28]. In order to define the free energy for such an infinite graph, one takes the limit of the free energies of a suitable increasing sequence of finite subgraphs (e.g., increasing rectangles in  $\mathbb{Z}^2$ ), after scaling them by their size. Lee and Yang [28] showed that, for infinite graphs of sub-exponential growth (including  $\mathbb{Z}^2$ ), the free energy obtained via this prescription is well defined and analytic for a range of parameters  $S$  provided that the partition functions of the finite graphs used in the limit definition, viewed as polynomials in the parameter, are zero-free in a *complex* neighborhood of  $S$ . Thus, proving zero-freeness of partition functions of such a sequence of finite graphs in a *fixed* (i.e., not depending upon the finite graphs in question) complex neighborhood of  $S$  implies the absence of phase transitions in  $S$ .

**Algorithms, phase transitions, and roots of polynomials.** While the algorithmic consequences of phase transitions defined in terms of decay of correlations have been well studied, first in the context of Markov Chain Monte Carlo algorithms (Glauber dynamics) and more recently in deterministic algorithms that directly exploit correlation decay, algorithmic use of the information on complex roots of the partition function originated only recently in the work of Barvinok (see [3] for a survey). This has led to increased interest in understanding the relationship between the above two notions of phase transitions. Such connections have been the focus of some recent work on the independent set (or “hard core lattice gas”) model; notably, connections similar to the ones in this paper have been explored for that model by Peters and Regts [20], while related ideas are harnessed in early work of Shearer [22], as later elucidated by Scott and Sokal [21] and further elaborated by Harvey *et al.* [10], to shed light on the Lovász Local Lemma.

The motivation for our work here is to take a step towards achieving a fuller understanding of these connections. Specifically, we study the zeros of the Ising partition function (at zero field), viewed as a polynomial in the interaction parameter. While the study of zeros in terms of the fugacity (or field) parameter was famously pioneered by Lee and Yang [12], and has given rise to a well developed theory, very little is known about the zeros in terms of the interaction parameter, which were first studied in the classical 1965 paper of Fisher [8] and are thus known as “Fisher zeros”.

Our main result is that the Ising model has no Fisher zeros in a region of the complex plane that contains the entire interval  $B$  on the positive real line where correlation decay holds. Our analysis crucially exploits the correlation decay property in order to understand the Fisher zeros. Thus, in the particular case of the zero field Ising model, we are able to establish a tight connection between correlation decay and the absence of zeros. Another potentially interesting aspect of this result is the use of algorithmic techniques associated with correlation decay (notably, Weitz’s algorithm [27]) to understand a classical concept in statistical physics.

We now proceed to formally describe our results. First we identify the range of the parameter  $\beta$  for which the Ising model is, in a certain sense, well-behaved on graphs of bounded degree  $\Delta$ .

► **Definition 1** (Correlation decay region). Given  $\Delta > 0$ , the *correlation decay region*  $B = B_\Delta$  for  $\beta$  is the interval  $(\frac{\Delta-2}{\Delta}, \frac{\Delta}{\Delta-2})$ .

The correlation decay region is very well studied in both physical and algorithmic contexts, and comes from a consideration of the behavior of the Gibbs measure on trees. In particular, it corresponds to those  $\beta$  for which there is exponential decay of correlations in the Gibbs measure on any finite subtree of the infinite  $\Delta$ -regular tree – a fact which has been used to

give a deterministic algorithm for approximating the partition function of the Ising model for such  $\beta$  [27, 29]. On the other hand, Sly and Sun [25] have shown that for  $\beta > \frac{\Delta}{\Delta-2}$ , this approximation problem is NP-hard under randomized reductions. In statistical physics, the correlation decay region describes those  $\beta$  for which the definition of the Gibbs measure given by eq. (1) for finite graphs can be extended in a unique way to a Gibbs measure on the *infinite*  $\Delta$ -regular tree [9]; for this reason, the correlation decay region is also referred to as the *uniqueness region*.

As advertised earlier, our goal is to prove the existence of a region of the complex plane, containing  $B$ , which contains no Fisher zeros. We state this now as our main theorem.

► **Theorem 2.** *Fix any  $\Delta > 0$ . For any real  $\beta \in B := (\frac{\Delta-2}{\Delta}, \frac{\Delta}{\Delta-2})$ , there exists a  $\delta > 0$  such that for all  $\beta' \in \mathbb{C}$  with  $|\beta' - \beta| < \delta$ , the Ising partition function  $Z_G(\beta') \neq 0$  for all graphs  $G$  of maximum degree  $\Delta$ . Moreover the same holds even if  $G$  contains an arbitrary number of vertices pinned to  $+$  or  $-$  spins.*

► **Remarks.**

- (1) It is worth noting that the choice of  $\delta$  does not depend on the size of the graph, only on  $\Delta$  and  $\beta$ . In particular, given any  $\delta_1 > 0$ , one can choose  $\delta > 0$  such that, for all  $\beta'$  in a complex neighborhood of radius  $\delta$  around the closed interval  $[\frac{\Delta-2}{\Delta} + \delta_1, \frac{\Delta}{\Delta-2} - \delta_1]$ ,  $Z_G(\beta')$  is non-zero for all graphs of degree at most  $\Delta$ .
- (2) For the case of the Ising model, the above theorem establishes a connection between the two notions of phase transition discussed above. Namely, for the zero-field Ising model, it shows that decay of correlations on the  $\Delta$ -regular tree also implies the absence of Fisher zeros for finite graphs of degree at most  $\Delta$ , and hence the analyticity of the free energy for appropriate infinite graphs (i.e., those of maximum degree at most  $\Delta$  and of subexponential growth, such as regular lattices).

**Discussion.** To the best of our knowledge, the previous best general result on the Fisher zeros of the Ising model appears in the work of Barvinok and Soberón [6], who showed that  $Z_G(\beta)$  is non-zero if  $|\beta - 1| < c/\Delta$ , where  $\Delta$  is the maximum degree of  $G$ , and  $c$  can be chosen to be 0.34 (and as large as 0.45 if  $\Delta$  is large enough). While this result provides a disk around 1 in which there are no Fisher zeros, it cannot guarantee the absence of Fisher zeros in a neighborhood of the correlation decay region  $B$  (which would require at least that  $c \geq 2 - o_\Delta(1)$ ). Our Theorem 2 therefore strengthens this result to a neighborhood of the entire correlation decay region  $B$ .<sup>4</sup>

Our main theorem on Fisher zeros can also be combined with the techniques of Barvinok [3] and Patel and Regts [19] to give a new deterministic polynomial time approximation algorithm for the partition function of the ferromagnetic Ising model with zero field on graphs of degree at most  $\Delta$  when  $\beta \in (\frac{\Delta-2}{\Delta}, \frac{\Delta}{\Delta-2})$ . In particular, combining Theorem 2 with Lemmas 2.2.1 and 2.2.3 of [3] (see also the discussion at the bottom of page 27 therein) and the proof of Theorem 6.1 of [19], we obtain the following corollary:

► **Corollary 3.** *Fix a positive integer  $\Delta$  and  $\delta > 0$ . There exist positive constants  $\delta_1 > 0$  and  $c$  such that for any complex  $\beta$  with  $\Re(\beta) \in [\frac{\Delta-2}{\Delta} + \delta, \frac{\Delta}{\Delta-2} - \delta]$  and  $|\Im(\beta)| \leq \delta_1$ , the following is true. There exists an algorithm which, on input a graph  $G$  of degree at most  $\Delta$  on  $n$  vertices, and an accuracy parameter  $\varepsilon > 0$ , runs in time  $O(n/\varepsilon)^c$  and outputs  $\hat{Z}$  satisfying  $|\hat{Z} - Z_G(\beta)| \leq \varepsilon |Z_G(\beta)|$ .*

<sup>4</sup> Technically the results are incomparable in the sense that, while our results cover a much larger portion of the real line than that in [6], the diameter of the disk centered around 1 in the region of [6] may be larger than the radius guaranteed by our result.

For real  $\beta$  in the same range, a deterministic algorithm with the above properties, based on correlation decay, was already analyzed in [29]. However, our extension to complex values of the parameter is also interesting in light of the fact that algorithms for approximating the Ising partition function at complex values of the parameters have recently been studied in the context of classical simulation of restricted models of quantum computation [16].

Finally, we emphasize that in contrast to most other recent applications of Barvinok’s method (e.g., [19, 5, 6, 4, 14]), where the required results on the location of the roots of the associated partition function are derived without reference to correlation decay, the algorithmic version of correlation decay is crucial to our proof. Indeed, implicit in our proof is an analysis of Weitz’s celebrated correlation decay algorithm [27] (proposed originally for the independent set (or “hard core”) model, and analyzed by Zhang, Liang and Bai [29] for the Ising model in the case of real positive  $\beta \in B$ ) for the Ising model with *complex*  $\beta'$  close to  $\beta \in B$ . Thus, as mentioned earlier, our work shows that Weitz’s algorithm can be viewed as a bridge between the “decay of correlations” and “analyticity of free energy” views of phase transitions. We note also that our work is close in spirit to recent work of Peters and Regts [20] (see also [7]), who employ correlation decay in the hard core model to prove stability results for the hard core partition function.

## 2 Outline of proof

We fix  $\Delta$  to be the maximum degree throughout, and let  $d = \Delta - 1$ . Let  $G$  be any graph of maximum degree  $\Delta$ . Our starting point is a recursive criterion that guarantees that the partition function  $Z_G(\beta)$  has no zeros. For any non-isolated vertex  $v$  of  $G$ , let  $Z_{G,v}^+(\beta)$  (respectively,  $Z_{G,v}^-(\beta)$ ) be the contribution to  $Z_G(\beta)$  from configurations with  $\sigma(v) = +$  (respectively, with  $\sigma(v) = -$ ), so that  $Z_G(\beta) = Z_{G,v}^+(\beta) + Z_{G,v}^-(\beta)$ . Define also the ratio  $R_{G,v}(\beta) := \frac{Z_{G,v}^+(\beta)}{Z_{G,v}^-(\beta)}$ . Now note that  $Z_{G,v}^+(\beta)$  and  $Z_{G,v}^-(\beta)$  can be seen as Ising partition functions defined on the same graph  $G$  with the vertex  $v$  *pinned* to the appropriate spin; i.e., they are partition functions defined on a graph with one less unpinned vertex. Thus we may assume recursively that neither  $Z_{G,v}^+(\beta)$  nor  $Z_{G,v}^-(\beta)$  vanishes. Under this assumption, the condition  $Z_G(\beta) \neq 0$  is equivalent to  $R_{G,v}(\beta) \neq -1$ .

Our next ingredient is a formal recurrence, due to Weitz [27], for computing ratios such as  $R_{G,v}(\beta)$  in two-state spin systems. This recurrence is based on the so-called “tree of self-avoiding walks” (or “SAW tree”) in  $G$ , rooted at  $v$ , with appropriate boundary conditions (i.e., initial inputs, or fixed values at the leaves of the tree). Weitz’s recurrence has been used in the development of several approximate counting algorithms based on decay of correlations (see, e.g., [27, 29, 13, 24]). We now state a precise version of Weitz’s result that is tailored to our application.

► **Lemma 4.** *Let  $G$  be a graph of maximum degree  $\Delta = d + 1$ , with some vertices possibly pinned to spins “+” or “−”. Given  $\beta \in \mathbb{C}$ , define  $h_\beta(x) := \frac{\beta+x}{\beta x+1}$ . For integers  $k \geq 0$  and  $s$ , define the maps*

$$F_{\beta,k,s}(\mathbf{x}) := \beta^s \prod_{i=1}^k h_\beta(x_i).$$

*Then, the ratio  $R_{G,v}(\beta)$  can be obtained by iteratively applying a sequence of multivariate maps of the form  $F_{\beta,k,s}(\mathbf{x})$  such that, in all but the final application, one has  $1 \leq k + |s| \leq d$ , while for the final application one has  $1 \leq k + |s| \leq \Delta$ , and any initial input to these maps is  $x_i = 1$ .*

For completeness we sketch a proof of Lemma 4 at the end of this section.

Returning now to the condition  $R_{G,v}(\beta) \neq -1$  derived above, we see from Lemma 4 that a sufficient condition for the absence of zeros of  $Z_G(\beta)$  is the existence of a subset  $D \subseteq \mathbb{C}$  such that  $1 \in D$ ,  $-1 \notin D$ , and  $D$  is closed under the recurrence  $F_{\beta,k,s}$  (in the sense that  $F_{\beta,k,s}$  maps  $D^k$  into  $D$ ). These properties guarantee that the recurrence, with initial inputs 1 at the leaves, can never yield the value  $-1$ , and hence that  $R_{G,v}(\beta) \neq -1$ , so  $Z_G(\beta) \neq 0$ . The main technical content of this paper is to prove, under the conditions on  $\beta$  stated in Theorem 2, the existence of such a set  $D$ , a result which we formally state as follows.

► **Theorem 5.** *Fix a degree  $\Delta = d + 1$ . For any  $\beta \in (\frac{\Delta-2}{\Delta}, \frac{\Delta}{\Delta-2})$ , there exists  $\delta_\beta > 0$  such that, for any  $\beta' \in \mathbb{C}$  with  $|\beta' - \beta| \leq \delta_\beta$ , there exists a set  $D \subseteq \mathbb{C}$  with  $1 \in D$ ,  $-1 \notin D$ , and*

- (a)  $F_{\beta',k,s}(D^k) \subseteq D$  for integers  $k \geq 0$  and  $s$  such that  $1 \leq k + |s| \leq d$ ;
- (b)  $-1 \notin F_{\beta',k,s}(D^k)$  for integers  $k \geq 0$  and  $s$  such that  $1 \leq k + |s| \leq \Delta$ .

At the end of this section, we spell out the details of how to combine Lemma 4 and Theorem 5 into a proof of our main result, Theorem 2.

The main technical task of the paper is to prove Theorem 5. We briefly sketch our approach in this extended abstract; the details can be found in the full version [15]. The first step is to simplify the problem by working with a *univariate* version of the recurrence  $F_{\beta,k,s}$  defined in Lemma 4. The univariate version is defined as  $f_{\beta,k,s}(x) := \beta^s h_\beta(x)^k$ , and we can show that it satisfies  $F_\beta(D^k) = f_\beta(D)$  for any set  $D$  such that  $C := \log(h_\beta(D))$  is convex in the complex plane. (Henceforth we will drop the subscripts  $k, s$  for simplicity.) This means that the set  $D$  we seek in Theorem 5 should be the image of a convex set  $C$  under the map  $\log \circ h_\beta$ .

Next, to enable us to exploit the fact that  $\beta$  is in the correlation decay interval  $B = (\frac{\Delta-2}{\Delta}, \frac{\Delta}{\Delta-2})$ , we further modify the univariate recurrence to  $f_\beta^\varphi := \varphi \circ f_\beta \circ \varphi^{-1}$ , where  $\varphi(x) := \log x$ . This is an example of the use of a so-called “potential” function  $\varphi$  in order to smooth a recurrence, as has been useful in several correlation decay arguments. The key point here is that, when  $\beta \in B$ ,  $f_\beta^\varphi$  (unlike  $f_\beta$  itself) is actually a uniform *contraction* on an appropriate domain in  $\mathbb{C}$ ; hence we can conclude that  $f_\beta^\varphi(S) \subseteq S$  for “nice” sets  $S$  (i.e.,  $S$  that are convex and symmetric around the origin). Since the condition  $f_\beta(D) \subseteq D$  is equivalent to  $f_\beta^\varphi(\log D) \subseteq \log D$ , this imposes the further constraint that  $\log D$  be a “nice” set.

Putting together the constraints in the previous two paragraphs, we need to construct a suitable convex set  $C$  whose image  $\log(h_\beta^{-1}(\exp(C)))$  is nice; our set  $D$  in Theorem 5 will then be defined as  $h_\beta^{-1}(\exp(C))$  (and this set must include 1 and exclude  $-1$ ). This turns out to be hard to achieve directly due to the complexity of the map  $p := \log \circ h_\beta^{-1} \circ \exp$ . However, we are able to show that one can instead work with a (non-analytic) approximation of  $p$  under which the image of a natural convex  $C$  becomes a nice (in fact, rectangular) set. Moreover, this holds even for complex  $\beta$  that are sufficiently close to the region  $B$ . This fact then allows us to push through the analysis and arrive at a proof of Theorem 5.

We conclude this overview with the proofs of Lemma 4 and Theorem 2 promised earlier. The proof of our main technical result, Theorem 5, can be found in the full version [15].

**Proof of Lemma 4 (Sketch).** This description is exactly the same as the version of Weitz’s result used for the Ising model in, e.g., [24] and [29], except that there, only the maps  $F_{\beta,k,0}$  for  $1 \leq k \leq d$  (with at most one final application with  $k = \Delta$ ) are used, and the initial values come from the set  $\{0, \infty\}$ ; these initial values are the values of the ratio for single leaf vertices in the SAW tree pinned to  $-$  and  $+$  respectively, and the maps  $F_{\beta,k,0}$  describe how to combine the ratios from  $k$  subtrees. The version in the lemma follows by

noticing that  $h_\beta(1) = 1, h_\beta(0) = \beta$  and  $h_\beta(\infty) = 1/\beta$ , so that  $F_{\beta,k,0}$  applied to a vector  $\mathbf{x}$  with  $k$  coordinates,  $s_1$  of which are set to 0 and  $s_2$  to  $\infty$ , produces the same output as  $F_{\beta,k-|s_1-s_2|,s_1-s_2}$  applied to the vector  $\mathbf{x}'$  of  $k - |s_1 - s_2|$  coordinates obtained from  $\mathbf{x}$  by removing the 0 and  $\infty$  entries, and then appending  $s_1 + s_2 - |s_1 - s_2|$  entries which are 1. ◀

**Proof of Theorem 2.** As indicated earlier, the induction is on the number of unpinned vertices,  $n$ , of  $G$ . For the base case  $n = 0$ ,  $Z_G(\beta) = \beta^k$ , where  $k$  is the number of pairs of adjacent vertices in  $G$  that are pinned to different spins. Therefore,  $Z_G(\beta) \neq 0$  unless  $\beta = 0$ . Next suppose that for some positive integer  $t$ , it holds that for every  $\beta \in B$ , there exists a  $\delta > 0$  such that for all  $\beta' \in \mathbb{C}$  with  $|\beta' - \beta| < \delta$ ,  $Z_G(\beta') \neq 0$  for all graphs  $G$  of maximum degree  $\Delta$  with at most  $t$  unpinned vertices. Now, let  $G'$  be any graph of the same maximum degree with  $t + 1$  unpinned vertices. Fix any non-isolated vertex  $v$  in  $G'$ , and let  $Z_{G',v}^+(\beta'), Z_{G',v}^-(\beta')$  be the contributions to the partition function from configurations with  $\sigma(v) = +, \sigma(v) = -$ , respectively. By the induction hypothesis, we know that  $Z_{G',v}^+(\beta') \neq 0, Z_{G',v}^-(\beta') \neq 0$  as they are exactly the Ising partition function defined on the same graph  $G'$  with the vertex  $v$  pinned (thus reducing the number of unpinned vertices to  $t$ ). Further, Lemma 4 implies that  $R_{G',v}(\beta') = \frac{Z_{G',v}^+(\beta')}{Z_{G',v}^-(\beta')}$  can be computed by iteratively applying a sequence of maps of the form  $F_{\beta',k,s}$  for  $1 \leq k + |s| \leq d$ , followed by at most one application where  $k + |s| = \Delta$ , starting with initial values of 1. Part (a) of Theorem 5 then implies that the outputs of all except possibly the final application remain in the set  $D$  defined in that theorem, and part (b) of the theorem implies that the final output, which is equal to  $R_{G',v}(\beta)$  by Lemma 4, is not  $-1$ . Since  $Z_{G',v}^+(\beta')$  and  $Z_{G',v}^-(\beta')$  are non-zero, this implies that  $Z_{G'}(\beta') \neq 0$ , completing the induction. ◀

## Abstract

We define a model of size- $S$   $R$ -way branching programs with oracles that can make up to  $S$  distinct oracle queries over all of their possible inputs, and generalize a lower bound proof strategy of Beame [SICOMP 1991] to apply in the case of random oracles. Through a series of succinct reductions, we prove that the following problems require randomized algorithms where the product of running time and space usage must be  $\Omega(n^2/\text{poly}(\log n))$  to obtain correct answers with constant nonzero probability, even for algorithms with constant-time access to a uniform random oracle (i.e., a uniform random hash function):

- Given an unordered list  $L$  of  $n$  elements from  $[n]$  (possibly with repeated elements), output  $[n] - L$ .
- Counting satisfying assignments to a given 2CNF, and printing any satisfying assignment to a given 3CNF. Note it is a major open problem to prove a time-space product lower bound of  $n^{2-o(1)}$  for the *decision version* of SAT, or even for the decision problem Majority-SAT.
- Printing the truth table of a given CNF formula  $F$  with  $k$  inputs and  $n = O(2^k)$  clauses, with values printed in lexicographical order (i.e.,  $F(0^k), F(0^{k-1}1), \dots, F(1^k)$ ). Thus we have a  $4^k/\text{poly}(k)$  lower bound in this case.
- Evaluating a circuit with  $n$  inputs and  $O(n)$  outputs.

As our lower bounds are based on  $R$ -way branching programs, they hold for any reasonable model of computation (e.g. log-word RAMs and multitape Turing machines).

**2012 ACM Subject Classification** Theory of computation → Circuit complexity, Theory of computation → Oracles and decision trees

## 1 Introduction

Infamously little progress has been made towards the resolution of P vs NP. It is still open whether there are linear time algorithms for solving generic NP-hard problems such as CIRCUIT SAT although for certain NP-hard problems, non-linear lower bounds on multitape Turing machines are known [23, 18]. In fact it remains open whether CIRCUIT SAT has a generic algorithm in a random-access machine model running in  $O(n^{1.9999})$  time and  $O(\log n)$  additional space beyond the input.<sup>2</sup> Currently the best known time lower bound for solving SAT in  $O(\log n)$  space is  $n^{2 \cos(\pi/7) - o(1)} \geq n^{1.801}$  ([27, 14], building on [17]).

Other prominent work has used combinatorial methods to prove time-space lower bounds for decision problems in P [10, 3, 12, 11, 25, 4, 22]. For general random-access models of computation, modest super-linear (e.g.  $n \log n$ -type) time lower bounds for explicit problems in P are known when the space is restricted to  $n^{.99}$  or less (for randomized models as well [11, 22]). Thus for such problems, the time-space product can be lower-bounded to nearly  $\Omega(n^2)$  when the space is close to  $n$ ; however, when the space is  $O(\log n)$ , the best time lower bound against RAMs appears to be the aforementioned  $n^{1.801}$  bound for SAT.

All the above cited lower bounds are for *decision* problems. For example, the SAT lower bound applies to algorithms which are only required to determine if a given formula is satisfiable or not. There are several well-studied extensions of SAT which are *function* problems, outputting multiple bits:

1. **How difficult is it to *print* a satisfying assignment, when one exists?** For 3CNF formulas, call this problem PRINT-3SAT. Of course, PRINT-3SAT has a polynomial-time algorithm if and only if P = NP, but perhaps it is easier to prove concrete lower bounds for it, compared to the decision version.
2. **How difficult is #2SAT, in which we *count* the number of satisfying assignments to a 2CNF?** Since #2SAT is #P-complete, the problem should intuitively be harder to solve than 3SAT.
3. **How difficult is it to print the truth table of a CNF?** Given a CNF formula  $F$  of  $n$  variables and up to  $2^n$  size,  $F$  can be evaluated on all possible  $2^n$  inputs in  $4^n \cdot \text{poly}(n)$  time and  $\text{poly}(n)$  space (using a linear-time, log-space algorithm for evaluating a CNF on a given input). Call this problem TTPRINT (for truth-table printing).

**Is this quadratic running time optimal?** This question is considerable interest for SAT algorithms; for some circuit classes, the only known SAT algorithms beating exhaustive search (e.g., [28]) proceed by reducing SAT to a quick truth table evaluation.

In this paper, we prove that for essentially any generic randomized computation model using  $n^{o(1)}$  space but having  $O(1)$ -access to a random oracle (i.e., a random string of  $2^{n^{o(1)}}$  bits), the above three problems all require nearly quadratic time to compute with nonzero constant probability. We revisit a quadratic time-space lower bound of Beame [8] for the UNIQUE ELEMENTS problem, show that his technique can be used to prove an analogous lower bound for an even “simpler” problem that we call NON-OCCURRING ELEMENTS, extend the lower bound’s reach to include random oracles, and give succinct reductions from NON-OCCURRING ELEMENTS to the above problems, proving hardness for them.

<sup>2</sup> Note that for multitape Turing machines, such lower bounds are not hard to show [24]. However, these lower bounds rely on the sequential access of Turing machines on tapes; once random access is allowed, these lower bounds break.

### Lower Bound for Non-Occurring Elements

We define the NON-OCCURRING ELEMENTS problem to be: *given an unordered list  $L$  of  $n$  elements from  $[n]$ , output  $[n] - L$  in any order.*<sup>3</sup> That is, we simply wish to output the elements that do not occur in the given list.

Observe it is easy to get a space- $O(s(n))$  algorithm on the  $\log(n)$ -word RAM for computing NOE with running time  $O(n^2/s(n))$ . Start by partitioning  $[n]$  into  $n/s(n)$  blocks of  $s(n)$  elements each. Do  $n/s(n)$  passes over  $L$ , where in the  $i$ th pass, check which numbers in the  $i$ th block do not occur in  $L$ : this can be done in  $s(n)$  bits of space by simply keeping a bit vector. Hence we would say NOE has *time-space product*  $O(n^2)$  for all  $n \leq t(n) \leq n^2$ .

Our first main theorem builds on the aforementioned work of Beame to show that this time-space product is optimal, even when programs have access to a random oracle and can err with high probability.

► **Theorem 1.** *For all  $p \in (0, 1]$ , every random oracle  $n$ -way branching program family of size  $2^{s(n)}$  and height  $t(n)$  computing NOE with success probability  $p$  has  $t(n) \cdot s(n) \geq \Omega(n^2)$  for all sufficiently large  $n$ .*

(Note, we need to formally define what a “random oracle branching program” even means. For now, think of it as a non-uniform version of space-bounded computation with constant-time access to a uniform random  $2^{s(n)}$ -bit string. The preliminaries in Section 2 give full detailed definitions.) Using a standard translation of word-RAMs into branching programs, it follows that every probabilistic word-RAM with a random oracle and wordsize  $\log(n)$  computing NOE in time  $t(n)$  and space  $s(n)$  must have  $t(n) \cdot s(n) \geq \Omega(n^2)$  in order to have any non-zero constant success probability.

### Lower Bound for Sorting and Circuit Evaluation

Informally, we say that a reduction from a problem  $A$  to a problem  $B$  is *succinct* if any particular output bit of the reduction can be computed in  $\text{poly}(\log n)$  time with random access to the input. (Definitions can be found in the Preliminaries.) As a warm-up, in Theorem 24 of the paper, we use a simple succinct reduction to obtain an analogous random oracle lower bound for the problem of sorting  $n$  unordered elements from  $[n]$ , which we call SORT. (A tight lower bound without random oracles was proved by Beame [8].) The sorting lower bound is combined with another simple reduction to obtain an analogous lower bound for evaluating a circuits. Let FCIRCEVAL be the problem: *Given a circuit of size  $n$  with at most  $n$  inputs (all fixed to 0-1 values) and at most  $n$  outputs, determine its output.* The decision version of FCIRCEVAL is well-known to be P-complete.

► **Theorem 2.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of FCIRCEVAL is at least  $\Omega(n^2/\log^k n)$ .*

As in the case of NOE, Theorem 2 implies analogous time-space lower bounds on probabilistic random access machines computing FCIRCEVAL. We note that without the “random oracle” modifier, Theorem 2 is almost certainly folklore; it follows from our simple reduction and the  $\tilde{\Omega}(n^2)$  time-space product lower bound on sorting of Borodin and Cook [13].

<sup>3</sup> As usual, we define  $[n] := \{1, \dots, n\}$ .

### Lower Bound for Printing SAT Assignments

Any practical algorithm for Satisfiability would need to print satisfying assignments when they exist. We give a succinct reduction from Circuit Evaluation to the printing problem for 3SAT, proving a nearly-quadratic time lower bound in the  $n^{o(1)}$  space setting.

► **Theorem 3.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of PRINT-3SAT is at least  $\Omega(n^2/\log^k n)$ .*

### Lower Bound for Computing Truth Tables of CNFs

We show that the trivial algorithm for computing the truth table of a large CNF has optimal time-space product, even for randomized algorithms.

► **Theorem 4.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of TTPRINT for CNF formulas with  $n$  clauses and  $\log(n) + \log \log(n)$  many variables is at least  $\Omega(n^2/\log^k n)$ .*

The proof of Theorem 4 works by giving a succinct reduction from NOE to TTPRINT, constructing a CNF whose truth table encodes (at the bit level) the non-occurring elements of a given list.

### Lower Bound for #2SAT

Finally, we give a succinct reduction from the truth table problem TTPRINT for CNF formulas to *counting* SAT assignments to a given 2CNF, implying an analogous lower bound for #2SAT. In particular, we encode the output 2CNF in such a way that the bits of its number of satisfying assignments encode the *value* of the original CNF on various inputs.

► **Theorem 5.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of #2SAT is at least  $\Omega(n^2/\log^k(n))$ .*

### Lower Bounds Beyond?

Finally, we note that the random oracle model we consider may not be the most general possible one. We could also consider oracles where the queries are on write-only storage that does not count towards the space bound. Although such oracles are sometimes used in space-bounded complexity ([20]), it is hard for us to see how such queries could help in the *random* oracle setting. In the paper’s conclusion (Section 5) we outline how to coherently define this sort of oracle access in branching programs, and conjecture that our lower bounds also hold in this “extended oracle” model.

## 1.1 Intuition for the NOE Lower Bound

Our proof of the NOE lower bound (Theorem 1) starts from Beame’s lower bound for UNIQUE ELEMENTS [8]. We generalize his proof, and use our generalization to show that any function problem satisfying two basic properties has a non-trivial branching program lower bound, even when the branching program has access to a huge number of random bits.

► **Theorem 6.** *Let  $\{f_n : \Sigma_n^n \rightarrow \Sigma_n^*\}$  be a family of functions,  $\{D_n\}$  be a family of distributions, and let  $g : \mathbb{N} \rightarrow \mathbb{N}$  satisfy the following properties.*

1. [***f* typically has “long” outputs**]. For all  $\varepsilon > 0$ , there is an  $n_0 \geq 0$  such that for all  $n > n_0$ , there is a  $\delta > 0$  such that

$$\Pr_{x \in D_n} [|f_n(x)| > \delta g(n)] > 1 - \varepsilon.$$

2. [**Short random-oracle branching programs have low probability of printing long substrings of *f***]. Let  $U_n$  be the uniform distribution over  $\Sigma_n$  and let  $N \leq 2^{s(n)}$  be an integer. There is an  $\varepsilon > 0$  such that for all  $\Sigma_n$ -way branching programs  $P$  of height at most  $n/4$ ,

$$\Pr_{(x,r) \sim D_n \times U_n^N} [(P(xr) \text{ is a substring of } f_n(x)) \wedge (|P(xr)| \geq m)] < e^{-\varepsilon m}.$$

Then, for all  $n > n_0$  and  $p \in (0, 1]$ , and for every random oracle  $\Sigma_n$ -way branching program of size  $2^{s(n)}$  and height  $t(n)$  computing  $f_n$  with success probability at least  $p$  on inputs drawn from  $D_n$ , it must be that  $t(n) \cdot s(n) \geq \Omega(n g(n))$ .

The intuition behind Theorem 6 is that, if a function  $f$  on input  $x$  requires a long output (Property 1), then some (possibly many) subprograms of an efficient branching program  $P$  computing  $f$  will need to produce somewhat-long output. But by Property 2, this is “hard” for all short subprograms even with a random oracle: they have low probability of correctly answering a large fraction of  $f$ .

Beame’s original lower bound for UNIQUE ELEMENTS [8] follows a similar high-level pattern (as we review in Theorem 21). One of our insights is that the NON-OCCURRING ELEMENTS problem satisfies stronger versions of the properties used in his proof for UNIQUE ELEMENTS; these stronger properties give us extra room to play with the computational model in our lower bound against NON-OCCURRING ELEMENTS. Another insight is that the conditioning on uniform random input in his argument can be modified to accommodate very long auxiliary random inputs. Together, this allows us to extend the lower bounds to models equipped with random oracles.

### Why Random Oracles?

Let us give one comment on the model itself. One may wonder why it is even necessary to add random oracles to branching programs (BPs), which are a *non-uniform* model of computation. Can’t we use Adleman’s argument [5] to show that the randomness can be hard-coded in the non-uniform model, similarly to how  $\text{BPP} \subset \text{P/poly}$ ?

Indeed, a random-oracle BP can always be simulated by a deterministic BP; however, the running time of the deterministic BP increases by a multiplicative factor of  $\Omega(n)$  (hence, a time lower bound of  $\Theta(n^2)$  on a deterministic BP says nothing *a priori* about randomized BPs). Given a randomized BP for a decision problem with constant success probability  $1/2 < p < 1$ , it is derandomized by taking  $\Omega(n)$  copies of the BP (with independent random bits filled in each copy), and computing the majority value of the BP outputs. The  $\Omega(n)$  copies are needed because one needs to guarantee correctness over all  $2^n$  possible inputs: this increases the running time by an  $\Omega(n)$  multiplicative factor. In our case, the situation is even more complicated because we are concerned with function problems. The upshot is that  $n^2$  lower bounds on random-oracle BPs give strictly more information than a typical randomized model with one-way access to random bits, or a deterministic model.

Another randomized branching program model considered in prior work (e.g., [9]) is to define a randomized time- $T$  space- $S$  branching program to be a *distribution*  $\mathcal{D}$  of deterministic time- $T$  and space- $S$  BPs. Such a model is said to compute a function  $f$  with error  $\varepsilon$  if, on

every input  $x$ , a randomly drawn BP from  $\mathcal{D}$  outputs  $f(x)$  with probability at least  $1 - \varepsilon$ . This model looks even more general than our random oracle model, since no resources are spent accessing randomness (the randomness is “drawn” prior to any computation, then fixed for free). An anonymous reviewer for ITCS observed that our time-space lower bound for NON-OCCURRING ELEMENTS also holds in this BP model. The idea is to apply Yao’s principle [29] which reduces worst-case lower bounds for distributions of BPs to finding a hard distribution of inputs for deterministic BPs, and to verify that our proofs essentially show that the uniform distribution is hard for deterministic BPs.

## 2 Preliminaries

We assume basic familiarity with computational complexity [5]. Here we recall (and introduce) various computational models and notations needed in the paper.

All of our lower bounds are on the product of time and space for various problems. For clarity, we define the time-space product as follows.

► **Definition 7.** Let  $f$  be a function. We say that *the time-space product of  $f$  is at least  $b(n)$*  if for every algorithm running in  $t(n)$  time and  $s(n)$  space for  $f$ , it must be the case that  $t(n) \cdot s(n) \geq \Omega(b(n))$ .

### Random Access Machines With Oracles

For this work, we consider random access machines (RAMs) with access to an oracle and a write-only output tape. More precisely, our RAMs can only append new characters to the end of their output tape.

► **Definition 8.** Let  $O$  be a language over a finite alphabet. An **oracle RAM**  $M^O$  is a random access machine with an additional *oracle tape*. During a time step, in addition to any normal RAM operations, an oracle RAM can read or write a character to the oracle tape, can move the oracle tape head left or right, or can query the oracle with the contents of the tape to obtain a uniform random bit. Additionally,  $M^O$  has a write-only output tape to which it can append a character in any step.

### R-Way Branching Programs With Oracles and Output

Our lower bounds for NON-OCCURRING ELEMENTS (Theorem 1) will be against a generalization of branching programs with a (large) alphabet of size  $R$ , often called  $R$ -way branching programs [13]. We recall the definition here.

► **Definition 9.** Let  $R \geq 2$  be an integer. An  **$R$ -way branching program** with  $n$  inputs  $x_1, \dots, x_n$  is a directed acyclic graph with one source node in which every non-sink node has out-degree  $R$ . Every non-sink node is labeled with an index  $i \in [n]$  corresponding to an input variable, and each edge is labeled with an element of  $[R]$  such that no edge  $(u, v)$  and  $(u, w)$  where  $v \neq w$  share a label. Additionally, each vertex  $v$  is labeled with an instruction to print a value  $p(v)$  (which may be empty). The **height** of an  $R$ -way branching program  $P$  is the length of the longest path in its graph, and the **size** is the number of vertices. The **computation path of  $P$  on input  $x$**  is the unique path  $\pi = (v_0, v_1), (v_1, v_2), \dots, (v_{k-1}, v_k)$  such that  $v_0$  is the source node,  $v_k$  is a sink node, and for all  $i \in \{0, \dots, k-1\}$ , if vertex  $v_i$  is labeled  $j$ , then the label on  $(v_i, v_{i+1})$  is the value of  $x_j$ . The **output of  $P$  on input  $x$** , denoted as  $P(x)$ , is the concatenation of the values printed by the vertices along the computation path of  $P$  on input  $x$ , i.e.,  $p(v_0)p(v_1) \cdots p(v_k)$ .

Let  $\Sigma$  be a finite alphabet. For notational convenience, we call a  $P$  a  $\Sigma$ -way branching program if  $P$  is a  $|\Sigma|$ -way branching program with edges labeled with elements of  $\Sigma$  instead of  $[|\Sigma|]$ .

► **Definition 10.** A function  $f : \Sigma^* \rightarrow \Sigma^*$  has a  $\Sigma$ -way branching programs of height  $t(n)$  and size  $S(n)$  if for all  $n \geq 0$ , there is a  $\Sigma$ -way branching program  $P_n$  of height  $t(n)$  and size  $S(n)$  such that for all  $x \in \Sigma^n$ ,  $P_n(x) = f(x)$ .

We study a natural generalization of  $R$ -way branching programs with oracles whose queries count towards the space bound. This is a natural set-up for the random oracle setting, where random oracles model truly random hash functions. Let  $O : \Sigma^* \rightarrow \{0, 1\}$  in the following.

► **Definition 11.** An  $O$ -oracle  $R$ -way branching program with  $n$  inputs is an  $R$ -way branching program with the following additional properties. Each vertex is labeled with either a *variable index*  $i \in [n]$  or with a string  $q_j \in \{0, 1\}^*$  (where  $j$  is an integer ranging from 1 to the number of vertices in the program); we call the latter  $Q$ -vertices (for “Query”). All  $Q$ -vertices have two outgoing arcs, labeled with the two possible query answers *yes* or *no* (i.e., 1 or 0). Computation on an  $O$ -oracle branching program is defined analogously to usual branching programs, with the following extra rule for  $Q$ -vertices. Each time a  $Q$ -vertex  $v$  is reached during a computation, the outgoing *yes* (i.e., 1) edge of  $v$  is taken in the computation path if and only if the label  $q_j$  of  $v$  satisfies  $O(q_j) = 1$ .

► **Remark.** Note that in the above definition, the oracle queries could be strings of *arbitrary* length, but in a size- $S$  branching program we are only allowed  $S$  possible distinct oracle queries over all possible inputs. So the above definition is more general than the condition that “oracle queries count towards the space bound”. In the random oracle setting, this distinction will make little difference; we might as well think of the query strings as being of length about  $\log_2(S)$ .

It is natural to augment branching programs with oracles. Barrington and McKenzie [6], motivated by an approach to proving  $\text{NC}^1 \neq \text{P}$ , defined an oracle branching program model in terms of finite automata, where instead of branching on individual input bits, the program can branch on (in principle) all possible  $n$ -bit inputs, corresponding to oracle queries on the input. The usual branching program model is captured in their model by a branching program with an oracle for the predicate  $\text{BIT}(x, i)$  which returns the  $i$ th bit of the input  $x$ . They proved exponential size lower bounds for branching programs with certain weak oracles. Our oracle model is designed to give a natural correspondence between  $O$ -oracle  $R$ -way branching programs and word RAMs with wordsize  $\log(R)$  and oracle access to  $O$ .

It is helpful to think of oracle branching programs as simply branching programs *which receive the oracle as part of their input*. The following proposition formalizes this:

► **Proposition 2.1.** Let  $P^O$  be an  $O$ -oracle  $\Sigma$ -way branching program with  $n$  inputs, height  $T$ , and size  $S$ , and let  $q_1, \dots, q_m$  be the set of all possible oracle queries appearing at  $Q$ -vertices of  $P^O$ . There is a  $\Sigma$ -way branching program  $P'$  of height  $T$  and size  $S$  such that for all  $x \in \Sigma^n$ ,  $P^O(x) = P'(xy)$ , where  $y = O(q_1), \dots, O(q_m)$ .

**Proof.** The branching program  $P'$  is simply a relabeling of  $P$  in which every  $Q$ -vertex with label  $q_j$  is instead labeled by the variable index  $n + j$ . ◀

### Random Oracles

We will ultimately study  $R$ -way branching programs with random oracles. All of our random oracles will have the form  $O : \Sigma^* \rightarrow \Sigma$  for a finite alphabet  $\Sigma$ . Thus we define random oracles as a random elements of the set  $(\Sigma^* \rightarrow \Sigma)$ .

► **Definition 12.**  $\mathcal{D}_\Sigma$  is the uniform distribution over functions in  $(\Sigma^* \rightarrow \Sigma)$ . That is, drawing some  $f \sim \mathcal{D}_\Sigma$  is equivalent to, for each  $x \in \Sigma^*$ , choosing an element of  $\Sigma$  uniformly at random as  $f(x)$ .

We define computation with a random oracle branching program as follows.

► **Definition 13.** A function  $f$  has a **random oracle branching program family of height  $t(n)$  and size  $2^{s(n)}$  with success probability  $p \in (0, 1]$**  if there is a family of oracle branching programs  $\{P_n^O\}$  such that the height of each  $P_n^O$  is at most  $t(n)$ , the size of each  $P_n^O$  is at most  $2^{s(n)}$ , and for all inputs  $x$ ,

$$\Pr_{O \sim \mathcal{D}_\Sigma} \left[ P_{|x|}^O(x) = f(x) \right] \geq p.$$

Borodin and Cook show that  $R$ -way branching programs of height  $O(t(n))$  and size  $2^{O(s(n))}$  can simulate time- $t(n)$  space- $s(n)$  RAMs of wordsize  $\lceil \log_2 R \rceil$  [13]. We observe that their proof relativizes to allow oracle  $R$ -way branching programs to simulate oracle RAMs with wordsize  $\lceil \log_2 R \rceil$ .

► **Lemma 14.** *For every language  $O$  and oracle RAM  $M^O$  running in time  $t(n) \leq 2^{O(s(n))}$  and space  $s(n) \geq \log(n)$  with wordsize  $\log(\Sigma)$ , there is an oracle  $\Sigma$ -way branching program of height  $O(t(n))$  and size  $2^{O(s(n))}$  such that  $M^O(x) = P^O(x)$  for all inputs  $x$ .*

**Proof.** Without loss of generality, assume that at any step,  $M^O$  either accesses its input of length  $n$  by writing an index  $j \in [n]$  to an “access register”, or  $M^O$  queries  $O$  by writing the character  $Q$  to the access register. Let the configuration of machine  $M$  contain the description of the random access memory of  $M$ , the state of  $M$ , and the character currently being output, if any. For integer  $n \geq 1$ , define a graph  $G_n = (V_n, E_n)$  as follows. Let

$$V_n = \{(C, i, j) \mid C \text{ is a space-}s(n) \text{ configuration of } M, i \in \{0, 1, \dots, t(n)\}, j \in [n] \cup \{Q\}\}.$$

Our corresponding branching program, has each vertex  $(C, i, j)$  with  $j \in [n]$  labeled by  $j$ , and those  $(C, i, j)$  with  $j = Q$  are  $Q$ -vertices, which we label with a string  $q_j$  representing the content of the oracle tape of  $M^O$  in configuration  $C$ .

For  $j \in [n]$ , we put the edge  $((C_1, i, j), (C_2, i + 1, j')) \in E_n$  and label it with a string  $p$  if and only if  $M^O$  in configuration  $C_1$  would transition to configuration  $C_2$  given that in configuration  $C_1$ ,  $j$  is put in the access register,  $x_j = p$ , and  $j'$  is put in the access register in  $C_2$ . For configurations making an oracle query, put  $((C_1, i, Q), (C_2, i + 1, j')) \in E_n$  and label it with  $b \in \{0, 1\}$  if and only if  $M^O$  in configuration  $C_1$  would transition to configuration  $C_2$  given that in configuration  $C_1$ ,  $Q$  is written on the access register in  $C_1$ , the oracle query  $O$  returns  $b$ , and  $j'$  is written on access register in  $C_2$ .

Observe that  $|V_n| \leq 2^{O(s(n))} \cdot t(n) \cdot n \leq 2^{O(s(n))}$ , assuming the size of the tape alphabet and the number of states in the state machine of  $M^O$  are constants. Further observe that all paths in  $G_n$  have length at most  $t(n)$ , since every step in the path must be from some  $(C, i, j, k)$  to some  $(C', i + 1, j', k')$  and  $i, i + 1 \in [t(n)]$ . Finally, the oracle branching program  $P_n^O$  is defined to be the  $\Sigma$ -way branching program which is the induced subgraph of  $G_n$  containing all vertices reachable from  $v_0 = (C_0, 0, j_0)$  (with the labels prescribed above), where  $C_0$  is the initial configuration of  $M^O$ , and  $j_0$  is the index of the input read in the initial configuration. We see that by construction, for all  $x \in \Sigma^n$ ,  $P_n^O(x) = M^O(x)$ . ◀

Lemma 14 immediately implies that  $R$ -way branching program lower bounds provide analogous RAM lower bounds:

► **Proposition 2.2.** *Let  $f : \Sigma^* \rightarrow \Sigma^*$ . Suppose there is no  $R$ -way branching program family of height  $O(t(n))$  and size  $2^{O(s(n))}$  computing  $f$ . Then there is no RAM of wordsize  $\log(R)$  running in time  $t(n)$  with space  $s(n)$  computing  $f$ .*

*Furthermore, if there is no random oracle  $R$ -way branching program family of height  $O(t(n))$  and size  $2^{O(s(n))}$  computing  $f$  with success probability  $p$ , then there is no oracle RAM  $M^O$  with wordsize  $\log(R)$  such that for all  $x \in \Sigma^*$ ,  $\Pr_{O \sim \mathcal{D}_\Sigma}[M^O(x) = f(x)] \geq p$ .*

### Succinct Reductions

After our lower bound for NOE has been proved, we can apply very efficient reductions from NOE to extend the lower bound to other problems. For this purpose, we need some notation. In what follows, let  $f$ ,  $g$ , and  $\pi$  be functions from  $\Sigma^*$  to  $\Sigma^*$ .

► **Definition 15.** We say  $A$  has a  $t(n)$ -time reduction with blowup  $b(n)$  to  $B$  if there is a many-one reduction  $f$  reducing  $A$  to  $B$  such that  $|f(x)| \leq b(|x|)$ , and any character in the string  $f(x)$  can be computed by an algorithm running in time  $t(|x|)$ , given the index  $i = 1, \dots, |f(x)|$  of the character and random access to  $x$ .

Polylog-time reductions with quasi-linear blowup essentially preserve lower bounds for our branching program model, up to polylog factors. As the proof is relatively straightforward and our space is limited, the proof is omitted (but appears in the full version).

► **Lemma 16.** *Let  $\pi$  be an  $O(\log^k(n))$ -time reduction with blowup  $b(n)$  from  $f$  to  $g$ , and suppose  $g$  has an oracle branching program family  $\{P_n^O\}$  of height  $t(n)$  and size  $2^{s(n)}$  with success probability  $p > 0$ . Then  $f$  has an oracle branching program family  $\{Q_n^O\}$  of height  $t(b(n)) \log^k(n)$  and size  $2^{O(s(b(n)) + \log^k(n))}$  with success probability at least  $p$ .*

► **Definition 17.** The **random oracle  $\Sigma$ -way branching program time-space product of  $f$  is at least  $b(n)$**  if for every constant  $p \in (0, 1]$  and every random oracle branching program family of height  $t(n)$  time and size  $2^{s(n)}$  computing  $f$  with success probability  $p$ , it must be that  $t(n) \cdot s(n) \geq \Omega(b(n))$ .

We also note (proof omitted in this version) that lower bounds on time-space products are roughly preserved by polylog-time reductions of quasi-linear blowup.

► **Lemma 18.** *Let  $\pi$  be an  $O(\log^j(n))$ -time reduction with blowup  $O(n \log^j(n))$  from  $f$  to  $g$ . Suppose there are  $k$  and  $d$  such that the random oracle  $\Sigma$ -way branching program time-space product of  $f$  is at least  $\Omega(n^d) / \log^k(n)$ . Then there is some  $k'$  such that the random oracle  $\Sigma$ -way branching program time-space product of  $g$  is at least  $\Omega(n^d) / \log^{k'}(n)$ .*

For our #2SAT lower bound, we inspect a reduction of Hoffmeister, and note that it is succinct.

► **Theorem 19** ([19]). *There is a  $\log(n)$ -time reduction from #3-SAT to #2-SAT with blowup  $\tilde{O}(n)$ .*

Finally, our lower bound for FCIRCEVAL exploits the fact that there are highly efficient circuits for sorting  $n$  items from  $[n]$ .

► **Theorem 20** ([7, 26, 15]). *There is a  $k$  such that SORT has  $O(\log^k(n))$  time uniform circuits of size  $O(n \log^k(n))$ .*

### Other Related Work

Besides the work cited earlier, there is an extensive literature on proving  $\Omega(\tilde{n}^2)$  time-space product lower bounds for computing functions in generic word-RAM-like models (usually by proving a  $R$ -way branching program lower bound). The functions include matrix multiplication and the discrete Fourier transform [30], generalized string matching [1], bit-vector convolution and integer multiplication [2], universal hashing from  $n$  bits to  $O(n)$  bits [21], and computing various functions over sliding windows [9].

## 3 Lower Bound for NOE and Sorting

In this section, we abstract out key properties of the UNIQUE ELEMENTS problem that were used in Beame’s proof of an  $\Omega(n^2)$  time-space product lower bound for UNIQUE ELEMENTS against  $R$ -way branching programs [8]. This abstraction is useful in two ways. First, it allows us to easily prove lower bounds for other problems, by simply verifying that the key properties hold. Second, this level of abstraction helps us identify stronger generalizations of the lower bounds: average-case lower bounds against  $R$ -way branching programs and RAMs with random oracles.

### 3.1 Beame’s Method (Without Random Oracles)

To give intuition for our lower bound theorem for branching programs with random oracles (Theorem 6), we begin with a similar but weaker theorem, which is an abstraction of the technique used by Beame [8].

► **Theorem 21.** *Let  $\{f_n : \Sigma_n^n \rightarrow \Sigma_n^*\}$  be a family of functions,  $\{D_n\}$  be a family of distributions, and  $g : \mathbb{N} \rightarrow \mathbb{N}$  with the following properties.*

1. *[ $f$  typically has “long” outputs]. There is an  $\varepsilon > 0$  and  $\delta > 0$  such that*

$$\Pr_x [ |f(x)| > \delta g(n) ] > \varepsilon.$$

2. *[Short branching programs have low probability of printing long substrings of  $f$ ]. There is an  $\varepsilon > 0$  such that, for all  $\Sigma_n$ -way branching programs  $P$  of height at most  $n/4$ , and for all  $m \geq 1$ ,*

$$\Pr_{x \sim D} [ P(x) \text{ is a substring of } f(x) \wedge |P(x)| \geq m ] < e^{-\varepsilon m}.$$

*Then for  $n > n_0$ , every  $\Sigma_n$ -way branching program of size  $2^{s(n)}$  and height  $t(n)$  for  $f_n$  has  $s(n)t(n) \geq \Omega(ng(n))$ .*

Theorem 21 is motivated by the observation that if a function  $f$  on input  $x$  requires a long output (Property 1), then some (possibly many) subprograms of a branching program  $P$  computing  $f$  need to output a large fraction of  $f$ . But by Property 2, this is “hard” for all short subprograms: they have low probability of correctly answering a large fraction of  $f$ .

**Proof of Theorem 21.** Let  $f, D, g(n), \varepsilon, \delta$  be given as above. We prove the lower bound by demonstrating that any space- $S$  branching program  $P$  of sufficiently low height  $T$  has a nonzero probability of error on an input  $x$  drawn from  $D$ . To do this, we lower bound the probability of error by

$$\Pr_{x \sim D} [ |f(x)| > \delta g(n) ] - \Pr_{x \sim D} [ (|f(x)| > \delta g(n)) \wedge (P(x) = \text{NOE}(x)) ].$$

By Property 1 of the hypothesis, the first term is lower bounded by some constant  $\varepsilon > 0$ . The second term is at most  $\Pr_{x \sim D}[|P(x)| > \delta g(n)]$ , giving us an error probability of at least

$$\varepsilon - \Pr_{x \sim D}[|P(x)| > \delta g(n)].$$

We now upper-bound  $\Pr_{x \sim D}[|P(x)| > \delta g(n)]$ .

Without loss of generality, let  $P$  be layered, having size  $2^S$  in each layer, and height  $T$ . Partition  $P$  into  $4T/n$  layers of height  $n/4$ . By the pigeonhole principle, some layer must output at least  $ng(n)/4T$  elements of the output. There are at most  $2^S$  such subprograms in that layer, and the probability that  $P$  outputs at least  $\delta g(n)$  elements correctly is upper bounded by the probability that some layer outputs  $m := \delta ng(n)/4T$  elements correctly. As there are at most  $2^S$  such subprograms, by a union bound over property 2 of the hypothesis, the probability that  $P$  outputs all elements correctly is upper bounded by

$$2^S e^{-\varepsilon' \delta ng(n)/4T}$$

for some  $\varepsilon' > 0$ . This implies that the error probability of  $P$  on an input  $x$  drawn from  $D$  is at least  $\varepsilon - 2^S e^{-\varepsilon' \delta ng(n)/4T}$ .

Finally, we observe that if  $ST \leq \alpha \cdot ng(n)$  for sufficiently small  $\alpha > 0$ , the term  $2^S e^{-\varepsilon' \delta ng(n)/4T}$  becomes less than  $\varepsilon$ . Thus there is some input length  $n$  such that the probability of error for  $P$  on an input  $x$  drawn from  $D$  is nonzero. This implies that  $ST \geq \Omega(ng(n))$ . ◀

Beame's lower bound against UNIQUE ELEMENTS follows from showing that UNIQUE ELEMENTS has the properties required by Theorem 21. In particular, on random inputs UNIQUE ELEMENTS has long outputs with high probability, and it is difficult to guess even a small number of elements in the output of a random input, without seeing most of the input. Instead of reproving the UNIQUE ELEMENTS lower bound, we give a lower bound against the problem NON-OCCURRING ELEMENTS (NOE) defined in the introduction, as it admits a slightly easier analysis.

First let us verify Property 1 of Theorem 21, for the uniform distribution  $U_n^n$  and  $g(n) = n$ .

► **Proposition 3.1** (Property 1 holds for NOE). *For all  $\varepsilon > 0$ , there is a  $\delta > 0$  such that for sufficiently large  $n$ ,  $\Pr_{x \in U_n^n}[|NOE(x)| > \delta n] > 1 - \varepsilon$ .*

**Proof.** The desired bound reduces to a weak version of a well-known Balls-and-Bins bound (see [16, p.75] for a reference). In particular, when selecting  $m$  integers from  $[n]$  uniformly at random, the number  $Z$  of integers in  $[n]$  not selected (the non-occurring elements) is tightly concentrated around its mean:

$$\Pr[|Z - E[Z]| > t] \leq 2 \exp(-2t^2/m).$$

For our problem, we have  $n = m$  and  $E[Z] = n/e$ . Let  $c > 0$  be a parameter, and let  $t = cn$ . Therefore we have

$$\Pr[|Z - n/e| > cn] \leq 2 \exp(-2c^2n).$$

Complementing and rearranging variables, the inequality becomes  $\Pr[Z \geq n/e - cn] \geq 1 - 2 \exp(-2c^2n)$ . Finally, for any  $\varepsilon > 0$ , we can pick  $c \in (0, 1/e)$  such that  $\varepsilon > 2 \exp(-2c^2n)$  for sufficiently large  $n$ . Letting  $\delta \in (0, 1/e - c)$ , we have  $\Pr[Z > \delta n] > 1 - \varepsilon$ . ◀

Note that the bound of Proposition 3.1 is stronger than that required by Theorem 21. This will be useful for the extension to random oracles later (Theorem 6).

Next, we verify that for NON-OCCURRING ELEMENTS, Property 2 of Theorem 21 holds as well. In fact, we prove a stronger statement that allows for extra side randomness in the input (and therefore random oracle branching programs). This randomness can be ignored in the application of Theorem 21.

► **Proposition 3.2** (Property 2 holds for NOE). *For all integers  $n, k, N \geq 0$  and all branching programs  $P$  of height at most  $n/4$  computing a function with  $m$  outputs,*

$$\Pr_{x \sim U_n^N, r \sim U_k^N} [P(xr) \text{ outputs } m \text{ non-occurring elements of } x] < e^{-3m/4}.$$

**Proof.** The desired probability equals

$$\sum_{\text{paths } \pi \text{ in } P} \Pr_{x,r} [P(xr) \text{ follows } \pi] \cdot \Pr_{x,r} [P(xr) \text{ has } m \text{ NOEs of } x \mid P(xr) \text{ follows } \pi].$$

We show that for all such  $\pi$ ,

$$\Pr_{x,r} [P(xr) \text{ has } m \text{ non-occurring elements of } x \mid P(xr) \text{ follows } \pi] < e^{-3m/4}.$$

From this, it will follow that our desired probability is less than  $e^{-3m/4}$ .

For a path  $\pi$ , let  $q$  be the number of distinct variable queries to  $x$  and let  $q'$  be the number of distinct queries made to  $r$ . Notice that  $q + q' \leq n/4$ . To bound the probability that  $P(xr)$  has at least  $m$  non-occurring elements of  $x$ , given that  $P(xr)$  follows  $\pi$ , we simply count the relevant numerator and denominator.

The total number of  $xr$  that follow  $\pi$  is  $n^{n-q} \cdot k^{N-q'}$ : there are  $n - q$  unqueried inputs of  $x$ , and  $N - q'$  unqueried inputs of  $r$ . The total number of  $xr$  that follow  $\pi$ , and for which the  $m$  outputs of  $\pi$  are non-occurring elements of  $x$ , is at most  $(n - m)^{n-q} \cdot k^{N-q'}$ : since the  $m$  outputs are supposed to be non-occurring in  $x$ , none of the remaining  $n - q$  unqueried variables can take on any of the  $m$  outputs. By simple manipulation, we have

$$\frac{(n - m)^{n-q} k^{N-q'}}{n^{n-q} k^{N-q'}} = (1 - m/n)^{n-q} \leq (1 - m/n)^{n-n/4} \leq (1 - m/n)^{3n/4} \leq e^{-3m/4}.$$

This completes the proof. ◀

## 3.2 Lower Bounds With Random Oracles

We are now ready to present our main lower bound theorem against branching programs with random oracles.

► **Reminder of Theorem 6.** *Let  $\{f_n : \Sigma_n^n \rightarrow \Sigma_n^*\}$  be a family of functions,  $\{D_n\}$  be a family of distributions, and let  $g : \mathbb{N} \rightarrow \mathbb{N}$  satisfy the following properties.*

1. [***f* typically has “long” outputs**]. *For all  $\varepsilon > 0$ , there is an  $n_0 \geq 0$  such that for all  $n > n_0$ , there is a  $\delta > 0$  such that*

$$\Pr_{x \in D_n} [|f_n(x)| > \delta g(n)] > 1 - \varepsilon.$$

2. [***Short random-oracle branching programs have low probability of printing long substrings of f***]. *Let  $U_n$  be the uniform distribution over  $\Sigma_n$  and let  $N \leq 2^{s(n)}$  be an integer. There is an  $\varepsilon > 0$  such that for all  $\Sigma_n$ -way branching programs  $P$  of height at most  $n/4$ ,*

$$\Pr_{(x,r) \sim D_n \times U_n^N} [(P(xr) \text{ is a substring of } f_n(x)) \wedge (|P(xr)| \geq m)] < e^{-\varepsilon m}.$$

Then, for all  $n > n_0$  and  $p \in (0, 1]$ , and for every random oracle  $\Sigma_n$ -way branching program of size  $2^{s(n)}$  and height  $t(n)$  computing  $f_n$  with success probability at least  $p$  on inputs drawn from  $D_n$ , it must be that  $t(n) \cdot s(n) \geq \Omega(ng(n))$ .

Theorem 6 prescribes a general scheme for proving time-space product lower bounds against random oracle  $R$ -way branching programs, and thus against word RAMs with random oracles as well.

**Proof of Theorem 6.** The proof is similar to Theorem 21; we focus on highlighting what is different. First, we note that by Proposition 2.1, it is sufficient to demonstrate that for all  $n > n_0$  and  $p \in (0, 1]$ , and for every  $\Sigma_n$ -way branching program of size  $2^{s(n)}$  and height  $t(n)$  where  $\Pr_{x \sim D_n, r \sim U_n^N}[P(xr) = f_n(x)] > p$ , it must be that  $t(n) \cdot s(n) \geq \Omega(ng(n))$ .

As in Theorem 21, we establish the lower bound by demonstrating that every  $n/4$ -height branching program  $P$  has a large probability of error on an input  $x \sim D_n$ . In what follows, assume  $P$  successfully computes  $f_n(x)$  on inputs  $(x, r)$  drawn from  $D_n \times U_n^N$  with probability at least  $p$ . By property 1 of the hypothesis, letting  $\varepsilon := p/2$ , there is a  $\delta$  such that  $\Pr_{x \in D, r \sim U_n^N}[|f(x)| > \delta g(n)] > 1 - p/2$ .

Analogously as in the proof of Theorem 21, we lower bound the probability of error of  $P$  on  $D_n$  by

$$\Pr_{x \sim D}[|f(x)| > \delta g(n)] - \Pr_{x \sim D, r \sim U_n^N}[|f(x)| > \delta g(n) \wedge P(xr) = f(x)];$$

note that this probability is at least  $(1 - p/2) - \Pr_{x \sim D, r \sim U_n^N}[|P(xr)| > \delta g(n)]$ .

Applying a union bound over all  $2^{s(n)}$  subprograms of  $P$  as before, but substituting property 2 from the hypothesis, we determine by an analogous argument as Theorem 21 that  $\Pr_{x \sim D, r \sim U_n^N}[|P(xr)| > \delta g(n)]$  is at most  $2^{s(n)} e^{-\varepsilon \delta n g(n)/4t(n)}$ . Therefore the error probability of  $P$  on  $D_n$  is at least

$$1 - p/2 - 2^S e^{-\frac{\varepsilon \delta n g(n)}{4t(n)}}.$$

Finally, if we assume  $s(n)t(n) \leq \alpha n \cdot g(n)$  for all  $\alpha > 0$ , we can tune  $2^{s(n)} e^{-\varepsilon \delta n g(n)/(4t(n))}$  to be arbitrarily small: it is at most  $2^{s(n)} e^{-\varepsilon \delta s(n)/(4\alpha)}$ . Thus we can make the error probability for  $P$  on an input  $x$  drawn from  $D_n$  to be at least  $1 - 2p/3$ , implying that the success probability is at most  $2p/3 < p$ . This is a contradiction, so there is some  $\alpha > 0$  (depending on  $\delta, \varepsilon$ , and  $p$ ) such that  $s(n)t(n) \leq \alpha n \cdot g(n)$ . ◀

► **Remark.** If a function does not satisfy Property 2 of Theorem 6 but satisfies a slightly weaker property, namely that there is an  $\varepsilon > 0$  such that for all  $|\Sigma_n|$ -way branching programs  $P$  of height at most  $n/4$ ,

$$\Pr_{x \sim D_n}[P(x) \text{ is a substring of } f(x) \wedge P(x) \geq m] < e^{-\varepsilon m},$$

we can still obtain an average case lower bound against  $f$  for inputs drawn from  $D_n$ , but not necessarily a lower bound against random-oracle branching programs. We omit an exposition of this result, because we have not yet found applications of it.

We conclude this subsection with the lower bound for NOE with a random oracle.

► **Reminder of Theorem 1.** For every  $p \in (0, 1]$ , every random oracle  $n$ -way branching program family of size  $2^{s(n)}$  and height  $t(n)$  computing NOE with success probability  $p$  must have  $t(n) \cdot s(n) \geq \Omega(n^2)$  for all sufficiently large  $n$ .

**Proof.** Applying Proposition 3.1 and 3.2 and set  $D_n := U_n^n$  and  $\varepsilon := 3/4$ . Then both properties 1 and 2 of Theorem 6 hold for NON-OCCURRING ELEMENTS. ◀

### 3.3 Sort and Random Oracles

By reducing from NON-OCCURRING ELEMENTS to SORT, it follows that random oracle  $n$ -way branching programs still require a time-space product of  $\Omega(n^2)$  to sort a list  $L \in [n]^n$ . (The proof is omitted due to space restrictions.)

► **Theorem 22.** *For any constant  $c \in (0, 1]$ , let  $\{P_n^O\}$  be an oracle  $n$ -way branching program family of size  $2^{s(n)}$  and height  $t(n)$  such that for all  $n, x \in [n]^n$ ,  $\Pr_{O \sim \mathcal{D}_{[n]}}[P_n^O(x) = \text{SORT}(x)] \geq c$ . Then,  $ST = \Omega(n^2)$ .*

To prove our lower bounds for other problems in the following section, we require a somewhat stronger result: a nearly-quadratic time-space product lower bound for computing the non-occurring elements of a list of  $n$  items from  $[n]$ , as well as sorting  $n$  items from  $[n]$  for lists encoded over a *finite* alphabet  $\Sigma$ . By a reduction, we can prove this using the general lower bounds of Theorem 1 and Theorem 22.

► **Lemma 23.** *Let  $\{f_n : \Sigma_n^n \rightarrow \Sigma_n^*\}$  be a family of functions, and let  $f_\Sigma : \Sigma^* \rightarrow \Sigma^*$  be such that  $f(\langle x \rangle_\Sigma) = \langle f_{|x|}(x) \rangle_\Sigma$ , where  $\langle s \rangle_\Sigma$  is  $s$  encoded by a string over  $\Sigma$ . Suppose  $\{f_n\}$  requires a random oracle  $\Sigma_n$ -way branching program time-space product of  $\Omega(n^d)$ . Then there is some  $k > 0$  such that  $f_\Sigma$  requires a random oracle  $\Sigma$ -way branching program time-space product of  $\Omega(n^d / \log^k(n))$ .*

**Proof.** By contradiction. Suppose for all  $k > 0$ ,  $f_\Sigma$  has random oracle  $\Sigma$ -way branching program family  $\{P_n^O\}$  of height  $t(n)$  and size  $2^{s(n)}$  with success probability  $p > 0$  where  $t(n)s(n) \leq O(n^d / \log^k(n))$ . We show that  $\{f_n\}$  has a random oracle  $n$ -way branching program family  $\{Q_n^O\}$  of height  $t'(n)$  and size  $2^{s'(n)}$  with success probability  $p > 0$  where  $t'(n)s'(n) \leq O(n^d / \log^k(n))$ . To do this, we simply simulate  $P_n^O$  with  $Q_n^O$ . We first consider the input  $l \in [n]^n$  a length  $n \lceil \log_{|\Sigma|}(n) \rceil$  string where each number is represented by some string of characters from  $\Sigma$ . We then modify  $P_{n \lceil \log_{|\Sigma|}(n) \rceil}^O$  as follows. For each vertex  $v$  which queries an input  $i$ , instead query input  $\lfloor i / \log_{|\Sigma|}(n) \rfloor$ . Then, for all edges  $(u, v)$  with label  $\alpha \in \Sigma$  in  $P_{n \lceil \log_{|\Sigma|}(n) \rceil}^O$ , add an edge from  $u$  to  $v$  with label  $\beta \in [n]$  for all  $\beta$  whose representation in base  $\Sigma$  contains  $\alpha$  at position  $i \bmod \lceil \log_{|\Sigma|}(n) \rceil$ . Finally, we need only modify the output behavior of  $P_{n \lceil \log_{|\Sigma|}(n) \rceil}^O$ . It prints the representation of characters  $\sigma \in \Sigma_n$  using characters from  $\Sigma$ . We need only  $O(\log(n))$  extra bits of storage to remember the last  $\lceil \log_{|\Sigma|}(n) \rceil$  characters  $P_{n \lceil \log_{|\Sigma|}(n) \rceil}^O$  would have printed, and upon reaching enough characters, we simply print the corresponding element of  $\Sigma_n$  and remember that we have started a new character. As in the proof of Theorem 22, we can do this by creating  $O(n)$  copies of our modified branching program and transitioning accordingly and letting this be  $Q_n^O$ .

Finally, we see that by construction,  $\{Q_n\}$  computes  $\{f_n\}$  with success probability  $p$ . Further, we see that the height of  $Q_n$  is  $O(t(n \log(n)))$  and the size is  $2^{O(s(n) + \log(n))}$ . By our assumption, we see that  $t(n \log(n))(s(n) + \log(n)) \geq \Omega(n^d)$  and  $t(n \log(n))(s(n) + \log(n)) \leq O((n \log(n))^d / \log^{d+1}(n))$ . This is a contradiction. ◀

From this we can conclude lower bounds for NON-OCCURRING ELEMENTS and SORT for strings over finite alphabets.

► **Lemma 24.** *Let  $\text{NON-OCCURRING ELEMENTS}_\Sigma : \Sigma^* \rightarrow \Sigma^*$  be a function which maps the encoding in  $\Sigma$  of a list  $\langle L \rangle$  (where  $L \in [n]^n$  for some  $n$ ) to  $\langle \text{NON-OCCURRING ELEMENTS}(L) \rangle$ , and let  $\text{SORT}_\Sigma : \Sigma^* \rightarrow \Sigma^*$  be the function which maps the encoding of a list  $\langle L \rangle$  where  $\exists n \in \mathbb{N}(L \in [n]^n)$  to  $\langle \text{SORT}(L) \rangle$ . For all  $\Sigma$ , there is some  $k > 0$  such that, the random oracle  $\Sigma$ -way branching program time-space product for both  $\text{NON-OCCURRING ELEMENTS}_\Sigma$  and  $\text{SORT}_\Sigma$  are both at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** This follows directly from Theorems 1 and 22 and Lemma 23. ◀

► **Remark.** It will be important later that the branching program lower bounds we have established hold even if we allow the branching program to make small perturbations on the output. For example, all above lower bound proofs still go through, if we permit branching programs to output 0 at any node that does not already output some other number. Thus our lower bounds hold for any BP computing NON-OCCURRING ELEMENTS or NON-OCCURRING ELEMENTS $_{\Sigma}$  which prints the binary representation of a list  $L$ , such that  $L$  contains all non-occurring elements of  $x$ , along with any number of elements which are 0.

## 4 Reductions

We now give a series of reductions from NOE and SORT, showing nearly-quadratic time-space product lower bounds for several natural circuit-analysis problems. Each reduction is very efficient, requiring only  $\text{poly}(\log n)$  time to look up any bit of the output of the reduction, and only creating problem instances of size  $\tilde{O}(n)$  from inputs of size  $n$ .

As a warm-up, we observe a very simple reduction from SORT $_{\{0,1\}}$  (sorting  $n \log(n)$ -bit strings) to FCIRCEVAL. Recall in FCIRCEVAL we are given a circuit of size  $n$  with at most  $n$  inputs (all fixed to 0-1 values) and at most  $n$  outputs, and want to determine its output.

► **Reminder of Theorem 2.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of FCIRCEVAL is at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** The idea is simple: on an unsorted input, we can succinctly produce a circuit for sorting and ask FCIRCEVAL for its output. We observe there is an  $O(\log n)$ -time reduction with blowup  $O(\log^k n)$  from SORT to FCIRCEVAL (for some  $k$ ). Given an input list  $x$  to be sorted, we produce a circuit  $C$  for SORT with  $x$  hard-coded as the input. Any bit of the circuit description can be computed in  $O(\log n)$  time, as SORT has  $O(\log n)$ -time uniform circuits of size  $\tilde{O}(n)$ , and any bit of  $x$  can trivially be produced in  $O(\log n)$  time. By Lemmas 24 and 18, we conclude a time-space lower bound of the form  $\Omega(n^2 / \log^k n)$  for FCIRCEVAL. ◀

A straightforward corollary of Theorem 2 is a similar lower bound against a seemingly weaker version of 3SAT.

► **Definition 25.** Let PROMISE-PRINTING-UNIQUE-SAT be the problem: given a circuit  $C$  promised to have exactly one satisfying assignment, print the satisfying assignment of  $C$ .

► **Lemma 26.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of PROMISE-PRINTING-UNIQUE-SAT is at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** We give a reduction from FCIRCEVAL to PROMISE-PRINTING-UNIQUE-SAT. Given an instance  $C$  of FCIRCEVAL with only constant inputs and  $m$  output bits  $y_1, \dots, y_m$ , consider the circuit  $C'(x)$  with  $m$  free input bits  $x_1, \dots, x_m$  and one output bit.  $C'$  can be made such that  $C'(x_1, \dots, x_m) = 1$  if and only if  $x_i = y_i$  by using only as many gates as an needed to construct  $C$  and  $O(m)$  additional gates to check equality of the output bits of  $C$  with the free input bits and then to take the conjunction of these equalities. In total, we see then that  $|C'| = O(|C|)$ . Finally we see this gives us an  $O(\log(n))$ -time reduction with blowup  $O(n)$  from FCIRCEVAL to PROMISE-PRINTING-UNIQUE-SAT, since  $\text{FCIRCEVAL}(C) = \text{PROMISE-PRINTING-UNIQUE-SAT}(C')$ , and each bit of  $C'$  can be computed by simply looking up bits of  $C$  directly or deciding if they are part of the equality check or conjunction of the equality checks added to  $C$ . By Lemma 18, we can conclude that PROMISE-PRINTING-UNIQUE-SAT has a time-space lower bound of  $\Omega(n^2 / \log^k n)$ . ◀

To establish a connection with printing satisfying assignments for 3CNFs, we consider the problem PROMISE-PRINTING-UNIQUE-3SAT, which is just PROMISE-PRINTING-UNIQUE-SAT restricted to 3CNF formulas. By another straightforward reduction, it follows that PROMISE-PRINTING-UNIQUE-3SAT cannot be computed more efficiently than FCIRCEVAL.

► **Lemma 27.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of PROMISE-PRINTING-UNIQUE-3SAT is at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** We present a reduction from the PROMISE-PRINTING-UNIQUE-SAT function to PROMISE-PRINTING-UNIQUE-3SAT. Consider the standard reduction from CIRCUIT SAT to 3SAT in which a circuit  $C$  with  $n$  variables  $x_1, \dots, x_n$  and  $m$  gates is mapped to a CNF  $\phi$  with  $O(m)$  clauses, variables  $x_1, \dots, x_n$  and  $m$  extra variables. Assume without loss of generality (blowing up only an additional constant factor in size otherwise) that  $C$  is comprised only of NAND gates. The typical reduction from CIRCUIT SAT to 3SAT uses an additional variable  $y_1, \dots, y_m$  for each gate  $g_1, \dots, g_m$ , and for each gate  $g_i = \neg(g_j \wedge g_k)$ ,  $g_i = \neg(g_j \wedge x_k)$ , or  $g_i = \neg(x_j \wedge x_k)$ , we add to  $\phi$  the constraints  $(y_i = \neg(y_j \wedge y_k))$ ,  $(y_i = \neg(y_j \wedge x_k))$ , or  $(y_i = \neg(x_j \wedge x_k))$  respectively, where each requires only  $O(1)$  clauses of width 3.

Notice that printing the first  $n$  bits of a satisfying assignment to  $\phi$  is sufficient for computing a satisfying assignment to  $C$ , and observe that this reduction can be done in  $O(\log^k(n))$  time with blowup  $O(\log^k(n))$  for some  $k$ . Analogously to Lemma 18, we can conclude that PROMISE-PRINTING-UNIQUE-3SAT requires a random oracle  $\Sigma$ -way branching program time-space product of  $\Omega(n^2 / \log^{k'}(n))$  for some  $k' > 0$ . ◀

As a corollary, we can immediately conclude that the harder problem of PRINT-3SAT also has a time-space lower bound of  $\Omega(n^2 / \log^k n)$  for some  $k$ .

► **Reminder of Theorem 3.** *For all finite  $\Sigma$ , there is a  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of PRINT-3SAT is at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** Follows from the trivial reduction from PROMISE-PRINTING-UNIQUE-3SAT to PRINT-3SAT and Lemma 18. ◀

Next, we show by a reduction directly from NON-OCCURRING ELEMENTS<sub>{0,1}</sub> that printing the truth tables of CNF formulas with a small number of variables admits a time-space lower bound similar to those above.

► **Reminder of Theorem 4.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of TTPRINT for CNF formulas with  $n$  clauses and  $\log(n) + \log \log(n)$  many variables is at least  $\Omega(n^2 / \log^k n)$ .*

**Proof.** We consider that the output of a machine computing NOE<sub>{0,1}</sub> can be a list  $L$  which contains the non-occurring elements of its input as well as any number of elements which are 0, as in Remark 3.3. We give a  $\text{poly}(\log(n))$ -time reduction with blowup  $\tilde{O}(n)$  from NON-OCCURRING ELEMENTS<sub>{0,1}</sub> to TTPRINT. That is, we will show that given a list  $L$  of  $n$  elements from  $[n]$ , we can produce a CNF formula whose truth table is a representation of a list  $L'$  of  $n$  strings each of  $\log(n)$  bits, where the  $i$ -th string in  $L'$  equals  $i$  if  $i \in [n] - L$ , otherwise the  $i$ -th string equals all-zeroes. Then, the lower bound for NON-OCCURRING ELEMENTS<sub>{0,1}</sub> will carry over to TTPRINT.

Given a list  $L \in \{1, \dots, n\}^n$ , we show how to efficiently construct a CNF formula  $F$  with  $\log(n) + \log \log(n)$  variables and  $O(n)$  clauses such that the truth table of  $F$  is the binary representation of the list of non-occurring elements of  $l$  separated by strings of 0's.

Denote the first  $\log(n)$  variables of  $F$  by  $x = x_1 \cdots x_{\log(n)}$ . Letting  $b \in \{0, 1\}^{\log(n)}$ , we make a clause  $C_b(x)$  expressing that  $x \neq b$ . In detail, suppose  $b$  is represented by the bit string  $b_1, \dots, b_{\log(n)}$ . Then

$$C_b(x) := ((x_1 \oplus b_1) \vee \dots \vee (x_{\log(n)} \oplus b_{\log(n)})).$$

Note for all  $i$ , we can think of  $C_b$  as containing the literal  $\bar{x}_i$  if  $b_i = 1$ , otherwise it contains the literal  $x_i$ .

Given a list  $L = \ell_1, \dots, \ell_n$  of elements of  $\{0, 1\}^{\log(n)}$ , we first construct a CNF formula  $F'(x)$  which says that  $x$  is a non-occurring element of  $\ell$ :

$$F'(x) := C_{\ell_1}(x) \wedge \dots \wedge C_{\ell_n}(x).$$

Suppose we can construct a CNF formula  $D(x, i)$  which is true exactly when the  $i$ -th bit of  $x$  is 1, and define our output formula to be

$$F(x, i) := F'(x) \wedge D(x, i)$$

where  $i = i_1 \cdots i_{\log \log(n)}$ . This  $F$  would have  $\log(n) + \log \log(n)$  variables, and its truth table in lexicographical order could be viewed as a list of  $n$  different  $\log(n)$ -bit strings, each of which are either a non-occurring element of  $\ell$ , or the all-zeroes string. (This would complete our reduction.)

We show how to construct such a  $D(x, i)$  with  $|x|$  clauses. For each variable of  $x$ , and  $j = 1, \dots, |x|$ , we construct a clause  $E_j$  which is true if and only if either  $i \neq j$  or  $x_j = 1$ . That is, we define  $E_j = ((i_1 \oplus j_1) \vee \dots \vee (i_{\log(|x|)} \oplus j_{\log(|x|)}) \vee x_j)$ . Then we can define

$$D(x, i) := \bigwedge_{j=1}^{|x|} E_j.$$

The final formula  $F(x_1, \dots, x_{\log(n)}, i_1, \dots, i_{\log \log(n)})$  is a width- $(\log(n)+1)$  CNF of  $O(n)$  clauses, and all of the clauses of  $F$  can be efficiently constructed in a local way. ◀

Using the lower bound on truth table printing, we can now show the lower bound for counting SAT assignments (Theorem 5). Again we do this by providing a  $\text{poly}(\log(n))$ -time reduction with blowup  $\tilde{O}(n)$  from one problem to another. We show how to modify a circuit  $C$  to efficiently produce another circuit  $C'$ , such that the bit representation of the number of SAT assignments of  $C$  equals the truth table of  $C$ .

► **Lemma 28.** *Let  $C$  be a circuit of size  $s$  with  $n$  input variables  $x_1, \dots, x_n$ . Then, there exists a circuit  $C'$  of size  $O(s + 2^n)$  with input variables  $x_1, \dots, x_n, y_1, \dots, y_{2^n}$  such that  $\#(C') = TT(C)$ . Moreover, there is an algorithm that given such a circuit and index  $i$  can produce the  $i$ -th bit of  $C'$  in time  $\tilde{O}(\log(s + n + i))$ .*

**Proof.** Let  $C$  be a circuit of size  $s$  with inputs  $x_1, \dots, x_n$ . First, we construct a new circuit  $D(x_1, \dots, x_n, y_1, \dots, y_{2^n})$  which outputs 1 if and only if  $y \leq 2^{\text{bin}(x)}$ , where  $\text{bin}(x)$  is the number in  $\{1, \dots, 2^n\}$  represented by the binary string  $x_1 \cdots x_n$ . Note that  $D$  can be constructed with  $O(2^n)$  gates (by standard arguments), and any particular gate of  $D$  can be constructed in  $\text{poly}(\log(n))$  time. Finally, we define the circuit  $C'$  on variables  $x_1, \dots, x_n, y_1, \dots, y_{2^n}$  by

$$C'(x, y) := C(x) \wedge D(x, y).$$

Observe that the number of assignments satisfying  $C'$  is  $\sum_{x \in \{0, 1\}^n} C(x) \cdot 2^{\text{bin}(x)}$ , as for each  $x \in \{0, 1\}^n$  there are  $2^{\text{bin}(x)}$  assignments to  $y \in \{0, 1\}^{2^n}$  such that  $C'(x, y) = 1$ . This is exactly the number represented in binary by  $TT(C)$ . ◀

From Lemma 28 and Theorem 4, we can conclude Lemma 29.

► **Lemma 29.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of  $\#\text{CIRCUIT SAT}$  is at least  $\Omega(n^2/\log^k n)$ .*

From Lemma 29, we can conclude Lemma 30.

► **Lemma 30.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of  $\#\text{3SAT}$  is at least  $\Omega(n^2/\log^k n)$ .*

**Proof.** The standard reduction from  $\#\text{CIRCUIT SAT}$  to  $\#\text{3SAT}$  can be implemented as an  $O(\log(n))$ -time reduction with blowup  $\tilde{O}(n)$ . ◀

From Lemmas 30 and 19, we can conclude Theorem 5.

► **Reminder of Theorem 5.** *For all finite  $\Sigma$ , there is some  $k > 0$  such that the random oracle  $\Sigma$ -way branching program time-space product of  $\#\text{2SAT}$  is at least  $\Omega(n^2/\log^k n)$ .*

**Proof.** Lemma 19 gives an  $O(\log^k(n))$  time reduction with blowup  $O(n\log^k(n))$  from  $\#\text{3SAT}$  to  $\#\text{2SAT}$ . Hence, by Lemmas 30 and 18, we can conclude that the random oracle  $\Sigma$ -way branching program time-space product of  $\#\text{2SAT}$  is at least  $\Omega(n^2/\log^k(n))$ . ◀

## 5 Conclusion

We extended a lower bound framework for branching programs, lifting it to random oracles. We demonstrated its utility for lower bound results by giving several unorthodox reductions which show sharp relationships between counting satisfying assignments, printing truth tables of CNFs, printing satisfying assignments, and evaluating circuits on given inputs. It would be interesting to find more applications of the encoding techniques used in our reductions. Perhaps they can be used to show lower bounds for other models, or better algorithms.

Another interesting direction would be to explore other lower bound methods, such as those for *decision* problems, and determine to what extent they can be “lifted” to lower bounds with random oracles. To give one tantalizing example, although it is known that deciding SAT requires  $n^{1.8}$  time on deterministic  $O(\log n)$ -space machines, and this paper shows that *printing* SAT assignments requires  $n^{2-o(1)}$  time on *randomized*  $O(\log n)$ -space machines with constant error probability, it is still open whether *deciding* SAT is in  $O(n)$  time and  $O(\log n)$  space on randomized machines with two-sided error(!). Perhaps it is easier to find bridges between function problems and decision problems when we consider efficient programs for NP problems (rather than decision problems in P).

Finally, our oracle model for branching programs is not the most general that one could imagine (although for the *random* oracle case, we believe it does not matter). One can define a sensible “extended oracle” model, where oracle queries can be as long as the height of the branching program. (This model is not very practical in a truly space-bounded setting, e.g., when we view a random oracle as a random hash function, but it would be interesting for lower bounds.)

At a high level, here is how such an “extended oracle” model can be defined. In each step, we allow the BP to output an “oracle character”  $\sigma$  from the input alphabet of the oracle (along with its usual outputs). Instead of labeling the query vertices of the BP with specific query strings (as in Definition 11), we instead label them with a special symbol  $Q$ . The  $Q$ -vertices still have two outgoing arcs for their yes/no query answers. However, each time a  $Q$ -vertex  $v$  is reached during a computation, the outgoing *yes* edge of  $v$  is now taken in the computation path if and only if the string of oracle characters  $y = \sigma_1 \cdots \sigma_t$  output since the

previous  $Q$ -vertex (or source node, if there is no previous  $Q$ -vertex) satisfies  $Q(y) = 1$ . One can think of this as allowing the BP “append-only” access to an arbitrarily long oracle tape, for which it can ask queries, and for which the oracle tape is reset to blank after each query (as in the oracle model of Ladner and Lynch [20]).

With the above model, we can ask queries whose length is only bounded by the height of the branching program (rather than the logarithm of its size). We strongly believe that our lower bounds also hold for random oracles in this more powerful model. The main conceptual bottleneck is that, unlike normal branching programs, we cannot easily partition these extended-oracle branching programs into short independent branching programs: the oracle queries have “memory” that can stretch all the way back to the source node. It seems likely that lower bounds based on Yao’s principle [29] can be extended to this model, but we have not yet confirmed this.

## Abstract

---

It has been recently shown via simulations [8] that random projection followed by a *cap* operation (setting to one the  $k$  largest elements of a vector and everything else to zero), a map believed to be an important part of the insect olfactory system, has strong locality sensitivity properties. We calculate the asymptotic law whereby the overlap in the input vectors is conserved, verifying mathematically this empirical finding. We then focus on the far more complex homologous operation in the mammalian brain, the creation through successive projections and caps of an assembly (roughly, a set of excitatory neurons representing a memory or concept) in the presence of recurrent synapses and plasticity. After providing a careful definition of assemblies, we prove that the operation of assembly projection converges with high probability, over the randomness of synaptic connectivity, even if plasticity is relatively small (previous proofs relied on high plasticity). We also show that assembly projection has itself some locality preservation properties. Finally, we propose a large repertoire of assembly operations, including *associate*, *merge*, *reciprocal project*, and *append*, each of them both biologically plausible and consistent with what we know from experiments, and show that this computational system is capable of simulating, again with high probability, arbitrary computation in a quite natural way. We hope that this novel way of looking at brain computation, open-ended and based on reasonably mainstream ideas in neuroscience, may prove an attractive entry point for computer scientists to work on understanding the brain.

*receptor* neurons, of which there are roughly fifty different kinds. So, each smell is initially coded as a vector in 50 dimensions, where each coordinate is the level of activity of neurons of each kind. Then a remarkable thing happens: This vector undergoes a *random projection* – a familiar ingredient of many algorithms, especially in connection to learning [7, 2, 23, 1, 3] – to a higher dimensional space. There is a  $50 \times 2000$  sparse, and by all evidence [6] random, bipartite graph of synapses projecting the 50 kinds of olfactory receptors to a population of 2000 neurons called *Kenyon cells*. Next, the resulting 2000-dimensional vector of synaptic inputs undergoes an operation that is routine in neural systems: The activity of the Kenyon cells excites an inhibitory neuron, and the resulting activity of this neuron, at equilibrium, has the effect of increasing everybody’s membrane potential, “turning off” all but roughly the 100 most active cells. We call this operation *cap*; it is also known as *k winners take all*, in this case with  $k = 100$ .

In a recent paper [8] it was shown empirically that this mapping, random projection followed by *cap*, has strong *locality sensitivity* properties (and therefore preserves similarity of smells, presumably to the animal’s advantage), in fact outperforming in simulations certain variants of locality-sensitive hashing<sup>1</sup>. One of our results in this paper puts some mathematical teeth to this interesting empirical observation: We prove that if two binary vectors of the same sparsity overlap in a fraction  $\alpha$  of their entries, and both undergo random projection to  $n$  dimensions followed by  $k$ -*cap*, then the two results will overlap in a fraction of about  $(\frac{k}{n})^{\frac{1-\alpha}{1+\alpha}}$  (Theorem 1). For the small numbers of the insect brain ( $\frac{n}{k} \approx \frac{2000}{100}$ ), this is substantial overlap that helps explain the empirical findings in [8] (see Figure 1).

In the mammalian brain numbers get roughly three orders of magnitude higher, and yet something similar seems to happen. Importantly, there is strong *recurrent synaptic connectivity* between excitatory neurons; that is, the random graph is now not just a directed bipartite graph, but the union of a bipartite directed graph and a non-bipartite directed graph interconnecting the receiving side (in contrast, synapses between the fly’s Kenyon cells, if any, play no role there). In mammals, the random projection and *cap* operation does take place, but it is only the first step of a complex and sophisticated process, culminating in the creation of an *assembly of neurons*.

**Assemblies.** Already in 1949, neuroscience pioneer Donald Hebb predicted that memories and concepts are represented by tightly connected sets of neurons he called *assemblies*, whose near-simultaneous firing is tantamount to these concepts being thought about. During the last decade, it has been established experimentally [13, 14, 19], see also the survey [5], that such near-simultaneous firing of stable sets of neurons is an important part of the way the brain works. Assemblies have been hypothesized to underlie many of the higher cognitive operations in mammals, such as memory, reasoning, language, planning, etc., and yet, the way and manner in which this happens has not begun to be articulated; the computational framework of this paper is a first attempt at understanding how assemblies of neurons can carry out computation.

**In our framework.** In our framework, the brain is divided into a bounded number of *brain areas*. Each brain area contains a number of excitatory neurons denoted by  $n$ ; there are of course other neurons as well, for instance see the discussion on inhibition below. These excitatory neurons are interconnected in a sparse directed  $G_{n,p}$  graph. Pairs of brain areas

---

<sup>1</sup> As Alex Andoni notes (private communication, 2018), this is not true of the more advanced versions of LSH.

may also be connected, in one or both directions, through bipartite directed  $G_{n,p}$  graphs<sup>2</sup>.

Finally, the other two important aspects of our model are *cap* and *plasticity*. We assume that neurons fire – or do not – in discrete time steps (a very convenient and unrealistic assumption, which however does not interfere much with the rest of our framework). At each time and each brain area, the  $k$  out of  $n$  neurons that have largest synaptic input fire. That is, at time  $t$  for each neuron we add together the weights of the incoming synapses that originate in neurons (in the same or different area) which fired the previous time  $t - 1$ , and select the  $k$  neurons out of the  $n$  in the brain area that have the largest sums. These are the neurons in the area that will fire at time  $t$ . The  $k$ -cap process is a simplification and approximation of the reality of *inhibition*, whereby an independent population of inhibitory neurons cause the excitatory neurons to have high enough membrane potential that an equilibrium at  $k$  firing neurons is quickly reached. Finally, *plasticity*: we assume that if there is a synapse from neuron  $i$  to neuron  $j$ , and neuron  $i$  fires at time  $t$  while neuron  $j$  at  $t + 1$ , the weight of the synapse is increased by a factor of  $1 + \beta$  with  $\beta > 0$ ; synaptic weights start at one, say<sup>3</sup>. Thus, the key parameters of our model are  $n, k, p, \beta$ , whose indicative intended values for the mammalian brain are, respectively,  $10^7, 10^4, 10^{-3} - 10^{-2}, 10^{-1}$ .

**Defining Assemblies.** An assembly is of course a set of neurons, in our framework all belonging to the same brain area. In past theoretical work [17] this is exactly how they were defined, a set of  $k$  neurons firing simultaneously. It is a highly interconnected set to ensure *stability*, that is, if enough neurons in it fire then soon all of them will<sup>4</sup> – and one of the main points of [17] was that there is a biologically plausible algorithm for selecting such a highly connected set of neurons in a sparse  $G_{n,p}$  graph. These neurons might be poised to fire in a particular pattern, not necessarily all simultaneously as was assumed in [17] – and indeed, in our simulations, as well as in the literature on assembly simulations, one does see nontrivial patterns of firing. We believe the right way to define assemblies is as *distributions over the set of neurons in a Brain area whose support has size at most a fixed multiple of the cap size  $k$* .

**Projection.** The most basic operation of assemblies is what we call *projection* – this is how assemblies are created and, once created, *copied* to other brain areas for further use. Assembly projection has been conjectured for a long time and has been established in several simulation papers [20, 18] and recently analytically proved [17] for a range of parameters. An assembly  $x$  in area  $A$  can project to a different area  $B$ , to which  $A$  has ample connectivity, creating a new assembly  $y$ ; this operation is denoted  $\text{project}(x, B, y)$ . If in the future  $x$  is activated,  $y$  will follow suit; we say that  $x = \text{parent}(y)$ . We show that the operation  $\text{project}(x, B, y)$  is carried out by assembly  $A$  simply *firing for a small number of steps*<sup>5</sup>. Once an assembly  $x$  has been created, its area is implicit, denoted by  $\text{area}(x)$ . To create

<sup>2</sup> See [17] for a technical discussion of *synaptic biases*, departures from the  $G_{n,p}$  model noted in experiments, and the reasons why they may provide further support for the assembly hypothesis. We do not pursue this direction in the present paper.

<sup>3</sup> There should also be a process of *homeostasis* which, at a slower time scale, keeps the sum of all weights from growing; but this aspect of the model, taken up in Section 5, does not affect the relative ordering of synaptic weights or sums thereof.

<sup>4</sup> This is one of the many important differences between this work and Valiant’s pioneering theory of *items* from the 1990s [21, 22]

<sup>5</sup>  $\text{project}(x, B, y)$  may seem superficially equivalent to an assignment  $x = y$  in a programming language – except that, after such an assignment, variables  $x$  and  $y$  go on to live largely independent lives, whereas in assemblies  $x$  retains power over  $y$ , while  $y$  can only exist through  $x$ .

an altogether new assembly  $y$  by  $\text{project}(x, B, y)$ ,  $x$  must be a “proto-assembly,” a set of neurons coding a world experience and residing at some higher area of the sensory cortex (such as the area IT of the visual cortex where whole objects are represented), projected to a non-sensory area admitting new assemblies (typically the hippocampus). One of our main results in this paper (Theorem 3) is that projection indeed works as described – with high probability, of course, with randomness supplied by the graph, and in fact for quite low plasticity.

The projection process is quite intricate. It starts with the random projection plus  $k$ -cap described early in this introduction, creating a set of neurons that we call  $A_1$ , namely, the cells that happen to have the largest synaptic input from the projecting assembly  $x$ . We *assume* that the synaptic input of a neuron from assembly  $x$  is a Bernoulli random variable with parameters  $k, p$  and  $n$  samples. Notice also that, after the first round, the synapses between  $x$  and  $A_1$  have been boosted by plasticity. As the projecting assembly keeps firing, cap will select the set of neurons  $A_2$  that have highest *combined* synaptic input from  $x$  and  $A_1$ , and these will include two kinds of cells: the *core* neurons in  $A_1 \cap A_2$ , and new winners from outside  $A_1$ . What fraction of  $A_1$  will become core? This is an important parameter of the situation, and we call it  $\lambda$ . To compute it, we set up an algebraic equation of Bernoulli expectations; as the expectation of a Bernoulli quantile depends explicitly on the fraction of winners, and concentration is strong, we can set up the equation and solve it in the “high probability” sense. For the parameter range of interest,  $\lambda$  is about half. Notice that, after this step, all synapses from  $x$  and  $A_1$  to  $A_2$  are boosted by plasticity.

Then the process is repeated,  $A_3, A_4, \dots, A_t, \dots$ , and we wish to show that  $|B^*| = |\bigcup_t A_t|$  converges to some finite multiple of  $k$  (recall that this is our definition of an assembly). That is, eventually there will be a time after which there are no first-time winners. Unfortunately our already complicated Bernoulli analysis is no longer an option, for a variety of reasons. First, at time  $t$  the number of types of neurons grows exponentially with  $t$ : the type of each neuron is the set of  $\tau$ 's for which the neuron was in  $A_\tau$ . In addition, the distribution of the synaptic input of neurons with complex type is not Bernoulli, because of conditioning. Instead, we resort to classifying each neuron by its *rough type at time  $t$* , which is the number of *consecutive* times  $\tau$  leading to  $t - 1$  during which the neuron was in  $A_\tau$ . A crucial lemma states that the probability that the run will end at time  $t$  and the neuron will find itself outside  $A_t$  decreases exponentially with the length of the run (that is to say, the neuron's rough type), and in fact uniformly in  $t$ . Convergence to a union size that is a multiple of  $k$  (with a multiplier that is, naturally, a steeply increasing function of  $\frac{1}{\beta}$ ) follows (Theorem 3).

The proof is quite a bit easier in the *high plasticity regime* defined by  $\beta > \sqrt{\frac{(1-p)\ln n}{pk}}$ , in which case convergence is stronger in that the sequence  $A_t$  itself converges in finitely many steps (as indicated in [17]).

**Operations on Assemblies.** What is the right scale for understanding computation in the brain? We suspect that assemblies may underlie an important and powerful mode of brain computation, complementary to the computation involved in the processing of sensory input – heretofore the main focus of neuroscience. Such computation would encompass memory recall and association, deduction and reasoning, generating and parsing natural language, generating and manipulating stories and plans, even math. It happens at a level of abstraction intermediate between individual neurons and synapses at the lowest level, and whole brain computation at the highest; it is far more expressive than the latter, and much less cumbersome to describe than the former. In our quest to understand the full power of this mode of computation, in Section 5 we identify a repertoire of additional operations on

assemblies, beyond projection. We only seek operations that are “realistic” in the following two orthogonal senses: (a) operations for which there is experimental evidence, in the sense that their existence would help explain extant experimental data, and which could possibly be themselves tested experimentally; and (b) operations which are in addition *plausible*, shown (analytically if at all possible, otherwise through simulations) to be realizable at the level of neurons and synapses in our framework. That is to say, each assembly operation must be “compiled down” to the level of neurons and synapses. Our list of operations includes, besides projection: *association*, in which two assemblies in the same area increase their intersection to reflect conceptual or statistical affinity – there is extensive experimental evidence for this operation, see [17] for an extensive discussion; *merge*, in which two assemblies from two different areas project to *the same new assembly* in a third area, an operation that seems important for processing syntax in natural language; *reciprocal project* (like project, except that the projected assembly is able to activate the original one, in addition to vice-versa); and *append*, an operation useful for creating and maintaining sequences. There are also several *control operations* allowing one to *read* the information of assembly activity in specific areas, or *disable* synaptic connectivity between areas – ultimately, to *write simple programs*. We show that this repertoire of assembly operations constitutes a programming system<sup>6</sup> which can simulate arbitrary computation in a way that is quite natural (Theorem 4). The point of this exercise is to demonstrate the power of this basis of primitives, not to hypothesize that the brain must function exactly this way.

## Related work

Our work on assemblies is superficially related to (and was undoubtedly inspired by) Valiant’s theory of *items*. There are stark contrasts between the two approaches: Assemblies are hypothesized to be densely connected, a requirement that makes their creation challenging, while items are ransom sets of neurons. And we believe that our model is far closer to the realities of the brain, as they are known now, than Valiant’s; for one key difference, Valiant assumes plasticity (change in synaptic weights) to be arbitrarily programmable at the post-synaptic site, while we assume a very simple implementation of Hebb’s rule. With this model we are able to address the problem of how the brain creates similar representations for similar stimuli.

Our earlier work on assemblies established experimentally the plausibility of projection and association [20], and theoretically so by relying on very high plasticity [17]. In this paper, we attack analytically the more realistic and considerably more challenging regime of small plasticity.

## 2 Model

We assume a finite number of brain areas, denoted by  $A, B, \dots$ . Each brain area is a weighted directed graph whose vertices are  $n$  (think of  $n$  as  $10^6$  or  $10^7$ ) excitatory neurons, and whose edges are synapses between neurons; the positive weights vary dynamically through plasticity, see below. We assume that the edges are drawn from a  $G_{n,p}$  distribution. That is, we assume that the probability of any edge is  $p$  and edges are chosen independently. In addition, between certain ordered pairs of areas  $(A, B)$  there is a  $G_{n,p}$  directed bipartite graph from nodes of  $A$  to nodes of  $B$ . In other words, there is a finite directed graph with the areas as

<sup>6</sup> Which, to our credit, we refrained from dubbing “Assembly Language”...

nodes, determining whether the two areas have synaptic connections. We assume that there is a mechanism to *disable* the synaptic connections between two areas  $A$  and  $B$  at any time.

We assume that events happen in discrete time steps (think of each step as about 20 ms). At each step  $t$ , every neuron  $i$  in every area  $A$  may or may not *fire*. Whether  $i$  fires depends on its *synaptic input* at time  $t$ . This is defined the sum over all neurons  $j$  that have synapses  $(j, i)$  (note that  $j$  can be either in area  $A$  or in an area  $B$  that does have synapses into  $A$  that are not disabled at time  $t$ ). Denote this quantity as  $SI(j)$ . We assume that neuron  $i$  in area  $A$  fires at time  $t$  if and only if  $|\{j \in A : SI(j) \geq SI(i)\}| < k$ , where  $k$  is a key parameter of the model (think of it as roughly  $\sqrt{n}$ ). We call the set of neurons firing at a time  $t$  the *cap* of the area. The cap is a mathematically tractable way of capturing the important process of *inhibition*, whereby inhibitory neurons in an area (typically outnumbering excitatory ones) are excited by the firing of excitatory neurons in the area, and in response fire, preventing some excitatory neurons from further firing, and eventually reaching an equilibrium (called the *E-I balance* in the literature). Here we model this equilibrium by a constant  $k$  and ignore the transient.

The other important ingredient of our model is plasticity: We assume that if there is a synapse with weight  $w$  from neuron  $i$  to neuron  $j$  (either in the same area, or in another area with enabled synapses), and it so happens that  $i$  fires in time  $t - 1$  and  $j$  fires in time  $t$ , then the weight of synapse  $ij$  is in time  $t + 1$  equal to  $w(1 + \beta)$ , where  $\beta$  (think of it as between 0 and 1, realistically at the lower end of this) is the plasticity coefficient. Plasticity is a very complex phenomenon with many important aspects and cases, but we feel that this simple rule (corresponding to Hebb's "fire together wire together" maxim) captures the essence of the matter reasonably well.

We shall elaborate certain further aspects of our model in the section on assembly operations.

### 3 The Overlap of Projections

In this and the next section we analyze how assemblies can be formed in our model. We assume that there is a *stimulus*  $A$  of  $k$  neurons firing in an area, with enabled synaptic projections to another area, where the assembly will be formed. We start with the simple case (modeling the insect brain) where  $A$  fires only once, forming the cap in the downstream area denoted  $\text{cap}(A)$ , and analyze how the overlap of two stimuli  $A$  and  $B$  is maintained in the process; note that here recurrent connections and plasticity do not get involved, and the weights can be thought to be one. The following observation will be useful: conditioning on a neuron not making it to a cap cannot increase its cap probability for future steps.

► **Lemma 1.** *Let  $A, B$  be two stimuli. Then for any node  $i \in V$ ,*

$$\Pr(i \in \text{cap}(B) \mid i \notin \text{cap}(A)) \leq \Pr(i \in \text{cap}(B)) = \frac{k}{n}$$

where the probability is over the randomness of the graph.

Also, we will need the following well-known bound on the Gaussian tail.

► **Lemma 2 (Gaussian tail).** *For  $x \sim N(0, 1)$  and  $t > 0$ ,*

$$\frac{1}{\sqrt{2\pi}} \left( \frac{1}{t} - \frac{1}{t^3} \right) \exp(-t^2/2) \leq \Pr(x \geq t) \leq \frac{1}{\sqrt{2\pi}t} \exp(-t^2/2).$$

Now we state and prove our quantitative assessment of the locality sensitivity properties of the insect olfactory map pointed out empirically in [8].

► **Theorem 3.** *The expected overlap of the caps two stimuli that overlap in an  $\alpha$  fraction of their nodes is*

$$\frac{|\text{cap}(A) \cap \text{cap}(B)|}{k} \gtrsim \frac{1}{(\ln(n/k))^{\frac{\alpha}{1+\alpha}}} \left(\frac{k}{n}\right)^{\frac{1-\alpha}{1+\alpha}}.$$

**Proof.** We bound the probability that any neuron  $i$  is in the cap of both  $A$  and  $B$ . For this, let  $x_i, y_i, z_i$  be the total input to node  $i \in V$  from  $A \setminus B, A \cap B$  and  $B \setminus A$ . Then  $x_i, z_i \sim N((1-\alpha)kp, (1-\alpha)kp(1-p))$  and  $y_i \sim N(\alpha kp, \alpha kp(1-p))$ . Then, using the independence of  $x_i + y_i$  and  $z_i + y_i$  given  $y_i$ ,

$$\begin{aligned} & \Pr i \in \text{cap}(A) \cap \text{cap}(B) \\ &= \int \int \int \chi(x_i + y_i \in \text{top } k \text{ of } \{x_j + y_j\} \text{ and } z_i + y_i \in \text{top } k \text{ of } \{z_j + y_j\}) d\gamma(x) d\gamma(z) d\gamma(y) \\ &= \int \int \int \chi(x_i + y_i \in \text{top } k \text{ of } \{x_j + y_j\} | y) \chi(z_i + y_i \in \text{top } k \text{ of } \{z_j + y_j\} | y) d\gamma(x) d\gamma(z) d\gamma(y) \\ &\geq \int \left( \int \chi(x_i + y_i \in \text{top } k \text{ of } \{x_j + y_j\} | y) d\gamma(x) \right)^2 d\gamma(y) \\ &\geq \int_{y_i} [\Pr(x_i \geq -y_i + kp + t | y_i)]^2 d\gamma(y_i). \end{aligned}$$

The last step above is the simple observation that a random draw  $x_i + y_i$  from  $N(kp, kp(1-p))$  is, with constant probability, in the top  $k$  of  $n$  iid draws from the same distribution if  $x_i + y_i \geq \mathbb{E}(x_i + y_i) + t$  where  $\Pr(x_i + y_i \geq t) \geq k/n$ . The tail bound below shows that

$$t \sim \sqrt{(2 \ln(n/k) - \ln(2 \ln(n/k)))kp}.$$

For convenience, we shift the distributions of  $x_i, y_i$  to  $\bar{x} = (x - (1-\alpha)kp)/kp$  and  $\bar{y} = (y - \alpha kp)/kp$  so that  $\bar{x} \sim N(0, (1-\alpha))$  and  $\bar{y} \sim N(0, \alpha)$ . For  $x \sim N(0, 1)$ , we will use the tail bound in Lemma 2:

$$\frac{1}{\sqrt{2\pi}} \left( \frac{1}{t} - \frac{1}{t^3} \right) \exp(-t^2/2) \leq \Pr(x \geq t) \leq \frac{1}{\sqrt{2\pi}t} \exp(-t^2/2).$$

Thus, for any  $\alpha < 1$ ,

$$\begin{aligned} & \Pr(i \in \text{cap}(A) \cap \text{cap}(B)) \\ &\geq \int_{\bar{y}} \Pr(\bar{x} \geq -\bar{y} + t)^2 d\gamma(\bar{y}) \\ &\geq \int_{\bar{y}} \frac{1}{2\pi(1-\alpha)} \min \left\{ \frac{1-\alpha}{(t-\bar{y})^2}, 1-\alpha \right\} \exp \left( -2 \frac{(t-\bar{y})^2}{2(1-\alpha)} \right) \frac{1}{\sqrt{2\pi\alpha}} \exp \left( -\frac{\bar{y}^2}{2\alpha} \right) d\bar{y} \\ &\geq \left( \frac{1}{2\pi t^{2/(1+\alpha)}} \exp \left( -\frac{t^2}{1+\alpha} \right) \right) \int_{\bar{y}} \frac{t^{2/(1+\alpha)}}{\sqrt{2\pi\alpha}} \min \left\{ \frac{1}{(t-\bar{y})^2}, 1 \right\} \exp \left( -\frac{(\bar{y} - \frac{2\alpha}{(1+\alpha)}t)^2}{2\alpha(1-\alpha)/(1+\alpha)} \right) d\bar{y} \\ &\geq \sqrt{\frac{1-\alpha}{1+\alpha}} \left(\frac{k}{n}\right)^{\frac{2}{1+\alpha}} \frac{1}{t^{2\alpha/(1+\alpha)}} \int_y \frac{\min \left\{ \frac{1}{\left(\frac{1-\alpha}{1+\alpha} - \frac{y}{t}\right)^2}, 1 \right\}}{\sqrt{2\pi\alpha(1-\alpha)/(1+\alpha)}} \exp \left( -\frac{y^2}{2\alpha(1-\alpha)/(1+\alpha)} \right) dy \\ &\geq \sqrt{\frac{1-\alpha}{1+\alpha}} \left(\frac{k}{n}\right)^{\frac{2}{1+\alpha}} \frac{1}{t^{2\alpha/(1+\alpha)}} \int_y \frac{1}{\sqrt{2\pi}} \min \left\{ \frac{1}{\left(\frac{1-\alpha}{1+\alpha} - \frac{y}{t} \sqrt{\frac{\alpha(1-\alpha)}{1+\alpha}}\right)^2}, 1 \right\} \exp \left( -\frac{y^2}{2} \right) dy \\ &\geq \frac{\sqrt{\frac{1-\alpha}{1+\alpha}}}{(2 \ln(n/k))^{\alpha/(1+\alpha)}} \left(\frac{k}{n}\right)^{\frac{2}{1+\alpha}}. \end{aligned}$$

■ **Figure 1** The first figure is with  $n = 2000, k = 100$  and the second with  $n = 10000, k = 100$ ; each empirical plot is the average of 5 independent trials. For the assembly creation we used plasticity of  $\beta = 0.1$ . The theoretical bound plotted is  $(k/n)^{(1-\alpha)/(1+\alpha)} / \ln(n/k)^{\alpha/(1+\alpha)}$ , while the conjectured bound is the same without the log factor.

Thus the expected fraction of overlap is this probability times  $n$  divided by  $k$ , i.e.,

$$\Omega \left( \frac{1}{(\ln(n/k))^{\frac{\alpha}{1+\alpha}}} \left( \frac{k}{n} \right)^{\frac{2}{1+\alpha}} \frac{n}{k} \right) = \Omega \left( \frac{1}{(\ln(n/k))^{\frac{\alpha}{1+\alpha}}} \left( \frac{k}{n} \right)^{\frac{1-\alpha}{1+\alpha}} \right). \quad \blacktriangleleft$$

It seems that the steps in this proof, including the suppression of constants in the end, are quite parsimonious, in that the stated lower bound is not very far from the truth. In Figure 1 we compare our bound with simulations of the map for various values of  $\alpha$  and with  $n/k = 2000/100 = 20$  (the values that pertain to insect olfaction) and  $n = 10^4, k = 100$ , and also to our bound without the logarithmic factor.

#### 4 Bounding the Support of an Assembly

In this section we turn to assemblies in the mammalian brain, in which recurrent synapses and plasticity become important. We assume that a stimulus consisting of  $k \geq \sqrt{n}$  neurons in an upstream area fires repeatedly. The cap at  $t = 1$ , denoted  $A_1$ , which was analyzed in the previous section, is only the preamble of a complex process. At  $t = 2$  the stimulus fires again, and now the area receives combined input from the stimulus *and* from  $A_1$ . A cap denoted  $A_2$  will be formed, probably containing a considerable part of  $A_1$  but also *first-timers* (by which we mean, neurons not heretofore participating in any cap). Meanwhile, plasticity has changed the weights. The process is repeated a number of times, with new winners displacing some past winners from the new cap, while plasticity acts in a stabilizing way. Convergence – that is,  $A_t = A$  for all  $t > t_0$  – cannot be guaranteed with high probability (experiments show some periodic-like movement of neurons, without any new first-timers). The interesting question is, will the process converge, in that after some point and after there will be no new winners? (Recall that this is what we mean by an assembly, a set of neurons of size a small multiple of  $k$  firing in a pattern.). If so, we are interested in the size of the assembly's *support*, the union of all the  $A_t$ s. The bound on the support depends crucially on the plasticity parameter  $\beta$ , with high plasticity leading to small support (close to the cap size  $k$ ) but even very small positive plasticity leading to bounded support size (a fact that is harder to prove). We denote by  $A^*$  the union of  $A_0, A_1, A_2, \dots$

► **Theorem 4** (High Plasticity). *Assume that the plasticity parameter  $\beta \geq \beta_0 = \frac{(\sqrt{2}-1)\sqrt{\ln n} + \sqrt{2}}{\sqrt{pk} + \sqrt{\ln n}}$ . Then WHP the total support of the assembly can be bounded as*

$$|A^*| \leq k \frac{1}{1 - \exp(-(\frac{\beta}{\beta_0})^2)} \leq k + O\left(\frac{\ln n}{p\beta^2}\right).$$

**Proof.** Let  $\mu_1 = 1, \mu_2, \dots, \mu_t, \dots$  be the fraction of first-timers in the cap at step  $t$ . The process stabilizes when  $\mu_t < 1/k$ . Using the tail bound of the Gaussian, since the new winners must be in the top  $\mu_t k$  of remaining  $n - k \sim n$  neurons, the activation threshold at step  $t$  is therefore very close to

$$C_1 = pk + \sqrt{2pk \ln \frac{n}{k}}, \quad C_t = 2pk + 2\sqrt{pk \ln \frac{n}{\mu_t k}} \text{ for } t \geq 2.$$

Note that the mean term is  $pk$  for the first step and  $2pk$  for all subsequent steps since the number of neurons firing is the  $k$  stimulus ones plus  $k$  from the brain area.

First consider a neuron that make it to the first cap. To bound the probability that that it will remain in the next cap, we note that at this point, the total activation from the input synapses is at least  $(1 + \beta)C_1$  and from the recurrent synapses it is at least  $X$  where  $X \sim N(pk, p(1-p)k)$  is the signal from the recurrent synapses coming from nodes in the first cap. In order for a node to remain in the next cap, we need that

$$(1 + \beta)C_1 + pk + X \geq C_2$$

where now  $X \sim N(0, p(1-p)k)$ . Substituting for  $C_1, C_2$ , and using  $L = 2 \ln(n/k)$ , and  $\mu$  as the fraction of first-timers in the second cap, we have

$$\begin{aligned} \Pr(j \in C_2 | j \in C_1) = 1 - \mu &\geq \Pr(X \geq -\beta pk - (1 + \beta)\sqrt{pkL} + \sqrt{2pk(L + 2 \ln(1/\mu))}) \\ &\geq \Pr(X \geq -\beta\sqrt{pk} + \sqrt{2(L + \ln(1/\mu))} - (1 + \beta)\sqrt{L}) \\ &\quad \text{rescaling so that } X \sim N(0, 1). \\ &\gtrsim 1 - \exp\left\{-\left(\beta\sqrt{pk} + (1 + \beta)\sqrt{L} - \sqrt{2(L + \ln(1/\mu))}\right)^2/2\right\}. \end{aligned}$$

In other words,

$$\sqrt{2 \ln(1/\mu)} \leq \beta\sqrt{pk} + (1 + \beta)\sqrt{L} - \sqrt{2(L + \ln(1/\mu))}.$$

Now setting

$$\beta \geq \beta_0 = \frac{(\sqrt{2}-1)\sqrt{L} + \sqrt{2}}{\sqrt{pk} + \sqrt{L}}$$

gives  $\mu < 1/e$ , i.e., the overlap with the next cap is at least a  $1 - (1/e)$  fraction. The probability of remaining in the cap rapidly increases with the number of consecutive times a neuron stays in the cap. To see this, suppose neuron  $j$  enters the cap for the first time at time  $t$ , by exceeding the threshold  $C_t$  and stays for  $i$  consecutive caps (including  $C_t$ ). The, to stay in the next cap, it suffices that

$$(1 + \beta)^i C_1 + pk + X \geq C_{i+1}$$

where  $X \sim (0, p(1-p)k)$ . Then, rescaling so  $X \sim N(0, 1)$ ,

$$\begin{aligned} \Pr(j \in C_{i+1} | j \in C_1) &= 1 - \mu \\ &\geq \Pr(X \geq (1 - (1 + \beta)^i)\sqrt{pk} - (1 + \beta)^i\sqrt{L} + \sqrt{2(L + 2 \ln(1/\mu))}) \\ &\gtrsim 1 - \exp\left\{-\left(i\beta\sqrt{pk} + (1 + i\beta)\sqrt{L} - \sqrt{2(L + \ln(1/\mu))}\right)^2/2\right\}. \end{aligned}$$

## 57:10 Computation with Assemblies

Rewriting,

$$\sqrt{2\ln(1/\mu)} + \sqrt{2(L + \ln(1/\mu))} - \sqrt{L} \leq i\beta(\sqrt{pk} + \sqrt{L})$$

or

$$\beta \geq \frac{1}{i} \cdot \frac{\sqrt{2\ln(1/\mu)} + \sqrt{2(L + \ln(1/\mu))} - \sqrt{L}}{(\sqrt{pk} + \sqrt{L})}$$

which is less than  $\beta_0$  for  $\mu = e^{-i^2}$ .

Next we consider a new first time winner in round  $t$ . In order for this neuron to make it to the cap at time  $t + 1$ , we need that

$$(1 + \beta) \frac{(2 - \mu)}{2} C_t + \mu pk + X \geq C_{t+1}$$

where  $\mu = \mu_{t+1}$  is the fraction of newcomers in the next cap and  $X \sim N(0, \mu p(1 - p)k)$ . Rescaling so that  $X \sim N(0, \mu)$ , we have  $\Pr(j \in C_{t+1} | j \in C_t)$  is

$$1 - \mu \geq \Pr(X \geq -\beta(1 - \frac{\mu}{2})2\sqrt{pk} - (1 + \beta)(1 - \frac{\mu}{2})\sqrt{2(L + \ln(1/\mu_t))} + \sqrt{2(L + \ln(1/\mu))})$$

Using the tail bound and rewriting as before, we have

$$\beta \geq \frac{2\ln(1/\mu) + \frac{\mu}{2}\sqrt{2(L + \ln(1/\mu_t))} + \frac{\ln(\mu_t/\mu)}{L}}{(1 - \frac{\mu}{2})(2\sqrt{pk} + \sqrt{2(L + \ln(1/\mu_t))})}$$

which is less than  $\beta_0$  for  $\mu = \mu_t/e$ . In other words, the  $\beta$  threshold to do this and ensure that  $\mu$  drops by a constant factor is lower than the threshold  $\beta_0$  for the first step. Finally, as before, the probability of staying in the cap increases rapidly with the length of the neurons' winning streak.

If  $\beta \geq \beta_0$ , then  $\mu_t$  drops off exponentially. i.e., the probability of leaving the cap once in the cap for  $i$  consecutive times  $1 - p_i^t$  drops off exponentially. Using these facts, we get

► **Claim 1.**

$$\prod_{i \geq 1} p_i \geq \prod_{i \geq 1} (1 - \exp(-i^2(\frac{\beta}{\beta_0})^2)) \geq \frac{1}{2}.$$

The claim gives a lower bound on the probability that a neuron that makes it to a cap for the first time remains in the cap for all future times. As a result, each neuron that makes it a cap for the first time has a probability of at least  $q = 1 - \exp(-(\frac{\beta}{\beta_0})^2)$  of remaining in all future caps. Thus, the total support of all caps together is at most  $k/q$  in expectation. This completes the proof of the theorem. ◀

We now turn to the regime of low plasticity, including zero plasticity. The bounds here will be higher asymptotically, as reflected also in our experiments (see Figure 2). We note however that for parameter ranges of interest for the brain, e.g.,  $n = 10^6, k = 10^3$ ,

$$\left(\frac{n}{k}\right)^{1/4} < \ln(n/k).$$

The guarantees below are meaningful and nontrivial only when  $k$  is sufficiently large as a function of  $n$ .

■ **Figure 2** The total support size at different values of plasticity  $\beta$  ranging from 0 to just over 0.5 for a random network with  $n = 10^4$  neurons, edge probability  $p = 0.01$  and assembly size  $k = 100$ . The  $x$  axis is the number of iterations.

► **Theorem 5 (Low Plasticity).** *Let a network with  $n$  nodes have edge density  $p$ , plasticity parameter  $\beta$ , and cap size  $k \geq \sqrt{n}$ . For a sequence of caps  $A_0, A_1, A_2, \dots, A_t, \dots$ , let  $A^*$  be their union. Denote  $\mu = \sqrt{k/n}$ . Then,*

1. for  $\beta = 0$ ,

$$\mathbb{E}(|A^*|) \leq k \left(\frac{1}{\mu}\right)^{\frac{1}{\mu}}.$$

2. for  $\beta > 0$ ,

$$\mathbb{E}(|A^*|) \leq k \left(\frac{1}{\mu}\right)^{\frac{1}{2\beta}}.$$

**Proof.** For the first part, let  $\mu_0, \mu_1, \dots, \mu_t, \dots$  be defined as  $\mu_0 = 0$  and

$$\mu_t = \frac{|A_t \cap A_{t-1}|}{k},$$

the fraction of the cap that persists to the next step.

We will show that the expected values of  $\mu_t$  form an increasing sequence and give a recursive lower bound. To get a lower bound on  $\mu_1$ , for a neuron  $j$ , let  $x$  be the total signal from the stimulus and  $y$  from  $A_0$ , normalized, i.e.,  $x, y \sim N(0, 1)$ . Then,

$$\begin{aligned} & \Pr(j \in A_1 \mid j \in A_0) \\ & \geq \Pr(x + y \geq 2\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))} \mid x \geq \sqrt{2 \ln(n/k) - \ln(2 \ln(n/k))}) \\ & \geq \Pr(y \geq (2 - \sqrt{2})\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))}) \\ & \geq \mu_0 = \left(\frac{k}{n}\right)^{-(\sqrt{2}-1)^2}. \end{aligned}$$

## 57:12 Computation with Assemblies

For general  $t > 1$ , let  $x$  be the signal from the stimulus  $y$  from the overlap  $A_t \cap A_{t-1}$  and  $z$  from the rest of  $A_t$ . Then, with  $z \sim N(0, (1 - \mu_t))$ ,

$$\begin{aligned}
\mu_{t+1} &= \Pr(j \in A_{t+1} \mid j \in A_t) \\
&\geq \Pr(x + y + z \geq 2\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))} \mid x \geq \sqrt{2 \ln(n/k) - \ln(2 \ln(n/k))}, \\
&\quad \text{and } y \geq \mu_t(2 - \sqrt{2})\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))}) \\
&\geq \Pr(x \geq (2 - \sqrt{2})(1 - \mu_t)\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))}) \\
&\geq \left(\frac{k}{n}\right)^{-(\sqrt{2}-1)^2(1-\mu_t)} \\
&= \mu_0^{1-\mu_t}.
\end{aligned}$$

The probability that a neuron  $j$ , which enters the cap at the first step, stays in the cap is thus at least

$$\begin{aligned}
\prod_t \mu_t &\geq \mu_0 \cdot \mu_0^{1-\mu_0} \cdot \mu_0^{1-\mu_0^{1-\mu_0}} \cdot \dots \\
&= \mu_0^{1+(1-\mu_0)+(1-\mu_0^{1-\mu_0})+\dots} \\
&\geq \mu_0^{1+(1-\mu_0)+(1-\mu_0)^2+(1-\mu_0)^3+\dots} \\
&= \mu_0^{\frac{1}{\mu_0}}
\end{aligned}$$

where we used the fact that  $1 - \mu_0^{(1-\mu_0)^i} = 1 - (1 - (1 - \mu_0))^{(1-\mu_0)^i} \geq (1 - \mu_0)^{i+1}$ .

So far, the computation was only for neurons that were in the very first caps. For neurons that make their first entrance later, the calculation is a bit different. Suppose a neuron enters the cap for the first time at iteration  $t$ . For general  $t > 1$ , let  $x$  be the signal from the stimulus  $y$  from the overlap  $A_t \cap A_{t-1}$  and  $z$  from the rest of  $A_t$ . Then, with  $z \sim N(0, (1 - \mu_t))$ , noting that  $x, y$  make up  $(1 + \mu_t)/2$  of the threshold  $C_t$ ,

$$\begin{aligned}
\mu_{t+1} &= \Pr(j \in A_{t+1} \mid j \in A_t) \\
&\geq \Pr(x + y + z \geq 2\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))} \mid x + y \\
&\geq (1 + \mu_t)\sqrt{\ln(n/k) - \ln(2 \ln(n/k))}) \\
&\geq \Pr(x \geq (1 - \mu_t)\sqrt{\ln(n/k) - 0.5 \ln(2 \ln(n/k))}) \\
&\geq \left(\frac{k}{n}\right)^{-(1-\mu_t)/2} \\
&= \mu^{1-\mu_t}.
\end{aligned}$$

Note that  $\mu$  here is smaller than  $\mu_0$  for neurons that enter in the first cap. The computation for later steps, for such a neuron is similar, and we get that the probability that such a neuron stays in the cap forever is

$$\prod_t \mu_t \geq \mu \cdot \mu^{1-\mu} \cdot \mu^{1-\mu^{1-\mu}} \cdot \dots \geq \mu^{\frac{1}{\mu}}$$

as before. This completes the first part for  $\beta = 0$ .

For the second part, with  $\beta > 0$ , the calculation follows the same outline, except that the signal from the input is boosted by a factor of  $(1 + \beta)$  in each iteration, and the signal from previous caps is boosted by  $(1 + \beta)$  for a diminishing fraction  $\prod_t \mu_t$ . Ignoring the latter boost (for a lower bound),

$$\begin{aligned} \mu_{t+1} &\geq \Pr(x + y + z \geq 2\sqrt{\ln(n/k) - 0.5\ln(2\ln(n/k))} \mid x \geq \sqrt{2\ln(n/k) - \ln(2\ln(n/k))}, \\ &\quad \text{and } y \geq \mu_t(2 - \sqrt{2})\sqrt{\ln(n/k) - 0.5\ln(2\ln(n/k))}) \\ &\geq \Pr(x \geq (2 - \sqrt{2})(1 + \beta)^t(1 - \mu_t)\sqrt{\ln(n/k) - 0.5\ln(2\ln(n/k))}) \\ &\geq \left(\frac{k}{n}\right)^{-(\sqrt{2} - (1 + \beta)^t)^2(1 - \mu_t)} \\ &= \mu^{(1 - t\beta)(1 - \mu_t)}. \end{aligned}$$

We can now lower bound the probability of a neuron staying in the cap once it enters, and thereby the expected size of the total support. ◀

**Locality Sensitivity of Assemblies.** Returning to the motivating story on fly olfaction, is the assembly projection operation as locality sensitive as the simpler variant in insects? It appears that overlap of assemblies is an important indication of affinity of various sorts (co-occurrence, correlation, connection, similarity, etc.), and thus it matters whether or not it is preserved in projection. What we are able to show is that, if two sets of  $k$  cells overlap in a fraction of  $\alpha$ , and these two sets are projected sequentially to the same brain area, *the cores* of two resulting assemblies will share at least  $\lambda^2$  fraction of the overlap of their initial projections (given by Theorem 3); recall that  $\lambda$  is the size of the core over  $k$ , and for the parameters of interest is about half. Such a modest overlap at the core – the best connected part of the assembly – is a good omen for a large overlap of the two assemblies that will eventually emerge, an intuition that is supported by simulations, see Figure 1.<sup>7</sup>

## 5 Computing with Assemblies

The assembly hypothesis proposes that assemblies are the standard representations used in higher brain functions – memory, language, reasoning, decision-making, planning, math, music, story-telling and discourse – suggesting a grand and mysterious computational system with assemblies at its center, its basic data type. *How does this computational system work?* Foremost, what are its elementary operations?

- Assemblies do appear to *project* (see the discussion in [12] for an inspiring description of the process in the mouse piriform cortex): this is about the only way that assemblies can be created, and projection appears to be a most useful operation – in fact, in its absence, it is hard to imagine what assemblies may be good for. We denote the operation of an assembly  $x$  projecting to area  $A$  to create a new assembly  $y$  as  $\mathbf{project}(x, A, y)$  (the area of assembly  $x$ , denoted  $\mathbf{area}(x) \neq A$ , is implicit). Henceforth,  $\mathbf{parent}(y) = x$ <sup>8</sup>. Through  $\mathbf{project}$ , arbitrary relations can be maintained, with brain areas being the columns and time steps the rows; for example, a recent experiment [11] seems to suggest that the “subject-verb-object” relation in natural language may be achieved this way.

<sup>7</sup> We can prove something weaker, namely that substantial overlap persists to the assemblies, albeit only for sufficiently high plasticity, and under the additional assumption that the synaptic weights from the first projection have “faded” enough by homeostasis.

<sup>8</sup> As we shall see, some operations such as  $\mathbf{reciprocal-project}$  make the  $\mathbf{parent}$  function ambiguous, but we shall be ignoring this issue here.

- We also know from experiments [15, 9] that assemblies *associate* by exchanging cells (apparently a few percentage points of their support) when they become related through co-occurrence in the world and perhaps through other acquired relations. We denote this by  $\text{associate}(x, y)$  –  $x$  and  $y$  should of course be in the same area. It can be provably carried out by activating  $\text{parent}(x)$  and  $\text{parent}(y)$ , assumed to be in different areas, for a few steps [17]. It is natural to hypothesize that cell sharing between  $x$  and  $y$  has the effect that  $y$  may be henceforth activated, with some non-zero probability, when  $x$  is activated, and vice-versa. This opens up intriguing possibilities of sophisticated probabilistic reasoning and programming, and we suspect that much of the power of the assembly model may lie in this direction – which however we do not explore or exploit here.
- On another front, recent fascinating experiments [10, 24, 25, 16] suggest that *language processing* in humans involves the building and maintenance of syntactic structures such as syntax trees, and it is natural to assume that assemblies representing words are implicated there as well. We postulate the operation  $\text{merge}(x, y, A, z)$  which takes two assemblies  $x, y$  in different areas, and projects them *both* to assembly  $z$  in a third area  $A$ . Merge, the ability to consider two things as one, has been hypothesized in linguistics to be the quintessence of syntax, see for example [4]. It follows from the results in this paper that it can be implemented in our framework.
- A more complex and very useful operation is  $\text{reciprocal-project}(x, A, y, B, z)$  which creates in two areas  $A$  and  $B$  two assemblies  $y$  and  $z$  that can activate one another (while  $y$  can be activated by  $x$ , as in ordinary  $\text{project}$ ). It is assumed that there is synaptic connectivity from  $\text{area}(x)$  to  $A$  and both ways between  $A$  and  $B$ . The original assembly  $x$ , residing in a third area, can activate directly  $y$ . We conjecture that this operation can be carried out in our framework with high probability; it works reliably in simulations.  $\text{reciprocal-merge}$  is a straightforward generalization, which seems useful for language generation. Finally, another related operation is  $\text{append}(x, A, y)$ , useful for creating sequences, which we do not detail here.

## 5.1 The Power of Computation with Assemblies

According to the assembly hypothesis, assemblies and their operations are crucial for higher mental activities such as planning, language, and reason. The question may then arise: Is this purported computational system powerful enough? In particular, *is it Turing complete?* Many computer scientists are by instinct dubious about the value of such a pursuit; we agree, and in addition we are convinced that, if the assembly hypothesis is correct, the computational power of assemblies is wielded through means that are orthogonal to computer programming. On the other hand, an assessment of the computational power of this system can usefully inform our modeling, and in particular our search for essential primitives.

To continue on this path, we must create a programming system, formal enough to address the Turing completeness question, for writing simple programs with lines such as

```
if  $\text{area}(y) = A$ ,  $\text{project}(\text{parent}(y), B, z)$ .
```

To this end, we need to assume an environment in which names of assemblies, once declared – typically in a command such as  $\text{project}(x, A, y)$  – can be used in subsequent steps of the same program (area names are finite and fixed). Also, we introduce certain new primitives:  $\text{activate}(x)$  simply activates assembly  $x$  for a few steps; that is, we assume that  $\text{project}$  creates as a side-effect a *fuse* that can activate the new assembly. Also, we assume that

the downstream synapses from area  $A$  to area  $B$  are by default inactive, and must be activated explicitly by the operation `enable( $A, B$ )`. To illustrate, `project( $x, A, y$ )` is almost equivalent to

```
enable(area( $x$ ),  $A$ ); repeat  $T$  times: activate( $x$ ); disable(area( $x$ ),  $A$ ),
```

missing only a mechanism that names the new assembly  $y$ . Here  $T$  is the number of spikes required for assembly projection (about a dozen in simulations). Of course, it is debatable how realistically one expect such a programming framework to be operating in the brain.

We also introduce a *read* operation<sup>9</sup> returning information about the assemblies that are presently active, and their areas. Notice that all this assumes a simple computational mechanism acting as an *interpreter*, and lying outside our framework<sup>10</sup>.

Finally, we must address the issue of *reliability* in assembly computation. We shall make some assumptions:

- Any newly created assembly is a *random* set of  $k = \gamma\sqrt{n}$  neurons in its area.
- Two assemblies can interfere destructively in their operations, for example by spurious associations between them, but only if they overlap in more than  $\epsilon\sqrt{n}$  cells; the literature seems to suggest that  $\epsilon$  is at least 1%.
- At last we need to introduce *homeostasis*:. We assume that synaptic weights *fade* with time, regressing to the value 1. That is, at every time step weight  $w$  becomes  $\max\{\frac{w}{(1+\beta')}, 1\}$ , where  $0 < \beta' \ll \beta$ , the plasticity parameter.<sup>11</sup>  
Fading is both realistic and necessary for the simulation, since in its absence the computational system cannot erase information, and is therefore severely limited.
- Fading means that eventually all assemblies will lose their synaptic density and connection with their parent. To prevent this, we introduce *permanent versions* of operations such as `project`. For example, `permanent_project( $x, A, y$ )` involves, besides executing an ordinary `project` operation, repeating `activate( $x$ )` every  $\tau$  steps (with synaptic connections between the two areas in focus enables), where  $\tau$  is a small constant, much smaller than  $\frac{\beta}{\beta'}$ , either indefinitely or until an explicit `fade( $y$ )` command. There is evidence that such processes do happen in the brain, for example by fading, or reviving through rehearsal raw memory traces in the hippocampus.

The following is needed in the proof of the main result:

► **Lemma 6.** *The probability that a new assembly will interact destructively with a particular already existing assembly in the same area is at most  $\exp(-\frac{\epsilon\sqrt{n}}{\gamma^2})$ .*

► **Theorem 7.** *The computational system described above can correctly simulate arbitrary  $O(\sqrt{n})$ -space computations with probability  $1 - \exp(O(\sqrt{n}))$ .*

**Sketch:** A Turing machine with a one-way circular tape of length  $m = O(\sqrt{n})$ , tape alphabet  $\Sigma$  and state set  $K$  can be simulated by a program of assembly operations. Let us assume the input-output convention that a new assembly appears in one of two designated input areas  $I_0, I_1$  at designated and well separated times, encoding a binary input tape; and that, upon

<sup>9</sup> Following a suggestion by Buszáki [5] that assemblies must be accompanied by a reader mechanism – as Buszáki puts it: “if a tree falls in the forest and there is nobody around to hear it fall, has it really fallen?”

<sup>10</sup> We do realize this is a strong assumption, unlikely to be literally true; we expect that the computational power of assemblies is realized through more organic means

<sup>11</sup> An equivalent, and perhaps more realistic, model of homeostasis would be to normalize the incoming weights of each neuron separately.

■ **Figure 3** Our representation of configuration (state, circular tape contents)  $[p, 011a]$ .

accepting termination, an assembly will appear in another area  $T$ . The Turing machine will be simulated by  $|\Sigma| + |K| + 6$  brain areas: the three input-output areas  $I_1, I_0, O$ , two areas for representing the tape denoted  $T_1$  and  $T_2$ , one area for representing the current state, denoted  $S$ , plus one area for each tape symbol  $a$  and state  $q$ , denoted, respectively,  $L_a$  and  $S_q$ . See Figure 3.

In the input phase, while the input is read from either  $I_0$  or  $I_1$  (depending on whether the input symbol is 0 or 1, assumed both to be in  $\Sigma$  (recall the input-output conventions), a chain of assemblies is created projecting back and forth between the two  $T_i$  areas (see Figure) through *permanent project* operations.

Each assembly in these two areas represents a tape square. The current symbol  $a$  in this square is represented through a projection to an assembly in area  $L_a$ , a projection that is permanent until it is explicitly faded when the same tape square is scanned again.

Similarly, another standard assembly  $s$  in area  $S$  points, through a projection (non-permanent, since the state changes at every step), to an area  $S_q$  representing the current state  $q$  (initially the starting state). The synapses from  $S$  to  $S_q$  are enabled, while the synapses from  $S$  to all other  $S_p$ 's are not<sup>12</sup>.

When the square corresponding to an assembly  $x$ , in one of the areas  $T_1, T_2$ , is scanned by the tape head, then  $x$  and  $s$  fire and a **read** is issued. Depending on the areas where assembly activity is read, say  $S_q$  and  $L_a$ , the correct current symbol  $a$  and state  $q$  are identified. Suppose that Turing machine's transition is  $\delta(q, a) = (p, b)$ . The synapses from  $S$  to  $S_q$  are disabled and those to  $S_p$  enabled, the assembly representing the previous symbol  $q$  is faded, and *permanent\_project*( $x, L_b, y$ ) is executed to record the current symbol of the tape square represented by  $x$ ; similarly for state. Then  $x$  fires again and a read is issued, to identify the tape assembly corresponding to the tape square that is next, and the computation continues. The straightforward details are omitted. ◀

<sup>12</sup>Notice that this effectively stores the state in the current instruction of the program; it can be done in more natural ways.

## 6 Discussion and open questions

We have identified a basic computational operation – random synaptic projection to a brain area followed by the selection, through inhibition, of the  $k$  neurons with the highest synaptic input – that appears to be ubiquitous in the animal brain and also useful for implementing more complex operations, but also happens to be mathematically concrete, productive, and interesting. Assembly projection can be the basis of a computational system at an intermediate level of abstraction – and unlike anything else that we have seen in theoretical neuroscience. Such a system, we hypothesize, may underlie the higher mental functions of the human brain – not an intensely researched subject in neuroscience. This hypothesis must be pursued both analytically, and – importantly – experimentally. We also believe that this line of work, and the rather simple and concrete model of brain operation it entails involving distinct brain areas, random graph connections, inhibition through cap, and probabilistic analysis, may constitute a promising entry point for theoretical computer scientists who want to work on brain-related problems. One of the contributions of this paper is pointing out the locality sensitive nature of assembly projection; this, together with the computational nature of association (which we did not consider here) promise to be important future directions for this work.

Assemblies may be implicated in implementing *natural language* in the human brain. Many recent experimental papers, see [24, 25, 11, 16, 10] among many others, appear to suggest that assembly-like operations like **projection** and **merge** may be implicated in language generation and processing.

We conclude with some more precise questions, that are motivated directly by our findings, and will help solidify the mathematical theory of assemblies, some of which we have already discussed in context in this paper.

1. Assembly support size. Is there a phase transition in the support size of an assembly (from  $\omega(k)$  to  $k + o(k)$ ) as the plasticity parameter  $\beta$  increases?
2. Assembly convergence. For high plasticity and with high probability, the limit of the random project plus cap process is a single fixed subset of size  $k$ . What are other possible limiting behaviors? E.g., is it possible to get two subsets of size  $k$  (possibly overlapping) that fire alternately? (We know cases where this happens at a small scale, that is, the two subsets of size  $k$  differ in 1-3 cells.) Will the limit have a common core (of what size as a function of plasticity) that always fires? Is the limit an activity pattern of finite length/description?
3. Model. Can our results be extended to less stylized models in which neurons fire asynchronously, or there is explicit inhibition (instead of cap)?
4. Base graph. We have assumed the base graph to have independently chosen edges. What is a deterministic condition on the base graph that suffices? E.g., is it enough to have expansion and roughly uniform degrees? Is global expansion necessary or do sufficiently strong local properties suffice (e.g., degree and co-degree)?
5. Extending GNP. Are richer models, e.g., those with higher reciprocity or triangle density, useful? For example, do they enable more powerful or efficient computations?
6. Computational power. Show that randomized  $s(n)$  space bounded computation can be simulated with  $n$  neurons and  $O(1)$  brain areas for some function  $s(n)$  larger than  $\sqrt{n}$ .
7. Capacity. Suppose that, in a brain area, we want to maintain with high probability pairwise intersections: two assemblies that intersect in a large ( $\alpha$  or more, say) fraction of their support should continue to so intersect, and similarly for pairs that intersect in less than  $\alpha$  fraction. For how many assemblies can we guarantee this invariant, as a function of  $n$ ?

8. Learning. Can assemblies perform learning (supervised or unsupervised)? Simulations suggest that assemblies can learn well-separated half-spaces quite naturally. Can this be proved formally? And what more ambitious forms of learning through assemblies are possible?
9. Assemblies vs 1-step Projections. Are assemblies (created as the limit of iterated random-project-and-cap) better for learning than 1-step (insect-like) projections? Is the recurrence of the mammalian brain a bonus or a handicap for learning?
10. Articulate a brain architecture for syntax (the building of syntactic trees) based on the assemblies operations project and merge and involving the medial temporal lobe, the superior temporal gyrus, and Broca's area of the left human brain.

## Abstract

---

A graph spanner is a fundamental graph structure that faithfully preserves the pairwise distances in the input graph up to a small multiplicative stretch. The common objective in the computation of spanners is to achieve the best-known existential size-stretch trade-off *efficiently*.

Classical models and algorithmic analysis of graph spanners essentially assume that the algorithm can read the input graph, construct the desired spanner, and write the answer to the output tape. However, when considering massive graphs containing millions or even billions of nodes not only the input graph, but also the output spanner might be too large for a single processor to store.

To tackle this challenge, we initiate the study of *local computation algorithms (LCAs)* for graph spanners in general graphs, where the algorithm should locally decide whether a given edge  $(u, v) \in E$  belongs to the output (sparse) spanner or not. Such LCAs give the user the “illusion” that a *specific* sparse spanner for the graph is maintained, without ever fully computing it. We present several results for this setting, including:

- For general  $n$ -vertex graphs and for parameter  $r \in \{2, 3\}$ , there exists an LCA for  $(2r - 1)$ -spanners with  $\tilde{O}(n^{1+1/r})$  edges and sublinear probe complexity of  $\tilde{O}(n^{1-1/2r})$ . These size/stretch trade-offs are best possible (up to polylogarithmic factors).
- For every  $k \geq 1$  and  $n$ -vertex graph with maximum degree  $\Delta$ , there exists an LCA for  $O(k^2)$  spanners with  $\tilde{O}(n^{1+1/k})$  edges, probe complexity of  $\tilde{O}(\Delta^4 n^{2/3})$ , and random seed of size  $\text{polylog}(n)$ . This improves upon, and extends the work of [Lenzen-Levi, ICALP’18].

We also complement these constructions by providing a polynomial lower bound on the probe complexity of LCAs for graph spanners that holds even for the simpler task of computing a sparse connected subgraph with  $o(m)$  edges.

To the best of our knowledge, our results on 3 and 5-spanners are the first LCAs with sublinear (in  $\Delta$ ) probe-complexity for  $\Delta = n^{\Omega(1)}$ .

## 1 Introduction

One of the fundamental structural problems in graph theory is to find a *sparse* structure which preserves the pairwise distances of vertices. In many applications, it is crucial for the sparse structure to be a *subgraph* of the input graph; this problem is called the *spanner* problem. For an input graph  $G = (V, E)$ , a  $k$ -spanner  $H \subseteq G$  (for  $k \geq 1$ ) satisfies that for any  $v, u \in V$ , the distance from  $v$  to  $u$  in  $H$  is at most  $k$  times the distance from  $v$  to  $u$  in  $G$ , where  $k$  is referred to as the *stretch* of the spanner. Furthermore, to reduce the *cost* of the solution, it is desired to output a minimum size/weight such subgraph  $H$ . The notion of spanners was introduced by Peleg and Schäffer [31] and has been used widely in different applications such as routing schemes [3, 30], synchronizers [2, 32], SDD's [37] and spectral sparsifiers [19].

It is folklore that for every  $n$ -vertex graph  $G$ , there exists a  $(2k - 1)$ -spanner  $H \subseteq G$  with  $O(n^{1+1/k})$  edges. In particular, if the *girth conjecture* of Erdős [14] is true, then this size-stretch trade-off is optimal. Spanners have been considered in many different models such as distributed algorithms [5, 8–11, 13, 33] and dynamic algorithms [4, 6, 12].

**Local computation of small stretch spanners.** When the graph is so large that it does not fit into the main memory, the existing algorithms are not sufficient for computing a spanner. Instead, we aim at designing an algorithm that answers *queries* of the form “is the edge  $(u, v)$  in the spanner?” without computing the whole solution upfront. One way to get around this issue is to consider the *Local Computation Algorithms (LCAs)* model (also known as the *Centralized Local model*), introduced by Rubinfeld et al. [35] and Alon et al. [1]. There can be many different plausible  $k$ -spanners; however, the goal of LCAs for the  $k$ -spanner problem is to design an algorithm that, given access to *primitive* probes (i.e. NEIGHBOR, DEGREE and ADJACENCY probes) on the input graph  $G$ , for each *query* on an edge  $e \in E(G)$  *consistently* with respect to a *unique*  $k$ -spanner  $H \subseteq G$  (picked by the LCA arbitrarily), outputs whether  $e \in H$ . The performance of the LCA is measured based on the *quality of solution* (i.e. number of edges in  $H$ ) and the *probe complexity* (the maximum number of probes per each query) of the algorithm<sup>5</sup>. In other words, an LCA gives us the “illusion” as if we have query access to a precomputed  $k$ -spanner of  $G$ .

The study of LCAs with *sublinear* probe complexity for *nearly linear* size spanning subgraphs (or *sparsifiers*) is initiated by Levi, Ron, and Rubinfeld [24, 25] for some restricted families of graphs such as minor-closed families. However, their focus is mainly on designing LCAs that preserve the *connectivity* while allowing the stretch factor to be as large as  $n$ . Moreover, in their work, the input graph is sparse (has  $O(n)$  edges), while the classical  $k$ -spanner problem becomes relevant only when the input graph is dense (with superlinear number of edges). Recently, Lenzen and Levi [21] designed the first sparsifier LCA in *general graphs* with  $(1 + \varepsilon)n$  edges, stretch  $O(\log^2 n \cdot \text{poly}(\Delta/\varepsilon))$  and probe complexity of  $O(\text{poly}(\Delta/\varepsilon) \cdot n^{2/3})$ , where  $\Delta$  is the maximum degree of the input graph.

<sup>5</sup> We may also measure the *time complexity* of an LCA. In our LCAs, the time complexities are clearly only a factor of  $\text{poly}(\log n)$  higher than the corresponding probe complexities, so we focus our analysis on probe complexities.

In this work, we show that sublinear time LCAs for spanners are indeed possible in several cases. We give: (I) 3 and 5-spanners for general graphs with optimal trade-offs between the number of edges and the stretch parameter (up to polylogarithmic factors), and (II) general  $k$ -spanners, either in the dense regime (when the minimum degree is at least  $n^{1/2-1/(2k)}$ ) or in the sparse regime (when the maximum degree is  $n^{1/12-\varepsilon}$ ).

**Broader scope and agenda: local computation algorithms for dense graphs.** LCAs have been established by now for a large collection of problems, including Maximal Independent Set, Maximum Matching, and Vertex Cover [1, 15, 26, 27, 29, 34, 35]. These algorithms typically suffer from a probe complexity that is exponential in  $\Delta$  and thus are efficient only in the sparse regime when  $\Delta = O(1)$ .

To this end, obtaining LCAs even with a polynomial dependency in  $\Delta$  is a major open problem for many classical local graph problems, as noted in [16, 26, 28]. For instance, recently Ghaffari and Uitto [16] obtained an LCA for the MIS problem with probe complexity of  $\Delta^{O(\log \log \Delta)} \cdot \log n$  improving upon a long line of results. Their result also illustrates the connection between LCAs with good dependency on  $\Delta$ , and algorithms for the massively parallel computation model with sublinear space per machine. Recently, [26] and [21] provided LCAs with probe complexities *polynomial* in  $\Delta$  for the problems of  $(1-\varepsilon)$ -maximum matching and sparse connected subgraphs, respectively. Note that in the context of spanners, such algorithms are still inefficient when the maximum degree is polynomial in  $n$ , which is precisely the setting where graph sparsification is applied.

## 1.1 Our results and techniques

In this paper we initiate the study of LCAs for graph spanners in *general graphs* which concerns with the following task: *How can we decide quickly (e.g., sublinear in  $n$  time) if a given edge  $e$  belongs to a sparse spanner (with fixed stretch) of the input graph, without preprocessing and storing any auxiliary information?* In the design of LCAs for graph problems, the set of defined *probes* to the input graph plays an important role. Here we consider the following common probes: NEIGHBOR probes (“what is the  $i^{\text{th}}$  neighbor of  $u$ ?”), DEGREE probes (“what is  $\deg(u)$ ?”) and ADJACENCY probes (“are  $u$  and  $v$  neighbors?”) [17, 18]. We emphasize that the answer to an ADJACENCY probe on an ordered pair  $\langle u, v \rangle$  is the index of  $v$  in  $\Gamma(u)$  if<sup>6</sup> the edge exists and  $\perp$  otherwise. Note that if the maximum degree in the input graph is  $O(1)$ , each ADJACENCY probe can be implemented by  $O(1)$  number of NEIGHBOR probes.

The problem of designing LCAs for spanners is closely related to designing LCAs for *sparse connected subgraphs* with  $(1+\varepsilon)n$  edges which was first introduced by [24]. With the exception of [21], a long line of results for this problem usually concerns special *sparse* graph families, rather than general graphs. A summary of these results with a comparison to our results is provided in Table 1.

### 1.1.1 LCAs for 3 and 5-Spanners for General Graphs

Our first contribution is the local construction of 3 and 5-spanners for general graphs, while achieving the optimal trade-offs between the number of edges and the stretch factors (up to polylogarithmic factors)<sup>7</sup>. In particular, our LCAs have  $n^{1-\varepsilon}$  probe complexity even when the input graph is dense with  $\Delta = \Omega(n)$ ; note that in such a case, given a query

<sup>6</sup>  $\Gamma(u)$  denotes the neighbor set of  $u$ , whereas  $\Gamma^+(u) = \Gamma(u) \cup \{u\}$ .

<sup>7</sup> Indeed, the girth conjecture of Erdős is resolved for these stretch factors; see e.g., [39].

■ **Table 1** Table of results on LCAs for the spanner problem. The symbol ‘-’ indicates that the stretch is not analyzed. The input graph is a simple graph with  $n$  vertices,  $m$  edges, maximum degree  $\Delta$ , and belongs to the indicated graph family.  $\tilde{O}$  hides a factor of  $\text{poly}(\log n, k)$ .

edge  $(u, v)$ , the LCA should return yes or no without being able to inspect the neighbor lists  $\Gamma(u)$  and  $\Gamma(v)$ . In what follows we show how to manipulate the common distributed construction by Baswana and Sen [5] to yield LCAs for 3-spanners and 5-spanners with sublinear probe complexity.

**The common distributed approach.** Most distributed spanner constructions are based on thinning the graph via clustering: construct a random set  $S$  of *centers* by adding each vertex to  $S$  independently with some fixed probability. For each vertex  $v$  sufficiently close to a center in  $S$ , include the edges of the shortest path connecting  $v$  to its closest member  $s \in S$ : this induces a *cluster* around each center  $s \in S$ , where every pair of vertices in the same cluster are connected by a short path. Then, add edges connecting pairs of neighboring clusters to ensure the desired stretch factor.

The following algorithm constructs a 3-spanner  $H \subseteq G$  with  $\tilde{O}(n^{3/2})$  edges. First, add to  $H$  all edges incident to vertices of degree at most  $\sqrt{n}$ . Second, pick a collection  $S$  of centers by sampling each vertex independently with probability  $\Theta(\log n/\sqrt{n})$ . Each vertex  $v$  of degree at least  $\sqrt{n}$  picks a *single* neighboring center  $s \in S \cap \Gamma(v)$  (which exists w.h.p.) as its *center*, then adds  $(v, s)$  to  $H$ , forming a collection of  $|S| = O(\sqrt{n})$  clusters (stars) around these centers. Lastly, every vertex  $u$  adds only one edge to each of its neighboring clusters – note that this last step may add edges whose endpoints are both non-centers. This results in a 3-spanner: For omitted edge  $(u, v)$  in  $G$ , if  $u$  and  $v$  are in the same cluster, then they have a path of length 2 through their shared center  $s$ . If  $u$  and  $v$  are in different clusters, an edge from  $u$  to some other vertex  $w$  in  $v$ ’s cluster would have been chosen, providing the path  $\langle u, w, s, v \rangle$  of desired stretch 3 connecting  $u$  and  $v$ , where  $s$  is  $v$ ’s center.

**The challenge and key ideas.** Recall that our goal is to design an LCA for 3-spanners  $H \subseteq G$  of size  $\tilde{O}(n^{3/2})$  and probe complexity of  $\tilde{O}(n^{3/4})$ : the LCA is given an edge  $(u, v)$  and must answer whether  $(u, v) \in E(H)$ . First, if  $\text{deg}(u)$  or  $\text{deg}(v)$  is at most  $\sqrt{n}$ , then the algorithm can immediately say YES. This requires only two DEGREE probes for the endpoints  $u, v$ . Hence, the interesting case is where both  $u$  and  $v$  have degrees at least  $\sqrt{n}$ .

We start by sampling each vertex into the center set  $S$  with probability of  $p = \Theta(\log n/\sqrt{n})$ , thus w.h.p. guaranteeing that each high-degree vertex has at least one sampled neighbor. For clarity of explanation, assume that given the ID of a vertex  $v$ , the LCA algorithm can decide

(with no further probes) whether  $v$  is sampled. Upon selecting the set of centers  $S$ , the above mentioned distributed algorithm has two degrees of freedom (which our LCA algorithm will enjoy). First, for a high-degree vertex  $v$ , there could be potentially many sampled neighbors in  $S$ : the distributed algorithm lets  $v$  join the cluster of an arbitrarily sampled neighbor. The second degree of freedom is in connecting a high-degree vertex to neighboring clusters. In the distributed algorithm, a vertex connects to an arbitrarily chosen neighbor in each of its neighboring clusters. Since the answers of the LCA algorithm should be consistent, it is important to carefully fix these decisions to allow small probe complexity.

**The naïve approach for 3-spanners and its shortcoming.** The most naïve approach is as follows: for each  $v$ , traverse the list  $\Gamma(v)$  in a fixed order and pick the *first* neighbor that satisfies the required conditions. That is, a vertex joins the cluster of its *first* sampled neighbor (center) and connects to its *first* representative neighbor in each of its neighboring clusters. To analyze the probe complexity of such a construction, consider a query edge  $(u, v)$  where  $\deg(u), \deg(v) \geq \sqrt{n}$ . By probing for the first  $\sqrt{n}$  neighbors of  $u$  and  $v$ , one can compute the cluster centers  $c_u$  and  $c_v$  of  $u$  and  $v$  with high probability. The interesting case is where  $u$  and  $v$  belong to different clusters. In such a case, the LCA algorithm should say YES only if  $v$  is the first neighbor of  $u$  that belongs to the cluster of  $c_v$ . To check if this condition holds, the algorithm should probe for each of the neighbors  $w$  of  $u$  that appears before  $v$  in  $\Gamma(u)$ , and say NO if there exists such earlier neighbor  $w$  that belongs to the cluster of  $c_v$ . Here, it remains to show how this cluster-membership testing procedure is implemented.

A *cluster-membership test*, for a pair  $\langle s, w \rangle$  with  $s \in S$ , must return YES iff  $w$  belongs to the cluster of the center  $s$ . The above mentioned algorithm thus makes  $O(\deg(v))$  cluster-membership tests for each  $w$  preceding  $u$  in  $\Gamma(v)$  and  $s = c_v$ . Since each center is sampled with probability  $p = \log n / \sqrt{n}$ , the probe complexity of a single cluster-membership test is  $O(\sqrt{n})$  w.h.p., leading to a total probe complexity of  $O(\deg(v) \cdot \sqrt{n})$ .

**Idea (I) – Multiple centers for efficient cluster-membership test.** The key idea in our solution is to pick the cluster centers in a way that allows answering each cluster-membership test for a pair  $\langle s, w \rangle$  using a single NEIGHBOR probe! Towards this goal, we let each high-degree vertex join *multiple* clusters, instead of just one. In particular, for a vertex  $w$ , we look at the subset  $\Gamma_1(w)$  consisting of its first  $\sqrt{n}$  neighbors in  $\Gamma(w)$ . We then let  $w$  join the clusters of all sampled neighbors in  $\Gamma_1(w) \cap S$ . Since each vertex is a center with probability  $p$ , this implies that, w.h.p.,  $w$  joins  $\Theta(p \cdot |\Gamma_1(w)|) = \Theta(\log n)$  many clusters. Though this approach adds a multiplicative  $O(\log n)$  factor to the size of our spanner, it will pay off dramatically in terms of the probe complexity of our LCA. In particular, this modification enables the algorithm to test cluster-membership with a single ADJACENCY probe: the vertex  $w$  belongs to the cluster of  $s$ , if the index of  $s$  in  $w$ 's neighbor-list is at most  $\sqrt{n}$  (the index is returned by the ADJACENCY probe on  $u$  and  $s$ ). This idea alone decreases the probe complexity of our LCA to  $\tilde{O}(\deg(w))$ .

**Idea (II) – Neighborhood partitioning.** The multiple center technique above allows our LCA to handle edges adjacent to a vertex  $u$  of degree at most  $n^{3/4}$ . For  $\deg(u) > n^{3/4}$ , our LCA cannot afford to look at all neighbors of  $u$ . To this end, we *partition* the neighbors of  $u$  into *blocks* of size  $n^{3/4}$  each. Rather than adding only one edge between  $u$  to each neighboring cluster, we make the decision on which edges to keep for each block *independently*, by scanning only the block containing  $v$  and keeping  $(u, v)$  if  $v$  belongs to the cluster that was not previously seen in this block. Though this leads to an increase in the number of

edges by a factor of  $\deg(u)/n^{3/4} \leq n^{1/4}$ , we can now keep the probe complexity down to  $\tilde{O}(n^{3/4})$  as we only need to scan the block containing  $v$  given the query  $(u, v)$  instead of  $u$ 's entire neighbor-list. To keep the size of the spanner small, e.g.,  $\tilde{O}(n^{3/2})$ , we use the fact that  $O(n^{1/4} \log n)$  sampled vertices are enough to hit the neighborhoods of all vertices with degree more than  $n^{3/4}$  with high probability. Since for each block of size  $n^{3/4}$  in the neighborhood of  $u$  the algorithm adds  $O(|S|)$  edges, the total number of edges added per vertex is  $O(|S| \cdot \deg(u)/n^{3/4}) = \tilde{O}(n^{3/2})$ , as desired.

**Overview of the LCA for 5-spanners.** For 5-spanners, the desired number of edges is  $\tilde{O}(n^{4/3})$ . This allows us to immediately add to the spanner all edges incident to low-degree vertices  $u$  with  $\deg(u) = \tilde{O}(n^{1/3})$ . The common distributed construction for 5-spanners computes  $O(n^{2/3})$  clusters by sampling each center independently with probability  $\Theta(\log n/n^{1/3})$ . By letting each high-degree vertex (i.e., with  $\deg(u) = \Omega(n^{1/3})$ ) join the cluster of one of its sampled neighbors, the spanner contains a collection of  $O(n^{2/3})$  (vertex-disjoint) clusters that, w.h.p., cover all high-degree vertices. Finally, each pair of neighboring clusters  $C_1, C_2$  are connected by adding an edge  $(u, v) \in (C_1 \times C_2) \cap E$  to the spanner  $H$ . It is straightforward to verify that  $H$  is a 5-spanner of size  $\tilde{O}(n^{4/3})$ .

Designing LCAs for the 5-spanner problem turns out to be significantly more challenging than the 3-spanner case. The reason is that deciding whether an edge  $(u, v)$  is in the 5-spanner requires information from the *second neighborhoods* of  $v$  and  $u$ , which is quite cumbersome when one cannot even read the entire neighborhood of a vertex. Our solution extends the 3-spanner construction in two ways: some of the edges added to our 5-spanner are between *cluster* pairs, instead of edges between a vertex and a cluster as in the 3-spanner solution. Another set of edges added to the 5-spanner is between pairs of vertex and cluster, but unlike the 3-spanner case, these clusters have now *radius two*.

**Idea (III) – Cluster partitioning (bucketing).** The standard clustering-based construction of 5-spanners adds an edge between every pair of neighboring clusters (stars). This clustering-based construction cannot be readily implemented with the desired probe complexity. To see why, consider clusters centered at  $s$  and  $t$ , containing  $u$  and  $v$  respectively. A naïve attempt spends  $\deg(s) \cdot \deg(t)$  probes for vertices between these clusters, as to consistently pick a unique edge between the two clusters.

One of our tools extends the idea of neighborhood partitioning from 3-spanner into cluster partitioning. Each of the  $O(n^{2/3})$  clusters is partitioned into balanced *buckets* of size  $\Theta(n^{1/3})$ .<sup>8</sup> The algorithm then picks only one edge between any pair of neighboring buckets. Since the number of buckets can be shown to be  $\tilde{O}(n^{2/3})$ , the spanner size still remains  $\tilde{O}(n^{4/3})$ . Unlike partitioning *neighbor-lists*, partitioning a *cluster* requires the full knowledge of its members – which are no longer nicely indexed in a list. To be able to efficiently partition a clusters, the algorithm allows only vertices with degree at most  $n^{5/6}$  to be chosen as cluster centers. The benefit of this restriction is that one can inspect the entire neighborhood of a center in  $O(n^{5/6})$ . The drawback of this approach is that it only clusters vertices that have sufficiently many neighbors (i.e., at least  $n^{1/3}$ ) with degree less than  $n^{5/6}$ . The remaining vertices are handled via their high-degree neighbors (i.e., of degree at least  $n^{5/6}$ ) as described next.

<sup>8</sup> Note that each cluster may have at most one bucket of size  $o(n^{1/3})$ .

**Idea (IV) – Representatives.** Using the neighborhood-partitioning idea from 3-spanner, all vertices with degree at least  $n^{5/6}$  can be clustered by sampling  $\tilde{O}(n^{1/6})$  cluster centers. By partitioning the neighborhood of each high-degree vertex into disjoint blocks each of size  $\tilde{O}(n^{5/6})$ , one can construct a 3-spanner for all edges incident to these high-degree vertices with probe complexity of  $\tilde{O}(n^{5/6})$  while using  $\tilde{O}(n^{4/3})$  edges. To take care of vertices of degrees less than  $n^{5/6}$  that have many high-degree neighbors, we let them join the cluster of their high-degree neighbors, hence creating *clusters of depth 2*.

To choose which cluster to join (in the second level), our vertex, which has many high-degree neighbors, simply chooses and connects itself to one or more high-degree neighbors, called its *representatives*. To determine the representatives of a vertex  $u$ , we simply pick  $\Theta(\log n)$  random neighbors of  $u$ , and w.h.p. one of them will have high-degree, and hence is chosen as  $u$ 's representative.

We implement our LCA by first picking  $|S| = \tilde{O}(n^{1/6})$  centers. Consider the query edge  $(u, v)$  where  $\deg(u), \deg(v) \geq n^{1/3}$  and  $u$  has many high-degree neighbors. Here,  $u$  has  $\Theta(\log n)$  representatives, each of which has  $\Theta(\log n)$  centers in  $S$  w.h.p., so  $u$  belongs to  $O(\log^2 n)$  clusters. As in the 3-spanner case, we keep  $(u, v)$  if  $v$  is the first neighbor of  $u$  in the cluster that  $v$  belongs to. We find the representatives of each neighbor of  $u$  by making  $O(\log n)$  probes, and for all these  $\deg(u) \cdot O(\log n) = \tilde{O}(n^{5/6})$  representatives, check if they belong to any of  $v$ 's  $O(\log^2 n)$  clusters with  $\tilde{O}(n^{5/6})$  total probes.

► **Theorem 1** (3 and 5-spanners). *For every  $n$ -vertex simple undirected graph  $G$ , there exists an LCA for  $(2r - 1)$ -spanners with  $\tilde{O}(n^{1+1/r})$  edges and probe complexity  $\tilde{O}(n^{1-1/(2r)})$  for  $r \in \{2, 3\}$ . Moreover, the algorithm only uses a seed of  $O(\log^2 n)$  random bits.*

In fact, if  $G$  has *minimum* degree  $\omega(n^{1/3})$ , we may apply the 5-spanner construction (with modified parameters) to obtain 5-spanners with even smaller number of edges as indicated in Table 1 (Theorem 12): this minimum degree assumption indeed allows even sparser spanners, bypassing the girth conjecture that holds for *general* graphs. We also remark that, in the somewhat related setting of dynamic computation, spanner algorithms with worst-case *sublinear* update time are currently known only for 3 and 5-spanners as well (see Bodwin and Krinninger, [6]).

### 1.1.2 LCA for $O(k^2)$ -spanners

Our second contribution is the local construction of  $O(k^2)$ -spanners with  $O(n^{1+1/k})$  edges for any  $k \geq 1$ , which has sub-linear probe complexity for graphs of maximum degree  $\Delta = O(n^{1/12-\varepsilon})$ . Our approach improves upon and extends the recent work of Lenzen and Levi [21]. The work of [21] aims at locally constructing a spanning subgraph with  $O(n)$  edges, but the stretch parameter of their subgraph might be as large as  $O(\text{poly}(\Delta) \log^2 n)$ . In addition, this construction requires a random seed of polynomial size. In our construction, we reduce the stretch parameter of the constructed subgraph to  $O(k^2)$ , independent of both  $n$  and  $\Delta$ , while using only  $\tilde{O}(n^{1+1/k})$  edges. In addition, we implement our randomized constructions using  $\text{poly}(\log n)$  independent random bits, whereas [21] uses  $\text{poly}(n)$  bits. We remark that for the LCAs with large stretch parameter considered in [21], our techniques can still be applied to exponentially reduce the required amount of random bits, and save a factor of  $\Delta$  in the probe complexity. The details of  $O(k^2)$ -spanners are omitted in this version: please refer to the longer version of this paper for the missing details of this result.

► **Theorem 2** ( $O(k^2)$ -spanners). *For every integer  $k \geq 1$  and every  $n$ -vertex simple undirected graph  $G$  with maximum degree  $\Delta$ , there exists a (randomized) LCA for  $O(k^2)$ -spanner with  $\tilde{O}(n^{1+1/k})$  edges and probe complexity  $\tilde{O}(\Delta^4 n^{2/3})$ . Moreover, the algorithm only uses  $O(\log^2 n)$  random bits.*

The high level structure is as in [21]: for a given stretch parameter  $k$ , partition the edges in  $G$  into the *sparse* set  $E_{\text{sparse}}$  and the *dense* set  $E_{\text{dense}}$ . Roughly speaking, the sparse set  $E_{\text{sparse}}$  only consists of edges  $(u, v)$  for which the  $k$ -neighborhood in  $G$  of either  $u$  or  $v$  contains at most  $O(n^{2/3})$  vertices. For this sparse region in the graph, we can simulate a standard distributed algorithm for spanners [5, 7] (using only a poly-logarithmic number of random bits), with small probe complexity. This yields an LCA handling the sparse edges with  $O(\Delta^2 n^{2/3})$  probe complexity.

To take care of the dense edges, we sample a collection of  $O(n^{2/3} \log n)$  centers and partition the (dense) vertices into *Voronoi cells* around these centers.

The main challenge is in connecting the Voronoi cells, keeping in mind that taking an edge between every pair of cells adds too many edges to the spanner. To get around it, the main contribution of [21] was in designing a set of rules for connecting bounded-size sub-structures in Voronoi cells, called *clusters*. The high-level description of the rules are as follows<sup>9</sup>: *mark* a random subset of  $O(n^{1/3} \log n)$  Voronoi cells (among the  $n^{2/3}$  Voronoi cells), then *connect*<sup>10</sup> them according to the following rules using  $\tilde{O}(n)$  edges each. Rule (1): connect every marked Voronoi cells to each of its neighboring Voronoi cells. Rule (2): if a Voronoi cell has no neighboring marked Voronoi cells, then connect it to all its neighboring Voronoi cells as well. Rule (3): For each pair of (not necessarily adjacent) Voronoi cell  $\mathbf{a}$  and marked Voronoi cell  $\mathbf{c}$  sharing common neighboring Voronoi cells  $\Gamma(\mathbf{a}) \cap \Gamma(\mathbf{c})$ , keep an edge from  $\mathbf{a}$  to a single Voronoi cell  $\mathbf{b}^* \in \Gamma(\mathbf{a}) \cap \Gamma(\mathbf{c})$  (i.e.,  $\mathbf{b}^*$  has the minimum ID in  $\Gamma(\mathbf{a}) \cap \Gamma(\mathbf{c})$ ). This last rule handles the edges of (unmarked) Voronoi cells that have some neighboring marked Voronoi cell.

**Idea (V) – Establishing the  $O(k^2)$  stretch guarantee.** In our implementation, the radius of each Voronoi cell is  $O(k)$  (as opposed to  $O(\Delta \log n)$  in [21]). Thus, it suffices to show that the spanner path from Voronoi cell supervertices  $\mathbf{a}$  to  $\mathbf{b}$  only visits  $O(k)$  other Voronoi cells. To this end, we impose a random ordering of the Voronoi cells, by assigning them distinct random *ranks*. We then make the following modification to Rule (3): add an edge from  $\mathbf{a}$  to  $\mathbf{b}$  if there exists a marked Voronoi cell  $\mathbf{c}$  such that the rank  $r(\mathbf{b})$  of  $\mathbf{b}$  is among the  $O(n^{1/k} \log n)$  lowest ranks in  $\Gamma(\mathbf{a}) \cap \Gamma(\mathbf{c})$ , restricted to those discovered by the LCA. This modified rule allows us to extend the inductive connectivity argument of [21] to show that every pair of adjacent cells are connected by a path that goes through  $O(k)$  cells – since each cell has radius  $O(k)$ , the final stretch is  $O(k^2)$ .

**Idea (VI) – Graph connectivity with bounded independence.** One of our key technical contributions is in showing that one can implement the above randomized random rank assignment using small number of random bits. We show that the ranks of Voronoi cells can be computed using  $T = \Theta(k)$  hash functions  $h_1, \dots, h_T$  chosen uniformly at random form a family of  $O(\log n)$ -wise independent hash functions of the form  $\{0, 1\}^{\log n} \rightarrow \{0, 1\}^{O((\log n)/k)}$ . We define our rank function as a concatenation of  $h_i$ 's on the ID of the Voronoi cell's center: for the Voronoi cell centered at  $v$ ,  $r(v) = h_1(\text{ID}(v)) \circ \dots \circ h_T(\text{ID}(v))$ . We then carefully adopt the inductive stretch argument to this randomized rank assignment with limited independence so that in the  $i^{\text{th}}$  step, our analysis only relies on the hash function  $h_i$ .

<sup>9</sup> Here, we state a simplified version of the rules. In particular, the rules are expressed in terms of clusters whose exact definitions are skipped for now. Refer to the longer version of our paper for the precise definitions of the rules.

<sup>10</sup> We *connect* two vertex sets by adding the unique lexicographically-first edge between the two vertex sets (if any exists) based on the vertex IDs of the endpoints.

### 1.1.3 Lower Bounds

To establish the lower bound, we construct two distributions over undirected  $d$ -regular graph instances that contain a designated edge  $e$ . For graphs in the first family, it holds that after removing  $e$ , w.h.p., they remain connected while in the second family, removing  $e$  disconnects the endpoints of  $e$  and leave them in separate connected components. We show that for the edge  $e$ , any LCA that makes  $o(\min\{\sqrt{n}, n/d\}) = o(\min\{\sqrt{n}, n^2/m\})$  probes can only distinguish whether the underlying graph is from the first family or the second family with probability  $1/2 + o(1)$ .

Our approach mainly follows from the analysis of Kaufman, Krivelevich, and Ron [20], on the lower bound construction of [24]. While [20] studies a rather different problem of bipartiteness testing, we consider similar probe types and obtain a similar lower bound as those of [20]. On the other hand, the construction of [24] shows the probe complexity of  $\Omega(\sqrt{n})$  for LCAs for spanning graphs that only use NEIGHBOR probes, not ADJACENCY probes.

► **Theorem 3** (Lower Bound). *Any local randomized LCA that computes, with success probability at least  $2/3$ , a spanner of the simple undirected  $m$ -edge input graph  $G$  with  $o(m)$  edges, has probe complexity  $\Omega(\min\{\sqrt{n}, n^2/m\})$ .*

The details of this result are deferred to the longer version of this paper.

## 1.2 Model Definition and Preliminaries

**Graph notation.** Throughout, we consider simple unweighted undirected graphs  $G = (V, E)$  on  $n = |V|$  vertices and  $m = |E|$  edges. Each vertex  $v$  is labeled by a unique  $O(\log n)$ -bit value  $\text{ID}(v)$ <sup>11</sup>. For  $u \in V$ , let  $\Gamma(u, G) = \{v : (u, v) \in E\}$  be the neighbors of  $u$ ,  $\deg(u, G) = |\Gamma(u, G)|$  be its degree, and define  $\Gamma^+(u, G) = \Gamma(u, G) \cup \{u\}$ . Denote  $V_I = \{v \in V : \deg(v, G) \in I\}$  where  $I$  is an interval. For  $u, v \in V$ , let  $\text{dist}(u, v, G)$  be the shortest-path distance between  $u$  and  $v$  in  $G$ . Let  $\Gamma^k(u, G) = \{v : \text{dist}(u, v, G) \leq k\}$  be the  $k^{\text{th}}$ -neighborhood of  $u$ , and denote its size  $\deg_k(u, G) = |\Gamma^k(u, G)|$ . For subsets  $V_1, V_2 \subseteq V$ , let  $E(V_1, V_2) = E \cap (V_1 \times V_2)$ . The parameter  $G$  may be omitted for the input graph.

We assume that the input graph has an adjacency list representation: each neighbor set has a fixed ordering,  $\Gamma(u) = \{v'_1, \dots, v'_{\deg(u)}\}$ ; this ordering may be arbitrarily (e.g., not necessarily sorted by vertex IDs). Many of the algorithms in this paper are based on partitioning the neighbor-list into balanced-size blocks. For  $\Delta \in [n]$  and  $u \in V$  such that  $\deg(u) \geq \Delta$ , let  $\Gamma_{\Delta, 1}(u), \dots, \Gamma_{\Delta, \Theta(\deg(u)/\Delta)}(u)$  be blocks of neighbors obtained by partitioning  $\Gamma(u)$  into consecutive parts. Each block is of size  $\Delta$ , except possibly for the last block that is allowed to contain up to  $2\Delta$  vertices.

**Local Computation Algorithms.** We adopt the definition of LCAs by Rubinfeld et al. [35]. A local algorithm has access to the *adjacency list oracle*  $\mathcal{O}^G$  which provides answers to the following probes (in a single step):

- **Neighbor probes:** Given a vertex  $v \in V$  and an index  $i$ , the  $i^{\text{th}}$  neighbor of  $v$  is returned if  $i \leq \deg(v)$ . Otherwise,  $\perp$  is returned. The orderings of neighbor sets are fixed in advance, but can be arbitrary.
- **Degree probes:** Given a vertex  $v \in V$ , return  $\deg(v)$ . This probe type is defined for convenience, and can alternatively be implemented via a binary search using  $O(\log n)$  NEIGHBOR probes.

<sup>11</sup> We do *not* require IDs to be a bijection  $V \rightarrow [n]$  as in other LCA papers.

- **Adjacency probes:** Given an ordered pair  $\langle u, v \rangle$ , if  $v \in \Gamma(u)$  then the index  $i$  such that  $v$  is the  $i^{\text{th}}$  neighbor of  $u$ . Otherwise,  $\perp$  is returned.

► **Definition 4** (LCA for Graph Spanners). An LCA  $\mathcal{A}$  for graph *spanners* is a (randomized) algorithm with the following properties.  $\mathcal{A}$  has access to the adjacency list oracle  $\mathcal{O}^G$  of the input graph  $G$ , a tape of random bits, and local read-write computation memory. When given an input (query) edge  $(u, v) \in E$ ,  $\mathcal{A}$  accesses  $\mathcal{O}^G$  by making probes, then returns YES if  $(u, v)$  is in the spanner  $H$ , or returns NO otherwise. This answer must only depend on the query  $(u, v)$ , the graph  $G$ , and the random bits. For a fixed tape of random bits, the answers given by  $\mathcal{A}$  to all possible edge queries, must be consistent with one particular sparse spanner.

The main complexity measures of the LCA for graph spanners are the size and stretch of the output spanner, as well as the probe complexity of the LCA, defined as the maximum number of probes that the algorithm makes on  $\mathcal{O}^G$  to return an answer for a single input edge. Informally speaking, imagine  $m$  instances of the same LCA, each of which is given an edge of  $G$  as a query, while the *shared* random tape is broadcasted to all. Each instance decides if its query edge is in the subgraph by making probes to  $\mathcal{O}^G$  and inspecting the random tape, but may not communicate with one another by any means. The LCA succeeds for the input graph  $G$  and the random tape if the collectively-constructed subgraph is a desired spanner. All the algorithms in this paper are randomized and, for any input graph, succeed with high probability  $1 - 1/n^c$  over the random tape.

**Paper Organization.** In Section 2 and 3 we describe our results for 3 and 5-spanners in general graphs. For simplicity, we first describe all our randomized algorithms as using full independence, then in Section 4, we explain how these algorithms can be implemented using a seed of poly-logarithmic number of random bits).

**Clarification.** Throughout we use the term “spanner construction” when describing how to construct our spanners. These construction algorithms are used only to define the unique spanner, based on which the LCA makes its decisions: we never construct the full, global spanner at any point.

## 2 LCA for 3-Spanners

In this section, we present the 3-spanner LCA with probe complexity of  $\tilde{O}(n^{3/4})$ . We begin in Section 2.1 by establishing some observations that allow us to “take care” of different types of edges separately based on the degrees of their endpoints. In Section 2.2-2.3 we provide constructions that take care of each type of edges; the analysis of stretch, probe complexity and spanner size for each case is included in their respective sections. We establish our final LCA for 3-spanners in Section 2.4.

### 2.1 Edge classification

► **Definition 5** (Subgraphs taking care of edges). For stretch parameter  $k$  and set of edges  $E' \subseteq E$ , we say that the subgraph  $H' \subseteq G$  *takes care* of  $E'$  if for every  $(u, v) \in E'$ ,  $\text{dist}(u, v, H') \leq k$ .

Observe that if we have a collection of subgraphs  $H_i$ 's such that every edge in  $(u, v) \in E$  is taken care by at least one  $H_i$ , then the union  $H$  of the  $H_i$ 's constitutes a  $k$ -spanner for  $G$ .

► **Observation 6** (Spanner construction by combining subgraphs). *For a collection of subsets  $E_1, \dots, E_\ell \subseteq E$  where  $\cup_{i \in [\ell]} E_i = E$ , if  $H_i$  is a subgraph of  $G$  that takes care of  $E_i$ , then  $H = \cup_{i \in [\ell]} H_i$  is a  $k$ -spanner of  $G$ . Further, if we have an LCA  $\mathcal{A}_i$  for computing each  $H_i$  (i.e., deciding whether the query edge  $(u, v) \in H_i$  and reporting YES or NO accordingly), we may construct a final LCA that runs every  $\mathcal{A}_i$  and answer YES precisely when at least one of them does so. The performance of our overall LCA (number of edges, probes, or random bits) can then be bounded by the respective sum over that of  $\mathcal{A}_i$ 's.*

Note that  $H_i$  may contain edges of  $E$  that are not in  $E_i$ , thus it is necessary that the overall LCA invokes every  $\mathcal{A}_i$  even if  $\mathcal{A}_i$  does not take care of the query edge.

**Graph partitioning.** A vertex  $v$  is low-degree if  $\deg(v) \leq \sqrt{n}$ , it is high-degree if  $\deg(v) \geq \sqrt{n}$  and it is super-high degree if  $\deg(v) \geq n^{3/4}$ . Our LCA for 3-spanner assigns each edge of  $E$  into one or more of the subsets  $E_{\text{low}}$ ,  $E_{\text{high}}$ , or  $E_{\text{super}}$  based on the degrees of its endpoints, where

$$E_{\text{low}} = \{(u, v) \in E \mid \min\{\deg(u), \deg(v)\} \leq \sqrt{n}\},$$

$$E_{\text{high}} = \{(u, v) \in E \mid \sqrt{n} < \min\{\deg(u), \deg(v)\} \leq n^{3/4}\}, \text{ and } E_{\text{super}} = E \setminus (E_{\text{low}} \cup E_{\text{high}}).$$

Because vertices of degree at most  $\sqrt{n}$  have  $O(n \cdot \sqrt{n}) = O(n^{3/2})$  incident edges in total, we may afford to keep all these edges, letting  $H_{\text{low}} = (V, E_{\text{low}})$ . Thus, an LCA simply needs to check the degrees of both endpoints (via DEGREE probes), and answer YES precisely when both (or in fact, even one) have degrees at most  $\sqrt{n}$ . From now on, assume that  $\deg(u), \deg(v) \geq \sqrt{n}$ .

## 2.2 3-spanner for the edges $E_{\text{high}}$

We pick a random *center* set  $S$  of size  $O(\sqrt{n} \log n)$  by sampling vertex  $v \in V$  into  $S$  independently with probability  $p = \Theta((\log n)/\sqrt{n})$ . For now, we assume that given an ID of a vertex  $v$ , we can decide in  $O(1)$  time if  $v \in S$ . At the end of the section, we describe how to implement this using a seed of  $O(\log n)$  random bits. For each endpoint  $v$  of  $E_{\text{high}}$ , let  $S(v) = \Gamma'(v) \cap S$  where  $\Gamma'(v)$  is the set of the first  $\sqrt{n}$  neighbors of  $v$  in  $\Gamma(v)$ . By Chernoff bound we have that  $|S(v)| = \Theta(\log n)$  (and in particular,  $S(v)$  is non-empty). We call  $S(v)$  the *multiple-center* set of  $v$ . The algorithm adds to  $H_{\text{high}}$  the edges  $(v, s)$  connecting  $v$  to each of its centers  $s \in S(v)$ . This adds a total of  $O(n \log n)$  edges.

Next, for every  $v$  with  $\deg(v) = O(n^{3/4})$ , the algorithm traverses its neighbor list  $\Gamma(v) = \{u_1, \dots, u_\ell\}$  and adds the edges  $(u_i, v) \in E_{\text{high}}$  to the spanner  $H_{\text{high}}$  only if  $u_i$  belongs to a *new* cluster; i.e.,  $u_i$  has a center  $s \in S(u_i)$  that no previous neighbor  $u_j$ ,  $j < i$ , has as its center in  $S(u_j)$ . Since the algorithm adds an edge whenever a new center is revealed and there are  $O(\sqrt{n} \log n)$  centers, the total number of edges added to the spanner is  $O(n^{3/2} \log n)$ .

We next describe the LCA that, given an edge  $(u, v) \in E_{\text{high}}$ , says YES iff  $(u, v) \in H_{\text{high}}$ . We assume throughout that  $\deg(v) \leq \deg(u)$ , so  $\deg(v) = O(n^{3/4})$ . First, by probing for the first  $\sqrt{n}$  neighbors of  $u$  and  $v$ , one can compute the center-sets  $S(u)$  and  $S(v)$  each containing  $O(\log n)$  centers in  $S$ . Next, the algorithm probes for all of  $v$ 's neighbors  $\Gamma(v) = \{u_1, \dots, u_j = u, \dots, u_\ell\}$ . For every neighbor  $u_i$  appearing before  $u$  in  $\Gamma(v)$ , i.e., for every  $i < j$ , and for every center  $s \in S(u)$ , the algorithm makes a *cluster-membership test* for  $s$  and  $u_i$ . This cluster-membership test can be answered by making a single ADJACENCY probe on the pair  $\langle u_i, s \rangle$ , namely  $s \in S(u_i)$  only if  $s$  is among the first  $\sqrt{n}$  neighbors of  $u_i$ . Eventually, the algorithm  $\mathcal{A}_{\text{high}}$  answers YES only if there exists  $s' \in S(u)$  such that  $s' \notin \bigcup_{i=1}^{j-1} S(u_i)$ . It is straightforward to verify that the probe complexity is  $\tilde{O}(\deg(u) + \sqrt{n}) = O(n^{3/4})$ .

■ **Figure 1** Illustration for the local construction of  $H_{\text{high}}$ .

Finally, we show that  $H_{\text{high}}$  is indeed a 3-spanner. For every edge  $(u, v)$  not added to the spanner, let  $s \in S(u)$  and let  $u_i$  be the first vertex in  $\Gamma(v)$  satisfying  $s \in S(u_i)$ . By construction,  $(u_i, v) \in H_{\text{high}}$  and also the edges  $(u_i, s)$  and  $(u, s)$  are in the spanner  $H_{\text{high}}$ , providing a path of length 3 in  $H_{\text{high}}$ .

### 2.3 3-spanner for the edges $E_{\text{super}}$

We proceed by describing the construction of the 3-spanner  $H_{\text{super}}$  that takes care of the edges  $E_{\text{super}}$ . Let  $S'$  be a collection of  $O(n^{1/4} \log n)$  centers obtained by sampling each  $v \in V$  independently with probability  $p' = \Theta((\log n)/n^{3/4})$ . For each vertex  $v$ , define its center set  $S'(v)$  to be the members of  $S'$  among the first  $n^{3/4}$  neighbors of  $v$ , and if  $\deg(v) \leq n^{3/4}$ , then  $S'(v) = S' \cap \Gamma(v)$ . First, as in the construction of  $H_{\text{high}}$ , the algorithm connects each  $v$  to each of its centers by adding the edges  $(u, s)$  for every  $u$  and  $s \in S'(u)$  to the spanner  $H_{\text{super}}$ .

Consider a vertex  $v$  and divide its neighbor list into consecutive *blocks*  $\Gamma_1(v), \dots, \Gamma_\ell(v)$ , each of size  $n^{3/4}$  (expect perhaps for the last block). In every block  $\Gamma_i(v) = \{u_{i,1}, \dots, u_{i,\ell'}\}$ , the algorithm adds the edge  $(v, u_{i,j})$  to the spanner  $H_{\text{super}}$  only if  $u_{i,j}$  belongs to a *new* cluster with respect to all other vertices that appear before it in that block. Formally, the edge  $(v, u_{i,j})$  is added iff there exists  $s \in S'(u_{i,j})$  such that  $s \notin \bigcup_{q \leq j-1} S'(u_{i,q})$ . This completes the description of the construction. Observe that within each block, the LCA adds an edge for each new center. W.h.p., there are  $O(n/n^{3/4}) = O(n^{1/4})$  blocks and  $|S'| = O(n^{1/4} \log n)$  centers, so  $O(\sqrt{n} \log n)$  edges are added for each  $v$ , yielding a spanner of size  $O(n^{3/2} \log n)$ .

The LCA  $\mathcal{A}_{\text{super}}$  is very similar to  $\mathcal{A}_{\text{high}}$ : the main distinction is that given an edge  $(u, v)$  with  $\deg(u) \geq n^{3/4}$ , the algorithm  $\mathcal{A}_{\text{super}}$  will probe only for the block  $\Gamma_i(v) = \{u_{i,1}, \dots, u_{i,j} = u, u_{i,\ell'}\}$  to which  $v$  belongs, and will make its decision only based on that block. By probing for the degree of  $v$ , and the index  $j$  such that  $u$  is the  $j^{\text{th}}$  neighbor of  $v$ , one can compute the block  $\Gamma_i(v)$  by making  $n^{3/4}$  NEIGHBOR probes. In addition, by probing for the first  $n^{3/4}$  neighbors of both  $u$  and  $v$ , one can compute the multiple-center sets  $S'(u)$  and  $S'(v)$ . Finally, the algorithm applies a cluster-membership test for each pair  $s \in S'(u)$  and  $u_{i,q}$  for  $q \leq j-1$ . It returns YES only if there exists  $s \notin \bigcup_{q \leq j-1} S'(u_{i,q})$ . Hence, the number of probes made by the LCA is w.h.p. bounded by  $|\Gamma_i(v)| \cdot |S'(u)| = O(n^{3/4} \log n)$ .

We now show that  $H_{\text{super}}$  is a 3-spanner for the edges  $H_{\text{super}}$ . Let  $(u, v)$  be such that  $\deg(u) \geq n^{3/4}$  and let  $\Gamma_i(v)$  be the block in  $\Gamma(v)$  to which  $u$  belongs. Since  $\deg(u) \geq n^{3/4}$ , w.h.p.  $|S'(u)| = \Theta(\log n)$ . Assume that  $(u, v) \notin H_{\text{super}}$ . Fix  $s \in S'(u)$  and let  $u_{i,q}$  be the first vertex in  $\Gamma_i(v)$  that belongs to the cluster of  $s$ . Since  $(u, v) \notin H_{\text{super}}$ , such a vertex  $u_{i,q}$  is guaranteed to exist. The spanner  $H_{\text{super}}$  contains the edges  $(s, u)$ ,  $(s, u_{i,q})$  and  $(v, u_{i,q})$ , thus containing a path of length 3 between  $u$  and  $v$ .

■ **Figure 2** Illustration for the local construction of  $H_{\text{super}}$ .

## 2.4 The Final LCA

Given an edge  $(u, v)$  the algorithm says YES if one of the following holds:

- $\deg(u), \deg(v) \leq \sqrt{n}$ .
- $u \in S(v) \cup S'(v)$  (or vice versa).
- the local algorithm  $\mathcal{A}_{\text{high}}$  says YES on edge  $(u, v)$ .
- the local algorithm  $\mathcal{A}_{\text{super}}$  says YES on edge  $(u, v)$ .

This completes the 3-spanner LCA from Theorem 1.

**Missing piece: computing centers in the LCA model.** In the LCA model, we do not generate the entire set  $S$  (or  $S'$ ) up front. Instead, we may verify whether  $v \in S$  on-the-fly using  $v$ 's ID by, e.g., applying a random map (chosen according to the given random tape) from  $v$ 's ID to  $\{0, 1\}$  with expectation  $p$ . In fact, this hitting set argument does not require full independence – the discussion on reducing the amount of random bits is given in Section 4, but for now we formalize it as the following observation.

► **Observation 7** (Local Computation of Centers). *Let  $S$  be a center set obtained by placing each vertex into  $S$  independently with probability  $p = \Theta(\log n / \Delta)$ . W.h.p.,  $S$  forms a hitting set for the collection of neighbor sets of all vertices of degree at least  $\Delta$ . Further, under the LCA model, we may check whether  $v \in S$  locally without making any probes.*

## 3 LCA for 5-Spanners

We now consider LCAs for 5-spanners, aiming for spanners of size  $\tilde{O}(n^{4/3})$  with probe complexity  $\tilde{O}(n^{5/6})$ . We start by noting that the construction of  $H_{\text{super}}$  for the 3-spanners in fact gives for every  $r \geq 1$ , a 3-spanner of size  $\tilde{O}(n^{1+1/r})$  for the subset of edges  $(u, v)$  with  $\min\{\deg(u), \deg(v)\} \geq n^{1-1/(2r)}$ : this is achieved by instead setting the threshold for super-high degree at  $n^{1-1/(2r)}$ , pick  $|S'| = \tilde{O}(n^{1/(2r)})$  centers, and use block size  $n^{1-1/(2r)}$ . The probe complexity for querying the spanner is  $\tilde{O}(n^{1-1/(2r)})$ . For 5-spanner, by taking  $r = 3$ , one takes care of all edges  $(u, v)$  with  $\max\{\deg(u), \deg(v)\} \geq n^{5/6}$ .

Let  $\Delta_{\text{low}} = n^{1/r}$ ,  $\Delta_{\text{med}} = n^{1/2-1/(2r)}$  and  $\Delta_{\text{super}} = n^{1-1/(2r)}$ . For the purpose of constructing 5-spanners for general graphs, we let  $r = 3$ , simplifying the thresholds to  $\Delta_{\text{low}} = \Delta_{\text{med}} = n^{1/3}$  and  $\Delta_{\text{super}} = n^{5/6}$ .) Again, we may afford to keep all edges incident to some vertex of degree at most  $\Delta_{\text{low}}$ .

For integers  $a \leq b$ , let  $V_{[a,b]} = \{v \in V(G) \mid \deg(v) \in [a, b]\}$ . We will design a subgraph  $H \subseteq G$  that will take care of the remaining edges  $E_{\text{med}} = E(V_{[\Delta_{\text{med}}, \Delta_{\text{super}]}, V_{[\Delta_{\text{med}}, \Delta_{\text{super}]})}$ .

■ **Table 2** Edge categorization for the construction of 5-spanners.

Subset	Criteria	# Edges	Probe Complexity
$E_{\text{low}}$	$(u, v) \in E(V, V_{[1, \Delta_{\text{low}}]})$	$O(n \cdot \Delta_{\text{low}}) = O(n^{1+\frac{1}{r}})$	$O(1)$
$E_{\text{bckt}}$	$(u, v) \in E(V_{\text{dsrt}}, V_{\text{dsrt}})$	$O(\frac{n^2 \log^2 n}{\Delta_{\text{med}}^2}) = O(n^{1+\frac{1}{r}} \log^2 n)$	$O((\Delta_{\text{super}} + \Delta_{\text{med}}^2) \log^2 n) = O(n^{1-\frac{1}{2r}} \log^2 n)$
$E_{\text{rep}}$	$(u, v) \in E(V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}, V_{\text{crwd}})$	$O(\frac{n^2}{\Delta_{\text{super}}} \cdot \log n) = O(n^{1+\frac{1}{r}} \log n)$	$O(\Delta_{\text{super}} \log^3 n) = O(n^{1-\frac{1}{2r}} \log^3 n)$
$E_{\text{super}}$	$(u, v) \in E(V, V_{[\Delta_{\text{super}}, n]})$	$O(\frac{n^2 \log n}{\Delta_{\text{super}}}) = O(n^{1+\frac{1}{r}} \log n)$	$O(\Delta_{\text{super}} \log n) = O(n^{1-\frac{1}{2r}} \log n)$

► **Definition 8** (Deserted and Crowded vertices). A vertex  $v \in V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$  is *deserted* if at least half of its neighbors in  $\Gamma_{\Delta_{\text{med}}, 1}(v)$  are of degree at most  $\Delta_{\text{super}}$ ; i.e.,  $|\Gamma_{\Delta_{\text{med}}, 1}(v) \cap V_{[1, \Delta_{\text{super}}]}| \geq \Delta_{\text{med}}/2$ . Otherwise, the vertex is *crowded*.

**Criteria for edges.** We aim to take care of edges for which both endpoints are in  $V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$ . To categorize our edges for the purpose of constructing 5-spanners, we need the following partition of these vertices.

Let  $V_{\text{dsrt}}$  (resp.,  $V_{\text{crwd}}$ ) be the set of deserted (resp., crowded) vertices in  $V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$ . Given a vertex, we can verify whether it is in any of these sets using  $O(\Delta_{\text{med}})$  probes by checking the degrees of  $v$  and each vertex in  $\Gamma_{\Delta_{\text{med}}, 1}(v)$ . We then assign each  $(u, v) \in E$  into one of the four cases {low, bckt, rep, super} as given in Table 2. It is straightforward to verify that when  $\Delta_{\text{low}} = \Delta_{\text{med}}$  (namely when we choose  $r = 3$ , which also yields the required performance), these four cases take care of all edges in  $E$ . We note that  $H_{\text{rep}}$  assumes that  $H_{\text{super}}$  is included:  $E_{\text{rep}}$  is taken care by  $H_{\text{rep}} \cup H_{\text{super}}$ , not by  $H_{\text{rep}}$  alone.

**LCA for  $E_{\text{bckt}}$ : the cluster partitioning method.** The algorithm is as follows.

- Only vertices of degree at most  $\Delta_{\text{super}}$  are chosen to be in  $S$  with probability  $p = \Theta((\log n)/\Delta_{\text{med}})$ . Since at least half the vertices in  $\Gamma_{\Delta_{\text{med}}, 1}(v)$  for any  $v \in V_{\text{dsrt}}$  have degree smaller than  $\Delta_{\text{super}}$ , we have that w.h.p.  $|S(v)| = \Theta(\log n)$  the cluster-membership test can be done with constant number of probes. Let us denote by  $C(s) = \{s\} \cup \{v : s \in S(v)\}$  the cluster of center  $s$ .
- The partitioning of clusters into buckets is defined in a consistent way (regardless of the given query edge); for instance, create a list of vertices in the cluster, sort them according to their IDs, divide the list into buckets of size  $\Delta_{\text{med}}$  possibly except for the last one. Note that we partition  $C(s)$  and  $C(t)$  separately – we do not combine their elements. Similarly, once we obtain buckets containing  $u$  and  $v$ , the order in which we check the adjacency of  $u'$  and  $v'$  must be consistent. To this end, define the ID of an edge  $(u, v)$  as  $(\text{ID}(u), \text{ID}(v))$ , where the comparison between edge IDs is lexicographic. Thus, this step only adds the edge of minimum ID between the two clusters.
- We also set the precondition  $(u, v) \in E(V_{[\Delta_{\text{med}}, n]}, V_{[\Delta_{\text{med}}, n]})$ , and consistently only allow candidate pairs  $(u', v') \in E(V_{[\Delta_{\text{med}}, n]}, V_{[\Delta_{\text{med}}, n]})$ , to ensure that the lexicographically first edge of this exact specification is added if one exists. We do not restrict to  $E_{\text{bckt}}$ , which require both endpoints to be deserted vertices, because checking whether  $(u', v') \in E_{\text{bckt}}$  would take  $\Theta(\Delta_{\text{med}})$  probes instead of constant probes. We restrict to edges whose endpoints have degrees at least  $\Delta_{\text{med}}$  instead of considering the entire  $E$  so that  $S$  would be well-defined.

**Local construction of  $H_{\text{bckt}}$ .** Each  $v \in V_{[1, \Delta_{\text{super}}]}$  is added to  $S$  with probability  $p = \Theta(\log n / \Delta_{\text{med}})$ .

(A) If  $u \in S(v)$  or  $v \in S(u)$ , answer YES.

(B) If  $(u, v) \in E(V_{[\Delta_{\text{med}}, n]}, V_{[\Delta_{\text{med}}, n]})$ :

- Compute  $S(u)$  and  $S(v)$  by iterating through  $\Gamma_{\Delta_{\text{med}}, 1}(u)$  and  $\Gamma_{\Delta_{\text{med}}, 1}(v)$ .
- For each pair of  $s \in S(u)$  and  $t \in S(v)$ :
  - Partition each of the clusters  $C(s)$  and  $C(t)$  into buckets of size (mostly)  $\Delta_{\text{med}}$ . Denote the buckets containing  $u$  and  $v$  by  $\text{Bucket}(u, s)$  and  $\text{Bucket}(v, t)$ , respectively.
  - Iterate through each pair of  $u' \in \text{Bucket}(u, s)$  and  $v' \in \text{Bucket}(v, t)$  and check if  $(u', v') \in E(V_{[\Delta_{\text{med}}, n]}, V_{[\Delta_{\text{med}}, n]})$ . Answer YES if the edge of minimum ID found is  $(u', v') = (u, v)$ .

► **Lemma 9.** For  $1 \leq \Delta_{\text{med}} \leq \sqrt{n} \leq \Delta_{\text{super}} \leq n$ , there exists a subgraph  $H_{\text{bckt}} \subseteq G$  such that w.h.p.:

- (i)  $H_{\text{bckt}}$  has  $O(\frac{n^2 \log^2 n}{\Delta_{\text{med}}^2})$  edges,
- (ii)  $H_{\text{bckt}}$  takes care of  $E_{\text{bckt}}$ ; that is, for every  $(u, v) \in H_{\text{bckt}}$ ,  $\text{dist}(u, v, H_{\text{bckt}}) \leq 5$ , and
- (iii) for a given edge  $(u, v) \in E$ , one can test if  $(u, v) \in H_{\text{bckt}}$  by making  $O((\Delta_{\text{super}} + \Delta_{\text{med}}^2) \log^2 n)$  probes.

**Proof.**

- (i) **Size.** In (A) we add  $|S(v)| = \Theta(\log n)$  edges for each  $v \in V_{\text{dsrt}}$ , which constitutes to  $O(n \log n)$  edges in total. In (B), we add one edge between each pair of buckets. We now compute the total number of buckets. The total size of clusters  $\sum_{s \in S} |C(s)| \leq |S| + \sum_{v \in V_{[\Delta_{\text{med}}, n]}} |S(v)| = O(n \log n)$ , so there can be up to  $O((n \log n) / \Delta_{\text{med}})$  full buckets of size  $\Delta_{\text{med}}$ . As buckets are formed by partitioning  $|S|$  clusters, there are up to  $|S| = \Theta((n \log n) / \Delta_{\text{med}})$  remainder buckets of size less than  $\Delta_{\text{med}}$ . Thus, there are  $\Theta((n \log n) / \Delta_{\text{med}})$  buckets, and  $O(((n \log n) / \Delta_{\text{med}})^2)$  edges are added in (B).
- (ii) **Stretch.** Suppose that  $(u, v)$  is omitted. Fix centers  $s \in S(u)$  and  $t \in S(v)$ , then the lexicographically-first edge  $(u', v') \in E(\text{Bucket}(u, s), \text{Bucket}(v, t))$  must have been added to  $H_{\text{bckt}}$ , forming the path  $\langle u, s, u', v', t, v \rangle$  (or shorter, if there are repeated vertices), yielding  $\text{dist}(u, v, H_{\text{bckt}}) \leq 5$ .
- (iii) **Probes.** Computing  $S(u)$  and  $S(v)$  takes  $O(\Delta_{\text{med}})$  probes. For each pairs of centers, we scan through the entire neighbor-lists  $\Gamma(s)$  and  $\Gamma(t)$  and collect all vertices in their respective clusters. This takes  $O(\Delta_{\text{super}})$  probes each because we restrict to centers of degree at most  $\Delta_{\text{super}}$ . Given the clusters, we identify the buckets containing  $u$  and  $v$  each of size  $O(\Delta_{\text{med}})$ . We then check through candidates  $(u', v')$  between these buckets, taking  $O(\Delta_{\text{med}}^2)$  ADJACENCY probes. So, each pair of centers requires  $O(\Delta_{\text{super}} + \Delta_{\text{med}}^2)$  total probes. We repeat the process for  $|S(u)| \cdot |S(v)| = O(\log^2 n)$  pairs of centers w.h.p., yielding the claimed probe complexity. ◀

**LCA for  $E_{\text{rep}}$ : the Representative method.** We first explain the computation of the representative set  $\text{Reps}(v)$  for a crowded vertex  $v \in V_{\text{crwd}}$ , i.e., a collection of neighbors of  $v$  that have degree at least  $n^{5/6}$ . Using the random bits and the vertex ID, we sample a set  $R_v$  of  $\Theta(\log n)$  (not necessarily distinct) indices in  $[\Delta_{\text{med}}]$  at random (for details, see Sec. 4). Denote the neighbor-list of  $v$  by  $\{x'_1, \dots, x'_{\deg(v)}\}$ , then define  $\text{Reps}(v) = \{x'_i : i \in R_v \text{ and } \deg(x'_i) \geq \Delta_{\text{super}}\}$ . Then since at least half of the vertices in  $\Gamma_{\Delta_{\text{med}}, 1}(v)$  are of degree

■ **Figure 3** Illustration for the local construction of  $H_{\text{bckt}}$ . Green lines show the partition of clusters into buckets.

at least  $\Delta_{\text{super}}$ , w.h.p.  $\text{Reps}(v) \neq \emptyset$ . For consistency, we allow the same definition for  $\text{Reps}(v)$  for any  $v \in V_{[\Delta_{\text{med}}, n]}$  as well, even if it may result in empty sets of representatives. Hence computing  $\text{Reps}(v)$  takes  $O(\log n)$  probes<sup>12</sup>.

Let  $E_{\text{super}} = \{(u, v) \in E \mid \max\{\deg(u), \deg(v)\} \geq n^{5/6}\}$  and apply the 3-spanner algorithm of Sec. 2 to construct a subgraph  $H_{\text{super}}$  that takes care of the edges  $E_{\text{super}}$ . To construct  $H_{\text{super}}$  the algorithm (fully described<sup>13</sup> in Sec. 2) samples a set  $S'$  of centers by picking each  $v \in V$  independently with probability  $O(\log n/n^{5/6})$ . For every  $v$  with  $\deg(v) \geq n^{5/6}$ , let  $S'(v)$  be the sampled neighbors in  $S' \cap \Gamma_1(v)$  where  $\Gamma_1(v)$  is the first block of size  $n^{5/6}$  in  $\Gamma(v)$ . This allows us to check membership to a cluster of  $s \in S'$  using a single adjacency probe. The idea would be to extend the 1-radius clusters of  $S'$  by one additional layer consisting of the crowded vertices connected to the cluster via their representatives.

For convenience, for a crowded  $v$ , define  $RS(v) = \cup_{x' \in \text{Reps}(v)} S'(x')$ , the set of (multiple) centers of any of  $v$ 's representatives. Observe that by adding the edge  $(v, x')$  to  $H_{\text{rep}}$  for every  $x' \in \text{Reps}(v)$ , it yields that  $\text{dist}(v, s, H_{\text{rep}} \cup H_{\text{super}}) \leq 2$  for any  $s \in RS(v)$ .

Consider the query  $(u, v)$ , and suppose that  $v = v'_i$  is the  $i^{\text{th}}$  neighbor in  $u$ 's neighbor-list,  $\Gamma(u) = \{v'_1, \dots, v'_{\deg(u)}\}$ . We then add  $(u, v)$  to  $H_{\text{rep}}$  if and only if  $v$  introduces a new center through some representative; that is,  $RS(v'_i) \setminus \cup_{j < i} RS(v'_j) \neq \emptyset$ . To verify this condition locally, we first compute  $RS(v)$ , and for each of  $\{v'_j\}_{j < i}$ ,  $\text{Reps}(v'_j)$ . Then, we discard  $(u, v)$  if for every center  $s \in RS(v)$ , there exists  $x$  and  $v'_j$  where  $x \in \text{Reps}(v'_j)$  and  $s \in S'(x)$ ; the last condition takes constant probes to verify. This gives the full LCA for constructing  $H_{\text{rep}}$  below.

**Local construction of  $H_{\text{rep}}$ .** Each  $v \in V$  is added to  $S'$  with probability  $p = \Theta((\log n)/\Delta_{\text{super}})$ .

(A) If  $v \in V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$  and  $u \in \text{Reps}(v)$ , answer YES.

(B) If  $u, v \in V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$ :

- Compute  $RS(v)$ .
- Denote the neighbor-list of  $u$  by  $\{v'_1, \dots, v'_{\deg(u)}\}$ ; identify  $i$  such that  $v = v'_i$ .
- For each vertex  $w \in \{v'_1, \dots, v'_{i-1}\}$ , if  $w \in V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}$ , compute  $\text{Reps}(w)$ .
- For each  $s \in RS(v)$ , iterate to check for a vertex  $x$  in any of the  $\text{Reps}(w)$ 's obtained above, such that  $s \in S'(x)$ . Answer YES if there exists a vertex  $s$  where no such  $x$  exists.

<sup>12</sup> The naïve solution traverses the entire  $\Delta_{\text{med}}$  first neighbors of  $v$  which is too costly.

<sup>13</sup> Upon replacing the degree threshold of  $n^{3/4}$  with  $n^{5/6}$ .

■ **Figure 4** Illustration for the local construction of  $H_{\text{rep}}$ .

► **Lemma 10.** For  $1 \leq \Delta_{\text{med}} \leq \Delta_{\text{super}} \leq n$ , there exists a subgraph  $H_{\text{rep}} \subseteq G$  such that w.h.p.:

- (i)  $H_{\text{rep}}$  has  $O(n^2/\Delta_{\text{super}} \cdot \log n)$  edges,
- (ii)  $H_{\text{rep}} \cup H_{\text{super}}$  takes care of  $E_{\text{rep}}$ ; that is, for every  $(u, v) \in E_{\text{rep}}$ ,  $\text{dist}(u, v, H_{\text{rep}} \cup H_{\text{super}}) \leq 3$ , and
- (iii) for a given edge  $(u, v) \in E$ , one can test if  $(u, v) \in H_{\text{rep}}$  by making  $O(\Delta_{\text{super}} \log^3 n)$  probes.

**Proof.**

- (i) **Size.** W.h.p., in (A) we add at most  $\sum_{v \in V_{[\Delta_{\text{med}}, \Delta_{\text{super}}]}} |\text{Reps}(v)| \leq n \cdot O(\log n) = O(n \log n)$ . Similarly to the analysis of  $H_{\text{high}}$ , in (B) we add  $|S'| = O((n \log n)/\Delta_{\text{super}})$  edges per vertex  $u$ , so  $|E(H_{\text{rep}})| = O(n^2/\Delta_{\text{super}} \cdot \log n)$ .
- (ii) **Stretch.** This claim follows from the argument given in the overview, and is similar to the analysis of  $H_{\text{high}}$ .
- (iii) **Probes.** Computing  $RS(v)$  takes  $O(\log n) \cdot \Delta_{\text{super}} = O(\Delta_{\text{super}} \log n)$  (recall that we only check  $\Gamma_{\Delta_{\text{super}}, 1}$  of each representative). Note also that  $|RS(v)| = O(\log^2 n)$  since  $v$  has  $O(\log n)$  representative, each of which belongs to  $\Theta(\log n)$  clusters. Computing  $\text{Reps}$  for each neighbor  $w \in \{v'_j\}_{j < i}$  of  $u$  takes  $O(\log n)$  probes each, which is  $O(\Delta_{\text{super}} \log n)$  in total since  $\deg(u) \leq \Delta_{\text{super}}$ . This also introduces up to  $\Delta_{\text{super}} \cdot O(\log n)$  representatives in total. Checking whether each of the  $O(\log^2 n)$  centers in  $RS(v)$  is a center of each of these  $O(\Delta_{\text{super}} \log n)$  representative takes, in total w.h.p.,  $O(\Delta_{\text{super}} \log^3 n)$  probes. ◀

**Final 5-spanner results.** To obtain an LCA for 5-spanners, we again invoke all of our LCAs for the four cases. Applying Lemma 9 and 10, we obtain the following LCA result for 5-spanner in general graphs.

► **Theorem 11.** For every  $n$ -vertex simple undirected graph  $G = (V, E)$  there exists an LCA for 5-spanner with  $O(n^{4/3} \log^2 n)$  edges and probe complexity  $O(n^{5/6} \log^3 n)$ .

Again, by combining results for larger degrees, we obtain an LCA for 5-spanners with smaller sizes on graphs with minimum degree at least  $n^{1/2-1/(2r)}$ .

► **Theorem 12.** For every  $r \geq 1$  and  $n$ -vertex simple undirected graph  $G = (V, E)$  with minimum degree at least  $n^{1/2-1/(2r)}$ , there exists a (randomized) LCA for 5-spanner with  $O(n^{1+1/r} \log^2 n)$  edges and probe complexity of  $O(n^{1-1/(2r)} \log^3 n)$ .

## 4 Bounded Independence

In this section, we show that all our LCA constructions succeed w.h.p. using  $\Theta(\log n)$ -wise independent hash functions which only require  $\Theta(\log^2 n)$  random bits. We use the following standard notion of  $d$ -wise independent hash functions as in [38]. In particular, our algorithms use the explicit construction of  $\mathcal{H}$  by [38], with the parameters as stated in Lemma 14.

► **Definition 13.** For  $N, M, d \in \mathbb{N}$  such that  $d \leq N$ , a family of functions  $\mathcal{H} = \{h : [N] \rightarrow [M]\}$  is  $d$ -wise independent if for all distinct  $x_1, \dots, x_d \in [N]$ , the random variables  $h(x_1), \dots, h(x_d)$  are independent and uniformly distributed in  $[M]$  when  $h$  is chosen randomly from  $\mathcal{H}$ .

► **Lemma 14** (Corollary 3.34 in [38]). *For every  $\gamma, \beta, d \in \mathbb{N}$ , there is a family of  $d$ -wise independent functions  $\mathcal{H}_{\gamma, \beta} = \left\{ h : \{0, 1\}^\gamma \rightarrow \{0, 1\}^\beta \right\}$  such that choosing a random function from  $\mathcal{H}_{\gamma, \beta}$  takes  $d \cdot \max\{\gamma, \beta\}$  random bits, and evaluating a function from  $\mathcal{H}_{\gamma, \beta}$  takes time  $\text{poly}(\gamma, \beta, d)$ .*

Then, we exploit the following result to show the concentration of  $d$ -wise independent random variables:

► **Fact 15** (Theorem 5(III) in [36]). *If  $X$  is a sum of  $d$ -wise independent random variables, each of which is in the interval  $[0, 1]$  with  $\mu = \mathbb{E}(X)$ , then:*

- (I) *For  $\delta \leq 1$  and  $d \leq \lfloor \delta^2 \mu e^{-1/3} \rfloor$ , it holds that  $\Pr[|X - \mu| \geq \delta \mu] \leq e^{-\lfloor d/2 \rfloor}$ .*
- (II) *For  $\delta \geq 1$  and  $d = \lceil \delta \mu \rceil$ , it holds that:  $\Pr[|X - \mu| \geq \delta \mu] \leq e^{-\delta \mu/3}$ .*

**Bounded independence for hitting set procedures.** Most of our algorithms are based on the following hitting set procedure. For a given threshold  $\Delta \in [1, n]$ , each vertex flips a coin with probability  $p = (c \log n)/\Delta$  of being head and the set of all vertices with head outcome join the set of centers  $S$ . Assuming the outcome of coin flips are fully independent, by the Chernoff bound, the followings hold w.h.p.:

(HI) There are  $\Theta(pn)$  sampled vertices  $S$ .

(HII) For each vertex of degree at least  $\Delta$ , it has  $\Theta(\log n)$  centers among its first  $\Delta$  neighbors. Here we show that to satisfy properties (HI) and (HII), it is sufficient to assume that the outcomes of the coin flips are  $d$ -wise independent. By Lemma 14, to simulate  $d$ -wise independent coin flips for all vertices, the algorithm only requires  $t = \Theta(d(\log n + \log 1/p))$  random bits: more precisely, setting  $\gamma = \Theta(\log n)$  and  $\beta = \log 1/p$  (for simplicity, lets assume that  $\log 1/p$  is an integer), there exists a family of  $d$ -wise independent functions  $\mathcal{H} = \left\{ h : \{0, 1\}^{\Theta(\log n)} \rightarrow \{0, 1\}^{\log(1/p)} \right\}$  such that a random function  $h \in \mathcal{H}$  can be specified by a string of random bits of length  $t$ . In other words, each function  $h \in \mathcal{H}$  maps the ID of each vertex to the outcome of its coin flip according to a coin with bias  $p$ . Then, from a string  $\mathcal{R}$  of  $t$  random bits, the algorithm picks a function  $h_{\mathcal{R}} \in \mathcal{H}$  at random to simulate the coin flips of the vertices accordingly: the outcome of the coin flip of  $v$  is head if  $h_{\mathcal{R}}(\text{ID}(v)) = 0$  (which happens with probability  $p$ ) and the coin flips are  $d$ -wise independent. Setting  $d = c \log n$  for some constant  $c > 1$ , we prove the following:

► **Claim 16.** *If the coin flips are  $d$ -wise independent then properties (HI) and (HII) holds. Furthermore, the sequence of  $n$   $d$ -wise independent coin flips can be simulated using a string of  $O(\log^2 n)$  random bits.*

**Construction of representatives in Section 3.** The analysis above also extends to the process of computing Reprs. Each crowded vertex chooses values  $c \log n$  random indices (of its neighbor-list) in  $[\Delta_{\text{med}}]$ , each of which has probability  $1/2$  of hitting a neighbor of degree at least  $\Delta_{\text{super}}$ . Let  $\{Z_i\}_{i \in [c \log n]}$  be indicators for these events and  $Z$  denote their sum, then the expected sum  $\mathbb{E}(Z) \geq (c/2) \log n$ . Imposing  $d$ -wise independence, Fact 15(I) implies that w.h.p.,  $Z > 0$ , so the representative set is non-empty. We apply the union bound to show that  $\text{Reps}(v) \neq \emptyset$  for every  $v \in V_{\text{crwd}}$ , as desired.

---

## Abstract

---

Proofs of space (PoS) [Dziembowski et al., CRYPTO’15] are proof systems where a prover can convince a verifier that he “wastes” disk space. PoS were introduced as a more ecological and economical replacement for proofs of work which are currently used to secure blockchains like Bitcoin. In this work we investigate extensions of PoS which allow the prover to embed useful data into the dedicated space, which later can be recovered.

Our first contribution is a **security proof** for the original PoS from CRYPTO’15 in the random oracle model (the original proof only applied to a restricted class of adversaries which can store a subset of the data an honest prover would store). When this PoS is instantiated with recent constructions of maximally depth robust graphs, our proof implies basically optimal security.

As a second contribution we show three different extensions of this PoS where useful data can be embedded into the space required by the prover. Our security proof for the PoS extends (non-trivially) to these constructions. We discuss how some of these variants can be used as **proofs of catalytic space** (PoCS), a notion we put forward in this work, and which basically is a PoS where most of the space required by the prover can be used to backup useful data. Finally we discuss how one of the extensions is a candidate construction for a **proof of replication** (PoR), a proof system recently suggested in the Filecoin whitepaper.

## 1 Introduction

### 1.1 Proofs of Space (PoS)

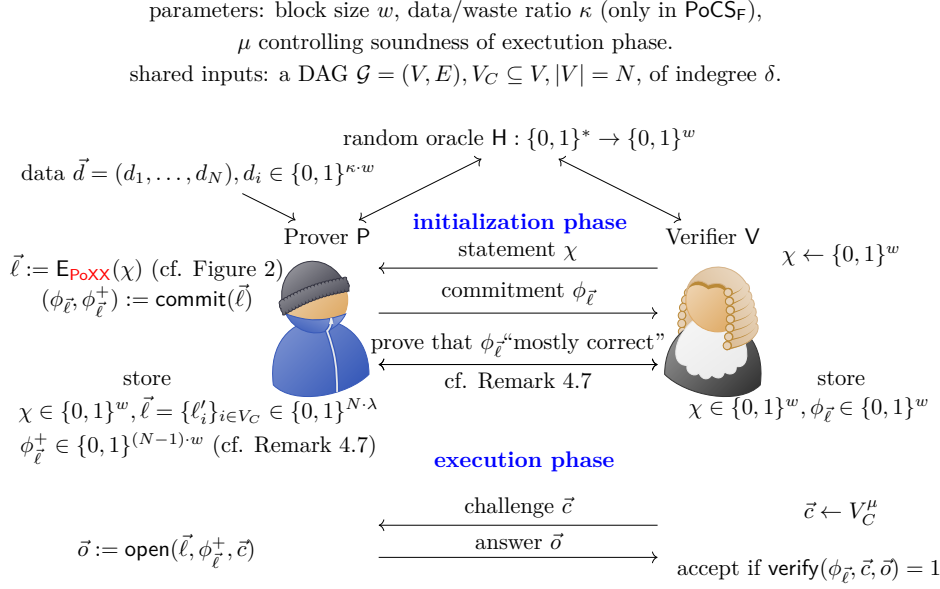

A proof of space (PoS) [16, 30, 3] is an interactive proof system in which a prover  $P$  can convince a verifier  $V$  that it “wastes” a large amount of disk-space. PoS were suggested as an alternative to proofs of work (PoW), which are currently used for securing blockchains including Bitcoin and Ethereum. PoS-based proposals include Spacemint [27] and the Chia network [1]. In the full version of this paper [29] we provide more discussion on sustainable blockchains and PoS.

The core of the pebbling-based PoS [16, 30] is a mode of operation for hash-functions  $E_{\text{PoS}}$ , which is specified by a directed acyclic graph (DAG)  $\mathcal{G} = (V, E)$  with a dedicated set  $V_C \subseteq V$  of  $|V_C| = N$  “challenge nodes”. The constructions in [16, 30] mostly differ in

■ **Figure 1** Illustration of protocol structure of the proof of space  $\text{PoS}_o$ , our proofs of catalytic space  $\text{PoCS}_F$ ,  $\text{PoCS}_\phi$  and the proof of replication  $\text{PoR}$  (replace  $\text{PoXX}$  in the figure with any of those). In  $\text{PoCS}_F$   $\kappa$  is a parameter, in  $\text{PoCS}_\phi$ ,  $\text{PoR}$  set  $\kappa = 1$  and for  $\text{PoS}_o$  set  $\kappa = 0$  (i.e.,  $\vec{d}$  is empty) in the figure. The label size  $\lambda$  is  $w(\kappa + 1)$  in  $\text{PoCS}_F$  and  $w$  in  $\text{PoS}_o$ ,  $\text{PoR}$  and  $\text{PoCS}_\phi$ .

what type of graphs are used. The only input  $E_{\text{PoS}_o}$  takes is a short statement  $\chi$  which is used to sample a hash function  $H_\chi$  (modelled as random oracle in all our proofs), and it outputs a large file  $\vec{\ell} = \{\ell_i\}_{i \in V_C}$  which P must store. P sends a commitment  $\phi_{\vec{\ell}}$  to  $\vec{\ell}$  to V. To check the prover really stores this file, the verifier can occasionally send a random challenge  $i \in V_C$  to the prover, who then must open the label  $\ell_i \in \vec{\ell}$  of this file. If such audits happen sufficiently often, the rational thing for P to do is to store  $\vec{\ell}$ , and not recompute labels as they are requested. The high level proof structure of this PoS, denoted  $\text{PoS}_o$ , is illustrated in Figure 1, the underlying mode of operation, denoted  $E_{\text{PoS}_o}$ , is illustrated in Figure 2.

## 1.2 An Unconditional Security Proof for the [16] PoS

Informally, the security we want from a PoS is as follows: if a malicious prover  $\tilde{P}$  dedicates slightly less space than the honest prover would after the initialization phase, say  $(1 - \epsilon) \cdot N$  instead  $N$  for some small  $\epsilon > 0$ , then it should be “expensive” for him to pass the audit. Note that  $\tilde{P}$  can always pass the audit by simply recomputing the entire  $\vec{\ell}$  right before the audit, so the best we can hope for is that passing the audit is almost as expensive for  $\tilde{P}$  as it is to compute the entire  $\vec{\ell}$ .

The first contribution in this paper is a security proof that shows  $\text{PoS}_o$  is a secure PoS in the random oracle model (Corollary 8 in §7.2). The existing proof from [16] only showed security against restricted adversaries who store a subset of the data  $\vec{\ell}$  an honest prover would store, but didn’t imply anything against more general adversaries who can store an arbitrary function of this data. We discuss this in more detail in §5.

When we instantiate  $E_{\text{PoS}_o}$  with recent constructions of depth-robust graphs, the security we get is basically optimal. Informally, for any  $\epsilon > 0$ , we can chose parameters such that any cheating prover who dedicates only an  $1 - \alpha$  fraction of the required space will fail to *efficiently* answer an  $\alpha - \epsilon$  fraction of the challenges (which simply ask to open some

$E_{\text{PoS}_\circ}$ : The **proof of space** from [DFKP15] instantiated with (a toy example of) a depth-robust graph.

$E_{\text{PoCS}_\phi}$ : Our **proof of catalytic space** where the data is committed by a standard Merkle tree commitment  $\phi_d$ . The hash function for this commitment depends on  $\chi$ , the hash function for the labelling also on  $\phi_d$ .

$E_{\text{PoCS}_F}$ : Our **efficiently updatable proof of catalytic space** where the catalytic data committed via random invertible function  $F$ .

$E_{\text{PoR}}$ : Our **proof of replication** is similar to  $E_{\text{PoCS}_\phi}$ , but the data is XOR'ed to the labels as the computation goes on, not just at the end.

■ **Figure 2** Illustration of the graph based modes of operation used in the proof of space  $\text{PoS}_\circ$ , proof of catalytic space  $\text{PoCS}_\phi$  and its efficiently updatable variant  $\text{PoCS}_F$  and the proof of replication  $\text{PoR}$ . We use a toy example of a depth robust DAG  $\mathcal{G} = (V, E)$ ,  $V = \{1, \dots, 6\}$  with  $V_C = \{3, \dots, 6\}$  being the challenge nodes. The embedded data is shown in blue, the labels the prover stores are in red. The values represented by all nodes are in  $\{0, 1\}^w$ , except the bold nodes in  $\text{PoCS}_F$ , where the  $d_i$  are in  $\{0, 1\}^{w \cdot \kappa}$  and the  $l_i, l'_i, i \in V_C$  are in  $\{0, 1\}^{w \cdot (\kappa+1)}$ .

blocks in the file  $\vec{\ell}$  the prover is committed to). Thus, if say  $\alpha = 2\epsilon$ , the prover fails on an  $\epsilon$  fraction, and we can amplify this to be overwhelmingly close to 1 by using  $O(1/\epsilon)$  challenges in parallel. Above, with “efficiently recover”, we mean it needs parallel time<sup>2</sup>  $N$ , this is basically optimal in terms of time complexity, as running the entire initialization phase takes only (sequential) time  $4N$ . We will discuss how our proof compares with existing results in more detail in §2.

The efficiency of our schemes (i.e., proof size, proof generation time, proof verification time) are all in  $O(\log N)$ , where the hidden constant depends on the above mentioned  $\epsilon$  (i.e., the constant grows as  $\epsilon$  goes to 0).

### 1.3 Embedding Useful Data into a PoS

The file  $\vec{\ell} := E_{\text{PoS}_\circ}(\chi)$  the prover is supposed to store just wastes disk space, and cannot be used for anything useful. This makes sense, as after all a PoS is supposed to prove the dedicated space is wasted.

In this paper we investigate the setting where the space dedicated towards the PoS can at the same time be used to encode some useful data  $\vec{d}$ . We identify two applications for such objects, *proofs of replication* (PoR), which were (informally) introduced in the Filecoin

<sup>2</sup> Our proof is in the random oracle model, and parallel time  $N$  means  $N$  rounds of queries, where in each round one can make many queries in parallel. In sequential time just one query is allowed.

paper [23] and *proofs of catalytic space* (PoCS), which we introduce and motivate in this work. The naming of the latter is inspired by *catalytic space computations* [9, 10], which are computations that can be done in small space, but only if one is additionally given “catalytic space”. This space is initially filled with arbitrary (potentially incompressible) data, and must be in the same state after the computation finishes. It thus functions like a catalyst in chemical reactions.

We introduce three new proof systems which allow for such embedded data. Two of them are intended to be used as PoCS, denoted  $\text{PoCS}_\phi$  and  $\text{PoCS}_F$ . The  $\text{PoCS}_F$  scheme has a worse *rate* than  $\text{PoCS}_\phi$ , by which we mean the ratio  $\|\vec{d}\|/\|\vec{\ell}\|$  of embedded data vs. dedicated space, but unlike  $\text{PoCS}_\phi$ , it allows for efficient updates of the embedded data. The third scheme we introduce is called PoR and is intended to be used as a PoR. Our new proof systems are derived from the [16] PoS  $\text{PoS}_o$  by replacing its underlying mode  $E_{\text{PoS}_o}$  by another mode of operation  $E_{\text{PoXX}} \in \{E_{\text{PoCS}_\phi}, E_{\text{PoCS}_F}, E_{\text{PoR}}\}$ . These modes take as input  $\chi$  (just like  $E_{\text{PoS}_o}$ ), and additionally some data  $\vec{d} = \{d_i\}_{i \in V_C}$  and output a file  $\vec{\ell} := E_{\text{PoXX}}(\chi, \vec{d})$  to be stored. The data  $\vec{d}$  can be recovered from  $\vec{\ell}$  at any time. These four modes are all illustrated in Figure 2.

## 1.4 Fisch’s PoR

That depth-robust graphs are useful to construct proofs of replication has been observed independently by Ben Fisch, he discusses this in a BPASE’18 talk<sup>3</sup> which took place almost a month before this paper was posted in a public archive.

In a recent paper [18] Fisch starts developing the foundations of PoR. His paper addresses many conceptual and technical aspects of PoR, including PoR constructions based on depth-robust graphs similar to the ones in this paper. His security proofs crucially use the main technical from this paper, i.e., that pebbling lower bounds for parallel time complexity imply lower bounds in the random oracle model as stated in Theorem 7. In a subsequent work Fisch presents PoR based on depth robust graphs with even better provable security guarantees [19]. The construction in that paper is conceptually somewhat different from ours in terms of the underlying graphs but also in the way in which the data is embedded. The graphs are stacked depth robust graphs, and are somewhat reminiscent of the simple and elegant PoS of Ren and Devadas [30] which is based on stacked expanders. We’ll say more on the efficiency of those constructions in §2.

## 1.5 Properties of PoS, PoCS and PoR

Fisch [18] observes that for any meaningful definition of PoR, a *PoR necessarily is also a PoS* as defined in [16]. Also a PoCS must necessarily be a PoS.

We (non-trivially) extend our security proof for  $\text{PoS}_o$  to prove that also the schemes  $\text{PoCS}_\phi$ ,  $\text{PoCS}_F$ , PoR are PoS (The final bound for  $\text{PoS}_o$ ,  $\text{PoCS}_\phi$ , PoR is stated in Corollary 8 in §8.2, the bound for  $\text{PoCS}_F$  is in the full version [29]. On the other hand, we observe that *being a PoS with the option to embed useful data is not sufficient to constitute a good PoCS or PoR*. Moreover the “whish list” of properties one might have for PoCS and PoR is somewhat contradictory. Our PoR candidate PoR is not a good PoCS, while  $\text{PoCS}_\phi$ ,  $\text{PoCS}_F$  do not make for a good PoR, as we’ll elaborate next.

The most important property we want from a PoCS is that any particular block of data from  $\vec{d} = \{d_i\}_{i \in V_C}$  cannot be recovered too efficiently from  $\vec{\ell}$ . The reason is that otherwise the PoCS wouldn’t compose: a malicious prover  $\tilde{P}$  could run a PoCS for some statement  $\chi$ ,

<sup>3</sup> [https://www.youtube.com/watch?v=8\\_90NpyRZEI](https://www.youtube.com/watch?v=8_90NpyRZEI)

and at the same time using the embedded data  $\vec{d}$  for a PoCS for other statement  $\chi'$ , thus pretending to dedicate more space than it does. To prevent this, we want the PoCS to *lock* the catalytic data, by which we mean accessing any particular block  $d_i \in \vec{d}$  should be almost as expensive as recovering the entire  $\vec{d}$  from  $\vec{\ell}$ .

In a typical application of a PoR, the data  $\vec{d}$  is not chosen by P but provided by V, together with some replication parameter  $r \in \mathbb{N}$  (and statement  $\chi$ ). P will then run the PoR for various statements  $\chi_1, \dots, \chi_r$  (generated from  $\chi$ ), each embedding  $\vec{d}$ . Informally, the security property we want is that a prover who later successfully passes the audits must have stored  $r$  *redundant* copies of  $\vec{d}$  (as  $\vec{d}$  can be incompressible, the redundancy requirement implies that PoR is a PoS). So unlike for a PoCS, in a PoR, being able to recover any data block efficiently is actually a feature, not an issue that breaks security.

We'll discuss those properties and how our schemes do or don't achieve them in more detail in §4, after having defined our various modes. We'll keep the discussion about the exact notion of a PoCS or PoR, and in particular any properties beyond being a PoS, like the locking and replication property mentioned above, informal. We expect future work to come up with the right definition for a PoCS, and also [18] is probably also not the last word on definitional issues for PoRs. There certainly are more properties one might need from a PoR or PoCS in particular applications that have not yet been identified, coming up with the right definitions and constructions satisfying them (in particular, showing that the constructions presented in this work do or do not satisfy them) is a promising research agenda.

## 2 Comparison With Previous Work

We somewhat divert from [16] when formally defining the security as a PoS. In [16], a PoS is defined to be  $(N_0, N_1, T)$ -secure if an adversary who stores a file  $\vec{\ell}$  of size  $N_0$  (recall that we measure size in blocks, typically of size something like  $w = 256$  bits) after the initialization phase, uses  $N_1$  space and  $T$  time during the proof executing phase, will fail in making the verifier accept with overwhelming probability. Below we shortly compare the four pebbling-based instantiations of the PoS<sub>o</sub> construction that so far have been suggested, and what security has been proven for them. Those just differ in the graphs  $\mathcal{G} = (V, E)$  and the dedicated set of challenge vertices  $V_C \subseteq V, |V_C| = N$ . We also mention the total number of edges  $|E|$ , as this basically determines the efficiency of the initialization procedure, and the indegree  $\delta$ , as this determines the size of the proofs and also the time to generate and verify proof. Let us mention that there is one work [3] constructing PoS using a completely different approach than graph-pebbling, for space reasons we'll only discuss his in the full version [29].

### 2.1 The original PoS [16]

[16] introduced the notion of PoS and gave two constructions, the first is

$$(\Theta(N/\log(N)), N/\log(N), \infty)\text{-secure with } |V| = N, \delta = 2, |E| = 2N$$

and based on a graph with high space pebbling complexity by Paul, Tarjan and Celoni [28], the second uses a rather sophisticated construction combining random bipartite graphs, superconcentrators and depth-robust graphs [17] and is

$$(\Theta(N), \infty, \Theta(N))\text{-secure with } |V| = N, \delta \in O(\log \log N), |E| \in O(N \log \log N)$$

## 2.2 The Ren-Devadas PoS [30]

Ren and Devadas [30] propose a very elegant instantiation of PoS<sub>o</sub> using stacked expanders and give a proof for it which in terms of security improves upon both constructions from [16] (just  $|E|$  is asymptotically larger). For any  $\alpha \in [0, 0.5]$ , their proof implies security (almost)

$$(\alpha \cdot N, (1 - \alpha) \cdot N, \infty)\text{-secure with } |V| \in O(N \log N), \delta \in O(1), |E| \in O(N \log N)$$

For say  $\alpha = 1/3$ , this means an adversary storing  $N_0 = N/3$  blocks after initialization, must use at least  $N_1 = 2N/3$  space during execution. Their construction is a stack of  $\log(N)$  expanders of indegree 2, and  $V_C$  is the graph on top of this stack.

## 2.3 Fisch’s tight PoS [19]

The PoS underlying Fisch’s recent PoR construction which we shortly discussed in §1.4, is based on a PoS that *for any*  $\epsilon > 0$  achieves

$$(N \cdot (1 - \epsilon), \infty, N)\text{-security with } |V| = O(N \log(1/\epsilon)), \delta \in O(1), |E| \in O(N \log(1/\epsilon))$$

Fisch provides concrete bounds for all the constants, the bounds are so good that he gets a very practical construction for parameters where the proofs guarantee good practical security. For our construction, which we discuss below, this is not the case. As there’s a huge gap between the lower and upper bounds on the security we can prove for PoS based on the simple depth robust graphs from [4, 6], it’s not clear whether the actual security of the “stacked” constructions as used in [19, 30] really is practically better, or if those constructions just allow for much tighter proofs, while not actually having better security in practice. Settling this is an interesting open question.

## 2.4 Our PoS

In this work we use the depth-robust graphs from [4, 6] to instantiate PoS<sub>o</sub>, and also our three new constructions which allow to embed useful data. *For any*  $\epsilon > 0$ , we can instantiate it as to get

$$(N \cdot (1 - \epsilon), \infty, N)\text{-security with } |V| = 4N, \delta \in O(\log(N)), |E| \in O(N \log N)$$

This might not seem terribly impressive, note that unlike [30] we don’t claim any lower bound on  $N_1$ , the space a cheating adversary must dedicate during proof execution. And asymptotically,  $|E|$  is larger than in the second construction of [16] which (ignoring constants) has the same security. But as we’ll explain next, we improve upon all existing constructions, except the subsequent work by Fisch [19], in three crucial points.

- 1. Unconditional Proof:** Our proof holds unconditionally (in the random oracle model), whereas [16, 30] only argued security against restricted adversaries who store a subset of the file an honest prover would store. Let us mention that for such relaxed adversaries, we can also prove bounds on the space a successful prover needs during execution.<sup>4</sup>

---

<sup>4</sup> Basically, for this restricted class of adversaries, whatever bound on time and/or space is proven for the underlying graph translates to a time and/or space bound for the construction. Our unconditional proof only translates parallel time complexity. The graphs we use to instantiate our construction are depth-robust, and such graphs are known [5] to have high “cumulative pebbling complexity”, which (for restricted adversaries as just mentioned) translates to the fact that if adversary runs in  $T$  rounds during proof execution, it must use  $\Omega(N^2/T)$  space on average during this computation.

2. **Tight Bound:** We get tight security: for any constant  $\epsilon > 0$ , we can instantiate our PoS to be  $((1 - \epsilon) \cdot N, \infty, N)$  secure. Equivalently, an adversary storing just an  $\epsilon$  fraction less than the honest prover, and which can run in time  $T = N$ , will still fail to make the verifier accept with overwhelming probability.

Having such a tight bound is crucial for many applications, as it means we get security against an adversary dedicating an  $(1 - \epsilon)$  fraction of the space for any  $\epsilon > 0$ . Note that even the (proof of the) [30] construction doesn't imply any security against adversary who dedicates just  $N_0 = N/2$ , i.e., half the claimed space.

3. **Security Against Parallelism:** The security we prove even holds if we strengthen the meaning of the parameter  $T$  from “total number of oracle queries”, to “total number of *parallel* oracle queries”, where each parallel query can contains many inputs, as long as in total they are bound by an exponential.

This stronger security notion implies that even massive parallelism doesn't help a potential adversary. This is useful in a setting where the timepoint at which audits happen is not known to the prover (in proofs of replication this can be achieved), and we have a bound on the latency of network between prover and verifier (so the prover cannot make  $T = N$  *sequential* computations in time less than this latency). Here we can be sure a prover who passes the audits really dedicates the claimed space, and does not simply reinitialize the entire space once the audit starts fast enough using massive parallelism. Compare this to the construction from [30], which can be initialized in sequential time  $\log(N)$  using parallelism  $N$ .

We will not use the formalism from [16] to quantify security outside of this subsection, but in our security statements explicitly state what is achieved, which should be easier to parse. The PoS security of  $E_{\text{PoS}_0}$  is stated in Corollary 8, The PoS security of  $E_{\text{PoCS}_\phi}$  and  $E_{\text{PoR}}$  in Corollary 13 and the PoS security of  $E_{\text{PoCS}_F}$  in the full version [29].

### 3 Basic Notation and Definitions

#### 3.1 Notation

For an object  $X$ ,  $\|X\|$  denotes its bitlength, for a set  $\vec{x}$ ,  $|\vec{x}|$  is the number of elements in  $\vec{x}$ . For an integer  $m$  we denote  $[m] \stackrel{\text{def}}{=} \{1, 2, \dots, m\}$  and for  $a, b \in \mathbb{R}$  we denote  $[a, b] \stackrel{\text{def}}{=} \{c : a \leq c \leq b\}$ . With  $\{0, 1\}^{\leq m}$  we denote the set of strings of length  $\leq m$ .

We typically use small greek letters  $\iota, \delta, \omega, \mu, \nu, \epsilon, \dots$  for our parameters used to quantify security, efficiency etc.. An exception is  $N$  which throughout denotes the space requirement of a prover. All these parameters are values in  $\mathbb{N}$  except  $\epsilon$  which is in  $[0, 1]$ . For the security games considered in this paper we use capital greek letters  $\Phi, \Lambda$ . The sans-serif font is used for interactive systems like parties  $V, P, \tilde{P}, A$  (modelled as randomized interactive Turing machines), functions  $H, F, g, f$  or algorithms like commitments discussed below ( $V, P$  and  $\tilde{P}$  are reserved for an honest verifier, an honest prover, and a potentially malicious prover, respectively). We use bold letters  $\vec{\ell}, \vec{d}, \vec{o}, \vec{c}, \dots$  for sets (usually ordered) of values, except for graph notation where we use simply  $\mathcal{G} = (V, E)$  to denote a graph with vertices  $V$  and directed edges  $E$ .

We will often consider a subset  $V_C \subset \mathbb{N}, |V_C| = N$  of challenge nodes. It will be convenient to define concise notion for mapping  $V_C$  to  $[N]$ , which we do using a tilde, i.e.,

$$V_C = (v_1, \dots, v_N) \quad \Rightarrow \quad (\tilde{v}_1, \dots, \tilde{v}_N) = (1, \dots, N) \quad (1)$$

## 3.2 Random Oracles

### 3.2.1 Fresh Random Oracles.

If  $H$  is a fixed random oracle and  $z \in \{0, 1\}^*$ , we denote with  $H_z$  the function  $H_z(\cdot) = H(z, \cdot)$ . If  $z$  is random and long enough (concretely, the amount of non-uniform advice an adversary has on  $H$  is not too large exponential in  $\|z\|$ ), we can treat  $H_z$  as a fresh uniformly random oracle [14]. We do this repeatedly in this work without always explicitly mentioning it.

### 3.2.2 The Parallel Random Oracle Model.

We prove security of our schemes in the *parallel random oracle model*, where in every round an adversary can output a set  $x_1, \dots, x_i$  of queries, and it receives the outputs  $H(x_1), \dots, H(x_i)$  at the beginning of the next round. For us the number of rounds will be important, but the total number of queries is secondary. Although also the total number of queries must be bound, in our proofs it can be as large as exponential in the block size  $w$ , and for the basic PoS<sub>o</sub>, the number of queries during the initialization phase can be even unbounded (not so for the other schemes). We will denote the number of oracle queries to  $H$  an adversary is allowed to make in the initialization and proof execution phase by  $q_1^H$  and  $q_2^H$ , respectively.

## 3.3 Commitments

We will make extensive use of a Merkle-tree commitment scheme, which allows to compute a short commitment to a long string, and later efficiently open any particular location of that long string. It is specified by a triple of algorithms `commit`, `open`, `verify` which use a hash-function  $H : \{0, 1\}^* \rightarrow \{0, 1\}^w$  as a building block. For the security as a commitment scheme, it's sufficient for  $H$  to be collision resistant. In our proofs we will sometimes need to extract committed values from the committing party, for this we must assume  $H$  is given as an oracle so our reduction can observe all queries.

If it's relevant what hash function is used it's shown as superscript (otherwise one can just assume any collision-resistant hash function is used). A party  $A$  which wants to commit to values  $\vec{x} = (x_1, \dots, x_m)$  invokes

$$(\phi_{\vec{x}}, \phi_{\vec{x}}^+) := \text{commit}^H(\vec{x})$$

here  $\phi_{\vec{x}}^+ \in \{0, 1\}^{(m-1)w}$  denotes the values of all inner nodes in the Merkle-tree, which are required to later efficiently open any position in  $\vec{x}$ , and  $\phi_{\vec{x}} \in \{0, 1\}^w$  is the value at the root, which is the commitment.

Once  $A$  announces  $\phi_{\vec{x}}$  it is committed to  $\vec{x}$ . It can then open any subset  $\vec{i} \subseteq [m]$  of the committed values (i.e.,  $\{x_i\}_{i \in \vec{i}}$ ) by invoking

$$\vec{o} := \text{open}^H(\vec{x}, \phi_{\vec{x}}^+, \vec{i}) \in \{0, 1\}^{\leq |\vec{i}| \lceil \log(m) \rceil \cdot w}.$$

Everyone can verify that  $\vec{o}$  is the correct opening by invoking  $\text{verify}^H(\phi_{\vec{x}}, \vec{i}, \vec{o})$  and accepting iff this value is 1.

## 3.4 Random Strings are Incompressible

In our proofs we'll repeatedly use the following fact, which states that a random string cannot be compressed.

► **Fact 1** (statement from [13]). *For any randomized encoding procedure  $\text{enc} : \{0, 1\}^r \times \{0, 1\}^n \rightarrow \{0, 1\}^m$  and decoding procedure  $\text{dec} : \{0, 1\}^r \times \{0, 1\}^m \rightarrow \{0, 1\}^n$  where*

$$\Pr_{x \leftarrow \{0, 1\}^n, \rho \leftarrow \{0, 1\}^r} [\text{dec}(\rho, \text{enc}(\rho, x)) = x] \geq \delta$$

we have  $m \geq n - \log(1/\delta)$ .

## 4 Overview of Our Modes and Protocols

In this section we will formally define the mode  $\mathbf{E}_{\text{PoS}_o}$  underlying the PoS from [16] and our new modes  $\mathbf{E}_{\text{PoR}}, \mathbf{E}_{\text{PoCS}_\phi}, \mathbf{E}_{\text{PoCS}_F}$  as illustrated in Figure 2. The actual protocols using those modes as illustrated in Figure 1 will then be defined in §4.5. As we define the modes, we will also continue our discussion from §1 showing how they (fail to) perform as PoCS or PoR. In particular, we'll show that our mode  $\mathbf{E}_{\text{PoR}}$  is not locking (and thus not suitable as PoCS), whereas  $\mathbf{E}_{\text{PoCS}_\phi}, \mathbf{E}_{\text{PoCS}_F}$  do not imply replication. All the modes are defined over a DAG  $\mathcal{G} = (V, E)$ , for  $i \in V$  we denote with  $\text{parents}(i) = \{j : (j, i) \in E\}$  the parents of  $i$ , and we define  $\vec{\ell}_{\text{parents}(i)} = \{\ell_j : j \in \text{parents}(i)\}$ .

### 4.1 The Mode $\mathbf{E}_{\text{PoS}_o}$

In the basic PoS the file  $\vec{\ell} := \mathbf{E}_{\text{PoS}_o}(\chi)$  contains the “labels” of nodes in  $V_C$ , where the labels of the nodes of the underlying DAG  $\mathcal{G} = (V, E)$  are computed in topological order by hashing (using a fresh random oracle sampled using  $\chi$ ) the labels of its parents

$$\forall i \in V : \ell_i = \mathbf{H}_\chi(i, \vec{\ell}_{\text{parents}(i)}) \quad , \quad \vec{\ell} \stackrel{\text{def}}{=} \{\ell_i\}_{i \in V_C} \quad (\mathbf{E}_{\text{PoS}_o}) \quad (2)$$

The most obvious way to somehow embed data  $\vec{d} = \{d_i\}_{i \in [N]}$  into this basic PoS is to simply XOR the data blocks to the labels in  $V_C$ . There are two natural ways to do this, XOR the data to the labels as the computation goes on, or first compute the labels and then XOR the data to it. The first approach is basically what we do in our construction PoR, and the second in  $\text{PoCS}_\phi$ . Before computing the labels, we first commit to  $\vec{d}$ , and then sample a fresh random oracle to compute the labels using this commitment. We'll explain below why without this trick our constructions would miserably fail to be PoS.

### 4.2 The Mode $\mathbf{E}_{\text{PoR}}$

In our PoR  $\vec{\ell} := \mathbf{E}_{\text{PoR}}(\chi, \vec{d})$ , the data  $\vec{d} = \{d_i\}_{i \in [N]}$  is first committed

$$(\phi_{\vec{d}}, \phi_{\vec{d}}^+) := \text{commit}^{\mathbf{H}_\chi}(\vec{d}) .$$

Then  $\phi_{\vec{d}}$  is used to sample a fresh random oracle  $\mathbf{H}_{\chi, \phi_{\vec{d}}}(\cdot) = \mathbf{H}_\chi(\phi_{\vec{d}}, \cdot)$ , which is then used to compute the labels. For labels of a node  $i \in V_C$ , one additionally XORs the data block  $d_i$  (recall that  $\{\vec{i}\}_{i \in V_C} = [N]$ ) to the label right after it has been computed.

$$\ell_i = \begin{cases} \mathbf{H}_{\chi, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) & \text{if } i \in V \setminus V_C \\ \mathbf{H}_{\chi, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) \oplus d_i & \text{if } i \in V_C \end{cases} \quad , \quad \vec{\ell} = \{\ell_i\}_{i \in V_C} \quad (\mathbf{E}_{\text{PoR}}) \quad (3)$$

### 4.3 The Mode $\mathbf{E}_{\text{PoCS}_\phi}$

In our PoCS  $\vec{\ell} := \mathbf{E}_{\text{PoCS}_\phi}(\chi, \vec{d})$  one first computes  $\phi_{\vec{d}}$  as above, uses this to sample a fresh random oracle  $\mathbf{H}_{\chi, \phi_{\vec{d}}}$  to compute labels (as in the basic PoS<sub>o</sub>), and only then XORs the data to the labels to be stored

$$\forall i \in V : \ell_i = \mathbf{H}_{\chi, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) \quad (4)$$

$$\forall i \in V_C : \ell'_i = \ell_i \oplus d_i, \quad \vec{\ell} = \{\ell'_i\}_{i \in V_C} \quad (\mathbf{E}_{\text{PoCS}_\phi}) \quad (5)$$

As mentioned above, the fact that the random oracle  $\mathbf{H}_{\chi, \phi_{\vec{d}}}$  used to compute the labels depends on the commitment  $\phi_{\vec{d}}$  to  $\vec{d}$  is crucial, let us sketch why. Assume we'd change  $\mathbf{H}_{\chi, \phi_{\vec{d}}}$  to  $\mathbf{H}_\chi$  in the definition of  $\mathbf{E}_{\text{PoCS}_\phi}$ . Now a malicious prover (in the protocol  $\text{PoCS}_\phi$  to be defined in §4.5) could set the  $\ell'_i$  to be stored to whatever it wants (and thus also store them using low space). Only after choosing the  $\ell'_i$ , it then fixes the data  $\vec{d} = \{d_i\}_{i \in [N]}$  by “equivocating” it, i.e., setting it as  $d_i := \ell'_i \oplus \ell_i$ , so everything is consistent. This malicious behaviour (not using any space) cannot be distinguished from honest behaviour, thus it's not a PoS.

Now let us observe that  $\text{PoCS}_\phi$  is not a good PoR, as it doesn't imply replication. A prover who is supposed to compute and store  $\vec{\ell}_i := \text{PoCS}_\phi(\chi_i, \vec{d})$  for  $r$  statements  $\chi_1, \dots, \chi_r$  but the same  $\vec{d}$  can instead store  $\vec{d}$  once in the clear, and for then for each  $\chi_j$  only store the labels  $\{\ell_i\}_{i \in V_C}$  as in eq.(4) instead  $\{\ell'_i = \ell_i \oplus d_i\}_{i \in V_C}$ , i.e., avoid the XORing step of eq.(5). Note that this prover has only stored one copy of  $\vec{d}$ , instead of storing it  $r$  times redundantly, while it can still pass the audits for all  $\chi_i, i \in [r]$  because it can compute the correct labels  $\ell'_i$  using its single copy of  $\vec{d}$  as  $\ell'_i = \ell_i \oplus d_i$ . The prover here doesn't seem to gain much, in particular it doesn't save on space by deviating from the honest behaviour. But in a PoR we probably want to enforce replication, or at least argue that it's not rational for a prover to deviate, and there are settings where deviating as just explained can be rational. Assume the prover has large remote storage space, but only low bandwidth to access it. By deviating as explained, it can use the space for the  $r$  proofs without large communication, in particular, without ever having to send  $\vec{d}$  to the remote disk.

In the other direction one can argue that  $\mathbf{E}_{\text{PoR}}$  is not a good PoCS as given all labels  $\{\ell_i\}_{i \in V}$  as in eq.(3), one can efficiently recover the embedded data as  $d_i = \ell_i \oplus \mathbf{H}_{\chi, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)})$ , so it doesn't provide the locking property we want from a PoCS. The above argument highlights a problem with the PoCS security of  $\mathbf{E}_{\text{PoR}}$ , but is not totally convincing, as the prover actually only needs to store the  $\ell_i$  for  $i \in V_C$  (not all  $i \in V$ ), so it couldn't necessarily recover those labels efficiently.

### 4.4 The Mode $\mathbf{E}_{\text{PoCS}_F}$

Besides  $\text{PoCS}_\phi$ , we propose a second PoCS  $\text{PoCS}_F$ , which allows for efficient updates. Instead of committing to  $\vec{d}$  and using this commitment to sample the random oracle  $\mathbf{H}_{\chi, \phi_{\vec{d}}}$  for computing the labels as in  $\text{PoCS}_\phi$ , in  $\text{PoCS}_F$  the labels are computed directly using  $\mathbf{H}_\chi$ , i.e., independently of  $\vec{d}$ . To prevent the “equivocation” attack outlined above, in  $\text{PoCS}_F$  the prover samples (using  $\chi$ ) a random invertible function  $\mathbf{F}_\chi : \{0, 1\}^{(\kappa+1) \cdot w} \rightarrow \{0, 1\}^{\kappa \cdot w}$  and applies it to the data before XORing it to the label, where  $\kappa$  is a parameter discussed below. The labels  $\ell_i, i \in V \setminus V_C$  have length  $w$  bits, the labels  $\ell_i, i \in V_C$  are  $(\kappa + 1) \cdot w$  bits long. Below  $\mathbf{H}_\chi : \{0, 1\}^{\leq \iota} \rightarrow \{0, 1\}^{(\kappa+1) \cdot w}$ , and  $\mathbf{H}_\chi(\cdot)|_w$  means we cap the output after  $w$  bits.

$$\ell_i = \begin{cases} \mathbf{H}_\chi(i, \vec{\ell}_{\text{parents}(i)}) & \text{if } i \in V_C \\ \mathbf{H}_\chi(i, \vec{\ell}_{\text{parents}(i)})|_w & \text{if } i \in V \setminus V_C \end{cases} \quad (6)$$

$$\forall i \in V_C : \ell'_i = \ell_i \oplus \mathbf{F}_\chi(d_i), \quad \vec{\ell} = \{\ell'_i\}_{i \in V_C} \quad (\mathbf{E}_{\text{PoCS}_\phi}) \quad (7)$$

A random invertible function  $F_\chi$  as used in this construction can be constructed efficiently, and with almost no loss in concrete security (which is crucial for our application) instantiated from a random oracle [21].

PoCS $_\phi$  has a better rate than PoCS $_F$ . In PoCS $_\phi$  we have rate  $\frac{\|\vec{d}\|}{\|\vec{\ell}\|} = 1$ , so the stored file  $\vec{\ell}$  is as big as the data  $\vec{d}$  that can be recovered from it.<sup>5</sup> The rate of PoCS $_F$  is only  $\frac{\|\vec{d}\|}{\|\vec{\ell}\|} = \frac{\kappa}{\kappa+1}$ . For efficiency reasons the  $\kappa$  can't be too large ( $\kappa \approx 10$  is reasonable, then the size of  $\vec{\ell}$  is  $\approx 10\%$  larger than  $\vec{d}$ ).

But unlike PoCS $_\phi$ , PoCS $_F$  allows for fast updates of the catalytic data: if P wants to change a single data block  $d_i$  (embedded in  $\ell'_i = \ell_i \oplus F_\chi(d_i)$ ) to  $d'_i$  then it can simply replace the label  $\ell'_i$  with  $\ell'_i \oplus F_\chi(d_i) \oplus F_\chi(d'_i)$ . It then must also update the commitment  $(\phi_\ell, \phi_\ell^\perp)$ , but this takes only time  $\log(N)$ . For this update P actually needs to know the currently embedded data block  $d_i$ . There are natural settings where  $\vec{d}$  is readily available in the clear. For example if the catalytic data  $\vec{d}$  encoded in  $\vec{\ell}$  is used as backup, and a working copy of  $\vec{d}$  is available in the clear. So we think this feature might be useful. This mode is somewhat different than the other three modes considered. Below we define and analyze the PoS $_o$ , PoR, PoCS $_\phi$  modes together as they're very similar, but PoCS $_F$  is different, and for space reasons the precise definitions and security proofs are only given in the full version [29].

► Remark (efficiently updatable PoR). Looking at Figure 2, one might wonder why there's no mode E $_{\text{PoR}_F}$ , where the data  $\vec{d}$  is first pre-processed by  $F_\chi$  as in E $_{\text{PoCS}_F}$ , but then XORed to the labels right after they are computed (as in E $_{\text{PoR}}$ ). The reason is that the only advantage of preprocessing  $\vec{d}$  using  $F_\chi$  as in E $_{\text{PoCS}_F}$  instead of committing to it as in E $_{\text{PoCS}_\phi}$  is the fact that it makes updating data blocks cheap. But if we XOR the data to the labels right after it has been computed as in E $_{\text{PoR}}$ , then updating a block in label  $\ell_i$ , will also change all subsequent labels  $\ell_j, j > i$ , even if the hash function used to compute labels is independent of  $\vec{d}$ . Thus, this update is not cheap after all. It's an interesting open problem to construct a candidate for a PoR where data blocks can be efficiently updated.

## 4.5 The Protocols PoS $_o$ , PoCS $_\phi$ and PoR

The protocols we consider in this work are a generalization of the pebbling-based PoS from [16] PoS $_o$ , where we allow the prover to chose and embed additional data  $\vec{d}$  into the file  $\vec{\ell}$  to be stored. We define PoS $_o$ , PoCS $_\phi$ , PoR together as they are very similar, we use PoXX  $\in \{\text{PoS}_o, \text{PoCS}_\phi, \text{PoR}\}$  as placeholder for any of those constructions.

$w, \mu$  : A block length  $w$  ( $w = 256$  is a typical value) and a statistical security parameter  $\mu$ .

$\mathcal{G}$  : A directed acyclic graph  $\mathcal{G} = (V, E)$  with max. indegree  $\delta$  and a designated set  $V_C \subseteq V$  of “challenge nodes” of size  $N = |V_C|$ .

$H$  : A hash function, which for the proof is modelled as a random oracle  $H : \{0, 1\}^{\leq \iota} \rightarrow \{0, 1\}^w$  which takes inputs of length at most  $\iota = (\delta + 2) \cdot w$  bits.

The space required by the honest prover is  $\approx N \cdot w = |V_C| \cdot w$  bits (we'll discuss the exact space requirement in Remark 4.7).

<sup>5</sup> The prover also must store opening information  $\phi_\ell^\perp$  for a Merkle commitment, but as we'll discuss in Remark 4.7 this is small compared to  $\vec{\ell}$ .

## 4.6 Initialization

V picks a random statement  $\chi \in \{0, 1\}^w$  and sends it to P.

If  $\text{PoXX} \neq \text{PoS}_o$ , the prover P can choose any data  $\vec{d} = \{d_i\}_{i \in [N]}$ ,  $d_i \in \{0, 1\}$  and then computes the file to store (if  $\text{PoXX} = \text{PoS}_o$ ,  $\vec{d}$  is empty)

$$\vec{\ell} := E_{\text{PoXX}}(\chi, \vec{d})$$

as shown in Figure 2 and explained in eq.(2)-(4).

Finally P computes the commitment  $(\phi_{\vec{\ell}}, \phi_{\vec{\ell}}^{\pm}) := \text{commit}(\vec{\ell})$  for all the labels  $i \in V_C$ , sends the short commitment  $\phi_{\vec{\ell}}$  to V and locally stores the opening information  $\phi_{\vec{\ell}}^{\pm}$ . This concludes the initialization if we assume P is honest during this phase (we'll discuss the general case in Remark 4.7).

At the end of the initialization phase the verifier stores the short strings  $\chi, \phi_{\vec{\ell}}$ . The prover stores  $\chi, \phi_{\vec{\ell}}^{\pm}$  and additionally a large file  $\vec{\ell} = \{\ell_i\}_{i \in V_C}$  of size  $\|\vec{\ell}\| = w \cdot N$ .

## 4.7 Proof execution

The protocol where  $P(\vec{\ell}, \chi, \phi_{\vec{\ell}}^{\pm})$  convinces  $V(\chi, \phi_{\vec{\ell}})$  that it stores  $\vec{\ell}$  is very simple. V samples a few nodes from the challenge set  $\vec{c} = (c_1, \dots, c_{\mu}) \subset V_C$  at random, and sends the challenge  $\vec{c}$  to P. P sends openings  $\vec{\sigma} := \text{open}(\vec{\ell}, \phi_{\vec{\ell}}^{\pm}, \vec{c})$  to the labels  $\{\ell_i\}_{i \in \vec{c}}$  to V, who then accepts iff  $\text{verify}(\phi_{\vec{\ell}}, \vec{c}, \vec{\sigma}) = 1$ .

► **Remark (prover is honest during initialization).** For most of the paper we will assume that even a malicious prover  $\tilde{P}$  follows the protocol during the initialization phase (i.e., behaves like the honest P). Of course we can't make this assumption in practice, that's why pebbling-based PoS have an extra communication round at the end of the initialization phase where – for some statistical security parameter  $\nu$  – V challenges  $\tilde{P}$  to open  $\nu$  labels and their parents to check that they were correctly computed. For this,  $\tilde{P}$  initially sends a commitment to all nodes  $V$ , not just  $V_C$ , and (except for  $\text{PoS}_o$ ) also a commitment to  $\vec{d}$ . If  $\tilde{P}$  committed to labels  $\{\ell_i^*\}_{i \in V}$  where it cheated on an  $\epsilon$  fraction of the labels, i.e., for  $\text{PoS}_o$  this means we have  $\ell_i^* \neq H_{\chi}(i, \ell_{p_1}^*, \dots, \ell_{p_{\delta_i}}^*)$ , then  $\tilde{P}$  will fail to pass this check with probability  $1 - (1 - \epsilon)^{\nu}$ .  $\tilde{P}$  can still get away with cheating at a small fraction of labels, but one can easily take care of this in the proof by assuming that storing such inconsistent labels can be done by P “for free”. As this is a minor technicality in the proof, we ignore this as not to obfuscate the main technical contributions.

► **Remark (P's space).** The size of the file  $\vec{\ell}$  is  $N \cdot w$  bits, which is basically the same as the  $(N - 1) \cdot w$  bits required to store the opening info  $\phi_{\vec{\ell}}^{\pm}$  of the Merkle-tree commitment to  $\vec{\ell}$ : on the 0'th level of the tree (the leaves) we have the  $N$  labels, then on level 1 we have  $N/2$  values, on level 2 we have  $N/4$  values, etc., for a total of  $N/2 + N/4 + \dots + 2 + 1 = N - 1$  labels of internal nodes that constitute  $\phi_{\vec{\ell}}^{\pm}$ . But the prover can decide to not store levels  $1 \dots k$ , thus saving only  $(N - 1)/2^k$  blocks, while all values in the omitted layers can be recomputed by hashing at most  $2^k$  leaf values (i.e., values from  $\vec{\ell}$ ). Thus, for say  $k = 5$ , the Merkle tree requires just a  $1/32$  fraction of the space of  $\vec{\ell}$ , but requires to hash 32 values. In practice that wouldn't be expensive as those leaf labels can always be stored consecutively on a disk, and thus reading them comes at small cost compared to reading the first random block (and hashing 32 blocks is not expensive compared to a disk access). In the discussions in this writeup we will thus mostly ignore the space required for storing the opening information  $\phi_{\vec{\ell}}^{\pm}$ .

## 5 The Main Proof Ideas

In this section we’ll discuss the main ideas used in the proofs of this paper, and give an overview of the work we borrowed ideas from. Pebbling is a game played on directed acyclic graphs (DAG), where a player can put pebbles on nodes of the graph according to some rules, and its goal is usually to pebble some particular node or set of nodes using as few “resources” as possible. There are various pebbling games one can consider, in this work we just consider the basic black-pebbling game, where the player can put a pebble on a node if all of its parents have pebbles. The resource considered is typically time (i.e., how many rounds it takes) or space (i.e., the maximum number of pebbles on the graph at any time), or combinations thereof. For example cumulative space (the sum of the number of pebbles on the graph over all rounds) [5] and sustained space (the number of rounds at which many pebbles were on the graph) [6] have been suggested to model memory-hard functions. Another important distinction is between sequential and parallel strategies; a parallel player can – in every round – put as many pebbles on the graph as he wants, whereas a sequential player can put only one. For reasons discussed below, in this paper we will consider **time complexity** in the **parallel black-pebbling** model.

As pebbling is a simple combinatorial game, it’s often possible to prove unconditional lower bounds on the resources required to pebble some graphs, and in some cases one can prove that these bounds imply lower bounds for problems in more interesting computational models. In particular, if the pebbling game considered is “deterministic” in the sense that the player is initially given the graph and a designated set of nodes to pebble, then one can use an elegant proof strategy (coined “ex-post facto” in the paper [15] that introduced it) to translate basically any pebbling lower bound to a corresponding lower bound in the random oracle model for computing the “labels” of the designated set of nodes, where the label of a node is the output of the random oracle on input the labels of its parents.<sup>6</sup>

Pebbling games capture most constructions of so called memory-hard functions (MHFs), which are functions that require a lot of memory to be computed. One distinguishes between *data-independent* MHFs, where the memory access pattern is independent of the functions input, and more general *data-dependent* MHFs. The pebbling game capturing data-independent MHFs is deterministic, but for data-dependent MHFs it’s randomized, for this reason almost all security proofs for data-dependent MHFs need to make additional assumptions on the adversary. An exception is the recent security proof for the data-dependent MHF called SCRYPT [7], which proves that SCRYPT has high cumulative memory complexity in the parallel random-oracle model. Despite the fact that here the underlying pebbling game is randomized, their proof does not need to make any assumptions on the adversarial behaviour.

Like data-dependent MHFs, also the pebbling game (called  $\Phi$  and defined in §6.1) underlying pebbling-based PoS [16, 30] is randomized. Prior to this work no pebbling-based PoS had an unconditional security proof in the random oracle model; one had to assume that an adversarial prover only stores a subset of the data the honest prover would store, but not arbitrary functions of this data.<sup>7</sup>

<sup>6</sup> The high-level idea of an “ex-post-facto” proof is to look at the execution of the game in the random oracle model and translate this to a pebbling strategy, where every time a label is computed, we put a pebble on the corresponding node. Now, if the resources (where a round the pebble game translates to a round of queries to the random oracle, and a pebble translates to space required to store one label) required by the labelling game are smaller than in the derived pebbling game, we can use the adversary in the labelling game to compress the random oracle. But this is impossible as a uniformly random string cannot be compressed, so we have a contradiction, and the labelling game must have used at least as many resources as the lower bound for the corresponding pebbling game dictates.

<sup>7</sup> In [16] some combinatorial conjectures were stated which – if true – would have implied that restricting

The key observation that allows us to translate pebbling-lower bounds for a “randomized” pebbling game like  $\Phi$  to lower bounds for the “labelling game”  $\Lambda_{\text{PoS}_o}$  in the random oracle model (this game is defined in §7.1) is already implicit in [7], and goes as follows: If the complexity we consider is *time* complexity in the *parallel* black-pebbling game, then the optimal pebbling strategy is oblivious to the randomness (which in our game is a random node we need to pebble). Concretely, the strategy minimizing the number of rounds required is to put in every round a pebble on every possible node (i.e., every node whose parents are pebbled). We observe that the reason “ex-post facto” proofs can’t be done for randomized pebbling games is that the adversaries’ pebbling strategy can depend on the game’s randomness, but as just outlined, for parallel time complexity we can assume the adversary is oblivious to the randomness, and this allows us to push through a pretty standard ex-post facto type proof (proof of Theorem 7 in §7.2) showing that lower bounds on the hardness of the game  $\Phi$  imply lower bounds on the game  $\Lambda_{\text{PoS}_o}$ , which captures the security of  $\text{PoS}_o$  as a PoS. Very informally, the proof is a compression argument, which uses an adversary that is “too successful” in computing the labels of nodes it is being challenged on into a compressing encoding algorithm for the random oracle  $H$ . As a random oracle is incompressible, such an encoding cannot exist, and we get a contradiction.

In Theorem 12 in §8.2 we extend this proof from the basic  $\text{PoS}_o$  to the modes  $\text{PoCS}_\phi$  and  $\text{PoR}$ . The problem we face is that now, the values this “too successful” adversary predicts are not just outputs (i.e., labels  $\ell_i$  as in  $\text{E}_{\text{PoS}_o}$ ) of the random oracle  $H$ , but now they are of the form  $\ell_i \oplus d_i$ , where  $d_i$  is chosen by the adversary itself. Thus we can’t readily use the fact that we learned them to compress  $H$ . To solve this problem, we use the fact that in  $\text{PoCS}_\phi, \text{PoR}$ , the adversary must first commit to the  $d_i$ ’s, and this commitment is then used to sample a fresh random oracle to compute the labels. We let our encoding algorithm first runs this adversary who chooses the  $d_i$ ’s and computes the commitment. From this adversary we can extract all the  $d_i$ ’s. Once these are known, the encoding proceeds basically as for the basic  $\text{PoS}_o$ .

Extending the proof to show that our efficiently updatable  $\text{PoCS}$   $\text{PoCS}_F$  is a PoS is much more challenging, and for space reasons we only provide the proof in the full version [29], now only giving a high level idea of the challenges. In  $\text{PoCS}_F$  the labels of the “too successful” adversary predicts are of the form  $\ell_i \oplus F(d_i)$ , but the adversary has not committed to the  $d_i$ ’s before computing the  $d_i$ ’s. The key idea is to replace in the security game the random invertible function  $F : \{0, 1\}^{\lambda-w} \rightarrow \{0, 1\}^\lambda$  with the composition of two randomly sampled functions  $\mathbf{g}(f(\cdot))$ , where  $f : \{0, 1\}^{\lambda-w} \rightarrow \{0, 1\}^{w/2}$ ,  $\mathbf{g} : \{0, 1\}^{w/2} \rightarrow \{0, 1\}^\lambda$ , and argue that with high probability this game will behave like the original one (in particular, the adversary is almost as successful here). In this new game, we can recover  $\ell_i$  from the labels the adversary predicts, which now are of the form  $\ell_i \oplus \mathbf{g}(f(d_i))$ , if additionally given only the short  $w/2$  bit string  $f(d_i)$ , this is good enough to get compression and again push through an ex-post-facto type proof.

## 6 The Graph Pebbling Game $\Phi$ and its Hardness

In this section we define a pebbling game  $\Phi$  and show it’s hard if instantiated with depth-robust graphs. Later we will prove that hardness of  $\Phi$  implies hardness of games capturing the PoS security of our schemes.

---

adversaries like this is without loss of generality. But these conjectures have been beautifully refuted in [24].

## 6.1 The Pebbling Game $\Phi(\mathcal{G}, V_C)$

The game is parameterized by a DAG  $\mathcal{G} = (V, E)$ , a subset  $V_C \subseteq V$  of  $|V_C| = N$  challenge nodes, and an integer  $s, 0 \leq s \leq N$ . It is played by an adversary given as a pair  $\mathbf{A}_\Phi = \{\mathbf{A}_\Phi^1, \mathbf{A}_\Phi^2\}$ .

**initialization:**  $\mathbf{A}_\Phi^1$  gets no input, and outputs the initial pebbling configuration, which is a subset  $P_0 \subseteq V$  of  $|P_0| = s$  nodes.

**execution:** A random challenge node  $c \leftarrow V_C$  is chosen.

$\mathbf{A}_\Phi^2$  gets as input  $P_0$  and the challenge  $c$ . It then proceeds in rounds, starting at round 1.

In round  $i$ ,  $\mathbf{A}_\Phi^2$  can place (arbitrary many) pebbles on the nodes of  $V$  to update the pebbling configuration from  $P_{i-1}$  to  $P'_i$  according to the following rule: a pebble can be placed on node  $v \in V$  only if all the parents of  $v$  are pebbled in  $P_{i-1}$ . It then can remove any number of pebbles to get the configuration  $P_i \subseteq P'_i$ .

► **Definition 2** (hardness of the game  $\Phi$ ). For  $s, t \in \mathbb{N}, \epsilon \in [0, 1]$ , we say  $\mathbf{A}_\Phi$  does  $(s, t, \epsilon)$ -win the pebbling game  $\Phi(\mathcal{G}, V_C)$  (as defined above) if the probability (over the choice of  $c$  and  $\mathbf{A}_\Phi$ 's random coins) that  $\mathbf{A}_\Phi^2$  puts a pebble on  $c$  in  $t - 1$  rounds or less is at most  $\epsilon$ .

We say  $\Phi(\mathcal{G}, V_C)$  is  $(s, t, \epsilon)$ -hard if no such  $\mathbf{A}_\Phi$  exists, that is, no adversary can pebble an  $\epsilon$  fraction of  $V_C$  in  $t$  rounds or less, having only  $s$  initial pebbles.

► **Remark** (greedy is best). We observe that the optimal strategy for  $\mathbf{A}_\Phi^2$  is trivial: the greedy strategy, where in every round  $\mathbf{A}_\Phi^2$  puts pebbles on all nodes possible and never removes a pebble, is at least as good as any other strategy. This greedy strategy is oblivious to the challenge  $c$ , which will be crucial in our proofs.

## 6.2 Depth Robust Graphs

► **Definition 3** (depth-robust graphs). A DAG  $\mathcal{G} = (V, E)$  on  $V = |N|$  nodes is  $(e, d)$ -depth robust if after removing any subset of  $e \cdot N$  nodes, there remains a path of length  $d \cdot N$ .

Such graphs were first considered by Erdős et al. [17], and recent work has made them more practical, cf. [4, 6] and references therein. Concretely, for any  $\epsilon > 0$ , [6] constructs a family  $\{\mathcal{G}_N^\epsilon\}_{N \in \mathbb{N}}$  of graphs of indegree  $O(\log N)$  (here the hidden constant depends on  $\epsilon$ ) which, for any  $e, d, e + d \leq 1 - \epsilon$  are  $(e, d)$ -depth robust.

Note that any graph, even the complete graph (which has indegree  $N - 1$ ) is only  $(e, d)$  depth-robust for  $e + d = 1$ . It is maybe surprising that one gets almost as good depth-robustness as the complete graph with only  $O(\log N)$  indegree (on the negative side, it's known that  $\Omega(\log N)$  indegree is necessary for this). Let us mention that the indegree of the  $\mathcal{G}$  we use to instantiate our schemes is important as the efficiency of our schemes (in particular the proof size) depends linearly on it.

## 6.3 $\Phi(\mathcal{G}, V_C)$ is Hard if $\mathcal{G}$ is Depth Robust

Let us observe that the  $\Lambda_{\text{PoS}_0}(\mathcal{G}, V_C)$  cannot be  $(s = N \cdot c_e, t, \epsilon = c_e)$ -hard for any  $c_e \in [0, 1]$  even for tiny  $t = 1$ , as one always can simply put those  $s$  initial pebbles on an  $c_e$  fraction of  $V_C$ , and this  $\epsilon = c_e$  fraction is then already pebbled in round 1. By the lemma below, using the depth-robust graphs  $\mathcal{G}_{4N}^{\epsilon'}$  the game becomes hard – i.e. we need  $t \geq N$  rounds – for just a slightly larger fraction  $\epsilon = c_e + 4\epsilon'$ .

► **Lemma 4** (hardness of  $\Phi$  with the depth-robust graphs from [6]). *For any  $N \in \mathbb{N}, \epsilon' > 0$  consider the graph  $\mathcal{G}_{4N}^{\epsilon'}$  from [6], which is  $(e, d)$ -depth robust for any  $e + d \geq 1 - \epsilon'$ . Let  $V_C \subseteq V, |V_C| = N$  be the  $N$  topologically last nodes in  $V$ . Then, for any  $c_e \in [0, 1]$  the game  $\Phi(\mathcal{G}_{4N}^{\epsilon'}, V_C)$  is  $(s, t, \epsilon)$ -hard with*

$$s = N \cdot c_e \quad , \quad t = N \quad , \quad \epsilon = c_e + 4\epsilon'$$

## 7.2 $\Phi$ Hardness Implies $\Lambda_{\text{PoSo}}$ Hardness

Before we show that lower bounds in the pebbling game  $\Phi$  translate to lower bounds on the labelling game  $\Lambda_{\text{PoSo}}$ , let us first mention the other (trivial) direction.

Any pebbling strategy  $A_\Phi = \{A_\Phi^1, A_\Phi^2\}$  can be transformed into a labelling strategy  $A_{\text{PoSo}} = \{A_{\text{PoSo}}^1, A_{\text{PoSo}}^2\}$  which has the same parallel time complexity and which uses  $w$  bits of space in its initial state  $S_0$  for pebble in the initial state  $P_0$ . The idea is to simply have  $A_{\text{PoSo}}$  mimic  $A_\Phi$ 's strategy, computing a label whenever  $A_\Phi$  places a pebble.

► **Proposition 6** ((trivial) hardness of  $\Lambda_{\text{PoSo}}$  implies hardness of  $\Phi$ ). *If an  $A_\Phi$  exists that  $(s, t, \epsilon)$ -wins the pebbling game  $\Phi(\mathcal{G} = (V, E), V_C)$ , then an  $A_{\text{PoSo}}$  exists which  $(m, t, \epsilon, q_2^H)$ -wins the  $\Lambda_{\text{PoSo}}(\mathcal{G}, V_C, w)$  labelling game for any  $w$ ,  $q_2^H = |V|$  and*

$$m = s \cdot w$$

**Proof.** By Remark 6.1 we can assume  $A_\Phi^2$  is a “greedy” adversary who never deletes pebbles, and thus puts at most  $|V|$  pebbles on  $\mathcal{G}$  during the entire game. If  $A_\Phi^1$  outputs an initial pebbling  $P_0$ , then  $A_{\text{PoSo}}^1$  will output an initial state that contains all the labels of the pebbles in  $P_0$

$$S_0 = \{\ell_v : v \in P_0\}.$$

Note that  $|S_0| = w \cdot |P_0| \leq w \cdot s$  as claimed.  $A_{\text{PoSo}}^2$  will also be greedy, i.e., store all the labels it ever computes. In step  $i$ , when  $A_\Phi^2$  puts fresh pebbles on  $P_i \setminus P_{i-1}$ ,  $A_{\text{PoSo}}^2$  makes a parallel query to  $H_*$  to compute all the new labels  $\{\ell_v : v \in P_i \setminus P_{i-1}\}$ . In the round where  $A_\Phi^2$  puts a pebble on  $c$ ,  $A_{\text{PoSo}}^2$  can compute and output  $\ell_{\text{guess}} = \ell_c$ . ◀

Proving the other direction – that pebbling lower bounds imply lower bounds on the labelling game – is more challenging.

► **Theorem 7** (hardness of  $\Phi$  implies hardness of  $\Lambda_{\text{PoSo}}$ ). *For any  $\alpha > 0$ , if the pebbling game  $\Phi(\mathcal{G}, V_C)$  is  $(s, t, \epsilon)$ -hard, then the labelling game  $\Lambda_{\text{PoSo}}(\mathcal{G}, V_C, w)$  is  $(m, t, \epsilon, 2^{-\alpha}, q_2^H)$ -hard where*

$$m \geq s \cdot (w - 2(\log N + \log q_2^H)) - \alpha$$

Before we get to proof of this theorem, let us state what security it implies for  $\text{PoSo}$  using the hardness of  $\Phi$  as stated in Lemma 4.

► **Corollary 8** (of Thm. 7 and Lem. 4). *For  $\mathcal{G}_{4N}^{\epsilon'}$ ,  $V_C$  as in Lemma 4, and any  $c_e \in [0, 1]$ ,*

$$\Lambda_{\text{PoSo}}(\mathcal{G}_{4N}^{\epsilon'}, V_C, w) \text{ is } (m, t, \epsilon, 2^{-\alpha}, q_2^H)\text{-hard}$$

$$\text{with } m = N \cdot c_e \cdot (w - 2(\log N + \log q_2^H)) - \alpha, \quad t = N, \quad \epsilon = c_e + 4\epsilon'$$

Let us observe that the hardness as stated is basically optimal. For slightly larger  $m = N \cdot c_e$  (i.e., if we ignore the additive log terms), it means an adversary dedicating  $N \cdot (1 - 4\epsilon' - \Delta) \cdot w$  (instead  $N \cdot w$ ) space after initialization will fail to answer a  $\Delta$  fraction of the challenges in parallel time  $< N$ . Note that in  $4N = |V|$  sequential time every challenge can be answered with no storage at all by recomputing the entire labelling. As always, by challenging this adversary on  $O(1/\Delta)$  queries in parallel we can amplify the probability of the adversary failing to answer fast arbitrary close to 1.

**Proof of Theorem 7.** To prove the theorem we assume an adversary  $A_{PoS_0} = (A_{PoS_0}^1, A_{PoS_0}^2)$  exists who  $(m, t, \epsilon, 2^{-\alpha}, q_2^H)$ -wins the labelling game. Let  $\mathcal{H}, \Pr[H_* \in \mathcal{H}] \geq 2^{-\alpha}$  be the subset of  $H_*$  for which  $A_{PoS_0}$  can win the labelling game like that, i.e., using an initial state of  $\leq m$  bits, in  $\leq t$  rounds, and for an  $\geq \epsilon$  fraction of challenges where  $A_{PoS_0}^2$  makes  $\leq q_2^H$  queries to  $H_*$  (cf. Definition 5).

We will consider the random experiment where for a given  $H_* \in \mathcal{H}$ , we first run  $A_{PoS_0}^1$  to get  $S_0$ , and then we run  $A_{PoS_0}^2$  on all challenges in parallel. This will define a set  $F$  of “fresh” labels, which are labels that occur during the execution *before* they have been actually computed (and thus intuitively must somehow have been stored in the initial state  $S_0$ ). We then prove two claims.

The first shows how the above execution translates into a strategy to  $(|F|, t, \epsilon)$ -win the pebbling game, as this game is  $(s, t, \epsilon)$ -hard, we have  $|F| \geq s$ . The second claim shows how to compress  $H_*$  by almost  $|F| \cdot w$  bits when given the initial state  $S_0$ . As most functions are incompressible, we get  $m = \|S_0\| \gtrsim s \cdot w$ . We now give the detailed proof.

As outlined above, consider any  $H_* \in \mathcal{H}$ , and let  $S_0 \leftarrow A_{PoS_0}^1$  be the initial state. Let  $V'_C \subseteq V_C$  be the set of challenges which  $A_{PoS_0}^2(S_0, \cdot)$  answers correctly in  $t$  rounds or less, as  $H_* \in \mathcal{H}$  we have  $|V'_C| \geq \epsilon|V_C|$ . In the proof we'll consider two algorithms

$A_{PoS_0}^{\parallel}$  runs  $A_{PoS_0}^2$  in parallel for all possible challenges  $c \in V_C$ . Concretely,  $A_{PoS_0}^{\parallel}$  invokes  $|V_C|$  instances of  $A_{PoS_0}^2(S_0, c)$ , one for every challenge  $c \in V_C$ . In each round,  $A_{PoS_0}^{\parallel}$  collects the queries made by all the instances of  $A_{PoS_0}^2$  that have not yet terminated, then makes one parallel query to  $H_*$  containing all the collected queries, and forwards the corresponding answers to the  $A_{PoS_0}^2$  instances. We let  $A_{PoS_0}^{\parallel}$  run for  $t$  rounds, and then stop.

$\mathcal{L}_G$  computes the labels  $\ell_1, \ell_2, \dots, \ell_{|V|}$  in topological order, making sequential queries to  $H_*$ . We refer to a query that correctly computes a label as in eq.(8), i.e., a query of the form

$$\ell_i = H_*(i, \vec{\ell}_{\text{parents}(i)})$$

as a **real query**. For  $i \in V$ , we say  $i$  is **fresh** if in some round  $A_{PoS_0}^{\parallel}$  uses a label  $\ell_i$  as (part of an) input to a query or the thread  $A_{PoS_0}^2(S_0, i)$  outputs  $\ell_i$  as its guess  $\ell_{\text{guess}} = \ell_i$  (note that then  $i \in V'_C$ ) before this label  $\ell_i$  was received as output of a real query. Let  $F \subseteq V$  denote the (indices of) the fresh labels. Thus,  $\{\ell_i\}_{i \in F}$  are all the labels that appear during  $A_{PoS_0}^{\parallel}$ 's execution before they have been computed, i.e., received as output on a real query.

► **Claim 9.** *There is an adversary  $A_{\Phi}$  that  $(s', t, \epsilon)$ -wins the pebbling game  $\Phi(\mathcal{G}, V_C)$  with  $s' = |F|$  initial pebbles (thus  $|F| \geq s$ ).*

**Proof of Claim.** Consider an  $A_{\Phi}^1$  which choses an initial pebbling  $P_0 = F$ . Then  $A_{\Phi}^2$  in round  $i$  puts a pebble on  $v$  if  $A_{PoS_0}^{\parallel}$  received  $\ell_v$  as output of a real query in round  $i$ . By construction this is a valid parallel black pebbling.

We claim that this  $A_{\Phi}^2$  puts a pebble on every node in  $V'_C$  in  $t$  steps or less, and thus  $(s, t, \epsilon)$ -wins  $\Phi(\mathcal{G}, V_C)$ . To see this, consider any  $c \in V'_C$ . If  $c \in F = P_0$  it's pebbled already in round 1. Otherwise, if  $c \in V'_C \setminus F$ , the label  $\ell_{\text{guess}} = \ell_c$  output by the thread  $A_{PoS_0}^2(S_0, c)$  was not fresh, and thus must have been received as output of a real query in some round  $j \leq t$ . By construction this  $A_{\Phi}^2$  will have put a pebble on  $c$  in round no later than  $j$ . ◀

Now that we have shown  $|F| \geq s$ , the next step is to lower bound  $\|S_0\|$ , the bitlength of the initial state, in terms of  $|F|$ . For this, we show how to compress the function table of  $H_*$  given

$S_0$  by almost by almost  $|F| \cdot w$  bits. Using the fact that a random oracle is incompressible (cf. Fact 1 in §3), we'll then derive a lower bound  $\|S_0\| \gtrsim |F| \cdot w$ . Let

$$[H_*] \in \{0, 1\}^{(2^{\ell+1}-1) \times w}$$

denote the function table of  $H_* : \{0, 1\}^{\leq \ell} \rightarrow \{0, 1\}^w$ .

► **Claim 10.** *There exists an encoding (enc, dec) which correctly decodes an  $2^{-\alpha}$  fraction of the tables*

$$\Pr_{H_*}[\text{dec}(\text{enc}([H_*])) = [H_*]] \geq 2^{-\alpha}$$

and the length of the encoding is  $\|\text{enc}([H_*], S_0)\| \leq \|[H_*]\| + \|S_0\| - |F| \cdot (w - 2(\log N + \log q_2^H))$ .

Before we prove this claim, let us observe this implies the statement of the theorem by using Fact 1, which implies

$$\|S_0\| \geq |F| \cdot (w - 2(\log N + \log q_2^H)) - \alpha.$$

**Proof of Claim.** The encoding enc/dec will correctly decode all the  $[H_*]$  which are in  $\mathcal{H}$ . For this,  $\text{enc}([H_*])$  first determines if  $H_* \in \mathcal{H}$ , and if this is not the case outputs whatever (say the bit 0). Let  $B$  denote the following computation: we first invoke  $A_{\text{PoSo}}^{\parallel}(S_0, V_C)$  followed by  $L_G$ , we'll denote with  $q \leq N \cdot (q_2^H + 1)$  the number of distinct  $H_*$  queries made during  $B$ 's execution (at most  $q_2^H$  for each invocation of the  $N$  invocations of  $A_{\text{PoSo}}^{\parallel}$  and  $N$  more for  $L_G$ ).

Let the list  $\vec{c}$  contain all the outputs of  $H_*$  queries made during  $B$ . The outputs in  $\vec{c}$  are stored in the order the queries were made, and if a query is repeated, the output is not stored. Let  $\bar{\vec{c}}$  denote the function table of  $H_*$  with the  $|\vec{c}|$   $w$ -bit entries that are in  $\vec{c}$  removed. Note that given  $\vec{c}, \bar{\vec{c}}, S_0, V_{C'}$  we can recover  $[H_*]$  by running  $B$  using  $\vec{c}$  to answer all the oracle queries. After this, we have learned all the inputs corresponding to the outputs stored in  $\vec{c}$ , and thus know which queries were deleted from  $[H_*]$  to get  $\bar{\vec{c}}$ . Thus now we can recover all of  $[H_*]$ . We haven't compressed anything yet (as  $\|\vec{c}\| + \|\bar{\vec{c}}\| = \|[H_*]\|$ , or as all elements in those sets and the table are  $w$  bit strings, equivalently  $|\vec{c}| + |\bar{\vec{c}}| = \|[H_*]\|$ ). Next we'll show how to compress  $\vec{c}$  into a smaller  $\vec{c}_F$  which, with some short extra information  $\vec{b}_F$ , will suffice to answer all  $H_*$  queries made during  $B$  correctly.

Recall that  $F \subseteq V$  are the fresh queries. Consider  $i \in F$ , at some point during the evaluation of  $B$  the real query  $\ell_i = H_*(i, \vec{\ell}_{\text{parents}(i)})$  is made (the only reason we invoke  $L_G$  as part of  $B$  is to ensure this query is made at some point). As  $i \in F$ , at the point where this query is made for the first time, we have already observed the value  $\ell_i$  as part of some query input. Let  $\vec{c}_F$  denote  $\vec{c}$ , but with the  $|F|$  entries corresponding to the real queries of  $i \in F$  deleted. With this  $\vec{c}_F$  we can answer all of  $B$ 's queries if we're given some extra information which, for every  $i \in F$ , tells as at which point during the execution of  $B$  we observe  $\ell_i$ , and where the corresponding real query is made. This extra information requires at most  $2 \log q$  bits for every  $i \in F$ , let  $\vec{b}_F$  denote a string encoding this information, we now define the encoding as

$$\text{enc}([H_*]) = (S_0, \vec{c}_F, \vec{b}_F, \bar{\vec{c}})$$

The decoding  $\text{dec}(S_0, \vec{c}_F, \vec{b}_F, \bar{\vec{c}})$  reconstructs  $[H_*]$  as outlined above. As

$$\begin{aligned} \|\vec{c}_F\| + \|\bar{\vec{c}}\| &= \|[H_*]\| - w \cdot |F| \\ \|\vec{b}_F\| &\leq |F| \cdot 2 \log q \leq |F| \cdot 2(\log N + \log q) \end{aligned}$$

the encoding length is  $\|\text{enc}([H_*], S_0)\| \leq \|S_0\| + \|[H_*]\| - |F| \cdot (w - 2(\log N + \log q))$  as claimed. ◀

## 8 PoS Security of PoCS $_\phi$ and PoR

In this section we extend the result from the previous section, and show that hardness of  $\Phi$  implies hardness of games  $\Lambda_{\text{PoCS}_\phi}$  and  $\Lambda_{\text{PoR}}$ , which capture the PoS security of our constructions PoCS $_\phi$  and PoR. We start with defining the games

### 8.1 The Labelling Games $\Lambda_{\text{PoCS}_\phi}$ and $\Lambda_{\text{PoR}}$

Let  $\text{PoXX} \in \{\text{PoCS}_\phi, \text{PoR}\}$ . The game is parameterized by a DAG  $\mathcal{G} = (V, E)$ , a subset  $V_C \subseteq V$  of  $|V_C| = N$  challenge nodes and a block size  $w$ . Moreover a function  $H_* : \{0, 1\}^{\leq \iota} \rightarrow \{0, 1\}^w$ ,  $\iota = (\delta + 2) \cdot w$ . The game is played by an adversary  $A_{\text{PoXX}} = \{A_{\text{PoXX}}^1, A_{\text{PoXX}}^2\}$ .

**initialization:**  $A_{\text{PoXX}}^1$  is given oracle access to  $H_*$ . It can choose any data  $\vec{d} = \{d_i\}_{i \in V_C}$ ,  $d_i \in \{0, 1\}^w$ , which defines labels  $\vec{\ell}$  to store as in eq.(3) and eq.(4), but using  $H_*$  instead  $H_X$ . Recall that for this we first compute  $(\phi_{\vec{d}}, \phi_{\vec{d}}^+) := \text{commit}^{H_*}(\vec{d})$ , now let  $H_{*, \phi_{\vec{d}}}$  be the function  $H_{*, \phi_{\vec{d}}}(\cdot) \equiv H_*(\phi_{\vec{d}}, \cdot)$ , and then compute  $\vec{\ell}$  as

$$\text{(if PoXX = PoR)} \quad \vec{\ell} = \{\ell_i\}_{i \in V_C} \text{ where } \ell_i = \begin{cases} H_{*, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) & \text{if } i \in V \setminus V_C \\ H_{*, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) \oplus d_i & \text{if } i \in V_C \end{cases}$$

$$\text{(if PoXX = PoCS}_\phi) \quad \vec{\ell} = \{\ell'_i\}_{i \in V_C} \text{ where } \forall i \in V : \ell_i = H_{*, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) \\ \forall i \in V_C : \ell'_i = \ell_i \oplus d_i$$

$A_{\text{PoXX}}^1$  outputs a string (the initial state)  $S_0$  of length  $\|S_0\| = m$  bits.

**execution:** A random challenge node  $c \leftarrow V_C$  is chosen.

$A_{\text{PoXX}}^2$  gets as input  $S_0$  and challenge  $c$ . It then proceeds in rounds starting with  $i = 1$ : In round  $i$ ,  $A_{\text{PoXX}}$  gets as input its state  $S_{i-1}$ . It can either decide to stop the game by outputting a single guess  $\ell_{\text{guess}}$  (for  $\ell_c$  in PoR or  $\ell'_c$  in PoCS $_\phi$ ), or it can make one parallel oracle query: on query  $(x_1, \dots, x_{q_i})$  it receives  $(y_1, \dots, y_{q_i})$  where  $y_i = H_*(x_i)$ . It can do any amount of computation before and after this query, and at the end of the round output its state  $S_i$  for the next round.

► **Definition 11** (hardness of the games  $\Lambda_{\text{PoXX}} \in \{\Lambda_{\text{PoR}}, \Lambda_{\text{PoCS}_\phi}\}$ ). For  $m, t, q_1^H, q_2^H, w \in \mathbb{N}$  and  $p_H, \epsilon \in [0, 1]$ , we say  $A_{\text{PoXX}} = (A_{\text{PoXX}}^1, A_{\text{PoXX}}^2)$  does  $(m, t, \epsilon, p_H, q_1^H, q_2^H)$ -win the labelling game  $\Lambda_{\text{PoXX}}(\mathcal{G}, V_C, w)$  (as defined above) if for all but a  $p_H$  fraction of  $H_*$  the following holds: for at most an  $\epsilon$  fraction of challenges  $c$ ,  $A_{\text{PoXX}}^2$  correctly guesses  $c$ 's label (i.e.,  $\ell_{\text{guess}} = \ell_c$ ) in round  $t$  or earlier. Moreover  $A_{\text{PoXX}}^1$  and  $A_{\text{PoXX}}^2$  make at most  $q_1^H$  and  $q_2^H$  queries to  $H_*$ , respectively. We say  $\Lambda_{\text{PoXX}}(\mathcal{G}, V_C, w)$  is  $(m, t, \epsilon, p_H, q_1^H, q_2^H)$ -hard if no such  $A_{\text{PoXX}}$  exists.

### 8.2 $\Phi$ Hardness Implies $\Lambda_{\text{PoR}}$ and $\Lambda_{\text{PoCS}_\phi}$ Hardness

► **Theorem 12** (hardness of  $\Phi$  implies hardness of  $\Lambda_{\text{PoR}} \& \Lambda_{\text{PoCS}_\phi}$ ). For any  $\alpha > 0$ , if the pebbling game  $\Phi(\mathcal{G}, V_C)$  is  $(s, t, \epsilon)$ -hard, then the labelling game  $\Lambda_{\text{PoR}}(\mathcal{G}, V_C, w)$  and also the labelling game  $\Lambda_{\text{PoCS}_\phi}(\mathcal{G}, V_C, w)$  is  $(m, t, \epsilon, 2^{-\alpha} + q_1^H/2^w, q_1^H, q_2^H)$ -hard where

$$m \geq s \cdot (w - 2(\log N + \log q_2^H)) - \alpha$$

Before we get to proof of this theorem, let us state what security it implies for PoR and PoCS $_\phi$  using the hardness of  $\Phi$  as stated in Lemma 4.

► **Corollary 13** (of Thm. 7 and Lem. 4). For  $\mathcal{G}_{4N}^{\epsilon'}$ ,  $V_C$  as in Lemma 4, and any  $c_e \in [0, 1]$ ,

$$\Lambda_{\text{PoCS}_\phi}(\mathcal{G}_{4N}^{\epsilon'}, V_C, w) \text{ and } \Lambda_{\text{PoR}}(\mathcal{G}_{4N}^{\epsilon'}, V_C, w) \text{ are } (m, t, \epsilon, 2^{-\alpha}, q_2^H)\text{-hard}$$

with  $m = N \cdot c_e \cdot (w - 2(\log N + \log q_2^H)) - \alpha$ ,  $t = N$ ,  $\epsilon = c_e + 4\epsilon'$

**Proof.** We assume the reader is familiar with the proof of Theorem 7, as we will only explain how that proof needs to be adapted.

The proof of Theorem 7 goes through almost unchanged for  $\text{PoXX} \in \{\text{PoR}, \text{PoCS}_\phi\}$  instead of  $\text{PoS}_o$ , the point where it fails is when we need to compress fresh labels. In the proof of Theorem 7 every fresh label  $\ell_i, i \in F$  allowed us to compress one element of  $H_*$ . Now the situation is seemingly more complicated. For concreteness, let's consider  $\text{PoR}$ . Now even if the encoding  $\text{enc}$  observes a fresh label  $\ell_i$  when invoking  $A_{\text{PoR}}^{\parallel}$  (which is defined analogous to  $A_{\text{PoS}_o}^{\parallel}$  in the proof of Theorem 7), it's not clear how to compress one entry of  $H_{*, \phi_{\vec{d}}}$ 's function table as now

$$\ell_i = H_{*, \phi_{\vec{d}}}(i, \vec{\ell}_{\text{parents}(i)}) \oplus d_i$$

only provides an output that is blinded with  $d_i$ . If we could make sure the encoding and decoding  $\text{enc}/\text{dec}$  knew the  $\vec{d}$ , this problem would disappear. We fix this problem as follows. We define  $A_{\text{PoR}}^{\parallel}$  analogous to  $A_{\text{PoS}_o}^{\parallel}$ , i.e., it runs  $A_{\text{PoR}}^2(S_0, c)$  on all challenges  $c \in V_C$  in parallel. But additionally, at the very beginning (before invoking the  $A_{\text{PoR}}^2$ 's), it invokes  $A_{\text{PoR}}^1$ , but only runs it to the point where the commitment  $\phi_{\vec{d}}$  is received as an output of  $H_*$  (recall we assume  $A_{\text{PoR}}^1$  follows the protocol, so this commitment must be computed at some point). This way  $\text{enc}/\text{dec}$ , we invoke  $A_{\text{PoR}}^{\parallel}$ , learn the entire  $\vec{d}$ , as it can be extracted from the  $H_*$  queries leading to  $\phi_{\vec{d}}$ . At the same time  $A_{\text{PoR}}^1$  will almost certainly not have made any  $H_{*, \phi_{\vec{d}}}(\cdot) = H_*(\phi_{\vec{d}}, \cdot)$  queries as  $\phi_{\vec{d}}$  is uniform and we stop executing  $A_{\text{PoR}}^1$  once  $\phi_{\vec{d}}$  is received. This is necessary, so a label that was fresh without running  $A_{\text{PoR}}^1$  first, will still be fresh if we do run  $A_{\text{PoR}}^1$ . The above argument works as long as  $A_{\text{PoR}}^1$  doesn't find a collision in  $H_*$  (otherwise we can't extract a unique  $\vec{d}$ ). For this reason in the theorem security holds only for a slightly smaller  $p_H = 2^{-\alpha} + q_1^{H^2}/2^w$  fraction of the  $H_*$  than the  $p_H = 2^{-\alpha}$  fraction we got for the  $\Lambda_{\text{PoS}_o}$  game in Theorem 7. ◀

## **A** Discussion and Motivation

### **A.1** The Quest for a Sustainable Blockchain

PoW based blockchains, most notably Bitcoin, have been criticized as the mining process (required to secure the blockchain) results in a massive energy waste. This is not only problematic ecologically, but also economically, as it requires high rewards for the miners to compensate for this energy loss.<sup>8</sup>

#### **A.1.1** Proofs of Stake

The idea behind “Nakamoto consensus” used in Bitcoin, is to randomly chose a miner to generate the next block, where the probability of any miner to be chosen is proportional to its hashing power. The most investigated idea to replace PoWs in blockchains are “proofs of stake” (PoStake), where the idea is to choose the winner proportional to the fraction of coins they hold. At first, this idea looks promising, but it seems to be difficult to actually realize it in a secure and efficient way. Early ad-hoc implementations of this idea include Peercoin [22] and NXT [31]. More recent proposals come with security proofs in various models [25, 12, 20], but those protocols are fairly complicated, and basically run a byzantine agreement protocol amongst rotating subsets of the miners, thus losing the appealing simplicity of Bitcoin, where a winning miner simply gossips the next block and no other interaction is required.

---

<sup>8</sup> The block reward currently used as main compensation for miners in Bitcoin is decreasing (it’s halved every four years), and thus ultimately will be replaced with only transaction fees, which might create serious problems [11].

### A.1.2 Space as a Resource

After time, space is the best investigated resource in computational complexity, it's thus only natural to try using disk space as a resource for mining. This has the potential to give blockchains which are much more sustainable than PoW based designs, while avoiding at least some of the technical issues that PoStake has. Permacoin [26] requires a miner to dedicate disk space, but it's still a proof of work based design, only now the computation itself (which is a so called "proof of retrievability") requires access to a large disk. A proposal which mostly uses space as resource is Burstcoin [2], this design is poorly document, but it seems to have security and efficiency issues.<sup>9</sup> Another suggestion are "proofs of space" (PoS), which are the topic of this paper and we'll discuss them in more detail below in §A.1.4.

### A.1.3 Useful Proofs

While PoStake aim to avoid wasting significant resources for mining in the first place, another approach to minimize the footprint of mining is to use the resources required to sustain the blockchain for something useful. A intriguing idea is to use the computing power wasted for PoWs for solving actual computational problems, we refer the reader to [8] and the references therein. In this work we also follow this approach and construct "proofs of catalytic space" (PoCS), which are defined like PoS, but where most of the space required by the prover can be used to store useful data.

### A.1.4 Proofs of Space (PoS)

Proofs of space (PoS) [16] are proofs systems that were developed to serve as a replacement for PoW in blockchain designs. The first proposal of a PoS-based blockchain is Spacemint [27], a recent ongoing effort which combines PoS with some type of proofs of sequential work is the Chia network [1]. A PoS [16] is a two stage protocol between a prover  $P$  and a verifier  $V$ . The first phase is an initialization protocol which is run only once, after which  $P$  has initialized its space. Then there's a proof execution phase which typically is run many times, in which an honest prover  $P$  can *efficiently* convince the verifier that dedicates the space. The verifier  $V$  is required to be very efficient during both phases, this means it can be polynomial in some security parameter, but should be almost independent (i.e., depend at most polylogarithmically) on the size  $N$  of the space committed by the prover. The honest prover  $P$  is required to be very efficient during the execution phases. During the initialization  $P$  cannot be very efficient, as it must at the very least overwrite all of the claimed space, but it shouldn't require much more than that.

To date two very different types of PoS have been suggested. PoS-based on hard to pebble graphs [16, 30] and PoS-based on inverting random functions [3], the new proofs systems – for proofs of catalytic space (PoCS) and proofs of replication (PoR) – we propose in this work extend the pebbling-based PoS. We leave it as an open problem to extend

---

<sup>9</sup> [27, Appendix B of the full version] discusses some issues with (our best guess on what is) Burst and the underlying proof system called "proofs of capacity" (PoC). In a nutshell, PoC are rather inefficient as the prover needs to access a constant (albeit small) fraction of the entire space for generating a proof, and verification requires over a Million hashes. As to security, PoC allow for strong time-memory trade-offs (a recent ad-hoc fix <https://www.burst-coin.org/wp-content/uploads/2017/07/The-Burst-Dymaxion-1.00.pdf> claims to address at least the most obvious time-memory attacks outlined in [27]). But most worryingly, the blockchain designs seems to have no mechanisms to address nothing-at-stake issues, which are responsible for the most delicate and complicated issue of any blockchain design not based on proofs of work.

the [3] PoS to PoR and PoCS, this would be very interesting as although the [3] PoS has worse *asymptotic* security than pebbling-based PoS, but it's much more efficient (with proofs of length a few hundred bits, and proof generation and verification requiring just a small constant number of hash queries). Moreover, unlike pebbling-based PoS, this PoS has a non-interactive initialization phase, which makes it easier to use it for a blockchain design where we have no dedicated verifier, and thus the proof must be made non-interactive.<sup>10</sup>

---

<sup>10</sup> Concretely, for subtle security reasons Spacemint [27] (which uses the pebbling-based PoS) requires the miners to commit to the transcript of a challenge response protocol which is run during the initialization phase. This is done by uploading this (short) transcript to the blockchain. The Chia network which are based on [3] will not require any such commitments.

# Simple Verifiable Delay Functions

Krzysztof Pietrzak<sup>1</sup>

Institute of Science and Technology Austria, Austria  
pietrzak@ist.ac.at

---

## Abstract

---

We construct a verifiable delay function (VDF) by showing how the Rivest-Shamir-Wagner time-lock puzzle can be made publicly verifiable.

Concretely, we give a statistically sound public-coin protocol to prove that a tuple  $(N, x, T, y)$  satisfies  $y = x^{2^T} \pmod{N}$  where the prover doesn't know the factorization of  $N$  and its running time is dominated by solving the puzzle, that is, compute  $x^{2^T}$ , which is conjectured to require  $T$  sequential squarings. To get a VDF we make this protocol non-interactive using the Fiat-Shamir heuristic.

The motivation for this work comes from the Chia blockchain design, which uses a VDF as a key ingredient. For typical parameters ( $T \leq 2^{40}$ ,  $N = 2048$ ), our proofs are of size around  $10KB$ , verification cost around three RSA exponentiations and computing the proof is 8000 times faster than solving the puzzle even without any parallelism.

## 1 Introduction

### 1.1 The RSW time-lock puzzle

Rivest, Shamir and Wagner [10] introduced the concept of a time-lock puzzle, and proposed the following elegant construction

**The puzzle** is a tuple  $(N, x, T)$  where  $N = p \cdot q$  is an RSA modulus,  $x \in \mathbb{Z}_N^*$  is random and  $T \in \mathbb{N}$  is a time parameter.

**The solution** of the puzzle is  $y = x^{2^T} \pmod{N}$ . It can be computed making two exponentiations by the party who generates the puzzle (and thus knows the group order  $\phi(N) = (p-1)(q-1)$ ) as

$$e := 2^T \pmod{\phi(N)} \quad , \quad y := x^e \pmod{N} \tag{1}$$

but is conjectured to require  $T$  sequential squarings if the group order (or equivalently, the factorization of  $N$ ) is not known

$$x \rightarrow x^2 \rightarrow x^{2^2} \rightarrow x^{2^3} \rightarrow \dots \rightarrow x^{2^T} \pmod{N} \tag{2}$$

---

<sup>1</sup> This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (grant agreement No 682815/TOCNeT).

To be more precise, the conjecture here is that  $T$  sequential steps are necessary to compute  $x^{2^T} \pmod N$  even if one can use large parallelism.

As an application, [10] show how to “encrypt to the future”: sample a puzzle  $(N, x, T)$  together with its solution  $y$ , then derive a key  $k_y$  from  $y$  and encrypt a message  $m$  into a ciphertext  $c = \text{ENC}(k_y, m)$ . Given  $(N, x, T)$  and  $c$  one can recover the message  $m$  in time required to compute  $T$  squarings sequentially, but (under the above conjecture) not faster.

## 1.2 Proofs of sequential work (PoSW)

Proofs of sequential work (PoSW) are closely related to time-lock puzzles. PoSW were introduced in [9], and informally are proof systems where on input a random challenge  $x$  and time parameter  $T$  one can compute a *publicly verifiable* proof making  $T$  sequential computations, but it’s hard to come up with an accepting proof in significantly less than  $T$  sequential steps, even given access to massive parallelism.

The PoSW constructed in [9] is not very practical (at least for large  $T$ ) as the prover needs not only  $T$  time, but also linear in  $T$  space to compute a proof. Recently [5] constructed a very simple and practical PoSW in the random oracle model. They were interested in PoSW as they serve as a key ingredient in the Chia blockchain design ([chia.net](https://chia.net)).

The main open problem left open in [5] was to construct PoSW that is *unique*, in the sense that one cannot compute two accepting proofs on the same challenge. The existing PoSW all allow to generate many accepting proofs at basically the same cost as honestly computing the proof. Unfortunately such PoSW cannot be used for the blockchain application just mentioned, as this would allow for so called grinding attacks. More precisely, the output of the PoSW is used to compute a challenge for generating the next block. If the PoSW is not unique, a malicious miner could compute many proofs, and then pick the one which results in a challenge that is most favourable for him.

## 1.3 Verifiable delay functions (VDF)

Boneh, Bonneau, Bünz and Fisch [3] recently introduced the notion of a verifiable delay function (VDF). A VDF can be seen as a relaxation of unique PoSW which still suffices for all known applications of unique PoSW. We refer the reader to [3] for a thorough discussion on VDFs including many interesting applications. In a VDF the proof on challenge  $(x, T)$  has two parts  $(y, \pi)$ , where  $y$  is a deterministic function of  $x$  that needs  $T$  sequential time to compute, and  $\pi$  is a proof that  $y$  was correctly computed (the reason this is not necessarily a unique PoSW is the fact that this  $\pi$  does not need to be unique). It must be possible to compute  $\pi$  with low parallelism and such that  $\pi$  can be output almost at the same time as  $y$ . In [3] this is achieved using incrementally verifiable computation [12]. The (very high level) idea is to compute a hash chain

$$y = \underbrace{h(h(\dots h(x) \dots))}_{T \text{ times}}$$

and at the same time use incrementally verifiable computation to compute the proof  $\pi$ , so the proof will be ready shortly after  $y$  is computed. To make this generic approach actually practical the  $h$  used in [3] is a particular algebraic function (a permutation polynomial) which has the property that one can invert it significantly faster than compute in forward direction (so instead of verifying the evaluation of  $h(\cdot)$ , one can just verify the much simpler computation of  $h^{-1}(\cdot)$ ), and also the proof system used to compute  $\pi$  is tailored so it can exploit the algebraic structure of  $h$ .

## 1.4 A VDF from RSW

The RSW time-lock puzzle looks like a promising starting point for constructing a VDF. The main difficulty one needs to solve is achieving public verifiability: to efficiently verify  $y \stackrel{?}{=} x^{2^T} \pmod{N}$  one needs the group order of  $\mathbb{Z}_N^*$  (or equivalently, the factorization of  $N$ ). But the factorization cannot be public as otherwise also computing  $y$  becomes easy.

One idea to solve this issue is to somehow obfuscate the group order so it can only be used to efficiently verify if a given solution is correct, but not to speed up its computation. There currently is no known instantiation to this approach.

In this work we give a different solution. We construct a protocol where a prover  $\mathcal{P}$  can convince a verifier  $\mathcal{V}$  it computed the correct solution  $y = x^{2^T} \pmod{N}$  without either party knowing the factorization (or any other hard to compute function) of  $N$ . Our interactive protocol is public-coin, but can be made non-interactive – and thus give a VDF – by the Fiat-Shamir transformation. Here the prover’s messages are replaced by simply applying a random function to the transcript. The Fiat-Shamir transformation applied to any constant-round public-coin interactive proof systems results in a sound non-interactive proof system in the random oracle model. Although our proof is not constant-round, we can still show that this transformation works, i.e., gives a sound non-interactive proof system relative to a random function (i.e., in the random oracle model). In practice the random function is instantiated with an actual hash-function like SHA256, as then soundness only holds computationally, such systems are called arguments, not proofs.

Our protocol is inspired by the sumcheck protocol [8, 11]. The key idea of the proof is very simple. Assume  $\mathcal{P}$  wants to convince  $\mathcal{V}$  that a tuple  $(x, y)$  satisfies  $y = x^{2^T}$ . For this,  $\mathcal{P}$  first sends  $\mu = x^{2^{T/2}}$  to  $\mathcal{V}$ . Now  $\mu = x^{2^{T/2}}$  together with  $y = \mu^{2^{T/2}}$  imply  $y = x^{2^T}$ . The only thing we have achieved at this point is to reduce the time parameter from  $T$  to  $T/2$  at the cost of having two instead just one statement to verify. We then show that the verifier can merge those two statements in a randomized way into a single statement  $(x', y') = (x^r \cdot \mu, \mu^r \cdot y)$  that satisfies  $y' = x'^{2^{T/2}}$  if the original statement  $y = x^{2^T}$  was true (and  $\mathcal{P}$  sends the correct  $\mu$ ), but is almost certainly wrong (over the choice of the random exponent  $r$ ) if the original statement was wrong, no matter what  $\mu$  the malicious prover did send. This subprotocol is repeated  $\log(T)$  times – each time halving the time parameter  $T$  – until  $T = 1$ , at which point  $\mathcal{V}$  can efficiently verify correctness of the claim itself.

The VDF we get has short proofs and is efficiently verifiable. For typical parameters (2048 bit modulus and  $\log(T) \leq 40$ ) a proof is about 10KB large and the cost for verification is around three full exponentiations (for comparison, a standard RSA decryption or RSA signature computation requires one full exponentiation).

The algebraic setting of our proof systems differs a bit from RSW, as we’ll discuss in §2. In a nutshell, to prove statistical soundness, we need to assume that  $N$  is the product of two *safe* primes, i.e.,  $N = p \cdot q$  where  $p' = (p - 1)/2$  and  $q' = (q - 1)/2$  are prime, as then a random quadratic residue  $x \in QR_N$  almost certainly is a generator of  $QR_N$ . We’ll actually preform all computations in the group of *signed* quadratic residues  $QR_N^+$ , as unlike for  $QR_N$ , one can efficiently decide if an element is in  $QR_N^+$ , which will make the protocol slightly simpler and more efficient. Using  $QR_N^+$  instead of  $QR_N$  will also make the proof unique, so our VDF is a unique PoSW.

## 1.5 Wesolowski's VDF

A closely related result to our VDF is a concurrent paper by Wesolowski [14]. A recent survey [4] compares his construction with the one presented in this paper.

Wesolowski also constructs a VDF by making the RSW time-lock puzzle publicly verifiable. The prover, who claims  $y = x^{2^T}$ , receives as challenge a large prime  $B$ , and must respond with the proof  $\pi = x^{\lfloor \frac{2^T}{B} \rfloor}$ . To verify this proof one checks  $\pi^B \cdot x^{2^T \bmod B} \stackrel{?}{=} y$ .<sup>2</sup> To get a VDF one makes this protocol non-interactive using the Fiat-Shamir heuristic, i.e.,  $B = \text{hash}(y)$  is computed as a hash of the first message.

To prove soundness (i.e., that it's hard to come up with a  $z \neq x^{2^T}$  together with a  $\pi$  that passes verification) one needs a computational hardness assumption which basically states that for any  $z \neq 1$  it is hard to compute the  $B$ 'th root of  $z$  (i.e. a  $y$  s.t.  $z^B = y$ ) in the underlying group when  $B$  is a large random prime (whereas soundness of our proof is unconditional).

The main advantage of Wesolowski's construction over ours is that his proof is just a single group element, and thus about a  $\log(T)$  factor smaller than in our VDF, also verification time is about this factor smaller. A drawback of his construction is that the overhead for computing the proof  $\pi$  is larger, though it improved significantly in the latest writeup. It's currently at  $O(T/\log(T))$  multiplications (our construction just needs  $O(\sqrt{T} \cdot \log(T))$ ). The computation of the proof can be parallelized to some extent in both constructions.

Another potential advantage (communicated to us by Dan Boneh) of our proof system is that it can be applied for any underlying endomorphism, not just the squaring operation. This could be useful to construct new VDFs, potentially achieving post-quantum security, though currently we don't know of any such instantiations.

In summary, Wesolowski's proof system has shorter proofs and faster verification time. Our proof system allows for more efficient computation of the proof, does not require any computational assumptions and seems to apply in a more general setting.

Wesolowski and the survey [4] also discuss how to instantiate those proof systems in other groups than  $\mathbb{Z}_N^*$ , including groups that will not require trusted setup. We'll discuss this in more detail in §6.1, for now let us just mention that if instantiated in such groups the proof systems will rely on a computational assumption (for Wesolowski's construction, in addition the root assumption), which basically states that it must be hard to find group elements of small order.

## 1.6 Outline

In §2 we discuss the slightly different algebraic setting used here as compared to [10]. We then present the protocol in §3 and the security proof in §4. In §5 we define VDFs, and in §6 we discuss how the protocol is turned into a VDF and discuss several efficiency and security issues.

## 1.7 Notation

For a set  $\mathcal{X}$ ,  $x \stackrel{\$}{\leftarrow} \mathcal{X}$  means  $x$  is assigned a random value from  $\mathcal{X}$ . For a randomized algorithm  $\text{alg}$  we denote with  $x \stackrel{\$}{\leftarrow} \text{alg}$  that  $x$  is assigned the output of  $\text{alg}$  on fresh random coins, if  $\text{alg}$  is deterministic we just write  $x \leftarrow \text{alg}$ .

---

<sup>2</sup> This construction appears in the 2nd version of the eprint paper [14] from July 1st and improves over the construction in the first posting.

## 2 The algebraic setting

The exact algebraic setting for our proof system differs slightly from the setting of the original RSW time-lock puzzle [10]. First, we require that  $N = p \cdot q$  is the product of *safe* primes (a prime  $p$  is safe if  $(p - 1)/2$  is also prime), and moreover we perform the computation in the group of *signed* quadratic residues  $QR_N^+$ . In an earlier version of this paper we used “normal” quadratic residues  $QR_N$ .  $QR_N^+$  is isomorphic to  $QR_N$ , but makes the protocol slightly simpler as unlike for  $QR_N$ , one can efficiently decide if an element is in  $QR_N^+$ . Moreover using  $QR_N^+$  instead of  $QR_N$  will make the proof *unique*, i.e., it’s hard to come up with any proof other than the one generated by the honest prover, so we even get a unique PoSW. As working with  $QR_N$  instead of  $QR_N^+$  is more intuitive, in the proof we’ll assume the proof is over  $QR_N$ .

As we’ll outline below, if computing  $x^{2^T}$  is hard in the original RSW setting, it will remain hard in our setting (the other direction is not clear, it might be that our setting is more secure).

### 2.1 Signed quadratic residues

For two safe primes  $p$  and  $q$ , and  $N := p \cdot q$  we denote the quadratic residues with  $QR_N \stackrel{\text{def}}{=} \{z^2 \bmod N : z \in \mathbb{Z}_N^*\}$ , and the signed quadratic residues [6, 7] are defined as the group

$$QR_N^+ \stackrel{\text{def}}{=} \{|x| : x \in QR_N\},$$

where  $|x|$  is the absolute value when representing the elements of  $\mathbb{Z}_N^*$  as  $\{-(N-1)/2, \dots, (N-1)/2\}$ . Since  $-1 \in \mathbb{Z}_N^*$  is a quadratic non-residue with Jacobi symbol  $+1$ , the map  $|\cdot|$  acts as an (efficiently-computable) isomorphism<sup>3</sup> from  $QR_N$  to  $QR_N^+$ , and as a result  $QR_N^+$  is also a cyclic group, with the group operation defined as

$$a \circ b \stackrel{\text{def}}{=} |a \cdot b \bmod N|.$$

However, unlike for  $QR_N$ , membership in  $QR_N^+$  can be efficiently tested since  $QR_N^+ = J_N^+$  where  $J_N$  is the group of elements with Jacobi symbol  $+1$  and

$$J_N^+ \stackrel{\text{def}}{=} \{|x| : x \in J_N\} = J_N / \{\pm 1\}.$$

In other words, to test whether a given  $x \in \mathbb{Z}_N^*$  (represented as  $\{-(N-1)/2, \dots, (N-1)/2\}$ ) belongs also to  $QR_N^+$ , ensure that  $x \geq 0$  and that its Jacobi symbol is  $+1$ .

### 2.2 Using $(QR_N^+, \circ)$ instead $(\mathbb{Z}_N^*, \cdot)$

Recall that the assumption underlying the security of the RSW time-lock puzzle [10] states that computing  $x^{2^T}$  is hard in  $(\mathbb{Z}_N^*, \cdot)$ . We note that using  $(QR_N^+, \circ)$  instead (i.e., when  $x \in QR_N^+$  and squaring is defined as  $x^2 \stackrel{\text{def}}{=} x \circ x$ ), as we require for our protocol, will not make this assumption any weaker. By the two reductions below, we’ll lose at most a factor  $4 \cdot 2 = 8$  in advantage.

First, let us observe that using  $(QR_N, \cdot)$  instead of  $(\mathbb{Z}_N^*, \cdot)$  can only make the problem harder: Because  $|QR_N| = |\mathbb{Z}_N^*|/4$ , a random element in  $\mathbb{Z}_N^*$  also belongs to  $QR_N$  with probability  $1/4$ . So if one can break the assumption with probability  $\epsilon$  over  $QR_N$ , we still can break it with probability  $\epsilon/4$  over  $\mathbb{Z}_N^*$ .

<sup>3</sup> Note, however, that the inverse of this isomorphism is hard to compute under the quadratic residuosity assumption.

Second, we observe that using  $(QR_N^+, \circ)$  instead of  $(QR_N, \cdot)$  will not make computing  $x^{2^T}$  significantly easier: Consider any  $x \in QR_N$  and let  $y := x^{2^T} \bmod N$  in  $(QR_N, \cdot)$ , and let  $x' = |x|$  and  $y' := x'^{2^T}$  in  $(QR_N^+, \circ)$ , as the groups are isomorphic,  $y' = |y|$ , so  $y = |y'|^{-1}$ , which means  $y \in \{y', N - y'\}$ . Although we can't efficiently decide if  $y = y'$  or  $y = N - y'$  (as it would contradict the quadratic residuosity assumption), we can pick one of the two values at random and will get the right one with probability  $1/2$ . This shows that given an algorithm that finds  $x^{2^T}$  in  $QR_N^+$  in time  $t$  with probability  $\delta$ , we get an algorithm that computes  $x^{2^T}$  in  $QR_N^+$  in basically the same time  $t$  and probability  $\delta/2$ .

### 2.3 On using safe primes

Another difference to the setting of [10] is that we assume that  $N = p \cdot q$  is the product of random *safe* primes, whereas [10] just assume random primes. We do this to make sure that  $QR_N$  (and thus also  $QR_N^+$ ) contains no sub-group of small order, this property is required to prove statistical soundness.

It is conjectured that for some constant  $c$ , there are  $c \cdot 2^\lambda/n^2$  safe  $\lambda$ -bit primes (cf. [13]), so a random  $n$  bit prime is safe with probability  $\approx c/n$ . Under this assumption, the product of two random  $n$ -bit primes will be the product of two safe primes with probability  $c^2/n^2$ .

## 3 The protocol

Our protocol, where  $\mathcal{P}$  convinces  $\mathcal{V}$  it solved an RSW puzzle, goes as follows:

- The verifier  $\mathcal{V}$  and prover  $\mathcal{P}$  have as common input an RSW puzzle  $(N, x, T)$  and a statistical security parameter  $\lambda$ . Here  $T \in \mathbb{N}$ ,  $N = p \cdot q$  is the product of safe primes and  $x \in QR_N^+$ .
- $\mathcal{P}$  solves the puzzle by computing  $y = x^{2^T}$  (making  $T$  sequential squarings in  $(QR_N^+, \circ)$ ), and sends  $y$  to  $\mathcal{V}$ .
- Now  $\mathcal{P}$  and  $\mathcal{V}$  iterate the “halving protocol” below. In this subprotocol, on common input  $(N, x, T, y)$  the output is either of the form  $(N, x', \lceil T/2 \rceil, y')$ , in which case it is used as input to the next iteration of the halving subprotocol, or the protocol has stopped with verifier output in  $\{\text{reject}, \text{accept}\}$ .

### 3.1 The halving subprotocol

On common input  $(N, x, T, y)$

1. If  $T = 1$  then  $\mathcal{V}$  outputs **accept** if  $y = x^{2^T} = x^2$  and **reject** otherwise. If  $T > 1$  go to the next step.
2. The prover  $\mathcal{P}$  sends  $\mu = x^{2^{T/2}}$  to  $\mathcal{V}$ .
3. If  $\mu \notin QR_N^+$  then  $\mathcal{V}$  outputs **reject**, otherwise  $\mathcal{V}$  samples a random  $r \xleftarrow{\$} \mathbb{Z}_{2^\lambda}$  and sends it to  $\mathcal{P}$ .
4. If  $T/2$  is even,  $\mathcal{P}$  and  $\mathcal{V}$  output

$$(N, x', T/2, y')$$

where

$$x' := x^r \cdot \mu \quad (= x^{r+2^{T/2}})$$

$$y' := \mu^r \cdot y \quad (= x^{r \cdot 2^{T/2} + 2^T})$$

(note that if  $y = x^{2^T}$  then  $y' = x'^{2^{T/2}}$ ). If  $T/2$  is odd, output

$$(N, x', (T+1)/2, y'^2).$$

### 3.2 Security statement

► **Theorem 1.** *If the input  $(N, x, T)$  to the protocol satisfies*

1.  $N = p \cdot q$  is the product of safe primes, i.e.,  $p = 2p' + 1, q = 2q' + 1$  for primes  $p', q'$ .
2.  $\langle x \rangle = QR_N^+$ .<sup>4</sup>
3.  $2^\lambda \leq \min\{p', q'\}$

*Then for any malicious prover  $\tilde{\mathcal{P}}$  who sends as first message  $y$  anything else than the solution to the RSW time-lock puzzle, i.e.,*

$$y \neq x^{2^T}$$

*$\mathcal{V}$  will finally output `accept` with probability at most*

$$\frac{3 \log(T)}{2^\lambda}.$$

## 4 Security proof

### 4.1 Usage of $QR_N$ instead $QR_N^+$ in the proof

We'll prove Theorem 1 where the signed quadratic residues  $(QR_N^+, \circ)$  are replaced with regular quadratic residues  $(QR_N, \cdot)$  throughout. This will make the proof a bit more intuitive as multiplication modulo  $N$  as in  $QR_N$  is a more familiar and simpler operation than the  $\circ$  operation in  $QR_N^+$  (which additionally requires the  $|\cdot|$  mapping after each multiplication). As discussed in §2, those two groups are isomorphic, so the proof for  $(QR_N, \cdot)$  implies the same security for  $(QR_N^+, \circ)$ .

The main reason we don't use  $(QR_N, \cdot)$  in the actual protocol is only because in step 3. of the halving subprotocol  $\mathcal{V}$  needs to check if  $\mu \in QR_N^+$ , which would not be efficient if we used  $QR_N$  (in an earlier version of the protocol we did use  $QR_N$ , and  $\mathcal{P}$  had to send  $\mu'$  s.t.  $\mu'^2 = \mu$ , the verifier would then compute  $\mu := \mu'^2$  can thus could be sure that  $\mu \in QR_N$ . As here  $\mathcal{P}$  can send any of the 4 roots of  $\mu$ , this protocol was not unique).

### 4.2 The language $\mathcal{L}$

It will be convenient to define the language

$$\mathcal{L} = \{(N, x, T, y) \quad : \quad y \neq x^{2^T} \pmod N \text{ and } \langle x \rangle = QR_N\}$$

We'll establish the following lemma.

► **Lemma 2.** *For  $N, \lambda$  as in Thm. 1, and any malicious prover  $\tilde{\mathcal{P}}$  the following holds. If the input to the halving protocol in §3.1 satisfies*

$$(N, x, T, y) \in \mathcal{L}$$

*then with probability  $\geq 1 - 3/2^\lambda$  (over the choice of  $r$ )  $\mathcal{V}$ 's output is either `reject` or satisfies*

$$(N, x', \lceil T/2 \rceil, y') \in \mathcal{L}$$

Before we prove the lemma, let's see how it implies Theorem 1.

<sup>4</sup> That is,  $x$  generates  $QR_N^+$ , the quadratic residues modulo  $N$ . For our choice of  $N$  we have  $|QR_N^+| = |QR_N| = p'q'$ , so  $\langle x \rangle \stackrel{\text{def}}{=} \{x, x^2, \dots, x^{p'q'}\} = QR_N^+$ .

**Proof of Theorem 1.** In every iteration of the halving protocol the time parameter decreases from  $T$  to  $\lceil T/2 \rceil$  and it stops once  $T = 1$ , this means we iterate for at most  $\lceil \log(T) \rceil$  rounds. By assumption, the input  $(N, x, T, y)$  to the first iteration is in  $\mathcal{L}$ , and by construction, the only case where  $\mathcal{V}$  outputs **accept** is on an input  $(N, x, 1, y)$  where  $y = x^{2^T} = x^2 \pmod N$ , in particular, this input is *not* in  $\mathcal{L}$ .

So, if  $\mathcal{V}$  outputs **accept**, there must be one iteration of the halving protocol where the input is in  $\mathcal{L}$  but the output is not. By Lemma 2, for any particular iteration this happens with probability  $\leq 3/2^\lambda$ . By the union bound, the probability of this happening in any of the  $\lceil \log(T) \rceil - 1$  rounds can be upper bounded by  $3 \log(T)/2^\lambda$  as claimed.  $\blacktriangleleft$

**Proof of Lemma 2.** We just consider the case where  $T$  is even, the odd  $T$  case is almost identical.

Assuming the input to the halving protocol satisfies  $(N, x, T, y) \in \mathcal{L}$ , we must bound the probability that  $\mathcal{V}$  outputs **reject** or the output  $(N, x', T/2, y') \notin \mathcal{L}$ .

If  $T = 1$  then  $\mathcal{V}$  outputs **reject** and we're done. Otherwise, if  $\tilde{\mathcal{P}}$  sends a  $\mu \notin QR_N$  in step 2. then  $\mathcal{V}$  outputs **reject** in step 3. and we're done. So from now we assume  $\mu \in QR_N$ . We must bound

$$\Pr_r[(y' = x'^{2^{T/2}}) \vee (\langle x' \rangle \neq QR_N)] \leq 3/2^\lambda$$

using  $\Pr[a \vee b] = \Pr[a \wedge \bar{b}] + \Pr[b]$  we rewrite this as

$$\Pr_r[y' = x'^{2^{T/2}} \wedge \langle x' \rangle = QR_N] + \Pr_r[\langle x' \rangle \neq QR_N] \leq 3/2^\lambda \quad (3)$$

Eq. (3) follows by the two claims below.

► **Claim 1.**  $\Pr_r[\langle x' \rangle \neq QR_N] \leq 2/2^\lambda$ .

**Proof of Claim.** We'll denote with  $e_\mu$  the unique value in  $\mathbb{Z}_{p'q'}$  satisfying  $x^{e_\mu} = \mu$  (it's unique as  $\mu \in \langle x \rangle = QR_N$  and  $|QR_N| = p'q'$ ). As  $x, \mu \in QR_N$ , also  $x' = x^r \cdot \mu = x^{r+e_\mu}$  is in  $QR_N$ , and  $\langle x' \rangle = QR_N$  holds if  $\text{ord}(x') = p'q'$ , which is the case except if  $(r+e_\mu) = 0 \pmod{p'}$  or  $(r+e_\mu) = 0 \pmod{q'}$  or equivalently (using that  $2^\lambda < \min(p', q')$ ) if

$$r \in \mathcal{B} \stackrel{\text{def}}{=} \{\mathbb{Z}_{2^\lambda} \cap \{(-e_\mu \pmod{p'}), (-e_\mu \pmod{q'})\}\}. \quad (4)$$

Clearly  $|\mathcal{B}| \leq 2$  and the claim follows.  $\blacktriangleleft$

► **Claim 2.**  $\Pr_r[y' = x'^{2^{T/2}} \pmod N \wedge \langle x' \rangle = QR_N] \leq 1/2^\lambda$ .

**Proof of Claim.** If  $y \notin QR_N$ , then also  $y' = \mu^r \cdot y \notin QR_N$  (as  $a \in QR_N, b \notin QR_N$  implies  $a \cdot b \notin QR_N$ ). As  $\langle x' \rangle = QR_N$  and  $y' \neq x'^{2^{T/2}}$  can't hold simultaneously in this case the probability in the claim is 0. From now on we consider the case  $y \in QR_N$ . We have

$$\begin{aligned} \Pr_r[y' = x'^{2^{T/2}} \wedge \langle x' \rangle = QR_N] &= \\ \Pr_r[y' = x'^{2^{T/2}} \mid \langle x' \rangle = QR_N] \cdot \Pr_r[\langle x' \rangle = QR_N] & \end{aligned} \quad (5)$$

For the second factor in (5) we have with  $\mathcal{B}$  as in (4)

$$\Pr_r[\langle x' \rangle = QR_N] = \frac{2^\lambda - |\mathcal{B}|}{2^\lambda}. \quad (6)$$

Conditioned on  $\langle x' \rangle = QR_N$  the  $r$  is uniform in  $\mathbb{Z}_{2^\lambda} \setminus \mathcal{B}$ , so the first factor in (5) is

$$\Pr_r[y' = x'^{2^{T/2}} \mid \langle x' \rangle = QR_N] = \Pr_{r \in \mathbb{Z}_{2^\lambda} \setminus \mathcal{B}}[y' = x'^{2^{T/2}}]. \quad (7)$$

Let  $e_y \in \mathbb{Z}_{p'q'}$  be the unique value such that  $x^{e_y} = y$ . Using  $\langle x \rangle = QR_N$  in the last step below we can rewrite

$$\begin{aligned} y' &= x'^{2^{T/2}} \pmod{N} && \iff \\ \mu^r y &= (x^r \mu)^{2^{T/2}} \pmod{N} && \iff \\ x^{r \cdot e_\mu + e_y} &= x^{(r+e_\mu) \cdot 2^{T/2}} \pmod{N} && \iff \\ r \cdot e_\mu + e_y &= (r + e_\mu) \cdot 2^{T/2} \pmod{p'q'} \end{aligned}$$

rearranging terms

$$r(e_\mu - 2^{T/2}) + e_y - e_\mu 2^{T/2} = 0 \pmod{p'q'}. \quad (8)$$

If  $e_\mu = 2^{T/2}$  this becomes

$$e_y - 2^T = 0 \pmod{p'q'}$$

which does not hold as by assumption we have  $y \neq x^{2^T}$ . So from now on we assume  $e_\mu \neq 2^{T/2} \pmod{p'q'}$ . Then for  $a = e_\mu - 2^{T/2} \neq 0 \pmod{p'q'}$  (and  $b = e_y - e_\mu 2^{T/2}$ ) eq. (8) becomes

$$r \cdot a = b \pmod{p'q'}$$

which holds for at most one choice of  $r$  from its domain  $\mathbb{Z}_{2^\lambda} \setminus \mathcal{B}$ , thus

$$\Pr_{r \in \mathbb{Z}_{2^\lambda} \setminus \mathcal{B}}[y' = x'^{2^{T/2}}] \leq \frac{1}{2^\lambda - |\mathcal{B}|}$$

and the claim follows from the above equation and (5)-(7) as

$$\begin{aligned} \Pr_r[y' = x'^{2^{T/2}} \wedge \langle x' \rangle = QR_N] &= \\ \Pr_{r \in \mathbb{Z}_{2^\lambda} \setminus \mathcal{B}}[y' = x'^{2^{T/2}}] \cdot \Pr_r[\langle x' \rangle = QR_N] &\leq \frac{1}{2^\lambda - |\mathcal{B}|} \cdot \frac{2^\lambda - |\mathcal{B}|}{2^\lambda} \leq \frac{1}{2^\lambda}. \end{aligned} \quad \blacktriangleleft$$

## 5 Verifiable delay functions

In this section we define verifiable delay functions (VDF) mostly following the definition from [3]. A VDF is defined by a four-tuple of algorithms:

**VDF.Setup**( $1^\lambda$ )  $\rightarrow$  **pp** on input a statistical security parameter  $1^\lambda$  outputs public parameters **pp**.

**VDF.Gen**(**pp**,  $T$ )  $\rightarrow$   $(x, T)$  on input a time parameter  $T \in \mathbb{N}$ , samples an input  $x$ .

**VDF.Sol**(**pp**,  $(x, T)$ )  $\rightarrow$   $(y, \pi)$  on input  $(x, T)$  outputs  $(y, \pi)$ , where  $\pi$  is a proof that the output  $y$  has been correctly computed.

**VDF.Ver**(**pp**,  $(x, T)$ ,  $(y, \pi)$ )  $\rightarrow$  {**accept/reject**} given an input/output tuple  $(x, T)$ ,  $(y, \pi)$  outputs either **accept** or **reject**.

The **VDF.Setup** and **VDF.Gen** algorithms are probabilistic, **VDF.Sol** and **VDF.Ver** are deterministic. They all run in time  $\text{poly}(\log(T), \lambda)$ .

## 5.1 The statistical security parameter

$\lambda$  measures the bit-security we expect from our protocol, i.e., an adversary of complexity  $\tau$  should have advantage no more than  $\approx \tau/2^\lambda$  in breaking the scheme. It only makes sense to consider time parameters  $T$  that are much smaller than  $2^\lambda$  (say we require  $T \leq 2^{\lambda/2}$ ) so the sequential running time of the honest prover is much smaller than what is required to break the underlying hardness assumptions.

## 5.2 Efficiency of solving

The  $\text{VDF.Sol}$  algorithm can compute the output  $y$  in  $T$  sequential steps (in this work a “sequential step” is the  $\circ$  operation, which basically is a multiplication modulo  $N$ ). Moreover we require that  $\pi$  can be computed with in much fewer than  $T$  steps. As we’ll discuss in §6.2, we’ll achieve  $O(\sqrt{T} \log(T))$  sequential steps, and less if parallelism is available. In [3] the requirement is more relaxed, they compute  $\pi$  in parallel with  $y$  using bounded  $\text{poly}(\log(T), \lambda)$  parallelism, so the  $\pi$  is available shortly after  $y$  is computed, but overall the computation is much larger than  $T$ . As discussed in the introduction, Wesolowski’s VDF [14] requires  $O(T/\log(T))$  steps to compute  $\pi$ .

## 5.3 Completeness

The completeness property simply requires that correctly generated proofs will always accept, that is, for any  $\lambda, T$

$$\Pr \left[ \begin{array}{l} \text{VDF.Ver}(\mathbf{pp}, (x, T), (y, \pi)) = \text{accept} \\ \text{where} \\ \mathbf{pp} \xleftarrow{\$} \text{VDF.Setup}(1^\lambda) \\ (x, T) \xleftarrow{\$} \text{VDF.Gen}(\mathbf{pp}, T) \\ (y, \pi) \leftarrow \text{VDF.Sol}(\mathbf{pp}, (x, T)) \end{array} \right] = 1$$

## 5.4 Security (sequentiality)

The first security property is sequentiality. For this we consider a two part adversary  $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$ , where  $\mathcal{A}_1$  can run a pre-computation and choose  $T$ . Then  $\mathcal{A}_2$  gets a random challenge for time  $T$  together with the output **state** of the precomputation, we require that whenever

$$\Pr \left[ \begin{array}{l} \text{VDF.Ver}(\mathbf{pp}, (x, T), (\tilde{y}, \tilde{\pi})) = \text{accept} \\ \text{where} \\ \mathbf{pp} \xleftarrow{\$} \text{VDF.Setup}(1^\lambda) \\ (T, \text{state}) \xleftarrow{\$} \mathcal{A}_1(\mathbf{pp}) \\ (x, T) \xleftarrow{\$} \text{VDF.Gen}(\mathbf{pp}, T) \\ (\tilde{y}, \tilde{\pi}) \xleftarrow{\$} \mathcal{A}_2(\mathbf{pp}, (x, T), \text{state}) \end{array} \right] \neq \text{negl}(\lambda)$$

the  $\mathcal{A}_2$  adversary must use almost the same *sequential* time  $T$  as required by an honest execution of  $\text{VDF.Sol}(\mathbf{pp}, (\pi, T))$ , and this even holds if  $\mathcal{A}$  is allowed massive parallel computation (say we just bound the total computation to  $2^{\lambda/2}$ ). This means there’s no possible speedup to compute the VDF output by using parallelism. Let us stress that by this we mean any parallelism that goes beyond what can be used to speed up a single sequential step, which here is a multiplication in  $\mathbb{Z}_N^*$ , and we assume the honest prover can use such bounded parallelism.

## 5.5 Security (soundness)

The second security property is soundness, which means that one cannot come up with an accepting proof  $\tilde{\pi}$  for a wrong statement. Formally, for an adversary  $\mathcal{A} = (\mathcal{A}_1, \mathcal{A}_2)$  we have (unlike in the previous definition, here we don't make any assumption about  $\mathcal{A}_2$ 's sequential running time, just the total running time of  $\mathcal{A}$  must be bounded to, say  $2^{\lambda/2}$ )

$$\Pr \left[ \begin{array}{l} \text{VDF.Ver}(\mathbf{pp}, (x, T), (\tilde{y}, \tilde{\pi})) = \text{accept} \\ \text{and } \tilde{y} \neq y \\ \text{where} \\ \mathbf{pp} \stackrel{\$}{\leftarrow} \text{VDF.Setup}(1^\lambda) \\ (T, \text{state}) \stackrel{\$}{\leftarrow} \mathcal{A}_1(\mathbf{pp}) \\ (x, T) \stackrel{\$}{\leftarrow} \text{VDF.Gen}(\mathbf{pp}, T) \\ (y, \pi) \leftarrow \text{VDF.Sol}(\mathbf{pp}, (x, T)) \\ (\tilde{y}, \tilde{\pi}) \stackrel{\$}{\leftarrow} \mathcal{A}_2(\mathbf{pp}, (x, T), \text{state}) \end{array} \right] = \text{negl}(\lambda)$$

## 6 A VDF from RSW

In this section we explain the simple transformation of the protocol from §3 into a VDF and then discuss the efficiency, security and some other issues of this construction.

To keep things simple we'll assume that the time parameter  $T = 2^t$  is a power of two. The four algorithms from §5 are instantiated as

**VDF.Setup**( $1^\lambda$ ) The statistical security parameter  $\lambda$  defines another security parameter  $\lambda_{\text{RSA}}$  specifying the bitlength of an RSA modulus, where  $\lambda_{\text{RSA}}$  should be at least as large so that an  $\lambda_{\text{RSA}}$  bit RSA modulus offers  $\lambda$  bits of security (e.g.  $\lambda = 100$  and  $\lambda_{\text{RSA}} = 2048$ ). As hardness of factoring is subexponential, while the soundness of our protocol is exponentially small in  $\lambda$  (in the random oracle model), we can without loss of generality assume that  $\lambda \leq \lambda_{\text{RSA}}/2$ , so point 3. in the statement of Theorem 1 is satisfied.

The setup algorithm samples two random  $\lambda_{\text{RSA}}/2$  bit safe primes  $p, q$  and outputs as public parameters the single  $\lambda_{\text{RSA}}$  bit RSA modulus  $N := p \cdot q$ .

**VDF.Gen**( $N, T$ ) samples a random  $x \in QR_N^+$  and outputs  $(x, T)$ .

**VDF.Sol**( $N, (x, T)$ ) outputs  $(y, \pi)$  where  $y = x^{2^T}$  is the solution of the RSW time-lock puzzle (but over  $(QR_N^+, \circ)$  not  $(\mathbb{Z}_N^*, \cdot)$ ) and  $\pi = \{\mu_i\}_{i \in [t]}$  is a proof that  $y$  has been correctly computed. It is derived by applying the Fiat-Shamir heuristic to the protocol in §3. Recall that in this heuristic the public-coin challenges  $r_i \in \mathbb{Z}_{2^\lambda}$  of the verifier are replaced with a hash of the last prover message. Concretely, we fix a hash function  $\text{hash} : \mathbb{Z} \times \mathbb{Z}_N^4 \rightarrow \mathbb{Z}_{2^\lambda}$ , let  $(x_1, y_1) := (x, y)$  and for  $i = 1 \dots t$  let<sup>5</sup>

<sup>5</sup> Note that in the Fiat-Shamir heuristic, we not just hash the first prover message  $\mu_i$  in eq. (9), but also the statement  $(x_i, T/2^{i-1}, y_i)$  of the halving subprotocol. It has been observed that this is necessary in a setting like ours, where the prover has some influence on the statement to be proven [1]. There exists an easy attack (communicated to us by Benjamin Wesolowski) on uniqueness of the VDF if the  $y$ 's are not included in the hash: for  $(x, T) = (x_1, T_1)$ , pick  $\mu_1$  at random, let  $r_1 = \text{hash}((x, T), \mu_1)$ ,  $y = (x^{2^{T/2}} / \mu_1)^{r_1} \mu_1^{2^{T/2}}$ ,  $x_2 = x_1^{r_1} \mu_1$ ,  $y_2 = \mu_1^{r_1} y$ . The above  $y$  is almost certainly wrong, i.e.,  $y \neq x^{2^T}$ , but by construction  $y_2 = x_2^{2^{T/2}}$ , so one can continue with the honest proof.

$$\begin{aligned}
\mu_i &:= x_i^{2^{T/2^i}} \in QR_N^+ \\
r_i &:= \text{hash}((x_i, T/2^{i-1}, y_i), \mu_i) \in \mathbb{Z}_{2^\lambda} \\
x_{i+1} &:= x_i^{r_i} \circ \mu_i \\
y_{i+1} &:= \mu_i^{r_i} \circ y_i
\end{aligned} \tag{9}$$

**VDF.Ver**( $N, (x, T), (y, \pi)$ ) parses  $\pi = \{\mu_i\}_{i \in [t]}$  and checks if  $x, y$  and all  $\mu_i$  are in  $QR_N^+$ , if this is not the case output **reject**. Otherwise set  $(x_1, y_1) := (x, y)$  and then for  $i = 1 \dots t$  compute

$$r_i := \text{hash}((x_i, T/2^{i-1}, y_i), \mu_i) \tag{10}$$

$$x_{i+1} := x_i^{r_i} \circ \mu_i \tag{10}$$

$$y_{i+1} := \mu_i^{r_i} \circ y_i \tag{11}$$

Finally check whether

$$y_{t+1} \stackrel{?}{=} x_{t+1}^2 \tag{12}$$

and output **accept** if this holds, otherwise output **reject**.

## 6.1 Public parameters for the VDF

For the security of the VDF it's crucial that a prover does not know the factorization of the public parameter  $N$ , as otherwise he could compute  $x^{2^T}$  in just two exponentiations as in eq. (1). Thus one either has to rely on a trusted party, or use multiparty-computation to sample  $N$ . In particular, it's possible to sample  $N$  securely as long as not all the participants in the multiparty computation are malicious. Such an ‘‘MPC ceremony’’ has been done before, e.g. to set up the common random string for Zcash.<sup>6</sup> This is in contrast to the random-oracle based PoSW [9, 5] which don't require a setup procedure at all.

To avoid trusted setup, Boneh et al. [4] and Wesolowski [14] suggested to use class groups of an imaginary quadratic field [2] instead of an RSA group. Recall that the statistical soundness of our proof systems relies on the fact that the underlying group (the quadratic residues of  $\mathbb{Z}_N^*$  where  $N$  is the product of safe primes) has no subgroups of small order. If the underlying group does have groups of small order, then *computational* soundness holds under the assumption that it's hard to find elements of small order, which is conjectured to hold for the class groups mentioned above.

## 6.2 Efficiency of the VDF

### 6.2.1 Cost of verification

The cost of running the verification  $\text{VDF.Ver}(N, (x, T = 2^t), (y, \pi))$  is dominated by the  $2t$  exponentiations (with  $\lambda$  bit long exponents) in eq. (10-11). As exponentiation with a random  $\lambda$  bit exponent costs about  $1.5\lambda$  multiplications,<sup>7</sup> the cost of verification is around  $3 \cdot \lambda \cdot t$

<sup>6</sup> <https://z.cash/technology/paramgen.html>

<sup>7</sup> Exponentiation is typically done via ‘‘square and multiply’’, which for a  $z$  bit exponent with hamming weight  $h(z)$  requires  $z + h(z)$  multiplications, or about  $1.5 \cdot z$  multiplication for a random exponent (where  $h(z) \approx z/2$ ).

multiplications.<sup>8</sup> For concreteness, consider an implementation where  $\lambda = 100$ ,  $\lambda_{\text{RSA}} = 2048$  and assume  $t = 40$ , this gives a cost of about  $3 \cdot \lambda \cdot t = 12000$  multiplications, which corresponds to  $12000/(2048 \cdot 1.5) \approx 4$  full exponentiations in  $\mathbb{Z}_N^*$ .

## 6.2.2 A minor efficiency improvement

There's a simple way to save on verification time and proof size. Currently, for  $T = 2^t$  we run the halving protocol for  $t$  rounds, and then in eq. (12) check if  $y_{t+1} \stackrel{?}{=} x_{t+1}^2$ . For any integer  $\Delta \geq 0$  we could run the protocol for just  $t - \Delta$  rounds, but then the verifier must check if  $y_{t+1-\Delta} \stackrel{?}{=} x_{t+1-\Delta}^{2^{2^\Delta}}$ , which requires  $2^\Delta$  squarings (more generally, if  $T$  is not a power of 2 then the check becomes  $y_{t+1-\Delta} \stackrel{?}{=} x_{t+1-\Delta}^{2^{T_{t+1-\Delta}}} \pmod N$  where  $T_1 = T, T_i = \lceil T_{i-1}/2 \rceil$ ).

If we set, say  $\Delta = 10$ , this saves 10 rounds and thus reduces the proof size by 25% from 40 to 30 elements. The verification time decreases by around 15% (we save 20 short exponentiations as in eq. (10,11) at the price of 1024 extra squarings).

## 6.2.3 Cost of computing the proof

Computing the proof  $(y, \pi) \leftarrow \text{VDF.Sol}(N, (x, T))$  requires one to solve the underlying RSW puzzle  $y = x^{2^T}$ , which is done by squaring  $x$  sequentially  $T$  times (the security of the RSW puzzle and thus also our VDF relies on the assumption that there's no shortcut to this computation).

On top of that, for the VDF we also must compute the proof  $\pi = \{\mu_i\}_{i \in [t]}$  where  $\mu_i = x_i^{2^{T/2^i}}$ . But we still assume that  $T = 2^t$  is a power of 2.

If naïvely implemented, computing the  $\mu_i$  will require  $T/2$  squarings for  $\mu_1$ ,  $T/4$  for  $\mu_2$  etc., adding up to a total of  $T \approx T/2 + T/4 + T/8 \dots + 1$  sequential steps. Fortunately we don't have to compute  $\mu_1 = x^{2^{T/2}}$  as we already did so while computing  $y = x^{2^T}$  by repeated squaring (cf. eq. (2)). This observation already saves us half the overhead. We can also compute the remaining  $\mu_2, \mu_3, \dots$  using stored values, but it becomes increasingly costly, as we discuss below.

In general, for some  $s \in [t]$  the prover can compute  $\mu_1, \dots, \mu_s$  using stored values, and then fully recompute the remaining  $\mu_{s+1} = x_{s+1}^{2^{T/2^{s+1}}}, \mu_{s+2}, \dots, \mu_t$  which will only require  $T/2^{s+1} + T/2^{s+2} \dots < T/2^s$  squarings.

To see how the  $\mu_i$ 's can be efficiently computed for small  $i$ , for  $z \in QR_N^+$  let  $\bar{z}$  denote  $z$ 's log to basis  $x$ , i.e.,  $x^{\bar{z}} = z$ . We have  $\bar{x}_1 = 1, \bar{y}_1 = 2^T$  and

$$\begin{aligned} \bar{\mu}_i &:= \bar{x}_i \cdot 2^{T/2^i} \\ \bar{x}_{i+1} &:= r_i \cdot \bar{x}_i + \bar{\mu}_i \\ \bar{y}_{i+1} &:= r_i \cdot \bar{\mu}_i + \bar{y}_i \end{aligned}$$

How those exponents concretely develop for  $i = 1$  to 3 is illustrated in Figure 1. For example, we can compute  $\mu_3$  assuming we stored the  $x^{2^{T/8}}, x^{2^{T^3/8}}, x^{2^{T^5/8}}, x^{2^{T^7/8}}$  values as

$$\mu_3 = (x^{2^{T/8}})^{r_1 \cdot r_2} \cdot (x^{2^{T^5/8}})^{r_2} \cdot (x^{2^{T^3/8}})^{r_1} \cdot x^{2^{T^7/8}}$$

<sup>8</sup> Here multiplication means the  $\circ$  operation, which requires one multiplication modulo  $N$ , followed by the map  $|\cdot|$ . As the cost of this map is marginal compared to the multiplication we just ignore it.

## 60:14 Simple Verifiable Delay Functions

$i$	$\bar{x}_i$	$\bar{\mu}_i$	$\bar{y}_i$
1	1	$2^{t/2}$	$2^t$
2	$r_1 + 2^{t/2}$	$r_1 \cdot 2^{t/4} + 2^{3t/4}$	$r_1 \cdot 2^{t/2} + 2^t$
3	$r_1 \cdot r_2 + r_2 \cdot 2^{t/2} + 2^{t/4} \cdot r_1 + 2^{3t/4}$	$r_1 \cdot r_2 \cdot 2^{t/8} + r_2 \cdot 2^{5t/8} + r_1 \cdot 2^{3t/8} + 2^{7t/8}$	$r_1 \cdot r_2 \cdot 2^{t/4} + r_2 \cdot 2^{3t/4} + r_1 \cdot 2^{t/2} + 2^t$
$\vdots$	$\vdots$	$\vdots$	$\vdots$

■ **Figure 1** Exponents of the the values in the protocol, here  $z = x^z$ .

In general, computing  $\mu_1, \dots, \mu_s$  will require to store  $2^s$  values  $\{x^{2^{T-i/2^s}}\}_{i \in [2^s]}$ , and then compute  $2^s$  exponentiations with exponents of bitlength at most  $\lambda \cdot (s-1)$  (and half that on average). We can't speed this up by first taking the exponents modulo the group order  $p'q'$  as it is not known, but if we have bounded parallelism  $2^p, p \leq (s-2)$  this can be done in  $2^{s-p} \cdot \lambda \cdot (s-1) \cdot \frac{3}{4}$  sequential steps. Summing up, with sufficient space to store  $2^s$  elements in  $\mathbb{Z}_N$  and  $2^p \leq 2^s$  parallelism the proof  $\pi$  can be computed in roughly

$$2^{s-p} \cdot \lambda \cdot (s-1) \cdot \frac{3}{4} + 2^{t-s} \text{ sequential steps and } 2^s \cdot \log(N) \text{ bits of storage}$$

after  $y$  has been computed. For example with a single core  $p = 0$  and  $s = t/2 - \log(t \cdot \lambda)/2$  the number of steps (i.e.,  $\circ$  operations) becomes

$$2^{t/2 - \log(t \cdot \lambda)/2} \cdot \lambda \cdot (s-1) \cdot \frac{3}{4} + 2^{t/2 + \log(t \cdot \lambda)/2} = 2^{t/2} \left( \frac{\lambda(s-1)}{\sqrt{t\lambda}} \cdot \frac{3}{4} + \sqrt{t\lambda} \right) < \sqrt{T} \cdot \frac{11}{8} \cdot \sqrt{\log(T) \cdot \lambda}$$

For our typical values  $t = 40, \lambda = 100$  this is  $\leq 2^{27}$ , and thus over  $2^{40-27} = 2^{13}$  times faster than computing  $y$ , e.g. if computing  $y$  takes  $1h$ , computing  $\pi$  just takes half a second on top. The memory required (to store intermediate values) is around  $2^s \cdot \log N = 2^{t/2 - \log(t \cdot \lambda)/2} \cdot 1024 \leq 2^{27}$  bits, or  $8MB$ .

## 6.3 Security of the VDF

### 6.3.1 Soundness

If we model *hash* as a random oracle, then by Lemma 2 (which is used in the proof of Theorem 1) we are guaranteed that a malicious prover will not find an accepting proof  $(\tilde{y}, \tilde{\pi})$  for a wrong statement  $\tilde{y} \neq x^{2^T}$  except with exponentially small probability. We can even let the malicious prover choose the challenge  $(x, T)$  for which it must forge such a proof itself, the only restriction being that  $x$  must be a generator  $\langle x \rangle = QR_N^+$  (a random  $x \in QR_N^+$  satisfies this almost certainly, but we can't efficiently verify if a given  $x$  is such a generator).

The well known Fiat-Shamir heuristic states that replacing the prover's queries with the output of a random oracle in a sound public-coin interactive proof system results in a sound non-interactive proof system, but this only applies for protocols with a constant number of rounds.

Even though our protocol has logarithmically many rounds, we can directly conclude that our non-interactive proof is sound as follows: if we are given a valid proof for a wrong statement, then, during the execution of the verification algorithm for this proof, we must make a query  $hash(x_i, T/2^{i-1}, y_i, \mu_i)$  where  $(N, x_i, T/2^{i-1}, y_i) \in \mathcal{L}$  ( $\mathcal{L}$  as defined in §4) but for the next query made  $hash(x_{i+1}, T/2^i, y_{i+1}, \mu_{i+1})$  we have  $(N, x_{i+1}, T/2^i, y_{i+1}) \notin \mathcal{L}$ . By Lemma 2, every random oracle query will correspond to such a query with probability at most  $3/2^\lambda$ . Thus, by the union bound, the probability that a malicious prover that makes up to  $q$  queries to *hash* will find such a query (which as outlined is necessary to find an accepting proof for a wrong statement) is at most  $q \cdot 3/2^\lambda$ .

### 6.3.2 Sequentiality

To break sequentiality means computing  $y$  faster than in  $T$  sequential computations. We rely on the same assumption as [10], which simply states that such a shortcut does not exist. As outlined in §2, the fact that we work over  $(QR_N^+, \circ)$  not  $(\mathbb{Z}_N, \cdot)$  only makes the assumption on which we rely weaker, and the fact that in our case  $N$  is the product of *safe* primes doesn't affect the assumption assuming that safe primes are not too sparse.

## Abstract

---

In this paper, we develop machinery which makes it much easier to prove sum of squares lower bounds when the problem is symmetric under permutations of  $[1, n]$  and the unsatisfiability of our problem comes from integrality arguments, i.e. arguments that an expression must be an integer. Roughly speaking, to prove SOS lower bounds with our machinery it is sufficient to verify that the answer to the following three questions is yes:

1. Are there natural pseudo-expectation values for the problem?
2. Are these pseudo-expectation values rational functions of the problem parameters?
3. Are there sufficiently many values of the parameters for which these pseudo-expectation values correspond to the actual expected values over a distribution of solutions which is the uniform distribution over permutations of a single solution?

We demonstrate our machinery on three problems, the knapsack problem analyzed by Grigoriev, the MOD 2 principle (which says that the complete graph  $K_n$  has no perfect matching when  $n$  is odd), and the following Turan type problem: Minimize the number of triangles in a graph  $G$  with a given edge density. For knapsack, we recover Grigoriev's lower bound exactly. For the MOD 2 principle, we tighten Grigoriev's linear degree sum of squares lower bound, making it exact. Finally, for the triangle problem, we prove a sum of squares lower bound for finding the minimum triangle density. This lower bound is completely new and gives a simple example where constant degree sum of squares methods have a constant factor error in estimating graph densities.

## 1 Introduction

The sum of squares hierarchy (which we call SOS for brevity), a hierarchy of semidefinite programs first independently investigated by Shor [33], Nesterov [27], Parrilo [28], Lasserre [22], and Grigoriev [15, 16], is an exciting frontier of algorithm design, complexity theory, and proof complexity. SOS is exciting because it provides a single unified framework which can be applied to give approximation algorithms for a wide variety of combinatorial optimization problems. Moreover, SOS is conjectured to be optimal for many of these problems. In particular, SOS captures the Goemans-Williamson algorithm for MAX-CUT [13], the Goemans-Linial relaxation for sparsest cut (analyzed by Arora, Rao, and Vazirani [2]), and the subexponential time algorithm for unique games found by Arora, Barak, and Steurer [1]. More recently, SOS has been applied directly to give algorithms for several problems including planted sparse vector [5], dictionary learning [6], tensor decomposition [12, 19, 25], tensor completion [8, 29], and quantum separability [7].

That said, there are limits to the power of SOS. As shown by SOS lower bounds for constraint satisfactions problems (CSPs) [16, 32, 3, 20] and gadget reductions [34], SOS requires degree  $\Omega(n)$  (and thus exponential time) to solve most NP-hard problems. As shown by SOS lower bounds on planted clique and other planted problems [26, 10, 17, 4, 18], SOS can have difficulty distinguishing between a random input and an input which is random except for a solution which has been planted inside it. Finally, as shown by Grigoriev's SOS lower bound for the knapsack problem [15], SOS has difficulty capturing integrality arguments, i.e. arguments which say that an expression must be an integer.

In this paper, we further explore this last weakness of SOS. In particular, we develop machinery which makes it much easier to prove SOS lower bounds when the problem is symmetric and the unsatisfiability of our problem comes from integrality arguments. The usual process for proving SOS lower bounds involves finding pseudo-expectation values (see subsection 2.3) and then proving that a matrix called the moment matrix is PSD (positive semidefinite), which can be quite difficult. Roughly speaking, to prove SOS lower bounds with our machinery it is sufficient to verify that the answer to the following three questions is yes:

1. Are there natural pseudo-expectation values for the problem?
2. Are these pseudo-expectation values rational functions of the problem parameters?
3. Are there sufficiently many values of the parameters for which these pseudo-expectation values correspond to the actual expected values over a distribution of solutions which is the uniform distribution over permutations of a single solution?

We demonstrate our machinery on three problems, the knapsack problem itself, the MOD 2 principle (which says that the complete graph  $K_n$  on  $n$  vertices does not have a perfect matching when  $n$  is odd), and the following Turan-type problem: Minimize the number of triangles in a graph  $G$  with a given edge density.

### 1.1 Equations and SOS lower bounds for knapsack, the MOD 2 principle, and a triangle problem

To state our SOS lower bounds on knapsack, the MOD 2 principle, and the triangle problem, we must first express these problems as infeasible systems of polynomial equations. We do this because as we will discuss in subsection 2.3, SOS gives a proof system for proving that systems of polynomial equations over  $\mathbb{R}$  are infeasible. Our lower bounds show that SOS requires high degree to prove that the systems of equations corresponding to knapsack, the MOD 2 principle, and the triangle problem are infeasible.

For the knapsack problem, we consider the simple case when all of the weights are 1, the knapsack capacity is  $k$ , and we are asked whether it is possible to fill the knapsack to its capacity. We can express this problem with equations as follows:

1.  $\forall i, x_i^2 - x_i = 0$
2.  $\sum_{i=1}^n x_i - k = 0$ .

These equations are clearly infeasible whenever  $k \notin \mathbb{Z}$ . However, as Grigoriev [15] showed, since SOS has difficulty capturing integrality arguments, SOS requires high degree to refute these equations.

► **Theorem 1** (Grigoriev's SOS lower bound for knapsack).

*Degree  $\min\{2\lfloor \min\{k, n-k\} \rfloor + 3, n\}$  SOS fails to prove that the knapsack equations are infeasible.*

In this paper, we observe that Grigoriev's lower bound (which is tight) follows immediately from our machinery.

For the MOD 2 principle, we are asked whether the complete graph  $K_n$  has a perfect matching. To express this problem with equations, we take a variable  $x_{ij}$  for each possible edge  $(i, j)$  and we want that  $x_{ij} = 1$  if the edge  $(i, j)$  is in our matching and  $x_{ij} = 0$  otherwise. We encode this and the claim that we have a perfect matching as follows:

1. For all  $i, j \in [1, n]$  such that  $i < j$ ,  $x_{ij}^2 - x_{ij} = 0$
2. For all  $i \in [1, n]$ ,  $\sum_{j \in [1, n]: j \neq i} x_{ij} - 1 = 0$  (where we take  $x_{ij} = x_{ji}$  whenever  $i > j$ )

These equations are infeasible whenever  $n$  is odd. However, Grigoriev [16] showed that SOS requires high degree to refute these equations. While Grigoriev's lower bound is shown via a reduction from the Tseitin equations and is tight up to a constant factor, in this paper we use our machinery to obtain the following tight SOS lower bound directly.

► **Theorem 2** (SOS lower bound for the MOD 2 principle).

*Degree  $\frac{n-1}{2}$  SOS fails to prove that the equations for the MOD 2 principle are infeasible.*

For the triangle problem, we want to minimize the number of triangles in a graph with edge density  $\rho$ . For this problem, Goodman [14] showed the following lower bound.

► **Theorem 3** (Goodman's bound). *The minimal number of triangles in a graph  $G$  with  $n$  vertices and edge density  $\rho$  is at least*

$$t(n, \rho) := \binom{n}{3} - \frac{n(n-1)(1-\rho)}{6}((1+2\rho)n - 2 - 2\rho)$$

As we will discuss in the full version of this paper, this bound is tight if there is an integer  $k$  such that

1.  $\frac{n}{k} - 1 = (1 - \rho)(n - 1)$
2.  $n$  is divisible by  $k$ .

If so, then we can take  $G$  to have  $k$  independent sets of size  $\frac{n}{k}$  and have all of the edges between different independent sets, which minimizes the number of triangles in  $G$  and matches Goodman's bound. Otherwise, Goodman's bound cannot be achieved.

To express this problem using equations, we again create a variable  $x_{ij}$  for each possible edge  $(i, j)$  and we want  $x_{ij} = 1$  if the edge  $(i, j)$  is in the graph and  $x_{ij} = 0$  if the edge  $(i, j)$  is not in the graph. We encode this, the requirement the edge density is  $\rho$ , and the claim that Goodman's bound can be achieved with the following equations

1. For all  $i, j \in [1, n]$  such that  $i < j$ ,  $x_{ij}^2 - x_{ij} = 0$
2.  $\sum_{i, j \in [1, n]: i < j} x_{ij} - \rho \binom{n}{2} = 0$
3.  $\sum_{i, j, k \in [1, n]: i < j < k} x_{ij}x_{ik}x_{jk} - t(n, \rho) = 0$  where  $t(n, \rho) = \binom{n}{3} - \frac{n(n-1)(1-\rho)}{6}((1+2\rho)n - 2 - 2\rho)$

Using our machinery, we show the following SOS lower bound which is completely new and was the motivation for developing our machinery.

► **Theorem 4** (SOS lower bound for the triangle problem).

Letting  $k$  be the number such that  $\frac{n}{k} - 1 = (1 - \rho)(n - 1)$ , degree  $\lfloor \min\{k, \frac{n}{k}\} \rfloor + 1$  SOS fails to refute the triangle problem equations.

## 1.2 Relation to previous work on symmetry and SOS

There is a considerable body of prior research on symmetry and SOS. Several works built on the difficulty on knapsack and/or further investigated symmetric polynomials on the variables  $\{x_1, \dots, x_n\}$ . Laurent [23] used the difficulty of knapsack to show that degree  $\lfloor \frac{n}{2} \rfloor$  SOS is required to capture the CUT polytope of the complete graph. Bleckherman, Gouveia, and Pfeiffer [9] used the difficulty of knapsack to construct degree 4 polynomials which are non-negative but cannot be written as a sum of squares of low degree *rational* functions. Lee, Prakash, Wolf, and Yuen [24] showed that there are symmetric non-negative polynomials on the variables  $\{x_1, \dots, x_n\}$  which cannot be approximated with low degree sums of squares. Kurpisz, Leppänen, and Mastroiilli [21] gave a general criterion for determining if a symmetric polynomial on  $\{x_1, \dots, x_n\}$  is a sum of squares or not.

While these prior works give more precise results for symmetric problems on the variables  $\{x_1, \dots, x_n\}$ , they do not show how to handle problems which are symmetric under permutations of  $[1, n]$  but have variables such as  $\{x_{ij} : i < j\}$  which depend on 2 or more indices. Thus, these prior works are incomparable with this work.

Another line of research on symmetry and SOS which is more closely connected to this work uses symmetry to reduce the algorithmic complexity of implementing SOS. Gatermann and Parrilo [11] showed how representation theory can be used to greatly reduce the search space for pseudo-expectation values, allowing SOS to be run more efficiently on symmetric problems. Recently, Raymond et. al. [30] combined the analysis of Gatermann and Parrilo with Razborov’s flag algebras [31] to show that in the case of  $k$ -subset hypercubes, the resulting semidefinite program has size which is independent of  $n$ . These results are quite general and apply to all of the problems we are considering. That said, these results do not tell us how to find or verify pseudo-expectation values by hand, which is generally what is needed for SOS lower bounds.

In this paper, we show how the representation theory which allows Gatermann and Parrilo [11] and Raymond et. al. [30] to dramatically reduce the size of the semidefinite programs for SOS on symmetric problems can also be used to help prove theoretical SOS lower bounds on symmetric problems. In particular, Theorem 21, which is a crucial part of our machinery, essentially follows from Corollary 2.6 of Raymond et. al. [30]. We obtain our lower bounds by combining this theorem with the additional assumption that the unsatisfiability of the problem we are analyzing comes from integrality arguments.

## 1.3 Paper outline

The remainder of the paper is organized as follows. In Section 2, we give some preliminaries. In Section 3 we describe how we can find candidate pseudo-expectation values from stories. In Section 4 we highlight how symmetry is useful for proving SOS lower bounds even without additional assumptions. In Section 5, we rigorously define what stories and good stories are and show that good stories imply SOS lower bounds. Finally, in Section 6, we show a method for verifying that stories are good stories.

## 2 Preliminaries

Before we can describe our machinery, we must first give some preliminaries. We begin by describing the class of symmetric problems which our machinery can be applied to. We then define the sum of squares hierarchy and discuss some notation for the paper.

### 2.1 Symmetric problems

► **Definition 5.** We make the following assumptions about the problem  $P$  we are analyzing:

1. We assume that  $P$  is a problem about hypergraphs  $G$  with vertices  $V(G) = [1, n]$  and a set of possible hyperedges  $E_P$ . We view the hyperedges  $e \in E_P$  as subsets of  $[1, n]$  which may be unordered or ordered depending on  $P$ . If all of these subsets have the same size  $t \geq 1$  then we say that the problem  $P$  has arity  $t$ .
2. We assume that  $P$  has variables  $\{x_e : e \in E_P\}$  and  $P$  is a YES/NO question which is described by a set of problem equations  $\{s_i(\{x_e : e \in E_P\}) = 0\}$ . The answer to  $P$  is YES if all of these equations can be satisfied simultaneously and NO otherwise.
3. We assume that the set  $E_P$  of possible hyperedges and the set  $\{s_i(\{x_e : e \in E_P\}) = 0\}$  of problem equations are both symmetric under permutations of  $[1, n]$ .

If a problem  $P$  satisfies all of these assumptions then we say that  $P$  is a symmetric hypergraph problem. Since we only consider problems of this type, for brevity we will just say symmetric problem rather than symmetric hypergraph problem.

► **Example 6.** Symmetric problems  $P$  of arity 1 are YES/NO questions on the variables  $\{x_1, \dots, x_n\}$  which are symmetric under permutations of  $[1, n]$ .

► **Example 7.** For symmetric problems  $P$  of arity 2,  $E_P$  is the set of subsets of  $[1, n]$  of size 2. If the subsets in  $E_P$  are unordered then  $G$  is an undirected graph and we have variables  $\{x_{ij} : i, j \in [1, n], i \neq j\}$  where we take  $x_{ji} = x_{ij}$ . If the subsets in  $E_P$  are ordered then  $G$  is a directed graph and we have distinct variables  $\{x_{ij} : i, j \in [1, n], i \neq j\}$ .

► **Remark.** While our machinery can handle symmetric problems of any arity, the examples we focus on all have arity 1 or 2. Knapsack with unit weights has arity 1 while the MOD 2 principle and the triangle problem have arity 2 and are about undirected graphs.

► **Remark.** Since our machinery is based on polynomial interpolation, it is important that the symmetric problem  $P$  does not have inequalities as well as equalities. If  $P$  has inequalities then our machinery does not immediately give an SOS lower bound and more analysis is needed.

### 2.2 Index degree

For our results, rather than considering the degree of a polynomial  $f$ , it is more natural to consider the largest number of indices mentioned in any one monomial of  $f$ . We call this the index degree of  $f$ .

► **Definition 8 (Index degree).**

1. Given a monomial  $p = \prod_{e \in E_P} x_e$ , we define  $I(p) = \{i : \exists e \in E_P : i \in e\}$  and we define the index degree of  $p$  to be

$$\text{indexdeg}(p) = \text{indexdeg}_{[1, n]}(p) = |I(p)|$$

In other words,  $\text{indexdeg}(p)$  is the number of indices which  $p$  depends on.

2. Given a polynomial  $f$ , if  $f = \sum_j c_j p_j$  is the decomposition of  $f$  into monomials then we define the index degree of  $f$  to be  $\text{indexdeg}(f) = \max_j \{\text{indexdeg}(p_j)\}$

► **Example 9.** If  $p$  is the monomial  $p = x_{12}x_{34}$  then  $p$  has degree 2 and index degree 4.

► **Example 10.** If  $f = x_{12}x_{13} + x_{24}^4$  then  $f$  has degree 4 and index degree 3.

We will also need an analagous definition where we only consider the indices outside of a subset  $I \subseteq [1, n]$ .

► **Definition 11** (Index degree outside of  $I$ ). Let  $I \subseteq [1, n]$  be a subset of indices.

1. Given a monomial  $p = \prod_{e \in E_p} x_e$ , we define the index degree of  $p$  on  $[1, n] \setminus I$  to be

$$\text{indexdeg}_{[1, n] \setminus I}(p) = |I(p) \setminus I|$$

In other words,  $\text{indexdeg}_{[1, n] \setminus I}(p)$  is the number of indices in  $[1, n] \setminus I$  which  $p$  depends on.

2. Given a polynomial  $f$ , if  $f = \sum_j c_j p_j$  is the decomposition of  $f$  into monomials then we define the index degree of  $f$  on  $[1, n] \setminus I$  to be  $\text{indexdeg}_{[1, n] \setminus I}(f) = \max_j \{\text{indexdeg}_{[1, n] \setminus I}(p_j)\}$

### 2.3 SOS and pseudo-expectation values

We now define SOS and pseudo-expectation values, which are used to prove SOS lower bounds. One way to describe SOS is through SOS/Positivstellensatz proofs, which are defined as follows:

► **Definition 12.** Given a system of polynomial equations  $\{s_i = 0\}$  over  $\mathbb{R}$ , an index degree  $d$  SOS/Positivstellensatz proof of infeasibility is an equality of the form

$$-1 = \sum_i f_i s_i + \sum_j g_j^2$$

where

1.  $\forall i, \text{indexdeg}(f_i) + \text{indexdeg}(s_i) \leq d$
2.  $\forall j, \text{indexdeg}(g_j) \leq \frac{d}{2}$

► **Remark.** This is a proof of infeasibility because the terms  $f_i s_i$  should all be 0 by the problem equations and the terms  $g_j^2$  must all be non-negative, so they can't possibly sum to  $-1$  if all of the problem equations are satisfied.

► **Definition 13.** Index degree  $d$  SOS gives the following feasibility test for whether a system of polynomial equations over  $\mathbb{R}$  is feasible or not. If there is an index degree  $d$  Positivstellensatz proof of infeasibility then index degree  $d$  SOS says NO. Otherwise, index degree  $d$  SOS says YES.

► **Remark.** Index degree  $d$  SOS may give false positives by failing to say NO on systems of equations which are infeasible but will never give a false negative.

In this paper, we show SOS lower bounds for the infeasible systems of equations described in subsection 2.1 by showing that for small  $d$  there is no index degree  $d$  Positivstellensatz proof of infeasibility for our system of equations. This can be done with index degree  $d$  pseudo-expectation values, which are defined as follows:

► **Definition 14.** Given a system of polynomial equations  $\{s_i = 0\}$  over  $\mathbb{R}$ , index degree  $d$  pseudo-expectation values are a linear mapping  $\tilde{E}$  from polynomials of index degree  $\leq d$  to  $\mathbb{R}$  which satisfies the following conditions:

1.  $\tilde{E}[1] = 1$
2.  $\forall i, f, \tilde{E}[f s_i] = 0$  whenever  $\text{indexdeg}(f) + \text{indexdeg}(s_i) \leq d$
3.  $\forall g, \tilde{E}[g^2] \geq 0$  whenever  $\text{indexdeg}(g) \leq \frac{d}{2}$

► **Proposition 15.** *If there are index degree  $d$  pseudo-expectation values  $\tilde{E}$  for a system of polynomial equations  $s_1 = 0, s_2 = 0, \dots$  over  $\mathbb{R}$ , then there is no index degree  $d$  Positivstellensatz proof of infeasibility for these equations.*

**Proof.** Assume that we have both index degree  $d$  pseudo-expectation values and an index degree  $d$  Positivstellensatz proof of infeasibility. Applying the pseudo-expectation values to the Positivstellensatz proof, we get the following contradiction:

$$-1 = \tilde{E}[-1] = \sum_i \tilde{E}[f_i s_i] + \sum_j \tilde{E}[g_j^2] \geq 0 \quad \blacktriangleleft$$

► **Remark.** Condition 3 of definition 14 is equivalent to the statement that the moment matrix  $M$  is PSD (positive semidefinite) where  $M$  is indexed by monomials  $p, q$  of index degree  $\leq \frac{d}{2}$  and has entries  $M_{pq} = \tilde{E}[pq]$ . Proving SOS lower bounds usually involves proving that  $M \succeq 0$ , which can be quite difficult. In this paper we can instead analyze  $\tilde{E}[g^2]$  more directly.

► **Remark.** The idea behind pseudo-expectation values is that they should mimic actual expected values over a distribution of solutions. In particular, as shown by the following proposition, if  $\tilde{E}$  comes from a distribution over actual solutions then it automatically gives pseudo-expectation values. This fact is crucial for our results.

► **Proposition 16.** *If the equations  $\{s_i = 0\}$  are feasible over  $\mathbb{R}$  and  $\Omega$  is a probability distribution over actual solutions then the linear mapping  $\tilde{E}[p] = E_\Omega[p]$  gives index degree  $d$  pseudo-expectation values for these equations for all  $d$ .*

**Proof.** Observe that:

1. For any  $x \sim \Omega$ ,  $1 = 1$ . Thus,  $\tilde{E}[1] = E_\Omega[1] = 1$ .
2. For any  $x \sim \Omega$ , for all  $i, f$ ,  $f(x)s_i(x) = 0$ . Thus, for all  $i, f$ ,  $\tilde{E}[f s_i] = E_\Omega[f s_i] = 0$ .
3. For any  $x \sim \Omega$ , for all  $g$ ,  $g(x)^2 \geq 0$ . Thus, for all  $g$ ,  $\tilde{E}[g^2] = E_\Omega[g^2] \geq 0$ . ◀

## 2.4 Sequences of distinct indices

We will need the following definitions about sequences of distinct indices in  $[1, n]$ .

► **Definition 17** (Operations on sequences).

1. Given a sequence of distinct indices  $A = (i_1, \dots, i_m)$ , we define the set  $I_A$  to be  $I_A = \{i_1, \dots, i_m\}$ . In other words,  $I_A$  is just  $A$  without the ordering.
2. Given two sequences of distinct indices  $A = (i_1, \dots, i_{m_1})$  and  $B = (i'_1, \dots, i'_{m_2})$ , we say that  $A \subseteq B$  if  $m_1 \leq m_2$  and  $\forall j \in [1, m_1], i'_j = i_j$ .
3. Given two sequences of distinct indices  $A = (i_1, \dots, i_{m_1})$  and  $B = (i'_1, \dots, i'_{m_2})$  such that  $I_A \cap I_B = \emptyset$ , we define  $A \cup B$  to be the sequence  $A \cup B = (i_1, \dots, i_{m_1}, i'_1, \dots, i'_{m_2})$

In this paper, we will never consider sequences of indices which are not distinct, so we assume without stating it explicitly that all of our sequences contain distinct indices.

## 3 Finding pseudo-expectation values: Stories and a verifier/adversary game for SOS

In this section, we describe a verifier/adversary game which we use to find pseudo-expectation values and deduce SOS lower bounds. We then describe how the adversary can play this game using stories and describe the resulting pseudo-expectation values for knapsack, the MOD 2 principle, and the triangle problem.

## 61:8 Sum of Squares Lower Bounds from Symmetry and a Good Story

The verifier/adversary game is as follows. The verifier queries sequences of indices  $\{A_i\}$ . For each sequence of indices  $A = (i_1, \dots, i_m)$  the verifier queries, for each  $j \in [1, m]$  and every possibility for what happens with the previous indices  $(i_1, \dots, i_{j-1})$ , the adversary must provide a probability distribution for what happens with the index  $i_j$ . Taken together, these answers give a probability distribution for all of the possibilities for what happens with the indices in  $A$ . From these probability distributions, we can obtain pseudo-expectation values.

The verifier wins if he/she detects one of the following flaws in the adversary's answers

1. The adversary gives a probability for some event which is either negative or undefined.
2. The adversary's answers do not result in well-defined pseudo-expectation values because they are inconsistent. More precisely, there exist two sequences of indices  $A = (i_1, \dots, i_m)$  and  $A' = (i'_1, \dots, i'_m)$  such that  $A'$  and  $A$  are equal as sets (i.e.  $\{i'_1, \dots, i'_m\}$  is a permutation of  $\{i_1, \dots, i_m\}$ ) and the resulting probability distributions for what happens with the indices  $\{i_1, \dots, i_m\}$  do not match.
3. The adversary's answers result in pseudo-expectation values such that some problem equation  $s_i = 0$  is violated i.e.  $\tilde{E}[fs_i] \neq 0$  for some polynomial  $f$ .

If the verifier is unable to find such a flaw then the adversary wins.

► **Remark.** Roughly speaking, when we say that the adversary specifies what happens with a set of indices  $I$  we mean that the adversary assigns values to all variables  $x_e$  such that the indices of  $e$  are contained in  $I$ . We make this more precise in Section 5.

The adversary often has a strategy for this game based on a story for what happens with the indices. For the problems we are analyzing, the adversary's stories are as follows:

1. Knapsack: We set  $k$  out of the  $n$   $x_i$  to be 1 and set the rest to 0.
2. The MOD 2 principle: For each vertex  $i$ , the perfect matching contains precisely one of the edges which are incident to  $i$ .
3. The triangle problem: We have  $k$  independent sets of size  $\frac{n}{k}$ .

► **Remark.** The adversary's stories are not convincing to us, as we can understand integrality arguments. However, the adversary just has to fool SOS, which is poor at capturing integrality arguments.

We now demonstrate how these stories naturally give probability distributions for what happens with the indices and thus give pseudo-expectation values.

► **Example 18 (Knapsack).** For knapsack, if the verifier first queries vertex  $i$ , the adversary says that  $x_i = 1$  with probability  $\frac{k}{n}$  and  $x_i = 0$  with probability  $\frac{n-k}{n}$ . Thus, according to the adversary the expected value of  $x_i$  is  $\frac{k}{n}$  so we take  $\tilde{E}[x_i] = \frac{k}{n}$

If the verifier then queries  $x_j$ , if we have  $x_i = 1$  then the adversary says that  $x_j = 1$  with probability  $\frac{k-1}{n-1}$  and  $x_j = 0$  with probability  $\frac{n-k}{n-1}$  as the adversary wants to set  $k-1$  of the remaining  $n-1$  variables to 1. If we have  $x_i = 0$  then the adversary instead says that  $x_j = 1$  with probability  $\frac{k}{n-1}$  and  $x_j = 0$  with probability  $\frac{n-k-1}{n-1}$  as the adversary wants to set  $k$  of the remaining  $n-1$  variables to 1. Thus, according to the adversary the expected value of  $x_i x_j$  is  $\frac{k(k-1)}{n(n-1)}$  so we take  $\tilde{E}[x_i x_j] = \frac{k(k-1)}{n(n-1)}$ .

Following similar logic, for all  $I \subseteq [1, n]$  such that  $|I| \leq d$ ,  $\tilde{E}[\prod_{i \in I} x_i] = \frac{\binom{k}{|I|}}{\binom{n}{|I|}}$

► **Example 19 (MOD 2 principle).** For the MOD 2 principle, if the verifier first queries  $i$ , the adversary gives no information because there is nothing distinguishing  $i$  from other vertices. If the verifier then queries  $j$ , the adversary says that  $x_{ij} = 1$  with probability  $\frac{1}{n-1}$  and  $x_{ij} = 0$  with probability  $\frac{n-2}{n-1}$  because the adversary wants to match 1 out of the remaining  $n-1$  vertices with  $i$ . Thus, we take  $\tilde{E}[x_{ij}] = \frac{1}{n-1}$

We now consider  $\tilde{E}[x_{ij}x_{kl}]$  where  $i, j, k, l$  are all distinct.  $x_{ij}x_{kl} = 0$  unless  $x_{ij} = 1$  so we can focus on the case when  $x_{ij} = 1$ , which according to the adversary happens with probability  $\frac{1}{n-1}$ . In this case, if the verifier queries  $k$ , the adversary gives no additional information because there is nothing distinguishing  $k$  from other vertices in  $[1, n] \setminus (i, j)$ . If the verifier then queries  $l$ , the adversary says that  $x_{kl} = 1$  with probability  $\frac{1}{n-3}$  and  $x_{kl} = 0$  with probability  $\frac{n-4}{n-3}$  because the adversary wants to match 1 of the  $n-3$  remaining vertices with  $k$ . Thus, we take  $\tilde{E}[x_{ij}x_{kl}] = \frac{1}{(n-1)(n-3)}$

Following similar logic, we obtain that for all  $E \subseteq \{(i, j) : i, j \in [1, n], i < j\}$  such that  $|E| \leq d$ ,  $\tilde{E}[\prod_{(i,j) \in E} x_{ij}] = \frac{1}{\prod_{j=1}^{|E|} (n-2j+1)}$  if  $E$  is a partial matching and  $\tilde{E}[\prod_{(i,j) \in E} x_{ij}] = 0$  otherwise.

► **Example 20 (Triangle Problem).** For the triangle problem, if the verifier first queries  $i$ , the adversary gives no information because there is nothing distinguishing  $i$  from other vertices. If the verifier then queries  $j$ , the adversary says that  $j$  is in the same independent set as  $i$  with probability  $\frac{\frac{n}{k}-1}{n-1}$  and is in a different independent set with probability  $\frac{n-\frac{n}{k}}{n-1}$ .

If the verifier then queries  $k$ , if  $i, j$  are in the same independent set then the adversary says that  $k$  is in the same independent set as  $i, j$  with probability  $\frac{\frac{n}{k}-2}{n-2}$  and is in a different independent set with probability  $\frac{n-\frac{n}{k}}{n-2}$ . If  $i, j$  are in different independent sets then the adversary says that  $k$  is in the same independent set as  $i$  with probability  $\frac{\frac{n}{k}-1}{n-2}$ ,  $k$  is in the same independent set as  $j$  with probability  $\frac{\frac{n}{k}-1}{n-2}$ , and  $k$  is in a different independent set with probability  $\frac{n-2\frac{n}{k}}{n-2}$ . Thus, the adversary gives the following probabilities for what happens with  $i, j, k$ :

1. The probability that  $i, j, k$  are all in the same independent set is  $\frac{(\frac{n}{k}-1)(\frac{n}{k}-2)}{(n-1)(n-2)}$
2. The probability that  $i, j$  are in the same independent set and  $k$  is in a different independent set is  $\frac{(\frac{n}{k}-1)(n-\frac{n}{k})}{(n-1)(n-2)}$ . This is also the probability that  $i, k$  are in the same independent set and  $j$  is in a different independent set and the probability that  $j, k$  are in the same independent set and  $i$  is in a different independent set.
3. The probability that  $i, j, k$  are all in different independent sets is  $\frac{(n-\frac{n}{k})(n-2\frac{n}{k})}{(n-1)(n-2)}$

This gives the following pseudo-expectation values:

1.  $\tilde{E}[x_{ij}] = \frac{n-\frac{n}{k}}{n-1}$
2.  $\tilde{E}[x_{ij}x_{ik}] = \tilde{E}[x_{ij}x_{jk}] = \tilde{E}[x_{ik}x_{jk}] = \frac{(\frac{n}{k}-1)(n-\frac{n}{k})}{(n-1)(n-2)} + \frac{(n-\frac{n}{k})(n-2\frac{n}{k})}{(n-1)(n-2)} = \frac{(n-\frac{n}{k})(n-\frac{n}{k}-1)}{(n-1)(n-2)}$
3.  $\tilde{E}[x_{ij}x_{ik}x_{jk}] = \frac{(n-\frac{n}{k})(n-2\frac{n}{k})}{(n-1)(n-2)}$

► **Remark.** For the triangle problem, it is difficult to write down the general expression for  $\tilde{E}$  explicitly. Fortunately, as we will show, we can verify the conditions of Definition 14 based on the story for  $\tilde{E}$

## 4 Symmetry and SOS lower bounds

In this section, we highlight how symmetry can help prove SOS lower bounds even without additional assumptions. In particular, we have the following theorem which essentially follows from Corollary 2.6 of [30].

► **Theorem 21.** *If  $\tilde{E}$  is a linear map from polynomials to  $\mathbb{R}$  which is symmetric with respect to permutations of  $[1, n]$  then for any polynomial  $g$ , we can write*

$$\tilde{E}[g^2] = \sum_{I \subseteq [1, n], j: |I| \leq \text{indexdeg}(g)} \tilde{E}[g_{Ij}^2]$$

where for all  $I, j$ ,

## 61:10 Sum of Squares Lower Bounds from Symmetry and a Good Story

1.  $g_{I_j}$  is symmetric with respect to permutations of  $[1, n] \setminus I$ .
2.  $\text{indexdeg}(g_{I_j}) \leq \text{indexdeg}(g)$
3.  $\forall i \in I, \sum_{\sigma \in S_{[1, n] \setminus (I \setminus \{i\})}} \sigma(g_{I_j}) = 0$

Theorem 21 is very useful for proving SOS lower bounds on symmetric problems because it implies that instead of checking that  $\tilde{E}[g^2] \geq 0$  for all polynomials of index degree  $\leq \frac{d}{2}$ , it is sufficient to check polynomials which are symmetric under permutations of all but  $\frac{d}{2}$  indices. However, despite its simplicity, Theorem 21 is quite deep. To prove Theorem 21, we must carefully decompose  $g$  and then use symmetry to analyze all of the non-square terms of  $g^2$  and either eliminate them or reduce them to square terms. Fortunately, this has already been done by Corollary 2.6 of [30] using representation theory. We now sketch how Theorem 21 follows from Corollary 2.6 of [30].

### Proof sketch of Theorem 21 using Corollary 2.6 of [30].

► **Definition 22** (Definition 2.1 of [30]). If  $\oplus_{\lambda} V_{\lambda}$  is the isotypic decomposition of the vector space of polynomials of degree  $\leq d$  and  $\tau_{\lambda}$  is a tableau of shape  $\lambda$ , define

$$W_{\tau_{\lambda}} := V_{\lambda}^{\mathcal{R}_{\tau_{\lambda}}}$$

to be the subspace of the isotypic  $V_{\lambda}$  fixed by the action of the row group  $\mathcal{R}_{\tau_{\lambda}}$  (which keeps each row of  $\tau_{\lambda}$  fixed but may permute the elements within each row of  $\tau_{\lambda}$ )

Corollary 2.6 of [30] (rephrased slightly) says the following:

► **Corollary 23** (Corollary 2.6 of [30]). *Suppose  $p$  is a polynomial on the variables  $\{x_{ij} : i, j \in [1, n], i < j\}$  such that  $p$  is symmetric under permutations of  $[1, n]$  and  $p$  can be written as a sum of squares of polynomials of degree  $\leq d$ . For each partition  $\lambda \vdash n$ , fix a tableau  $\tau_{\lambda}$  of shape  $\lambda$  and choose a vector space basis  $\{b_1^{\tau_{\lambda}}, \dots, b_{m_{\lambda}}^{\tau_{\lambda}}\}$  for  $W_{\tau_{\lambda}}$ . Then for each partition  $\lambda \in \Lambda$ , there exists an  $m_{\lambda} \times m_{\lambda}$  PSD matrix  $Q_{\lambda}$  such that*

$$p = \sum_{\lambda \in \Lambda} \text{tr}(Q_{\lambda} Y^{\tau_{\lambda}})$$

where  $\Lambda := \{\lambda \vdash n : \lambda \geq_{lex} (n - 2d, 1^{2d})\}$  and  $Y_{ij}^{\tau_{\lambda}} := \text{sym}(b_i^{\tau_{\lambda}} b_j^{\tau_{\lambda}})$

Using Corollary 2.6 of [30], we can prove Theorem 21 as follows. Since  $\tilde{E}$  is symmetric,  $\tilde{E}[g^2] = \tilde{E}[\text{sym}(g^2)]$  where  $\text{sym}(g^2) = \frac{1}{n!} \sum_{\sigma \in S_n} (\sigma(g))^2$ . Since  $\text{sym}(g^2)$  is symmetric and a sum of squares, by Corollary 2.6 of [30], there exist PSD matrices  $Q_{\lambda}$  such that

$$\tilde{E}[g^2] = \sum_{\lambda \in \Lambda} \tilde{E}[\text{tr}(Q_{\lambda} Y^{\tau_{\lambda}})]$$

Since  $\tilde{E}$  is symmetric, this implies that

$$\tilde{E}[g^2] = \sum_{\lambda \in \Lambda} \tilde{E}[\text{tr}(Q_{\lambda} Y'^{\tau_{\lambda}})]$$

where  $Y'^{\tau_{\lambda}} := b_i^{\tau_{\lambda}} b_j^{\tau_{\lambda}}$ . Now consider each  $\lambda \in \Lambda$  separately and observe that since  $Q_{\lambda} \geq 0$ , we can write  $Q_{\lambda} = \sum_j q^j q^{jT}$  for some vectors  $\{q^1, \dots, q^{m_{\lambda}}\}$ . Thus,

$$\text{tr}(Q_{\lambda} Y^{\tau_{\lambda}}) = \text{tr}\left(\sum_j q^j q^{jT} b^{\tau_{\lambda}} b^{\tau_{\lambda}T}\right) = \sum_j q^{jT} b^{\tau_{\lambda}} b^{\tau_{\lambda}T} q^j = \sum_j \left(\sum_{i \in m_{\lambda}} q_i^j b_i^{\tau_{\lambda}}\right)^2$$

which means we can reexpress  $\text{sym}(g^2)$  as a sum of squares, each of which has the form  $(\sum_{i=1}^{m_{\lambda}} c_i b_i^{\tau_{\lambda}})^2$  for some partition  $\lambda \vdash n$ , tableau  $\tau_{\lambda}$  of shape  $\lambda$ , and coefficients  $\{c_i\}$

For each square  $(\sum_{i=1}^{m_\lambda} c_i b_i^{\tau_\lambda})^2$ , let  $I$  be the set of indices which are not in the top row of  $\tau_\lambda$ . To show the first statement of Theorem 21, observe that permuting the indices of  $[1, n] \setminus I$  is just permuting the top row of  $\tau_\lambda$ . By definition, the elements of  $W_{\tau_\lambda}$  are all invariant under such permutations, so  $\sum_{i=1}^{m_\lambda} c_i b_i^{\tau_\lambda}$  is invariant under permutations of  $[1, n] \setminus I$ , as needed.

► **Remark.** In the setting of Corollary 2.6 of [30] the variables are  $\{x_{ij} : i, j \in [1, n], i < j\}$  so if  $g$  has degree  $d$ ,  $g$  can have index degree  $2d$  which matches the fact that  $\Lambda := \{\lambda \vdash n : \lambda \geq_{lex} (n - 2d, 1^{2d})\}$ . To prove Theorem 21 as stated using Corollary 2.6 of [30], Corollary 2.6 of [30] must be restated in terms of index degree and the proof adjusted accordingly.

The second statement of Theorem 21 is trivial as all of the  $b_i^{\tau_\lambda}$  are in the vector space of polynomials of degree  $\leq d$  and thus index degree  $\leq 2d$ .

To show the third statement of Theorem 21, we need to prove the following lemma

► **Lemma 24.** *For any  $\tau_\lambda$ , letting  $I$  be the set of indices which are not in the top row of  $\tau_\lambda$ , for any  $i \in I$  and any  $p \in W_{\tau_\lambda}$ ,*

$$\sum_{\sigma \in S_{([1, n] \setminus I) \cup \{i\}}} \sigma(p) = 0$$

**Proof sketch.** This lemma follows from the following claim:

► **Definition 25.** Define  $U_r = \text{span}\{p : \exists I \subseteq [1, n] : |I| = r, \forall \sigma \in S_{[1, n] \setminus I}, \sigma(p) = p\}$  and define

$$V_r = U_r / U_{r-1} = \text{span}\{p : \exists I \subseteq [1, n] : |I| = r, \forall \sigma \in S_{[1, n] \setminus I}, \sigma(p) = p, \\ \forall J \subseteq [1, n] : |J| \leq r - 1, \sum_{\sigma \in S_{[1, n] \setminus J}} \sigma(p) = 0\}$$

► **Claim 26.**  $V_r = \oplus_{\lambda: \text{The top row of } \lambda \text{ has length } n-r} V_\lambda$

Assuming this claim, for any  $\tau_\lambda$ , letting  $I$  be the set of indices which are not in the top row of  $\tau_\lambda$ , for any  $p \in W_{\tau_\lambda} \subseteq V_\lambda$  and any  $J$  such that  $|J| < |I|$ ,  $\sum_{\sigma \in S_{[1, n] \setminus J}} \sigma(p) = 0$ . Taking  $J = I \setminus \{i\}$ , the result follows.

We defer the proof of this claim to the full version. ◀

◀

However, Corollary 2.6 of [30] does not give us an explicit expression for  $\tilde{E}[g^2]$ , so we can ask whether we can obtain an explicit expression for  $\tilde{E}[g^2]$ . It turns out that there is such an expression but it is quite complicated. For an alternative proof of Theorem 21 which is explicit and combinatorial but technical, see the full version of this paper.

## 5 Sum of squares lower bounds from symmetry and a good story

In this section, we show how strategies for the verifier/adversary game described in section 3 with certain properties, which we call good stories, imply SOS lower bounds.

## 5.1 Stories

In this subsection, we rigorously define what we mean by stories. Once the definition is understood, stories are generally recognizable on sight.

► **Definition 27.** Given a subset  $I$  of  $[1, n]$ , we define  $\mathcal{P}_I$  to be the set of all polynomials which only depend on the variables  $\{x_e : e \subseteq I\}$

► **Definition 28 (Stories).** Let  $P$  be the problem we are analyzing and let  $A = (i_1, \dots, i_m)$  be a sequence of indices. We say that a strategy  $S$  for adversary is a level  $n'$  story for  $(P, A)$ , describing what will happen with the remaining indices after we have already queried  $A$ , if the following is true:

1.  $n' \leq n - |I_A|$
  2.  $S$  specifies what happened with the indices in  $A$ . More precisely, there is a linear map  $\tilde{E}_{S,A} : \mathcal{P}_{I_A} \rightarrow \mathbb{R}$  corresponding to  $S$
  3. For all  $i \in [1, n] \setminus I_A$ ,  $S$  gives values  $\{p_{ij}\}$  for the probabilities of level  $n' - 1$  stories  $S_{ij}$  for  $(P, A \cup (i))$ .
  4. We have that for all  $i \in [1, n] \setminus I_A$ ,  $\sum_j p_{ij} = 1$  and  $\forall f \in \mathcal{P}_{I_A}, \forall j, \tilde{E}_{S,A}[f] = \tilde{E}_{S_{ij},(A \cup (i))}[f]$
- Given a level  $n'$  story  $S$  for  $(P, A)$ , for all sequences  $B$  such that  $A \subseteq B$ , letting  $i$  be the next element in  $B$  after  $A$ , we define  $\tilde{E}_{S,B} = \sum_j p_{ij} \tilde{E}_{S_{ij},B}$

► **Remark.** Note that we do not require the values  $p_{ij}$  to be non-negative in this definition.

► **Remark.** For all of our examples we will have that  $n' = n - |I_A|$  but we do not force this to be the case in the definition.

## 5.2 Useful story properties part 1

We now define several properties our stories may have which are useful for proving SOS lower bounds. In Section 6 we will describe a method for verifying these properties.

The first property we want is that our story  $S$  gives the same linear map  $\tilde{E}_S$  regardless of the order we query the indices.

► **Definition 29.** We say that a level  $n'$  story  $S$  for  $(P, A)$  is self-consistent if whenever  $B, B'$  are sequences such that  $A \subseteq B, A \subseteq B', |I_B \setminus I_A| \leq n', |I_{B'} \setminus I_A| \leq n'$ ,

$$\forall p \in \mathcal{P}_{I_B \cap I_{B'}}, \tilde{E}_{S,B}[p] = \tilde{E}_{S,B'}[p]$$

If  $S$  is self-consistent then we define  $\tilde{E}_S : \{f : \text{indexdeg}_{[1,n] \setminus I_A}(f) \leq n'\} \rightarrow \mathbb{R}$  to be the linear map such that for all monomials  $p$  such that  $\text{indexdeg}_{[1,n] \setminus I_A}(p) \leq n'$ , for any sequence  $B$  of length at most  $n'$  such that  $I_B \cap I_A = \emptyset$  and  $B$  contains all indices in variables of  $p$  which are not in  $I_A$ ,  $\tilde{E}_S[p] = \tilde{E}_{S,(A \cup B)}[p]$

A second property we want is that our story sounds like we are taking the expected values over the uniform distribution of permutations of a single input graph  $G_0$ . To make this precise, we note a useful property such expected values have. We then define single-graph mimics to be stories/pseudo-expectation values which also have this property.

► **Proposition 30.** If  $\Omega$  is the trivial distribution consisting of a single graph  $G_0$  then for any polynomials  $f$  and  $g$ ,  $E_\Omega[fg] = E_\Omega[f]E_\Omega[g]$

**Proof.**  $E_\Omega[fg] = f(G_0)g(G_0) = E_\Omega[f]E_\Omega[g]$  ◀

► **Proposition 31.** If  $\Omega$  is the uniform distribution over all permutations of a single graph  $G_0$  then for all symmetric polynomials  $f$  and  $g$ ,  $E_\Omega[fg] = E_\Omega[f]E_\Omega[g]$ .

**Proof.** For any symmetric polynomial  $h$  and any permutation  $\sigma$ ,  $h(\sigma(G_0)) = h(G_0)$  which implies that  $E_\Omega[h] = h(G_0)$ . Thus, we again have that  $E_\Omega[fg] = f(G_0)g(G_0) = E_\Omega[f]E_\Omega[g]$ , as needed.  $\blacktriangleleft$

► **Remark.** The property that  $E[fg] = E[f]E[g]$  for all symmetric polynomials  $f, g$  is useful because it immediately implies that for all symmetric polynomials  $g$ ,  $E[g^2] = (E[g])^2 \geq 0$ .

We now define single graph mimics.

► **Definition 32.** Let  $P$  be a symmetric problem with equations  $\{s_i = 0\}$  and let  $I$  be a subset of  $[1, n]$ . We say that  $\tilde{E}$  is a level  $n'$  single graph mimic for  $P$  on  $[1, n] \setminus I$  if the following conditions hold:

1.  $\tilde{E} : \{p : \text{indexdeg}_{[1, n] \setminus I}(p) \leq n'\} \rightarrow \mathbb{R}$  is a linear map which is symmetric under permutations of  $[1, n] \setminus I$
2. For all  $i$  and all polynomials  $f$  such that  $\text{indexdeg}_{[1, n] \setminus I}(f) + \text{indexdeg}_{[1, n] \setminus I}(s_i) \leq n'$ ,  $\tilde{E}[fs_i] = 0$
3. For all polynomials  $f, g$  which are symmetric under permutations of  $[1, n] \setminus I$  such that  $\text{indexdeg}_{[1, n] \setminus I}(f) + \text{indexdeg}_{[1, n] \setminus I}(g) \leq n'$ ,  $\tilde{E}[fg] = \tilde{E}[f]\tilde{E}[g]$ .

We say that  $S$  is a level  $n'$  single-graph mimic for  $(P, A)$  if  $S$  is a self-consistent level  $n'$  story for  $(P, A)$  and  $\tilde{E}_S$  is a level  $n'$  single-graph mimic for  $P$  on  $[1, n] \setminus I_A$ .

A third property we want is that is that our story assigns non-negative probabilities to its substories as long as we don't query too many indices. If our story and all of its substories satisfy these three properties then we call it a good story.

► **Definition 33.** We say that  $S$  is a level  $(r, n')$  good story for  $(P, A)$  if the following conditions hold:

1.  $S$  is a level  $n'$  single graph mimic for  $(P, A)$ .
2. If  $r > 0$  then for any  $i \in [1, n] \setminus I_A$ , the values  $p_{ij}$  are non-negative and the stories  $\{S_{ij}\}$  are all level  $(r - 1, n' - 1)$  good stories for  $(P, A \cup (i))$ .

### 5.3 SOS lower bounds from good stories

We now prove that good stories imply SOS lower bounds.

► **Theorem 34.** *Let  $P$  be a symmetric problem with equations  $\{s_i = 0\}$ . If we have a level  $(r, n')$  good story for  $P$  then index degree  $d = \min\{2r, n'\}$  SOS fails to refute the equations for  $P$ .*

**Proof.** We need two components to prove this theorem. The first component is the following theorem which shows that if we have a good story then we satisfy all of the linear constraints on  $\tilde{E}$  and we have that  $\tilde{E}[g^2] \geq 0$  whenever  $g$  is symmetric under permutations of all but a few indices.

► **Theorem 35.** *Let  $P$  be a symmetric graph problem with constraints  $\{s_i = 0\}$  (where the  $\{s_i\}$  are polynomials in the input variables). If we have a level  $(r, n')$  good story  $S$  for  $P$  then the corresponding linear map  $\tilde{E}_S : \{f : \text{indexdeg}(f) \leq n'\} \rightarrow \mathbb{R}$  satisfies the following properties*

1.  $\tilde{E}_S$  is symmetric under permutations of  $[1, n]$
2. If  $I \subseteq [1, n]$  is a subset of indices of size at most  $r$  and  $g$  is a polynomial which is symmetric under permutations of  $[1, n] \setminus I$  such that  $\text{indexdeg}_{[1, n] \setminus I}(g) \leq \frac{n' - |I|}{2}$  then  $\tilde{E}_S[g^2] \geq 0$
3. For all  $i$  and all  $f$  such that  $\text{indexdeg}(f) + \text{indexdeg}(s_i) \leq n'$ ,  $\tilde{E}_S[fs_i] = 0$ .

## 61:14 Sum of Squares Lower Bounds from Symmetry and a Good Story

**Proof.** Since  $S$  is a single graph mimic and single graph mimics are symmetric with respect to permutations of  $[1, n]$ , the first statement follows. Similarly, the third statement follows directly from condition 2 of Definition 32

For the second statement, by conditions 1 and 2 of Definition 33, we can express  $\tilde{E}_S$  as a probability distribution  $\Omega$  over level  $n - |I|$  single graph mimics  $\tilde{E}_j$  for  $P$  on  $[1, n] \setminus I$ . Since  $g$  is symmetric under permutations of  $[1, n] \setminus I$ , for all of the  $\tilde{E}_j$ ,  $\tilde{E}_j[g^2] = \tilde{E}_j[g]\tilde{E}_j[g] \geq 0$ . We now have that  $\tilde{E}_S[g^2] = E_{E_j \sim \Omega} [\tilde{E}_j[g^2]] \geq 0$ , as needed.  $\blacktriangleleft$

The second component we need is Theorem 21, which shows that it is sufficient to verify that  $\tilde{E}_S[g^2] \geq 0$  whenever  $g$  is symmetric with respect to permutations of all but a few indices. which is exactly what is shown by Theorem 35.

With these components in hand, we now prove Theorem 34. We need to check the following:

1. Whenever  $\text{indexdeg}(f) + \text{indexdeg}(s_i) \leq d = \min\{2r, n'\}$ ,  $\tilde{E}_S[fs_i] = 0$ .
2. Whenever  $\text{indexdeg}(g) \leq \frac{d}{2} = \min\{r, \frac{n'}{2}\}$ ,  $\tilde{E}_S[g^2] \geq 0$

For the first statement, note that  $\text{indexdeg}(f) + \text{indexdeg}(s_i) \leq n'$ , so by Theorem 35,  $\tilde{E}_S[fs_i] = 0$ . For the second statement, given a polynomial  $g$  of index degree at most  $\frac{d}{2}$ , by Theorem 21 we can write

$$\tilde{E}_S[g^2] = \sum_{I \subseteq [1, n], j: |I| \leq \text{indexdeg}(g)} \tilde{E}_S[g_{I_j}^2]$$

where for all  $I, j$ ,

$$\forall i \in I, \quad \sum_{\sigma \in S_{[1, n] \setminus (I \setminus \{i\})}} \sigma(g_{I_j}) = 0$$

We now use the following lemma to upper bound  $\text{indexdeg}_{[1, n] \setminus I}(g_{I_j})$ :

► **Lemma 36.** *If  $g_{I_j}$  is symmetric with respect to permutations of  $[1, n] \setminus I$  and*

$$\forall i \in I, \quad \sum_{\sigma \in S_{[1, n] \setminus (I \setminus \{i\})}} \sigma(g_{I_j}) = 0$$

*then all monomials in  $g_{I_j}$  depend on all of the indices in  $I$*

**Proof.** Assume that there is an  $i \in I$  and some monomial  $p$  which does not depend on  $i$  which has a nonzero coefficient in  $g_{I_j}$ . By symmetry, for all permutations  $\sigma$  of  $[1, n] \setminus I$ , the coefficient of  $\sigma(p)$  is the same as the coefficient of  $p$ . However, these are also the coefficients of  $\sigma_2(p)$  for permutations  $\sigma_2$  of  $[1, n] \setminus (I \setminus \{i\})$ . Since  $\forall i \in I, \sum_{\sigma \in S_{[1, n] \setminus (I \setminus \{i\})}} \sigma(g_{I_j}) = 0$ , all of these coefficients must be 0, which is a contradiction.  $\blacktriangleleft$

This lemma implies that for all of the  $g_{I_j}$ ,  $\text{indexdeg}_{[1, n] \setminus I}(g_{I_j}) \leq \frac{n'}{2} - |I| \leq \frac{n' - |I|}{2}$ . Thus, by Theorem 35,  $\tilde{E}_S[g_{I_j}^2] \geq 0$ . Since this holds for all  $I, j$ ,  $\tilde{E}_S[g^2] \geq 0$ , as needed.  $\blacktriangleleft$

## 6 Verifying good stories

In this section, we describe a method to verify that a story  $S$  is a good story. For this method, we make the following assumption.

► **Definition 37.** We assume that the problem equations and  $S$  depend on a set of parameters and we take  $\alpha_1, \dots, \alpha_m$  to be these parameters.

► **Remark.** For knapsack and the triangle problem, we have two parameters  $n$  and  $k$ . For the MOD 2 principle we only have the parameter  $n$ .

## 6.1 Useful story properties part 2

We now describe two additional properties our stories may have which are useful for verifying that they are good stories. Once the definitions are understood, these properties are generally recognizable on sight.

One property  $S$  usually has is that the linear maps  $\tilde{E}_{S,B}$  assign values to monomials which are rational functions of the parameters  $\alpha_1, \dots, \alpha_m$ .

► **Definition 38.** We say that a level  $n'$  story  $S$  for  $(P, A)$  is rational if the following conditions hold

1. For all  $B$  such that  $A \subseteq B$  and  $|I_B \setminus I_A| \leq n'$ , for all monomials  $p$  such that  $I(p) \subseteq I_B$ ,  $\tilde{E}_{S,B}[p]$  is a rational function of the parameters  $\alpha_1, \dots, \alpha_m$ .
2. The rational functions  $\{\tilde{E}_{S,B}[p] : A \subseteq B, |I_B \setminus I_A| \leq n', I(p) \subseteq I_B\}$  have a common denominator  $q_S(\alpha_1, \dots, \alpha_m)$  and the degree of the numerator is bounded by a function of  $n'$  and  $\text{indexdeg}(p)$ .

A second property our stories may have is that there are many settings of the parameters  $\alpha_1, \dots, \alpha_m$  for which  $S$  and  $\tilde{E}_S$  actually correspond to probabilities and expected values of the uniform distribution over permutations of a single input  $G_0$ .

► **Definition 39.** Let  $S$  be a story for  $(P, A)$

1. We say that  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$  if  $S$  corresponds to what happens if we take the uniform distribution for all permutations of an actual input graph  $G_0$  over  $[1, n] \setminus I_A$  and  $G_0$  satisfies the equations for  $P$ . Note that if this is the case then  $S$  is automatically a single graph mimic for  $(P, A)$  for the parameter values  $(\alpha_1, \dots, \alpha_m)$  and  $\tilde{E}_S[p] = E_{\sigma \in S_{[1,n] \setminus I_A}}[p(\sigma(G_0))]$
2. We say that  $S$  is  $z$ -honest for  $(\alpha_1, \dots, \alpha_{m-1})$  if there are at least  $z$  values of  $\alpha_m$  such that  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$ .
3. For all  $j \in [1, m-2]$ , we say that  $S$  is  $z$ -honest for  $(\alpha_1, \dots, \alpha_j)$  if there are at least  $z$  values of  $\alpha_{j+1}$  such that  $S$  is  $z$ -honest for  $(\alpha_1, \dots, \alpha_{j+1})$ .
4. We say that  $S$  is  $z$ -honest if there are at least  $z$  values of  $\alpha_1$  such that  $S$  is  $z$ -honest for  $(\alpha_1)$ .

The intuition is that it is difficult for SOS to determine whether the parameters take one of these values for which we actually have a solution or we are in between these values.

The following lemma is very useful

► **Lemma 40.** *Let  $S$  be a story which is  $z$ -honest. If  $p(\alpha_1, \dots, \alpha_m)$  is a polynomial such that  $\text{deg}(p) < z$  and  $p(\alpha_1, \dots, \alpha_m) = 0$  whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$  then  $p(\alpha_1, \dots, \alpha_m) = 0$*

**Proof.** We prove this lemma by induction. Assume that  $p(\alpha_1, \dots, \alpha_m) = 0$  whenever  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_j$ .

Consider  $p$  as a polynomial in the variables  $\alpha_{j+1}, \dots, \alpha_m$ . Each monomial has a coefficient which is a polynomial  $c(\alpha_1, \dots, \alpha_j)$  and we must have that  $c(\alpha_1, \dots, \alpha_j) = 0$  whenever  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_j$ . We now show that all of these coefficients  $c(\alpha_1, \dots, \alpha_j)$  must be 0 whenever  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_{j-1}$ . To see this, consider such a polynomial  $c(\alpha_1, \dots, \alpha_j)$  and assume that we have  $\alpha_1, \dots, \alpha_{j-1}$  such that  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_{j-1}$ . Considering  $c$  as a polynomial in  $\alpha_j$ ,  $c(\alpha_j) = 0$  whenever  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_j$ , which by definition happens for at least  $z$  values of  $\alpha_j$ . Since  $\text{deg}(c) < z$ , we must have that  $c(\alpha_1, \dots, \alpha_j) = c(\alpha_j) = 0$ . Thus,  $p(\alpha_1, \dots, \alpha_m) = 0$  whenever  $S$  is  $z$ -honest for  $\alpha_1, \dots, \alpha_{j-1}$ , as needed. ◀

## 6.2 Sufficient conditions for single graph mimics

With these definitions, we can now give sufficient conditions for showing that a story  $S$  is a single graph mimic.

► **Lemma 41.** *Let  $S$  be a level  $n'$  story for  $(P, A)$ . If  $S$  and the parameter values  $\alpha_1, \dots, \alpha_m$  satisfy the following conditions*

1.  $S$  is rational and symmetric with respect to permutations of  $[1, n] \setminus I_A$ .
2. For all  $z > 0$ ,  $S$  is  $z$ -honest.
3. Letting  $q_S(\alpha_1, \dots, \alpha_m)$  be the common denominator for  $\{\tilde{E}_{S,B}[p] : A \subseteq B, |I_B \setminus I_A| \leq n', I(p) \subseteq I_B\}$ ,  $q_S(\alpha_1, \dots, \alpha_m) \neq 0$

then for the parameter values  $\alpha_1, \dots, \alpha_m$ ,  $S$  is a level  $n'$  single graph mimic for  $(P, A)$ .

**Proof.** We need to verify the following for the given values of  $\alpha_1, \dots, \alpha_m$ :

1.  $S$  is self-consistent.
2. For all  $i$  and all polynomials  $f$  such that  $\text{indexdeg}_{[1,n] \setminus I_A}(f) + \text{indexdeg}_{[1,n] \setminus I_A}(s_i) \leq n'$ ,  $\tilde{E}_S[fs_i] = 0$
3. For any polynomials  $f, g$  such that  $f, g$  are symmetric under permutations of  $[1, n] \setminus I_A$  and  $\text{indexdeg}_{[1,n] \setminus I_A}(f) + \text{indexdeg}_{[1,n] \setminus I_A}(g) \leq n'$ ,  $\tilde{E}_S[fg] = \tilde{E}_S[f]\tilde{E}_S[g]$ .

We first verify that  $S$  is self-consistent for the given values of  $\alpha_1, \dots, \alpha_m$ . Let  $p$  be a monomial and let  $B, B'$  be sequences of indices such that  $A \subseteq B$ ,  $A \subseteq B'$ , and  $I(p) \subseteq I_B \cap I_{B'}$ . Since  $S$  is rational,  $\tilde{E}_{S,B}[p] = \frac{p_1(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$  and  $\tilde{E}_{S,B'}[p] = \frac{p_2(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$  are rational functions of the parameters  $\alpha_1, \dots, \alpha_m$ . Now note that whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$ ,  $\tilde{E}_{S,B}[p] = \tilde{E}_{S,B'}[p]$  which implies that

$$p_1(\alpha_1, \dots, \alpha_m)q_S(\alpha_1, \dots, \alpha_m) = p_2(\alpha_1, \dots, \alpha_m)q_S(\alpha_1, \dots, \alpha_m)$$

Since  $S$  is  $z$ -honest for all  $z > 0$ , by Lemma 40 we have that  $p_1q_S = p_2q_S$  as polynomials in  $\alpha_1, \dots, \alpha_m$ . Plugging in our actual values of  $\alpha_1, \dots, \alpha_m$ ,  $q_S(\alpha_1, \dots, \alpha_m) \neq 0$  so  $p_1(\alpha_1, \dots, \alpha_m) = p_2(\alpha_1, \dots, \alpha_m)$  and thus  $\tilde{E}_{S,B'}[p] = \tilde{E}_{S,B}[p]$ , as needed.

We can use similar ideas to prove the second and third statements but there is a subtle point we must be careful of. A problem equations  $s_i$  may be a polynomial which is symmetric in  $n \setminus I_A$  rather than being a fixed polynomial. In this case,  $\tilde{E}_S[s_i]$  and  $\tilde{E}_S[fs_i]$  will still be rational functions in the parameters  $\alpha_1, \dots, \alpha_m$ . However, the equality  $\tilde{E}_S[fs_i] = \frac{p_{fs_i}(\alpha_1, \dots, \alpha_m)}{q_S(\alpha_1, \dots, \alpha_m)}$  may break down if

$$\text{indexdeg}_{[1,n] \setminus I_A}(f) + \text{indexdeg}_{[1,n] \setminus I_A}(s_i) > n'$$

► **Example 42.** If  $f = x_1x_2$  and  $s_i = \sum_{i=1}^n x_i - k$  then

$$fs_i = x_1^2x_2 + x_1x_2^2 + x_1x_2 \sum_{i \in [1,n] \setminus \{1,2\}} x_i - kx_1x_2$$

and by symmetry

$$\tilde{E}_S[fs_i] = \tilde{E}_S[x_1^2x_2] + \tilde{E}_S[x_1x_2^2] + (n-2)\tilde{E}_S[x_1x_2x_3] - k\tilde{E}_S[x_1x_2]$$

Thus,  $fs_i$  generally has index degree 3 and  $\tilde{E}_S[fs_i] = \frac{p_{fs_i}(\alpha_1, \dots, \alpha_m)}{q_S(\alpha_1, \dots, \alpha_m)}$  is a rational function of the parameters  $\alpha_1, \dots, \alpha_m$ . However, if  $n' = n = 2$  then we are missing the term  $x_1x_2 \sum_{i \in [1,n] \setminus \{1,2\}} x_i$  from  $fs_i$  which may break the equality  $\tilde{E}_S[fs_i] = \frac{p_{fs_i}(\alpha_1, \dots, \alpha_m)}{q_S(\alpha_1, \dots, \alpha_m)}$ . Note that this problem will not occur as long as

$$\text{indexdeg}_{[1,n] \setminus I_A}(f) + \text{indexdeg}_{[1,n] \setminus I_A}(s_i) \leq n'$$

With this point in mind, for the second statement, note that since  $S$  is rational and  $\text{indexdeg}(f) + \text{indexdeg}(s_i) \leq n'$ , we can write  $\tilde{E}_S[fs_i] = \frac{p_{fs_i}(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$ . Now observe that  $\tilde{E}[fs_i] = 0$  whenever  $\tilde{E}$  is honest for  $(\alpha_1, \dots, \alpha_m)$  and thus  $p_{fs_i}(\alpha_1, \dots, \alpha_m) = 0$  whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$ . Since  $S$  is  $z$ -honest for all  $z > 0$ , by Lemma 40,  $p_{fs_i}(\alpha_1, \dots, \alpha_m) = 0$  as a polynomial. Plugging in the given values of  $\alpha_1, \dots, \alpha_m$ ,  $q(\alpha_1, \dots, \alpha_m) \neq 0$  so  $\tilde{E}_S[fs_i] = \frac{p_{fs_i}(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)} = 0$ , as needed.

Similarly, for the third statement we want to view  $f$ ,  $g$ , and  $fg$  as polynomials which depend on  $n$  rather than being fixed polynomials. Still, since  $S$  is rational and  $\text{indexdeg}(f) + \text{indexdeg}(g) \leq n'$ , we can write  $\tilde{E}_S[f] = \frac{p_f(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$ ,  $\tilde{E}_S[g] = \frac{p_g(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$ , and  $\tilde{E}_S[fg] = \frac{p_{fg}(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)}$ . Now observe that  $\tilde{E}_S[fg] = \tilde{E}_S[f]\tilde{E}_S[g]$  whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$  and thus

$$p_f(\alpha_1, \dots, \alpha_m)p_g(\alpha_1, \dots, \alpha_m) - q(\alpha_1, \dots, \alpha_m)p_{fg}(\alpha_1, \dots, \alpha_m) = 0$$

whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$ . Since  $S$  is  $z$ -honest for all  $z$ , by Lemma 40,  $p_f p_g - q p_{fg} = 0$  as a polynomial. Plugging in the given parameters  $\alpha_1, \dots, \alpha_m$ ,  $q(\alpha_1, \dots, \alpha_m) \neq 0$  so

$$\tilde{E}_S[fg] = \frac{p_{fg}(\alpha_1, \dots, \alpha_m)}{q(\alpha_1, \dots, \alpha_m)} = \frac{p_f(\alpha_1, \dots, \alpha_m)p_g(\alpha_1, \dots, \alpha_m)}{(q(\alpha_1, \dots, \alpha_m))^2} = \tilde{E}_S[f]\tilde{E}_S[g] \quad \blacktriangleleft$$

### 6.3 Verifying good stories

We are now ready to give sufficient conditions for a story to be a good story.

► **Theorem 43.** *If  $S$  is a story for  $(P, A)$  such that*

1.  $S$  is symmetric with respect to permutations of  $[1, n] \setminus I_A$
2.  $S$  is rational
3. For all  $z > 0$ ,  $S$  is  $z$ -honest.

*then for a given choice of parameters  $\alpha_1, \dots, \alpha_m$ , if  $n'$  and  $r$  are numbers such that  $n' \leq n - |I_A|$  and*

1. *If we consider up to  $r$  further indices, the probabilities  $p_{ij}$  are always non-negative.*
2. *If we consider up to  $n'$  further indices, we may get negative values for some  $p_{ij}$  but these values are always well-defined (i.e. the denominator is nonzero).*

*then  $S$  is a level  $(n', r)$  good story for  $(P, A)$ .*

**Proof.** Since we can consider up to  $n'$  further indices and get well-defined values for the  $p_{ij}$ ,  $S$  is a level  $n'$  story for  $(P, A)$ . Now by Lemma 41,  $S$  is a level  $n'$  single graph mimic for  $(P, A)$ .

We now prove the theorem by induction on  $r$ . The base case  $r = 0$  is trivial. If  $r > 0$  then for all  $i \in [1, n] \setminus I_A$ ,  $S$  gives non-negative values  $\{p_{ij}\}$  for the probabilities of level  $n' - 1$  stories  $S_{ij}$  for  $(P, A \cup (i))$ . Now note that for each of these  $S_{ij}$ , the values of subsequent  $p_{ij}$  will always be non-negative if we consider up to  $r - 1$  further indices and will be well-defined if we consider up to  $n' - 1$  further indices. Moreover,  $S_{ij}$  is symmetric with respect to permutations of  $[1, n] \setminus (I_A \cup \{i\})$ , rational, and is  $z$ -honest because  $S_{ij}$  is honest for  $(\alpha_1, \dots, \alpha_m)$  whenever  $S$  is honest for  $(\alpha_1, \dots, \alpha_m)$ . Thus, by the inductive hypothesis, each  $S_{ij}$  is a level  $(r - 1, n' - 1)$  good story for  $(P, A \cup (i))$  so  $S$  is a level  $(r, n')$  good story for  $(P, A)$ , as needed. ◀

## 6.4 Good stories for knapsack, the MOD 2 principle, and the triangle problem

In this subsection, we apply Theorem 43 to verify that our stories for knapsack, the MOD 2 principle, and the triangle problem are good stories.

► **Theorem 44.**

1. *Saying that we take  $k$  out of  $n$  elements is a level  $(\lfloor \min\{k, n - k\} \rfloor + 1, n)$  good story for the knapsack problem.*
2. *Saying that every vertex is incident with precisely one edge is a level  $(\lfloor \frac{n}{2} \rfloor + 1, n)$  good story for the MOD 2 principle.*
3. *Saying that we have  $k$  independent sets of size  $\frac{n}{k}$  is a level  $(\lfloor \min\{k, \frac{n}{k}\} \rfloor + 1, n)$  good story for the triangle problem.*

**Proof.** For knapsack and the triangle problem, we take  $\alpha_1 = n$  and  $\alpha_2 = k$ . For the MOD 2 principle, we just take  $\alpha_1 = n$ .

Our stories are clearly rational and symmetric with respect to permutations of  $[1, n]$ . We now check that they are  $z$ -honest for all  $z$ .

For knapsack, note that our story is honest for  $(n, k)$  whenever  $k$  is an integer between 0 and  $n$ . Thus, whenever  $n \geq z$  there are at least  $z$  values of  $k$  such that our story is honest for  $(n, k)$ , which implies that our story is  $z$ -honest for  $(n)$  whenever  $n \geq z$ . For all  $z$  there are infinitely many values of  $n$  such that  $n \geq z$  so our story is  $z$ -honest for all  $z$ , as needed.

For the MOD 2 principle, note that our story is honest for  $(n)$  whenever  $n$  is an even integer. There are infinitely many even integers so our story is  $z$ -honest for all  $z$ , as needed.

For the triangle problem, note that our story is honest for  $(n, k)$  whenever  $k$  is an integer and  $n$  is divisible by  $k$ . Thus, whenever  $n = a!$  and  $a \geq z$  then there are at least  $z$  values of  $k$  such that our description is honest for  $(n, k)$ , which implies that our story is  $z$ -honest for  $(n)$  whenever  $n = a!$  and  $a \geq z$ . For all  $z$  there are infinitely many values of  $n$  such that  $n = a!$  where  $a \geq z$  so our story is  $z$ -honest for all  $z$ , as needed.

All that we have to do now is to determine  $n'$  and  $r$ .

For knapsack, when we consider polynomials of index degree at most  $n'$ , the common denominator will be  $n(n - 1) \dots (n - n' + 1)$  as we are choosing  $n'$  elements one by one from  $[1, n]$ . This is well-defined as long as  $n' \leq n$  so we may take  $n' = n$ . The probabilities will be non-negative up to the  $(\lfloor \min\{k, n - k\} \rfloor + 1)$ -th index we consider, so we may take  $r = \lfloor \min\{k, n - k\} \rfloor + 1$ .

For the MOD 2 principle, when we consider polynomials of index degree at most  $n'$ , the common denominator will be  $n(n - 1) \dots (n - n' + 1)$  as we are choosing  $n'$  elements one by one from  $[1, n]$ . This is well-defined as long as  $n' \leq n$  so we may take  $n' = n$ . The probabilities will be non-negative up to the  $(\lfloor \frac{n}{2} \rfloor + 1)$ -th index we consider, so we may take  $r = \lfloor \frac{n}{2} \rfloor + 1$ .

For the triangle problem, when we consider polynomials of index degree at most  $n'$ , the common denominator will be  $k^{n'} n(n - 1) \dots (n - n' + 1)$ . The additional  $k^{n'}$  factor appears because there are  $\frac{n}{k}$  choices for the first element in an independent set of size  $\frac{n}{k}$ ,  $\frac{n-k}{k}$  choices for the second element, etc. Again, this is well-defined as long as  $n' \leq n$  so we may take  $n' = n$ . The probabilities will be non-negative up to the  $(\lfloor \min\{k, \frac{n}{k}\} \rfloor + 1)$ -th index we consider, so we may take  $r = \lfloor \min\{k, \frac{n}{k}\} \rfloor + 1$  ◀

► **Corollary 45.**

1. *For all positive integers  $n$  and all non-integer  $k \in [0, n]$ , index degree  $\min\{2\lfloor \min\{k, n - k\} \rfloor + 3, n\}$  SOS fails to refute the knapsack equations.*

2. For all odd  $n$ , index degree  $n$  SOS fails to refute the equations for the MOD 2 principle.
3. For all  $n \geq 6$ , and all  $k \in [1, n]$  such that  $k \notin \mathbb{Z}$  or  $\frac{n}{k} \notin \mathbb{Z}$ , index degree  $2\lfloor \min\{k, \frac{n}{k}\} \rfloor + 2$  SOS fails to refute the claim that Goodman's bound can be achieved for the triangle problem.

## Abstract

We explore questions dealing with the learnability of models of choice over time. We present a large class of preference models defined by a structural criterion for which we are able to obtain an exponential improvement over previously known learning bounds for more general preference models. This in particular implies that the three most important discounted utility models of intertemporal choice – exponential, hyperbolic, and quasi-hyperbolic discounting – are learnable in the PAC setting with VC dimension that grows logarithmically in the number of time periods. We also examine these models in the framework of active learning. We find that the commonly studied stream-based setting is in general difficult to analyze for preference models, but we provide a redeeming situation in which the learner can indeed improve upon the guarantees provided by PAC learning. In contrast to the stream-based setting, we show that if the learner is given full power over the data he learns from – in the form of learning via membership queries – even very naive algorithms significantly outperform the guarantees provided by higher level active learning algorithms.

## 1 Introduction

We study the learnability of economic models of choice over time. Our setting is that of an analyst who first observes an agent’s choices between plans that specify payoffs over time, and then attempts to learn the preference parameters guiding the choices. While such parameters are stylized – in reality subjects are not likely to perform standardized computations according to private parameters before making decisions – experiments have shown that they often provide accurate descriptions of how an agent behaves. By observing enough choice data, one can hope to learn the economic parameters that most closely describe the agent’s preferences. Thus, learning theory provides an especially meaningful lens with which to view the theory of choice – it allows us to answer questions regarding the volume of data required to faithfully predict future decisions made by an observed agent. The overarching goal of this paper is to identify structural criteria that yield strong learnability results for preferences over time under different restrictions placed on the learner/analyst. The criteria we present captures a

large class of preference models that give the agent significant freedom in weighting decisions against time delays. In particular, it encompasses the most popular models of time dependent choice used by economists.

The main economic application of our results is in understanding the learnability of models of intertemporal choice. Intertemporal choice is what governs an agent’s decisions over several time periods. The most important models of intertemporal choice are discounted utility models, in which agents evaluate plans by discounting actions as they are delayed – in analogy to how markets value the loss or gain of money over time. The first axiomatic treatment of discounting was by Koopmans in 1960 [18], in which he demonstrates that simple postulates for preferences over an infinite time horizon yield “impatience”. The three most commonly studied discounting models are *exponential*, *hyperbolic*, and *quasi-hyperbolic*, and all have been studied by both economists and computer scientists (though less so by the latter) as well as researchers from various other fields. The importance of discounted utility in economics cannot be overstated – it is the canonical framework used by economists to study choice over time.

Problems of learning economic parameters have received recent attention from computer scientists; see, e.g., [1, 2, 3, 16, 21]. Inspired by a general theme of demanding computational robustness from economic models (Echenique, Golovin, and Wierman provide a nice discussion of this topic in [11]), the tools of learning theory provide relevant and exciting perspectives from which to view economic models that have been around for several decades. In contrast to the usual goal of truthfully extracting the agent’s parameters adopted by classical mechanism design, the learning problem aims to efficiently extract a truthful agent’s parameters in the restricted message space of binary classification. Our paper contributes to the line of work that specifically studies models of choice using the perspectives of learning theory. This confluence of decision theory and learning theory was initiated by Basu and Echenique [2], who consider the learning problem for models of choice under uncertainty. Our investigation in this paper is motivated by models of how agents make choices over time. We provide learnability results that are fine tuned to structural requirements on such models.

We now summarize our main contributions at a high level. Section 3 contains a more detailed exposition of our results.

## Summary of results and techniques

Our situation is one of an analyst trying to learn the parameters governing an agent’s preferences over time. The two main learning themes we consider are (1) when the analyst has no control over the data he sees and (2) when the analyst has some control over the data he sees. The first theme is aptly captured by *probably approximately correct (PAC) learning*. To analyze the second theme, we investigate two models of *active learning*: stream-based selective sampling and membership queries.

In the first part, we study the PAC model, where the analyst is presented with pairs of alternatives and a label for each pair indicating the agent’s preference between the alternatives. The data points are drawn according to some unknown distribution, and the analyst has no control over the data he is presented with. Our main result here is a structural criterion on preference models that allows for a drastic improvement over the PAC learning complexity bounds achieved in [2]. We stipulate that the agent weights time-delayed payoffs according to polynomials, which allows for considerable freedom in how payoffs are weighted. Under this requirement, we show that such classes of preference models admit an exponential improvement in sample complexity bounds over the more general preference models considered in [2]. This is achieved via a computation of the VC dimension (which

quantifies the complexity of PAC learning). A simple application of our result shows that each of the discounted utility models are learnable (and in fact admit polynomial time learning algorithms), with sample complexity that grows logarithmically in the number of time periods  $T$  over which decisions are being made. The computation of the VC dimension is due to a natural connection between pairs of choices and the signs of polynomials that arise from the choices.

In the second part, we consider active learning models, where the analyst is given a certain amount of control over the data that he uses to learn. The two active learning models we study are *stream-based selective sampling* and learning via *membership queries*. In the former, the analyst is given some control over what data he learns from: as in the PAC setting he is presented with points drawn from an unknown distribution, but now the analyst chooses whether or not to see the label representing the agent's choice for each point. In the latter, the analyst has complete control over the data he learns from: the analyst can at any time request the label for any point. The former model seems to have been commonly adopted in order to study the very general problem of concept learning, when there is no extra information about the structure of the concepts. We find that the *disagreement methods* used to study the stream-based setting are in general difficult to analyze in the context of preference models – requiring quantitative information about the underlying distribution from which points are drawn. However, we provide a redeeming situation (by examining a particular distribution) where we obtain an improvement over the PAC guarantees. Membership queries, on the other hand, allow us to heavily exploit the structure of the preference models we consider. We present a naive membership query-based algorithm that significantly outperforms the guarantees provided in the stream-based setting. Learning via membership queries, we conclude, seems to be the appropriate model to actively learn economic parameters. It allows the analyst to make use of the preference relations' structure, and also precisely captures the situation in which the analyst and agent are participating in a real time experiment.

## Related work

Discounted utility models of intertemporal choice have been studied extensively not only by economists, but also by researchers from various other fields. We first briefly survey some of the relevant work pertaining to the exponential, quasi-hyperbolic, and hyperbolic discounting models and then survey existing work in the more general topic of learning economic parameters.

In the exponential discounting model, the agent evaluates his utilities based on a discount factor  $\delta \in (0, 1)$ , where a delay of  $t$  time periods incurs an exponential discount in utility by  $\delta^t$ . Climate change policies are traditionally evaluated according to an exponential discounting model – for example, the *Stern review* on the economics of climate change deals with issues of how to choose an appropriate discount rate in evaluating such policies [20]. Chambers and Echenique [8] present results related to the problem of aggregating discount rates proposed by a group of experts facing disagreement. While it is the most commonly used discounting model due to its simplicity, the exponential discounting model has been criticized due to its inability to match empirical data recording actual human behavior. Quasi-hyperbolic and hyperbolic discounting aim to mend such issues. The quasi-hyperbolic discounting model is parametrized by  $\beta, \delta \in (0, 1)$ , where a delay of  $t$  time periods incurs a discount in utility by  $\beta\delta^t$ , and was first introduced by Phelps and Pollack [19] to study preferences over generations. They proposed that the constant  $\beta$  discount factor represents how much a given generation  $t$  is affected by the utilities of other people relative to their own – and remark that  $\beta = 1$  represents “perfect altruism”, while  $\beta < 1$  represents “imperfect altruism”. Kleinberg and

Oren [17] study agents with quasi-hyperbolic discounting and propose a graph-theoretic model to investigate phenomena such as procrastination and abandonment of long-range tasks. Hyperbolic discounting aims to capture the notion that people are more impatient in making short term decisions (today vs. tomorrow) than long term decisions (365 days from today vs. 366 days from today)<sup>1</sup>, and is modeled via a discount of  $(1 + t\alpha)^{-1}$  at time  $t$ . Researchers in fields such as psychology and neuroscience [4, 15] have adopted the hyperbolic discounting model to study, for example, issues of self control and anticipation in humans and animals, and have compared the predictions by the different discounted utility models to neurobiological data obtained via MRI scans. Chabris et al. [7] give an exposition of the discounted utility models of intertemporal choice and survey sociological research that examines empirical data pertaining to how discount rates are affected by factors like age, drug use, gambling, etc.

The study of economic models has witnessed a recent influx of work from computer scientists dealing with questions of robustness under various notions of complexity (learning complexity, computational complexity, communication complexity, etc.). Kalai [16] in 2001 studied the learnability of choice functions, where the observed choices are in the form of a given set of alternatives along with the most preferred alternative from the set. Beigman and Vohra [3], Zadimoghaddam and Roth [21], and Balcan et al. [1] investigate the problem of learning utility functions in the context of an expected utility maximizing agent in a demand environment. Most recently (and most related to our work), Basu and Echenique [2] study the learnability of preference models of choice under uncertainty, in which an agent is uncertain about states of a lottery and is made to choose between acts that encode utilities over each state. Here, the different models of choice under uncertainty arise from different ways of representing the subjective probability held by an agent. They are also the first to study learnability in the decision-theoretic setting where choice is modeled by preference relations rather than by expected utility maximizing behavior in a demand setting. However, it does not appear that the learnability of models of intertemporal choice has been previously studied.

## 2 Model and Preliminaries

We now formally set up the discounted utility models of intertemporal choice and state the standard definitions from learning theory in the context of preference relations. Much of the following material regarding learning and preference relations is taken from [2] since we require a similar list of definitions and setup. First, we sketch our high level model.

Let  $X$  be a Euclidean space equipped with a Borel  $\sigma$ -algebra. A *preference relation* on  $X$  is a binary relation  $\succsim \subseteq X \times X$  such that  $\succsim$  is measurable with respect to the product  $\sigma$ -algebra on  $X \times X$ . A *model*  $\mathcal{P}$  of preference relations is a collection of preference relations.

An agent makes choices from pairs of alternatives  $(x^i, y^i)_{i=1}^n$  that are drawn according to some unknown distribution on  $X \times X$ . The choices are presented as labels  $(a_i)_{i=1}^n$  where  $a_i = 1$  if the agent chooses  $x^i$  and  $a_i = 0$  if the agent chooses  $y^i$ . A *dataset* is any finite sequence of pairs of plans and their labels  $((x^1, y^1), a_1), \dots, ((x^n, y^n), a_n)$ . An analyst observes a dataset, and attempts to guess the preference relation governing the agent's choices. A *learning rule* is any map  $\sigma$  from datasets to preference relations. The output of the learning rule is the analyst's hypothesis as to what the agent's true preference relation is, having seen some finite dataset.

---

<sup>1</sup> In particular note that exponential discounting does not capture this issue, i.e. it is *dynamically consistent*, in that preferences do not change according to shifts in time.

## 2.1 Learnability

The two notions of learnability we consider are the PAC model and the active model. We now state the standard definitions of PAC and active learning in the context of preference relations. Most of the following definitions for the PAC setting are taken from [2] since the setup involving preference relations is identical. These definitions of course apply to the more general setting of concept learning (for example, see [6]).

► **Definition 1.** A collection  $\mathcal{P}$  of preference relations is (PAC) learnable if there is a learning rule  $\sigma$  such that for every  $0 < \varepsilon, \delta < 1$ , there is  $s(\varepsilon, \delta) \in \mathbb{N}$  such that for every  $n \geq s(\varepsilon, \delta)$ ,  $\succsim \in \mathcal{P}$ , and  $\mu \in \Delta(X \times X)$ ,

$$\mu^n(\{(x^1, y^1), \dots, (x^n, y^n) : \mu(\succsim^* \Delta \succsim) > \varepsilon\}) < \delta,$$

where

$$\succsim^* = \sigma(\{(x^1, y^1), I_{x^1 \succsim y^1}, \dots, (x^n, y^n), I_{x^n \succsim y^n}\})$$

is the hypothesis preference relation produced by the learning rule<sup>2</sup>. The quantity  $s(\varepsilon, \delta)$  is called the *sample complexity* of the learning rule  $\sigma$ .

The complexity of learning is commonly quantified by the Vapnik-Chervonenkis (VC) dimension, defined based on so-called shattered sets. A set of points  $\{(x^1, y^1), \dots, (x^n, y^n)\}$  from  $X \times X$  is *shattered* by a model of preferences  $\mathcal{P}$  if for every vector of labels  $(a_1, \dots, a_n) \in \{0, 1\}^n$ , there is a preference relation  $\succsim \in \mathcal{P}$  that realizes the labelling, i.e. for  $i = 1, \dots, n$  we have that  $x^i \succsim y^i$  if and only if  $a_i = 1$ . In this case,  $\mathcal{P}$  is said to *rationalize* the dataset  $\{(x^1, y^1), a_1), \dots, ((x^n, y^n), a_n)\}$ . The VC dimension of  $\mathcal{P}$ , denoted by  $VC(\mathcal{P})$ , is the largest integer  $n$  such that there exist  $n$  points that are shattered by  $\mathcal{P}$ .

Blumer et al. [6] in 1989 proved that learnability is equivalent to having a finite VC dimension<sup>3</sup>.

► **Theorem 2.** A model of preferences  $\mathcal{P}$  is learnable if and only if  $VC(\mathcal{P}) < \infty$ .

The VC dimension (denoted by  $d$  for the remainder of this subsection) additionally characterizes the sample complexity of learning a model of preferences: the optimal sample complexity of PAC learning is  $s(\varepsilon, \delta) = \Theta\left(\frac{1}{\varepsilon} \left(d + \log \frac{1}{\delta}\right)\right)$  [14].

The other learning model we consider is the active learning framework, where the analyst has some control over the data from which he learns. In stream-based selective sampling, points drawn according to an unknown distribution are presented to the analyst as before, but without the labels. The analyst can choose whether or not to query the label of a given point, and the complexity of the learning rule is measured by *label complexity*, i.e. the number of labels requested by the analyst. Disagreement based active learning refers to the paradigm in which the learner only requests labels on points that significantly reduce the hypothesis space. The disagreement of a preference model with respect to the underlying distribution is quantified through the *disagreement coefficient*  $\theta$ , which is defined in Section 5. A finite disagreement coefficient implies (for the underlying distribution) an exponential improvement in label complexity over the sample complexity of PAC learning. For example, the CAL algorithm [9, 10, 13], a simple disagreement based learning algorithm, yields a label complexity of

$$\ell_{CAL}(\varepsilon, \delta) = O\left(\theta \log \frac{1}{\varepsilon} \left(d \log \theta + \log \frac{\log(1/\varepsilon)}{\delta}\right)\right).$$

<sup>2</sup>  $\mu^n$  denotes the product measure induced by  $\mu$  on  $(X \times X)^n$ .

<sup>3</sup> This result requires  $\mathcal{P}$  to satisfy a certain measurability requirement. We note in Section 4 that the models of choice we consider all satisfy said requirement.

In the membership queries model, the analyst has complete control over the learning data and is allowed to request the label for any point at any time. Learning via membership queries is thus a question of optimal algorithm design, and bounds on query complexity obtained in this manner would presumably be independent from learning-theoretic quantities (e.g. VC dimension and disagreement coefficient). There appears to be a dearth of literature/results pertaining to the complexity of membership query algorithms for learning when the hypothesis space is infinite. One explanation for this is that improvements to the “passive” disagreement based methods used in the stream-based setting would need specific information about the problem domain: disagreement based methods are designed to work on a very general class of concept learning problems without assuming anything about the learning space. In our case, we have specific details about how the preference relations take shape. Thus, the membership query model turns out to be an interesting and useful perspective to use in the study of learning preference models.

For a more detailed survey of active learning, see [10].

## 2.2 Discounted utility

We now present the definitions for the discounted utility models of intertemporal choice. An agent chooses between *plans* or vectors in  $X = \mathbb{R}^T$  that encode payoffs over  $T$  time periods. A preference relation over plans is a binary relation  $\succsim \subseteq \mathbb{R}^T \times \mathbb{R}^T$ .

The most important model of intertemporal choice is the *discounted utility model*, in which the agent’s payoffs  $x_t$  for having chosen a plan  $x \in \mathbb{R}^T$  are reduced, or discounted, as  $t$  increases from 1 to  $T$ . In its most general form, we can characterize the preference relations that follow time discounting as follows:

► **Definition 3** (Discounted utility model). The class of preference relations  $\mathcal{P}_{\mathcal{D}}$  that satisfy the *discounted utility model* are those  $\succsim$  such that there exists a decreasing map  $D : \{1, \dots, T\} \rightarrow (0, 1)$  where

$$x \succsim y \text{ if and only if } \sum_{t=1}^T D(t)x_t \geq \sum_{t=1}^T D(t)y_t.$$

We use the following notation for the preference models arising from the three most commonly studied discounting functions  $D$ :

- $\mathcal{P}_{\mathcal{D}}$  denotes the set of preferences that satisfy the discounted utility model.
- $\mathcal{P}_{\mathcal{ED}}$  denotes the set of preferences that satisfy the discounted utility model with *exponential discounting*:  $D(t) = \delta^t$  for  $\delta \in (0, 1)$ .
- $\mathcal{P}_{\mathcal{HD}}$  denotes the set of preferences that satisfy the discounted utility model with *hyperbolic discounting*:  $D(t) = \frac{1}{1+t\alpha}$  for  $\alpha > 0$ .
- $\mathcal{P}_{\mathcal{QHD}}$  denotes the set of preferences that satisfy the discounted utility model with *quasi-hyperbolic discounting*:  $D(t) = 1$  if  $t = 1$ ,  $D(t) = \beta \cdot \delta^{t-1}$  if  $t > 1$  for  $\beta, \delta \in (0, 1)$ .

For a more thorough exposition on the various discounted utility models of intertemporal choice, see [7].

## 3 Main Results

In this section we provide a formal discussion and interpretation of our results, which is split into two themes: the first dealing with an analyst who has no control over the learning data, the second dealing with an analyst who has some control over the learning data.

## A powerless analyst

The first part of our paper investigates the situation of an analyst trying to learn the preference relation by which an agent makes choices, but has no control over what choices he gets to observe, and is agnostic to the process by which they are drawn. We thus adopt the PAC learning model.

The agent chooses between plans that encode payoffs over  $T$  periods of time and evaluates the total payoff of a plan vector  $x \in \mathbb{R}^T$  according to private weights  $w_1, \dots, w_T$  that he multiplicatively applies to each state:  $\text{payoff}(x) = \sum_{t=1}^T w_t x_t$ . This defines a model of preference relations, which we denote by  $\mathcal{P}_{\mathcal{W}}$ , where for any  $\succsim \in \mathcal{P}_{\mathcal{W}}$ , there exists a vector of weights  $w = (w_1, \dots, w_T) \in \mathbb{R}^T$  such that

$$x \succsim y \text{ if and only if } w \cdot x \geq w \cdot y.$$

In [2], it is shown that  $T - 1 \leq VC(\mathcal{P}_{\mathcal{W}}) \leq T + 1$ . In the context of choice over time, however, this model is extremely general and does not capture any of the intuitive notions of how an agent values payoffs when they are delayed<sup>4</sup>. For example, the discounted utility models of intertemporal choice require the weights to be of a particular functional form. Moreover, when there is no structure to the discount function we cannot improve the bounds on  $\mathcal{P}_{\mathcal{W}}$ :

► **Proposition 4.**  $T - 1 \leq VC(\mathcal{P}_{\mathcal{D}}) \leq T + 1$ .

This leads us to the motivating question of the first part of the paper: what structural conditions can we impose on the weights  $w_1, \dots, w_T$  such that this bound can be improved?

We investigate the situation where the agent computes his weights by evaluating polynomials at a private parameter  $\delta$ . Specifically, let  $Q_1, \dots, Q_T$  be polynomials of degree at most  $d$ , and suppose the agent evaluates total payoff of a plan vector  $x \in \mathbb{R}^T$  by  $\text{payoff}(x) = \sum_{t=1}^T Q_t(\delta)x_t$ . Consequently, let  $\mathcal{P}_{\mathcal{P}\mathcal{W}}$  be the model of preference relations parametrized by  $\delta$  such that

$$x \succsim y \text{ if and only if } \sum_{t=1}^T Q_t(\delta)x_t \geq \sum_{t=1}^T Q_t(\delta)y_t.$$

This class of preference models allows us to approximate preference relations where the weights are given by any real valued functions – we choose  $Q_1, \dots, Q_T$  to be the appropriate Taylor polynomials. Moreover, existing models of intertemporal choice fit this characterization – for example  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  and  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$ .

We additionally consider a slightly larger class of preference models where the agent has a private parameter  $\beta$  (in addition to  $\delta$ ) that in evaluating total payoff of a plan vector  $x \in \mathbb{R}^T$  allows the agent to modify the constant term  $\sum_{t=1}^T Q_t(0)x_t$  of the polynomial  $\sum_{t=1}^T Q_t(\delta)x_t$ . This model aims to more generally capture the effects of the  $\beta$  parameter in quasi-hyperbolic discounting. For polynomials  $Q_1, \dots, Q_T$  of degree at most  $d$ , let  $\mathcal{P}_{\mathcal{B}\mathcal{P}\mathcal{W}}$  be the model of preference relations parametrized by  $\beta$  and  $\delta$  such that  $x \succsim y$  if and only if

$$\left(\frac{1}{\beta} - 1\right) \sum_{t=1}^T Q_t(0)x_t + \sum_{t=1}^T Q_t(\delta)x_t \geq \left(\frac{1}{\beta} - 1\right) \sum_{t=1}^T Q_t(0)y_t + \sum_{t=1}^T Q_t(\delta)y_t.^5$$

<sup>4</sup> In [2] the complete control over weights is used to model choice under uncertainty, which calls for such generality since the agent's beliefs/weights are given by an element of the probability simplex on  $\mathbb{R}^T$ .

Our main results show that with this additional structure on the preference model, we can achieve an exponential improvement in the bounds for the VC dimension of  $\mathcal{P}_{\mathcal{W}}$  obtained in [2]<sup>6</sup>.

► **Theorem 5.** *For every  $\varepsilon > 0$ , there exists a  $d_\varepsilon$  such that for every  $d \geq d_\varepsilon$  we have  $VC(\mathcal{P}_{\mathcal{P}\mathcal{W}}), VC(\mathcal{P}_{\mathcal{B}\mathcal{P}\mathcal{W}}) \leq (1 + \varepsilon) \log d$  for any  $T$  and any  $T$  polynomials  $Q_1, \dots, Q_T$  of degree at most  $d$ .*

Note that when  $Q_1, \dots, Q_T$  have degree at most polynomial in  $T$ , we obtain an exponential improvement over the linear growth of  $VC(\mathcal{P}_{\mathcal{W}})$ . We show that in this case, we get a tight (asymptotic) bound of  $\log T$ :

► **Theorem 6.** *Let  $Q_1, \dots, Q_T$  be polynomials in  $\delta$  of degree at most  $T - 1$  that span the space of polynomials in  $\delta$  of degree at most  $T - 1$ . Then  $VC(\mathcal{P}_{\mathcal{P}\mathcal{W}}), VC(\mathcal{P}_{\mathcal{B}\mathcal{P}\mathcal{W}}) \geq \log(T - 1)$ .*

An interesting feature of Theorems 5 and 6 is that for fixed  $Q_1, \dots, Q_T$  with degrees at most  $T - 1$ ,  $VC(\mathcal{P}_{\mathcal{P}\mathcal{W}})$  and  $VC(\mathcal{P}_{\mathcal{B}\mathcal{P}\mathcal{W}})$  satisfy the same asymptotic bounds, so giving the agent an extra parameter that allows control over the constant term of the polynomial  $\sum_{t=1}^T Q_t(\delta)x_t$  does not introduce a significant amount of richness to the model.

Applying Theorems 5 and 6 to the discounted utility models, we have:

► **Corollary 7.**  $VC(\mathcal{P}_{\mathcal{E}\mathcal{D}}), VC(\mathcal{P}_{\mathcal{H}\mathcal{D}}), VC(\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}) \sim \log(T - 1)$

Thus,  $\mathcal{P}_{\mathcal{D}}$ ,  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$ ,  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$ , and  $\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}$  are all learnable.  $\mathcal{P}_{\mathcal{D}}$  requires a minimum sample size that grows linearly with  $T$ , while  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$ ,  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$ , and  $\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}$  require a minimum sample size that grows logarithmically in  $T$ . We also note that these classes are all efficiently learnable, that is, the learning rule can be described by a polynomial time algorithm.

The main technique in proving Theorems 5 and 6 is interpreting the shattering criteria as a statement about the sign combinations achieved by a collection of polynomials. The upper bound on the VC dimension follows from an upper bound on the number of sign combinations a collection of polynomials can achieve. In demonstrating the lower bound on the VC dimension, we construct a set of points that is shattered by finding polynomials achieving all possible sign combinations – chosen according to a Hamiltonian path in the  $\log(T - 1)$ -dimensional hypercube.

Table 1 summarizes the definitions and bounds on the VC dimensions for the various preference models we consider.

## A powerful analyst

Our other results concern the active learning framework, which broadly deals with situations in which the analyst has some control over the choices he observes and learns from. The two models we consider are *stream-based selective sampling* and learning via *membership queries*. A large body of active learning research is devoted to the stream-based model, specifically focusing on disagreement based algorithms – a class of learning algorithms that instructs the analyst only to request labels on points he sees that reduce the hypothesis space significantly. In the most general setting of concept learning, this is a useful framework since the error guarantees can be described using the same setup as the PAC model. Moreover without additional information about the problem domain, it is unclear how to devise efficient algorithms that are more specific in instructing the analyst on what questions to ask.

<sup>6</sup> It is important to note that the classes  $\mathcal{P}_{\mathcal{P}\mathcal{W}}$  and  $\mathcal{P}_{\mathcal{B}\mathcal{P}\mathcal{W}}$  are defined for a given  $Q_1, \dots, Q_T$ . That is, the analyst knows  $Q_1, \dots, Q_T$ , and is trying to learn the parameters  $\beta$  and  $\delta$ . If the  $Q_1, \dots, Q_T$  are private information only available to the agent, we are in no better shape than in the case of  $\mathcal{P}_{\mathcal{W}}$ .

■ **Table 1** VC dimensions of various preference models (the lower bounds for  $\mathcal{P}_{\mathcal{PW}}$  and  $\mathcal{P}_{\mathcal{BPW}}$  require that  $Q_1, \dots, Q_T$  span the space of polynomials with degree at most  $T - 1$ ).

Preference Model $\mathcal{P}$	Payoff( $x$ )	$VC(\mathcal{P})$ lower bound	$VC(\mathcal{P})$ upper bound
$\mathcal{P}_{\mathcal{W}}$	$w \cdot x$ for $w \in \mathbb{R}^T$	$T - 1$	$T + 1$
$\mathcal{P}_{\mathcal{PW}}$ (defined with respect to polynomials $Q_1, \dots, Q_T$ )	$\sum_{t=1}^T Q_t(\delta)x_t$ for $\delta \in (0, 1)$ .	$\log(T - 1)$	$(1 + \varepsilon) \log d$ , for $\varepsilon > 0$ and $d = \max\{\deg Q_t\}$ large enough.
$\mathcal{P}_{\mathcal{BPW}}$ (defined with respect to polynomials $Q_1, \dots, Q_T$ )	$(\frac{1}{\beta} - 1) \sum_{t=1}^T Q_t(0)x_t$ $+ \sum_{t=1}^T Q_t(\delta)x_t$ for $\delta, \beta \in (0, 1)$ .	$\log(T - 1)$	$(1 + \varepsilon) \log d$ , for $\varepsilon > 0$ and $d = \max\{\deg Q_t\}$ large enough.
$\mathcal{P}_{\mathcal{D}}$	$\sum_{t=1}^T D(t)x_t$ for $D: [T] \rightarrow (0, 1)$ a decreasing map.	$T - 1$	$T + 1$
$\mathcal{P}_{\mathcal{ED}}$	$\sum_{t=1}^T \delta^t x_t$ for $\delta \in (0, 1)$ .	$\log(T - 1)$	$(1 + \varepsilon) \log(T - 1)$ for $\varepsilon > 0$ and $T$ large enough.
$\mathcal{P}_{\mathcal{QHD}}$	$x_1 + \beta \sum_{t=2}^T \delta^{t-1} x_t$ for $\beta, \delta \in (0, 1)$ .	$\log(T - 1)$	$(1 + \varepsilon) \log(T - 1)$ for $\varepsilon > 0$ and $T$ large enough.
$\mathcal{P}_{\mathcal{HD}}$	$\sum_{t=1}^T \frac{1}{1+t\alpha} x_t$ for $\alpha > 0$ .	$\log(T - 1)$	$(1 + \varepsilon) \log(T - 1)$ for $\varepsilon > 0$ and $T$ large enough.

We find that the stream-based model is in general difficult to analyze for the preference relations we work with. This difficulty seems to arise from the apparent need to quantify disagreement in order to explicitly write down learning guarantees. Though in most general situations it is unclear how to quantify disagreement for our preference relations, we present a redeeming situation for which we are able to provide a precise analysis of the learning guarantees for  $\mathcal{P}_{\mathcal{ED}}$ . Here, the analyst can learn  $\mathcal{P}_{\mathcal{ED}}$  with an exponential improvement in label complexity over the guarantees provided by the PAC model. This is achieved via a computation of the disagreement coefficient (defined in Section 5) of  $\mathcal{P}_{\mathcal{ED}}$  for a specific distribution.

► **Theorem 8.** *There exists a distribution  $\mu$  on  $\mathbb{R}^T \times \mathbb{R}^T$  for which the disagreement coefficient of  $\mathcal{P}_{\mathcal{ED}}$  is  $\theta = 2$ . Thus, for this distribution,*

$$\ell_{CAL}(\varepsilon) = \tilde{O}\left(\log T \log \frac{1}{\varepsilon}\right),$$

where the  $\tilde{O}$  notation suppresses terms that are logarithmic in  $\log T$  and  $\log 1/\varepsilon$ .

The measure  $\mu$  we construct is induced by the product Lebesgue measure on  $(0, 1)^{T-1}$ , and allows us to precisely translate statements about disagreement into statements about the roots of polynomials arising from a given choice. Once we have defined  $\mu$ , the calculation of  $\theta$  follows from basic probability arguments.

Now, in our case the analyst has structural information regarding the preference relation of the agent he is questioning. We find that allowing the analyst full control over the

membership queries he makes yields a learning algorithm that, despite its simplicity, takes advantage of this extra structure and yields a significant improvement in complexity over the stream-based setting. Additionally, the membership queries model naturally describes an experimental environment in which the analyst is able to ask the agent questions in real time.

We show that when the preference model satisfies some relatively benign structural requirements, even very naive algorithms outperform the guarantees provided by CAL in the stream-based setting (we are not aware of any lower bounds on the sample complexity of disagreement based active learning, so this only an improvement over the current sample complexity upper bound of the CAL algorithm). The example algorithm we give, relying on a simple binary search, has a query complexity of  $O(\log 1/\varepsilon)$ , which gets rid of the  $\log T$  dependence in Theorem 8.

The class of preference models is defined as follows: let  $g_1, \dots, g_T : \mathbb{R} \rightarrow \mathbb{R}$  be a collection of functions satisfying the properties listed in Section 5.3 and consider the model of preference relations  $\mathcal{P}$  parametrized by  $\delta$  where  $x \succsim y$  if and only if  $\sum_{t=1}^T g_t(\delta)x_t \geq \sum_{t=1}^T g_t(\delta)y_t$ <sup>7</sup>. We have (where  $M$  and  $C$  are constants that depend on  $g_1, \dots, g_T$ )

► **Proposition 9.** *There exists an algorithm that takes as input  $\varepsilon > 0$  and using  $O(\log \frac{MC}{\varepsilon})$  membership queries outputs  $\delta^h$  such that  $|\delta - \delta^h| \leq \varepsilon$ , where  $\delta$  parametrizes the target preference relation in  $\mathcal{P}$ .*

The remainder of the paper is devoted to proving the results discussed in this section.

## 4 PAC Learning

In this section we prove Theorems 5 and 6. We first note a preliminary upper bound due to Basu and Echenique [2]. Let  $\mathcal{P}_{\mathcal{I}}$  be the set of preference relations that satisfy the following axioms:

**Order:** For all  $x, y$  either  $x \succsim y$  or  $y \succsim x$  (completeness). For all  $x, y, z$ , if  $x \succsim y$  and  $y \succsim z$ , then  $x \succsim z$  (transitivity).

**Independence:** For all  $x, y, z$  and for any  $\lambda \in (0, 1)$ ,  $x \succsim y$  if and only if  $\lambda x + (1 - \lambda)z \succsim \lambda y + (1 - \lambda)z$ .

The class  $\mathcal{P}_{\mathcal{I}}$  satisfies the property that for any  $\succsim \in \mathcal{P}_{\mathcal{I}}$ , there are finitely many vectors  $q_1, \dots, q_K$ , with  $K \leq T$ , such that  $x \succsim y$  if and only if  $(q_k \cdot x)_{k=1}^K \geq_L (q_k \cdot y)_{k=1}^K$ , where  $\geq_L$  denotes the lexicographic order [5]. Then,  $\mathcal{P}_{\mathcal{PW}}, \mathcal{P}_{\mathcal{BPW}} \subset \mathcal{P}_{\mathcal{W}} \subset \mathcal{P}_{\mathcal{I}}$ , since the aforementioned characterization is satisfied with  $K = 1$  and  $q_1 = (w_1, \dots, w_T)$ .

This has two main consequences. First,  $\mathcal{P}_{\mathcal{PW}}$  and  $\mathcal{P}_{\mathcal{BPW}}$  (and thus all the discounted utility models) satisfy the measurability requirement discussed in Lemma 4 of [2] for the equivalence result of Theorem 2 to hold. Second, the VC dimensions of  $\mathcal{P}_{\mathcal{PW}}$  and  $\mathcal{P}_{\mathcal{BPW}}$  are all bounded above by  $T + 1$  (and in particular  $T - 1 \leq VC(\mathcal{P}_{\mathcal{W}}) \leq T + 1$ ). This follows due to Theorem 3.1 of [2], in which an argument similar to that required to compute the VC dimension of the class of half-spaces is used to show that  $VC(\mathcal{P}_{\mathcal{I}}) = T + 1$ . In all cases excluding the most general model of discounted utility, we are able to bring this down to  $\log(T - 1)$  (which we then show is tight by demonstrating the corresponding lower bound).

We begin by demonstrating that even in the discounted utility setting, without any structure we cannot do better than the learning bounds obtained for  $\mathcal{P}_{\mathcal{I}}$ .

<sup>7</sup> As before, the  $g_1, \dots, g_T$  are known to the analyst.

► **Proposition 4** (restated).  $T - 1 \leq VC(\mathcal{P}_{\mathcal{D}}) \leq T + 1$ .

**Proof.** That  $VC(\mathcal{P}_{\mathcal{D}}) \leq T + 1$  follows from Theorem 3.1 of [2], since  $\mathcal{P}_{\mathcal{D}} \subset \mathcal{P}_{\mathcal{I}}$ .

Here is a simple construction that shows  $VC(\mathcal{P}_{\mathcal{D}}) \geq T - 1$ . Fix an  $\varepsilon > 0$ . Let  $e_1, \dots, e_T$  be the standard unit vectors in  $\mathbb{R}^T$ , and consider the set of points  $\{(x^1, y^1), \dots, (x^{T-1}, y^{T-1})\}$ , where  $x^i = (1 - \varepsilon)e_i$  and  $y^i = e_{i+1}$ .

This set is shattered by  $\mathcal{P}_{\mathcal{D}}$ : for any  $(a_i)_{i=1}^{T-1}$ , choose  $D(1)$  arbitrarily from  $(0, 1)$ , and if  $D(i)$  has been defined, inductively define  $D(i + 1)$  such that  $D(i + 1) \leq D(i)(1 - \varepsilon)$  if  $a_i = 1$  and  $D(i) > D(i + 1) > (1 - \varepsilon)D(i)$  if  $a_i = 0$ . ◀

We now prove Theorems 5 and 6, which are restated below for convenience.

► **Theorem 5** (restated). *For every  $\varepsilon > 0$ , there exists a  $d_\varepsilon$  such that for every  $d \geq d_\varepsilon$  we have  $VC(\mathcal{P}_{\mathcal{PW}}), VC(\mathcal{P}_{\mathcal{BPW}}) \leq (1 + \varepsilon) \log d$  for any  $T$  and any  $T$  polynomials  $Q_1, \dots, Q_T$  of degree at most  $d$ .*

**Proof.** It suffices to establish the bound for  $\mathcal{P}_{\mathcal{BPW}}$ .

Let  $(z^1, \dots, z^n)$  be a set of points in  $\mathbb{R}^T \times \mathbb{R}^T$ ,  $z^i = (x^i, y^i)$ . For each  $z^i = (x^i, y^i)$ , define the plan  $f^i := x^i - y^i$ . Then, note that  $(z^1, \dots, z^n)$  is shattered by  $\mathcal{P}_{\mathcal{BPW}}$  if and only if  $((f^1, 0), \dots, (f^n, 0))$  is shattered by  $\mathcal{P}_{\mathcal{BPW}}$ . Hence, we may (and do) restrict attention to datasets of the form  $((f^1, 0), \dots, (f^n, 0))$ .

We have that  $((f^1, 0), \dots, (f^n, 0))$  is shattered by  $\mathcal{P}_{\mathcal{BPW}}$  if and only if for all vectors  $(a_1, \dots, a_n) \in \{0, 1\}^n$ , there exists a  $\delta$  and  $\beta$  (which determines the preference relation) such that

$$(Q_T(\delta)f_T^i + \dots + Q_1(\delta)f_1^i) + \left(\frac{1}{\beta} - 1\right) (Q_T(0)f_T^i + \dots + Q_1(0)f_1^i) \geq 0 \text{ whenever } a_i = 1,$$

and

$$(Q_T(\delta)f_T^i + \dots + Q_1(\delta)f_1^i) + \left(\frac{1}{\beta} - 1\right) (Q_T(0)f_T^i + \dots + Q_1(0)f_1^i) < 0 \text{ whenever } a_i = 0.$$

Therefore, if the  $n$  points  $((f^1, 0), \dots, (f^n, 0))$  can be shattered, there are polynomials  $P_1, \dots, P_n$  in  $\delta$  (where  $P_i$  is the polynomial  $Q_1(\delta)f_1^i + \dots + Q_T(\delta)f_T^i$ ), each of degree at most  $d$ , such that for every labeling  $(a_1, \dots, a_n) \in \{0, 1\}^n$ , there exists a  $\delta$  and  $\beta$  such that<sup>8</sup>

$$(\text{sgn}(P_1(\delta) + (1/\beta - 1)P_1(0)), \dots, \text{sgn}(P_n(\delta) + (1/\beta - 1)P_n(0))) = (a_1, \dots, a_n).$$

First, for any  $n$  polynomials  $P_1, \dots, P_n$  of degree at most  $d$ , we give an upper bound on the number of possible values  $(\text{sgn}(P_1(\delta)), \dots, \text{sgn}(P_n(\delta)))$  can realize. Each polynomial has at most  $d$  real roots, so together  $P_1, \dots, P_n$  have at most  $nd$  distinct real roots. Since sign changes can only occur at the roots, there are at most  $nd + 1$  possible values of  $\{0, 1\}^n$  that  $(\text{sgn}(P_1(\delta)), \dots, \text{sgn}(P_n(\delta)))$  can realize.

Now, for a fixed  $\delta$ , varying  $\beta$  shifts the collection of polynomials

$$P_1(\delta) + (1/\beta - 1)P_1(0), \dots, P_n(\delta) + (1/\beta - 1)P_n(0)$$

vertically, which in the worst case induces sign changes in all entries. We thus get at most an additional  $n$  new sign combinations for every sign combination realized by

<sup>8</sup> For notational convenience, let  $\text{sgn}(x)$  be 1 if  $x \geq 0$  and 0 otherwise.

## 62:12 Learning Time Dependent Choice

$(\text{sgn}(P_1(\delta)), \dots, \text{sgn}(P_n(\delta)))$ . Hence, there are at most  $nd + 1 + n(nd + 1) = (n^2 + n)d + n + 1$  possible values of  $\{0, 1\}^n$  that

$$(\text{sgn}(P_1(\delta) + (1/\beta - 1)P_1(0)), \dots, \text{sgn}(P_n(\delta) + (1/\beta - 1)P_n(0)))$$

can realize.

In order for all  $2^n$  elements of  $\{0, 1\}^n$  to be realized, it must be that

$$(n^2 + n)d + n + 1 \geq 2^n.$$

If  $n > (1 + \varepsilon) \log d$ , then for large enough  $d$  this inequality does not hold, and so any set of  $n$  points cannot be shattered. Thus, for all  $\varepsilon > 0$ ,  $n \leq (1 + \varepsilon) \log d$  for large enough  $d$ , so  $VC(\mathcal{P}_{\mathcal{B}\mathcal{W}}) \leq (1 + \varepsilon) \log d$ . ◀

We now establish the corresponding lower bound when the polynomials  $Q_1, \dots, Q_T$  span the space of polynomials of degree at most  $T - 1$ .

► **Theorem 6 (restated).** *Let  $Q_1, \dots, Q_T$  be polynomials in  $\delta$  of degree at most  $T - 1$  that span the space of polynomials in  $\delta$  of degree at most  $T - 1$ . Then  $VC(\mathcal{P}_{\mathcal{W}}), VC(\mathcal{B}\mathcal{P}\mathcal{W}) \geq \log(T - 1)$ .*

**Proof.** It suffices to establish the bound for  $\mathcal{P}_{\mathcal{W}}$ .

Consider the graph on  $\{0, 1\}^n$  where two vertices are connected by an edge if they differ in exactly one location. Fix a Hamiltonian path  $v_1, v_2, \dots, v_{2^n}$  in this graph (the existence of which is well known). Let  $b_{1,2}, \dots, b_{2^n-1,2^n}$  be the sequence where  $b_{i,i+1}$  is the index of the location at which  $v_i$  and  $v_{i+1}$  differ. Note that if  $n = \log(T - 1)$ , the graph has  $T - 1$  vertices, so each index in  $\{1, \dots, n\}$  can appear in the sequence  $(b_{i,i+1})$  at most  $T - 1$  times.

Now, let  $r_1 < r_2 < \dots < r_{2^n}$  be any points in  $(0, 1)$ . Define  $n$  polynomials  $P_1, \dots, P_n$  by  $P_k(\delta) = \prod_{b_{i,i+1}=k} (\delta - r_i)$ , so the roots of  $P_k$  are precisely the  $r_i$ 's that correspond to a flip in the entry at the  $k$ th position of a vertex in the path. Then,  $(\text{sgn}(P_1(\delta)), \dots, \text{sgn}(P_n(\delta)))$  realizes every element of  $\{0, 1\}^n$ .

Since  $Q_1, \dots, Q_T$  span the space of polynomials of degree at most  $T - 1$ , for each  $P_i$  we can find  $f_1^i, \dots, f_T^i$  such that

$$P_i(\delta) = Q_1(\delta)f_1^i + \dots + Q_T(\delta)f_T^i,$$

which gives us a collection of  $\log(T - 1)$  points that is shattered. Hence  $\log(T - 1) \leq VC(\mathcal{P}_{\mathcal{W}})$ . ◀

It is readily seen that  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  and  $\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}$  satisfy the conditions of Theorems 5 and 6 ( $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  is given by  $\mathcal{P}_{\mathcal{P}\mathcal{W}}$  with  $Q_t(\delta) = \delta^{t-1}$  and  $\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}$  is given by  $\mathcal{B}\mathcal{P}\mathcal{W}$  with  $Q_t(\delta) = \delta^{t-1}$ ). We give a quick argument verifying that  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$  does as well: For  $1 \leq t \leq T$ , let  $Q_t(\alpha) = \prod_{\ell \in \{1, \dots, T\} \setminus \{t\}} (1 + \ell\alpha)$  (these are the polynomials obtained by clearing denominators of the hyperbolic discount factors). We argue that  $\{Q_t(\alpha)\}_{t=1}^T$  are linearly independent over (and thus span) the vector space of polynomials in  $\alpha$  of degree at most  $T - 1$ . Indeed, if  $Q_1(\alpha)f_1 + \dots + Q_T(\alpha)f_T = 0$ , then we must have that  $f_1 = \dots = f_T = 0$  since at  $\alpha = \frac{-1}{t}$  we get  $Q_t(\alpha)f_t = 0$ . Hence,  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$  is simply  $\mathcal{P}_{\mathcal{P}\mathcal{W}}$  with  $Q_t(\alpha) = \prod_{\ell \in \{1, \dots, T\} \setminus \{t\}} (1 + \ell\alpha)$ .

► **Remark.** These bounds also hold in the scenario where the agent can report indifference in the data. More precisely, the condition for  $x \succsim y$  is now a strict inequality, and we have three possible labels for the pair  $(x, y)$ :  $+1$  indicates that  $x \succ y$ ,  $-1$  indicates that  $y \succ x$ , and  $0$  indicates that  $x \sim y$ . Then, using a Hamiltonian path on  $\{-1, 0, 1\}^n$ , we can construct polynomials  $P_1, \dots, P_n$  such that  $(\text{sgn}(P_1(\delta)), \dots, \text{sgn}(P_n(\delta)))$  realizes all elements of  $\{-1, 0, 1\}^n$  as  $\delta$  ranges from 0 to 1 (where  $\text{sgn}$  is the true sign function).

## 4.1 A Remark on Efficient Learnability

While PAC learnability is a positive result, it does not take into account the computational complexity of computing a hypothesis. Blumer et. al. [6] show that any learning rule that outputs a hypothesis consistent with the data seen yields with high probability a hypothesis that has very low error. However, if the problem of outputting a consistent hypothesis is computationally intractable, PAC learnability on its own is perhaps unsatisfying. In this section we note that the discounted utility models of intertemporal choice are *efficiently* learnable. This is due to an algorithm of Grigor'ev and Vorobjov [12] for solving a system of polynomial inequalities.

For notational convenience, it will be useful to write  $\mathcal{P} = \{\mathcal{P}^T\}_{T \geq 1}$ , for each of the models above, where  $\mathcal{P}^T$  is the collection of preference relations for a given  $T$ . Moreover, suppose acts are chosen from  $[-1, 1]^T$  instead of  $\mathbb{R}^T$ . It is clear that this does not change any of the analysis above.

Polynomial learnability, as defined by Blumer et. al. [6], stipulates that the learning rule be computable in  $\text{poly}(1/\varepsilon, 1/\delta, T)$ -time (where  $\varepsilon$  and  $\delta$  denote the error threshold and confidence threshold respectively). Polynomial learnability is equivalent to the task of outputting a hypothesis consistent with the given data set in polynomial time [6].

► **Definition 10.** A *randomized polynomial hypothesis finder (r-poly hy-fi)* for  $\mathcal{P}$  is a randomized polynomial time algorithm that takes as input a sample of a preference relation in  $\mathcal{P}$ , and for some  $\gamma > 0$ , with probability at least  $\gamma$  produces a hypothesis that is consistent with the sample.

► **Theorem 11.**  $\mathcal{P}$  is properly polynomially learnable if and only if there is an r-poly hy-fi for  $\mathcal{P}$  and  $VC(\mathcal{P}^T)$  grows only polynomially in  $T$ .

We have just shown that  $VC(\mathcal{P}^T) \sim \log(T - 1)$ . Using techniques involving algebraic geometry, Grigor'ev and Vorobjov [12] present an algorithm to solve a system of  $N$  polynomial inequalities with a  $\text{poly}(N, T)$  runtime. This serves as our r-poly hy-fi, and thus we obtain:

► **Theorem 12.**  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$ ,  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$ , and  $\mathcal{P}_{\mathcal{Q}\mathcal{H}\mathcal{D}}$  are all properly polynomially learnable.

## 5 Active Learning

In this section we study two models of active learning: *stream-based selective sampling* and learning via *membership queries*. We first define a distribution for which the disagreement coefficient of  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  is 2, showing that disagreement methods (specifically the CAL algorithm [9, 10, 13]) in the stream-based model can yield an exponential improvement over the sample complexity of PAC learning (thus proving Theorem 8).

We then consider learning via membership queries and show that in this setting even very naive algorithms outperform the disagreement methods in the stream-based model (that is, the analyst needs to ask fewer questions to the agent in order to learn his preference than the number of label requests he would need to make using disagreement methods).

### 5.1 Preliminaries

For notational convenience,  $\succsim_\delta$  will refer to the preference relation in  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  with discounting factor  $\delta$ .

Let  $\mu$  be a distribution on  $\mathbb{R}^T \times \mathbb{R}^T$ .  $\mu$  induces a metric on  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  by  $d(\succsim_\delta, \succsim_\gamma) = \mu(\succsim_\delta \triangle \succsim_\gamma)$ , and thus we can define the closed ball of radius  $R$  centered at  $\succsim_\delta$  by

$$B(\succsim_\delta, R) = \{\succsim_\gamma: d(\succsim_\delta, \succsim_\gamma) \leq R\}.$$

## 62:14 Learning Time Dependent Choice

For  $V \subseteq \mathcal{P}_{\mathcal{E}\mathcal{U}}$ , the disagreement region of  $V$ ,  $\text{Dis}(V)$  is defined by

$$\text{Dis}(V) = \{(x, y) \in \mathbb{R}^T \times \mathbb{R}^T : \exists \succsim_\delta, \succsim_\gamma \in V \text{ s.t. } (x, y) \in \succsim_\delta \Delta \succsim_\gamma\} = \bigcup_{\succsim_\delta, \succsim_\gamma \in V} (\succsim_\delta \Delta \succsim_\gamma)$$

Intuitively,  $\text{Dis}(V)$  is the collection of points  $(x, y)$  such that we can find two hypothesis relations in the current version space that rank  $x$  and  $y$  differently.

If  $\succsim_\delta$  is the target preference relation, the disagreement coefficient of  $\succsim_\delta$  with respect to  $\mu$  is the quantity

$$\theta = \sup_{R>0} \frac{\mu(\text{Dis}(B(\succsim_\delta, R)))}{R}$$

### 5.2 Disagreement based active learning

In this subsection, we define a distribution  $\mu$  on  $\mathbb{R}^T \times \mathbb{R}^T$  and show that the disagreement coefficient of  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  with respect to  $\mu$  is 2.

#### Choosing a measure

The main challenge here is that  $\theta$  depends on the underlying distribution over  $\mathbb{R}^T \times \mathbb{R}^T$ . Since preferences are polynomial inequalities, the disagreement coefficient seems to lend itself to a characterization involving polynomials and their roots, which is the motivation for our choice of distribution. For a general distribution  $\mu$  over  $\mathbb{R}^T \times \mathbb{R}^T$ , it is not clear how to compute the disagreement coefficient.

We show that  $\theta = 2$  for a suitably chosen distribution on  $\mathbb{R}^T \times \mathbb{R}^T$ , which is induced by the Lebesgue measure on  $(0, 1)^{T-1}$ . This allows us to work with a measure on sets of roots of polynomials that arise from the definition of the preference relations.

Let  $\mu^{**}$  be a measure on  $(0, 1)^{T-1}$ . We interchangeably represent elements of  $\mathbb{R}^T$  as polynomials  $P$  of degree at most  $T - 1$  or as  $T - 1$ -tuples of coefficients. Let  $\sim$  be the equivalence relation on  $\mathbb{R}^T$  defined by  $P \sim Q \iff P = cQ$  for some constant  $c$ , and let  $\mathbb{R}^T / \sim$  be the resulting quotient space. Let  $g : (0, 1)^{T-1} \rightarrow \mathbb{R}^T / \sim$  be the map taking a tuple of roots to the equivalence class of the polynomials with those roots, and let  $h : \mathbb{R}^T \times \mathbb{R}^T \rightarrow \mathbb{R}^T / \sim$  be the map  $h(x, y) = [x - y]$ .

We define the following measures  $\mu^*$  and  $\mu$  on  $g((0, 1)^{T-1})$  and  $h^{-1}(g((0, 1)^{T-1}))$  respectively.

- Define  $\mu^*$  on all sets  $S \subset g((0, 1)^{T-1})$  such that

$$\{(r_1(P), \dots, r_{T-1}(P)) \in (0, 1)^{T-1} : P \in S\}$$

(where  $r_1(P), \dots, r_{T-1}(P)$  denote the roots of  $P$ ) is  $\mu^{**}$ -measurable, for which we set

$$\mu^*(S) = \mu^{**}(\{(r_1(P), \dots, r_{T-1}(P)) \in (0, 1)^{T-1} : P \in S\}).$$

- Define  $\mu$  on all sets  $S \subset h^{-1}(g((0, 1)^{T-1}))$  such that

$$\{[z] \in g((0, 1)^{T-1}) : \exists(x, y) \in S \text{ s.t. } z \sim x - y\}$$

is  $\mu^*$ -measurable, for which we set

$$\mu(S) = \mu^*(\{[z] \in g((0, 1)^{T-1}) : \exists(x, y) \in S \text{ s.t. } z \sim x - y\}).$$

Intuitively,  $\mu^*$  is defined only on those polynomials that have all their roots in  $(0, 1)$ . When  $T = 2$ , this is a desirable property since the analyst is only presented with polynomials that have some disagreement in  $(0, 1)$ . He is not presented with meaningless polynomials that are, for example, always positive on  $(0, 1)$  (the analyst has nothing to learn from such polynomials since such a polynomial will be preferred to 0 for all  $\delta \in (0, 1)$ ). For  $T \geq 3$ , this is a more restrictive property since the analyst is only presented with polynomials that have all  $T - 1$  roots in  $(0, 1)$ .

Let  $\mu^{**}$  be the product Lebesgue measure on  $(0, 1)^{T-1}$ . Choosing  $\mu^{**}$  in this fashion allows us to neatly characterize  $B(\succsim_\delta, R)$ .

Let  $X_1, \dots, X_{T-1}$  be uniform i.i.d. random variables on  $(0, 1)$ , and let  $Y_{\delta, \gamma}$  be the random variable  $Y_{\delta, \gamma} = |\{i : X_i \text{ is between } \delta \text{ and } \gamma\}|$ . Let  $E_{\delta, \gamma}^{odd}$  denote the event that  $Y_{\delta, \gamma}$  is odd, let  $E_{\delta, \gamma}^k$  denote the event  $Y_{\delta, \gamma} = k$ , and let  $E_{\delta, \gamma}^{\geq k}$  denote the event  $Y_{\delta, \gamma} \geq k$ .

► **Lemma 13.**  $\succsim_\gamma \in B(\succsim_\delta, R)$  if and only if  $\mathbb{P}[E_{\delta, \gamma}^{odd}] \leq R$ .

**Proof.** Given  $(x, y) \in \mathbb{R}^T \times \mathbb{R}^T$ , let  $P_{x-y}(X) = \sum_{t=1}^T X^{t-1} \cdot (x_t - y_t)$ . Then,

$$\begin{aligned} \succsim_\gamma \in B(\succsim_\delta, R) & \\ \iff \mu(\{(x, y) \in h^{-1}(g((0, 1)^{T-1})) : \text{sgn}(P_{x-y}(\delta)) \neq \text{sgn}(P_{x-y}(\gamma))\}) & \leq R \\ \iff \mu^*(\{[P] \in g((0, 1)^{T-1}) : \text{sgn}(P(\delta)) \neq \text{sgn}(P(\gamma))\}) & \leq R \\ \iff \mu^{**}(\{(r_1, \dots, r_{T-1}) \in (0, 1)^{T-1} : \text{sgn}(\prod(\delta - r_i)) \neq \text{sgn}(\prod(\gamma - r_i))\}) & \leq R \end{aligned}$$

But  $\text{sgn}(\prod(\delta - r_i)) \neq \text{sgn}(\prod(\gamma - r_i))$  occurs exactly when an odd number of roots lie between  $\gamma$  and  $\delta$  (modulo a set of measure 0 since the probability that we have a root of multiplicity greater than 1 is 0). ◀

While it seems difficult to write down a general characterization of  $\mu$ , Propositions 14 and 15 give some basic observations regarding the  $\sigma$ -algebras on which  $\mu^*$  and  $\mu$  are defined. We defer their proofs (along with a description of  $\mu^*$  in the case  $T = 2$ ) to the appendix:

► **Proposition 14.** The  $\sigma$ -algebra on  $g((0, 1)^{T-1})$  is the Borel  $\sigma$ -algebra.

The  $\sigma$ -algebra induced on  $h^{-1}(g((0, 1)^{T-1}))$  does not appear to yield a clean characterization, but we can show the weaker statement that  $\mu$  is a Borel measure, i.e. it is defined on all open sets of  $h^{-1}(g((0, 1)^{T-1}))$ .

► **Proposition 15.**  $\mu$  is a Borel measure on  $h^{-1}(g((0, 1)^{T-1}))$ .

## Computing $\theta$

We now show  $\theta = 2$  for the distribution  $\mu$  as chosen above. We use the notation  $d = d_{\delta, \gamma} := |\delta - \gamma|$  to denote the distance between  $\delta$  and  $\gamma$ . Let  $\succsim_\delta$  be the target preference relation.

First, note that since  $Y_{\delta, \gamma}$  is distributed according to  $\text{Bin}(T-1, d)$ ,  $\mathbb{P}[E_{\delta, \gamma}^{odd}] = \frac{1 - (1-2d)^{T-1}}{2}$ <sup>9</sup>. We use this fact to derive an explicit description of the preference relations  $\succsim_\gamma$  contained in the ball  $B(\succsim_\delta, R)$  in terms of  $d$ . We break the analysis up into a few cases.

First, when  $R > \frac{1}{2}$ , we have  $\sup_{R > \frac{1}{2}} \frac{\mu(\text{Dis}(B(\succsim_\delta, R)))}{R} = 2$ . Let  $R \leq \frac{1}{2}$ . By Lemma 13,

$$\succsim_\gamma \in B(\succsim_\delta, R) \iff \mathbb{P}[E_{\delta, \gamma}^{odd}] = \frac{1 - (1 - 2d)^{T-1}}{2} \leq R \quad (1)$$

<sup>9</sup> This is due to the general fact that if  $X$  is a random variable distributed according to  $\text{Bin}(n, p)$ , the probability that  $X$  is odd is  $\frac{1 - (1-2p)^n}{2}$ .

## 62:16 Learning Time Dependent Choice

Suppose  $d \leq \frac{1}{2}$ . Then  $1 - 2d$  and  $1 - 2R$  are both non-negative, so rearranging Equation (1) yields

$$d \leq \frac{1 - (1 - 2R)^{1/(T-1)}}{2}. \quad (2)$$

Suppose  $d > \frac{1}{2}$ , so  $1 - 2d < 0$ . Rearranging Equation (1), we get  $1 - 2R \leq (1 - 2d)^{T-1}$ . If  $T - 1$  is odd,  $(1 - 2d)^{T-1}$  is negative, so  $1 - 2R \leq (1 - 2d)^{T-1}$  does not hold. Thus, when  $T - 1$  is odd the ball consists of  $\zeta_\gamma$  such that  $d$  satisfies condition (2). If  $T - 1$  is even,  $(1 - 2d)^{T-1}$  is positive, so we get

$$d \geq \frac{1 + (1 - 2R)^{1/(T-1)}}{2}. \quad (3)$$

Thus, when  $T - 1$  is even the ball consists of  $\zeta_\gamma$  such that  $d$  satisfies conditions (2) or (3).

Now, the disagreement region of  $B(\zeta_\delta, R)$  consists of all points  $(x, y)$  such that the polynomial  $P_{x-y}$  (as defined in Lemma 13) has a root  $\gamma$  such that  $\zeta_\gamma \in B(\zeta_\delta, R)$  (since we can find two hypotheses that disagree on  $(x, y)$  by taking a point slightly below  $\gamma$  and a point slightly above  $\gamma$  such that  $P_{x-y}$  has no sign changes in between). Hence, with  $R_1 = \frac{1 - (1 - 2R)^{1/(T-1)}}{2}$  and  $R_2 = \frac{1 + (1 - 2R)^{1/(T-1)}}{2}$ , we have that

$$\mu(\text{Dis}(B(\zeta_\delta, R))) = \begin{cases} \mathbb{P}[E_{\delta-R_1, \delta+R_1}^{\geq 1}] & \text{if } T - 1 \text{ is odd} \\ \mathbb{P}[E_{\delta-R_1, \delta+R_1}^{\geq 1} \cup E_{0, \delta-R_2}^{\geq 1} \cup E_{\delta+R_2, 1}^{\geq 1}] & \text{if } T - 1 \text{ is even} \end{cases}$$

We have

$$\mathbb{P}[E_{\delta-R_1, \delta+R_1}^{\geq 1}] = 1 - (1 - 2R_1)^{T-1} = 2R,$$

and

$$\mathbb{P}[E_{\delta-R_1, \delta+R_1}^{\geq 1} \cup E_{0, \delta-R_2}^{\geq 1} \cup E_{\delta+R_2, 1}^{\geq 1}] = 1 - (2(R_2 - R_1))^{T-1} = 1 - 2^{T-1}(1 - 2R).$$

Therefore, when  $T - 1$  is odd  $\sup_{0 < R \leq 1/2} \frac{\mu(\text{Dis}(B(\zeta_\delta, R)))}{R} = 2$  and when  $T - 1$  is even

$$\sup_{0 < R \leq 1/2} \frac{\mu(\text{Dis}(B(\zeta_\delta, R)))}{R} = \sup_{0 < R \leq 1/2} \frac{1 - 2^{T-1}(1 - 2R)}{R} = 2,$$

which is achieved at  $R = 1/2$  since  $\frac{1 - 2^{T-1}(1 - 2R)}{R}$  is increasing on  $0 < R \leq \frac{1}{2}$ .

Finally,  $\theta = \sup_{R > 0} \frac{\mu(\text{Dis}(B(\zeta_\delta, R)))}{R} = 2$ .

We have thus established Theorem 8:

► **Theorem 8 (restated).** *There exists a distribution  $\mu$  on  $\mathbb{R}^T \times \mathbb{R}^T$  for which the disagreement coefficient of  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  is  $\theta = 2$ . Thus, for this distribution,*

$$\ell_{CAL}(\varepsilon) = \tilde{O}\left(\log T \log \frac{1}{\varepsilon}\right),$$

where the  $\tilde{O}$  notation suppresses terms that are logarithmic in  $\log T$  and  $\log 1/\varepsilon$ .

### 5.3 Learning via membership queries

In this subsection, we present a simple membership queries algorithm that outperforms the guarantees provided by the disagreement based CAL algorithm. For simplicity, we restrict attention to preference models that are parametrized by a single parameter (e.g.  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  and  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$ ).

Let  $g_1, \dots, g_T : \mathbb{R} \rightarrow \mathbb{R}$  be a collection of functions such that there exist  $1 \leq t_1, t_2 \leq T$  satisfying

1.  $M := \sup_{\delta} \frac{g_{t_1}(\delta)}{g_{t_2}(\delta)}$  is finite, and
2. The map  $\delta \mapsto \frac{g_{t_1}(\delta)}{g_{t_2}(\delta)}$  satisfies an inverse Lipschitz condition with constant  $C$  :

$$|\delta - \delta'| \leq C \left| \frac{g_{t_1}(\delta)}{g_{t_2}(\delta)} - \frac{g_{t_1}(\delta')}{g_{t_2}(\delta')} \right|.$$

Consider the model of preference relations  $\mathcal{P}$  parametrized by  $\delta$  such that

$$x \succsim y \text{ if and only if } \sum_{t=1}^T g_t(\delta)x_t \geq \sum_{t=1}^T g_t(\delta)y_t.$$

► **Proposition 9 (restated).** *There exists an algorithm that takes as input  $\varepsilon > 0$  and using  $O(\log \frac{MC}{\varepsilon})$  membership queries outputs  $\delta^h$  such that  $|\delta - \delta^h| \leq \varepsilon$ , where  $\delta$  parametrizes the target preference relation in  $\mathcal{P}$ .*

**Proof.** Fix a  $\rho > 0$  and an  $\eta$ -cover of  $[0, M\rho]$ , where  $0 < \eta \leq \frac{\rho\varepsilon}{C}$ . Let  $b_\rho$  be the quantity such that the agent is indifferent between receiving a payoff of  $\rho$  at time  $t_1$  or receiving a payoff of  $b_\rho$  at time  $t_2$ , i.e.  $b_\rho$  solves

$$g_{t_2}(\delta)b_\rho = g_{t_1}(\delta)\rho.$$

By running a binary search over the  $\eta$ -cover of  $[0, M\rho]$ , the analyst can find an approximation  $b_\rho^h$  to the indifference point for which  $|b_\rho - b_\rho^h| \leq \eta$  (the binary search is performed on the parameter  $b_\rho^h$  by requesting labels for pairs of the form  $(\rho e_{t_1}, b_\rho^h e_{t_2})$ ). The analyst then outputs the  $\delta^h$  that solves  $g_{t_2}(\delta^h)b_\rho^h = g_{t_1}(\delta^h)\rho$ .

We have

$$|\delta - \delta^h| \leq C \left| \frac{g_{t_1}(\delta)}{g_{t_2}(\delta)} - \frac{g_{t_1}(\delta^h)}{g_{t_2}(\delta^h)} \right| = C \left| \frac{b_\rho}{\rho} - \frac{b_\rho^h}{\rho} \right| \leq \frac{C\eta}{\rho} \leq \varepsilon,$$

as desired.

Since  $M := \sup_{\delta} \frac{g_{t_1}(\delta)}{g_{t_2}(\delta)}$  is finite,  $b_\rho \leq M\rho$ , so the binary search over the  $\eta$ -cover of  $[0, M\rho]$  terminates. ◀

► **Remark.** Outputting a hypothesis parameter  $\delta^h$  that is  $\varepsilon$ -close to  $\delta$  is a reasonable measurement for the error of learning via membership queries since there is no underlying distribution providing points to the analyst. However, note that for a distribution on  $\mathbb{R}^T \times \mathbb{R}^T$ , a hypothesis close to the target parameter implies the set of misclassified points is assigned a small measure, due to continuity of measure.

The main feature of this algorithm is that its query complexity has no dependence on the number of time periods  $T$ . Both  $\mathcal{P}_{\mathcal{E}\mathcal{D}}$  and  $\mathcal{P}_{\mathcal{H}\mathcal{D}}$  fit the conditions of Proposition 9, and thus we obtain a large improvement over the guarantees provided by disagreement methods in the stream-based model. Such methods assume no extra knowledge about the problem domain and are written to fit a wide class of learning problems. When we are learning economic parameters, membership queries allow us to take advantage of the extra structure present in preference models.

### A Properties of $\mu$ and $\mu^*$

**Proof of Proposition 14.** Let  $\mathcal{B}$  denote the Borel  $\sigma$ -algebra on  $(0, 1)^{T-1}$ .

Let  $X = \mathbb{R}^T / \sim$  endowed with the quotient topology, and  $g^* : [0, 1]^{T-1} \rightarrow X$  be the map  $g^*(r_1, \dots, r_{T-1}) = [\prod (x - r_i)]$ . Explicitly, the terms of  $g^*(r_1, \dots, r_{T-1})$  are given by symmetric sums:

$$g^*(r_1, \dots, r_{T-1}) = \left( c, -c \sum_i r_i, c \sum_{i,j} r_i r_j, \dots, (-1)^{T-1} c r_1 \cdots r_{T-1} \right),$$

where  $c$  is the appropriate constant for the representative of the equivalence class. Each symmetric sum is a continuous function of  $T - 1$  variables, so  $g^*$  is continuous. Moreover, note that  $g^*$  is injective. Then, with  $Y = g^*([0, 1]^{T-1})$ , we have that  $g^* : [0, 1]^{T-1} \rightarrow Y$  is a continuous bijection from a compact set into a Hausdorff space. Hence,  $g^*$  is a homeomorphism. Then  $g$ , which is the restriction of  $g^*$  to  $(0, 1)^{T-1}$  is a homeomorphism onto  $Z := g((0, 1)^{T-1})$ . Thus, the  $\sigma$ -algebra  $g(\mathcal{B})$  that we obtain on  $Z$  is the Borel  $\sigma$ -algebra.  $\blacktriangleleft$

When  $T = 2$ , we can give an explicit description of  $\mu^*$ . Identify  $\mathbb{R}^2 / \sim$  with the unit circle. Then, a degree 1 polynomial  $P$  is identified with the point  $(\cos \theta, \sin \theta)$ , where  $P(x) = (\cos \theta)x + \sin \theta$ .  $Z := g((0, 1)^{T-1})$  consists of the boundary of the unit circle for which the argument  $\theta$  satisfies  $-\tan \theta \in (0, 1)$ . This is satisfied precisely for  $\theta \in (3\pi/4, \pi) \cup (7\pi/4, 2\pi)$ . Hence, if  $U$  is a basic open subset of  $\{(\cos \theta, \sin \theta) : \theta \in (3\pi/4, \pi) \cup (7\pi/4, 2\pi)\}$ , we can write  $U = \{(\cos \theta, \sin \theta) : \theta_1 < \theta < \theta_2\}$  with  $\theta_1, \theta_2$  both in the same segment of the unit circle and

$$\mu^*(U) = \mu^{**}(\{-\tan \theta : \theta_1 < \theta < \theta_2\}) = |\tan \theta_1 - \tan \theta_2|.$$

**Proof of Proposition 15.** Let  $h : \mathbb{R}^T \times \mathbb{R}^T \rightarrow \mathbb{R}^T / \sim$  be the map  $h(x, y) = [x - y]$ . Let  $V \subseteq h^{-1}(g((0, 1)^{T-1}))$  be open. We show that

$$h(V) = \{[z] : \exists (x, y) \in V (z = x - y)\}$$

is open. Indeed, let  $z = x - y$  for  $(x, y) \in V$  and choose  $\varepsilon$  small enough such that the square with vertices  $\{(x + \varepsilon, y + \varepsilon), (x + \varepsilon, y - \varepsilon), (x - \varepsilon, y + \varepsilon), (x - \varepsilon, y - \varepsilon)\}$  is contained in  $V$ . Then, for any  $\lambda \leq \varepsilon$ ,  $[z + \lambda] = [(x + \lambda) - y]$  with  $(x + \lambda, y) \in V$  and  $[z - \lambda] = [x - (y + \lambda)]$  with  $(x, y + \lambda) \in V$ , so in particular the open ball with radius  $\lambda$  centered at  $[z]$  is contained in  $h(V)$ .  $\blacktriangleleft$

# Erasures vs. Errors in Local Decoding and Property Testing

## Abstract

---

We initiate the study of the role of erasures in local decoding and use our understanding to prove a separation between erasure-resilient and tolerant property testing. Local decoding in the presence of errors has been extensively studied, but has not been considered explicitly in the presence of erasures.

Motivated by applications in property testing, we begin our investigation with local *list* decoding in the presence of erasures. We prove an analog of a famous result of Goldreich and Levin on local list decodability of the Hadamard code. Specifically, we show that the Hadamard code is locally list decodable in the presence of a constant fraction of erasures, arbitrary close to 1, with list sizes and query complexity better than in the Goldreich-Levin theorem. We use this result to exhibit a property which is testable with a number of queries independent of the length of the input in the presence of erasures, but requires a number of queries that depends on the input length,  $n$ , for tolerant testing. We further study *approximate* locally list decodable codes that work against erasures and use them to strengthen our separation by constructing a property which is testable with a constant number of queries in the presence of erasures, but requires  $n^{\Omega(1)}$  queries for tolerant testing.

Next, we study the general relationship between local decoding in the presence of errors and in the presence of erasures. We observe that every locally (uniquely or list) decodable code that works in the presence of errors also works in the presence of twice as many erasures (with the same parameters up to constant factors). We show that there is also an implication in the other direction for locally decodable codes (with unique decoding): specifically, that the existence of a locally decodable code that works in the presence of erasures implies the existence of a locally decodable code that works in the presence of errors and has related parameters. However, it remains open whether there is an implication in the other direction for locally *list* decodable codes<sup>1</sup>. We relate this question to other open questions in local decoding.

## 1 Introduction

The contributions of this work are two-fold: on one hand, we initiate the investigation of erasures in local decoding; on the other hand, we apply our understanding of local list decoding to study the relative difficulty with which sublinear algorithms can cope with erasures and errors in their inputs.

Intuitively, a family of codes is *locally decodable* in the presence of a specified type of corruptions (erasures or errors) if there exists an algorithm that, given oracle access to a codeword with a limited fraction of specified corruptions, can decode each desired character of the encoded message with high probability after querying a small number of characters in the corrupted codeword. In other words, we can simulate oracle access to the message by using oracle access to a corrupted codeword. This notion can be extended to local *list* decoding by requiring the algorithm to output a list of descriptions of local decoders. Intuitively, a family of codes is *locally list decodable* in the presence of a specified type of corruptions if there exists an algorithm that, given oracle access to a corrupted codeword  $w$ , outputs a list of algorithms such that for each message  $x$  whose encoding sufficiently agrees with  $w$ , there is an algorithm in the list that, given oracle access to  $w$ , can simulate oracle access to  $x$ . In addition to the usual quantities studied in the literature on error-correcting codes (such as the fraction of corruptions a code can handle, its rate and efficiency of decoding), the important parameters in local decoding are the number of queries that the algorithms make to  $w$  and, in the case of local list decoding, list size.

The notion of locally decodable codes (LDCs) arose in the 1990s, motivated by numerous applications in complexity theory, such as program checking, probabilistically checkable proofs, derandomization, and private information retrieval. Locally decodable codes that work in the presence of errors have been extensively studied [2, 9, 16, 17, 35, 3, 40, 14, 13, 5]. The related notion of locally list decodable codes (LLDCs) has also received a lot of attention [19, 38, 27, 5, 31, 29, 22, 20] and found applications in cryptography, learning theory, average-to-worst-case reductions, and hardness amplification and derandomization. The literature on decoding in the presence of erasures is too vast to survey here. *List* decoding in the presence of erasures (without the locality restriction) has been addressed by Guruswami [23] and Guruswami and Indyk [24]. In particular, Guruswami [23] constructed an asymptotically good family of binary linear codes that can be list decoded from an arbitrary fraction of erasures with lists of constant size. Even though decoding in the presence of erasures is an important and well established problem, to the best of our knowledge, local (unique and list) decoding from erasures has not been studied before.

Motivated by applications in property testing [18, 37], we begin our investigation of effects of erasures with local *list* decoding. Our first result is a local list *erasure-decoder* for the Hadamard code. Local list decodability of the Hadamard code in the presence of errors is a famous result of Goldreich and Levin [19]. However, (local list) decoding of the Hadamard code is impossible when the fraction of errors reaches or exceeds  $1/2$ . In contrast, we show that the Hadamard code is locally list decodable in the presence of any constant fraction of erasures in  $[0, 1)$ . Moreover, the list size and the query complexity for our decoder is better than for the Goldreich-Levin decoder: for our decoder, both quantities are inversely proportional to the fraction of input that has not been corrupted, whereas for the Goldreich-Levin decoder they are quadratically larger and are known to be optimal for that setting. Thus, our Hadamard decoder demonstrates that a square-root reduction in the list size and query complexity in local list decoding can be achieved for some settings of parameters when we move from errors to erasures.

The second thrust of our work, enabled by our local list decoding results, is investigating the effects of adversarial corruption to inputs on the complexity of sublinear-time algorithms. Understanding the relative difficulty of designing algorithms that work in the presence of input errors and in the presence of input erasures is a problem of fundamental importance. The motivation of investigating adversarial input corruption spurred the generalization of property testing, one of the most widely studied models of sublinear-time algorithms, to (error) tolerant testing [34] and erasure-resilient testing [12].

Erasure-resilient property testing falls between (standard) property testing and tolerant testing. Specifically, an erasure-resilient tester for a property, in the special case when no erasures occur, is a standard tester for this property. Also, a tolerant tester for a property implies the existence of an erasure-resilient tester with comparable parameters for the same property. Fischer and Fortnow [15] separated standard and tolerant testing by describing a property that is *easy* to test in the standard model and *hard* to test tolerantly. Dixit et al. [12] showed that the property defined by Fischer and Fortnow separates standard property testing from erasure-resilient testing in the same sense. Dixit et al. [12] asked whether it is possible to obtain a separation between erasure-resilient and tolerant testing.

In this work, we provide such a separation. Specifically, we describe a property of binary strings that is easy to test in the erasure-resilient model, but hard to test tolerantly.

The key idea in our construction of the separating property is to encode *sensitive regions* of strings (without which testing becomes hard) with an error correcting code. We need a code that exhibits a difference in its local list decoding capabilities for the same fraction of erasures and errors. Specifically, we want, for some constant  $\alpha, q$  and  $L$ , a code that can be decoded from an  $\alpha$  fraction of erasures with  $q$  queries and lists of size  $L$ , but cannot be decoded from an  $\alpha$  fraction of errors. We first define a property where the sensitive regions are encoded with the Hadamard code and show that it is testable in the erasure-resilient model (with a constant number of queries), but is not testable tolerantly.

Next, we want to strengthen the separation to obtain a property that is testable with erasures, but requires as many queries as possible to test tolerantly. In our construction, the lower bound on the number of queries needed for tolerant testing is determined by the rate of the code. Since the Hadamard code has low rate, we only get a polylogarithmic lower bound on the query complexity of tolerant testing. To obtain a lower bound of  $n^{\Omega(1)}$ , we would need a code of polynomial rate. The question of whether there is a locally list erasure decodable code (with constant  $\alpha, q$  and  $L$ ) of polynomial rate remains open. An LLDC with such parameters is the holy grail of research on local decoding.

We circumvent the above difficulty by starting out with a property of binary strings that has a tester whose queries to a sensitive region of the input are *nearly uniformly* distributed. This implies that testing remains easy even if a constant fraction of the sensitive region is

corrupted. We construct a new separating property by encoding the sensitive region using a code that is *approximate locally list decodable* from erasures, where an approximate locally list decodable code (ALLDC) is defined identically to an LLDC except that the algorithms output by a decoder for such a code simulate oracle access to strings that are close to the original messages. We show that the resulting property can be erasure-resiliently tested using a constant number of queries but needs  $n^{\Omega(1)}$  queries in order to be tested tolerantly, thus obtaining a strengthened separation.

Next, we study the general relationship between local decoding in the presence of errors and in the presence of erasures. One can observe that every LLDC that works in the presence of errors also works in the presence of twice as many erasures (with the same parameters up to constant factors). We ask if LLDCs or ALLDCs that work in the presence of erasures can have significantly smaller list sizes and query complexity than LLDCs or ALLDCs of the same rate that work in the presence of errors. We also prove that such a statement cannot hold for the case of local unique decoding: specifically, we show that if a code is locally unique erasure-decodable, then there exists another comparable code that is locally unique decodable (up to minor losses in parameters).

## 1.1 Model Definitions and Our Results

This section contains descriptions and definitions of the codes and property testing models we study, and also statements and discussion of our main results.

### Local List Erasure-Decoding and the Hadamard Code

In this paper, we restrict our attention to binary codes. A binary code is an infinite family of maps  $\{C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N\}_{n \in \mathbb{N}}$ . The parameter  $n$  is called the message length,  $N$  is the block length, and  $n/N$  is the rate of the code. Corruptions in codewords can either be in the form of erasures (missing entries, denoted by the symbol  $\perp$ ) or in the form of errors (wrong values from  $\mathbb{F}_2$ ).

Recall that a local list decoder outputs a list of algorithms which give oracle access to decoded messages or, in other words *implicitly compute* the decoded messages. This, and the notion of local list erasure-decoders are formalized in the following definitions.

► **Definition 1.1** (Implicit Computation). An algorithm  $A$  is said to implicitly compute  $x \in \mathbb{F}_2^n$  if, for all  $i \in [n]$ , the algorithm  $A$  on input  $i$ , outputs the  $i^{\text{th}}$  bit of  $x$ .

► **Definition 1.2** (Locally List Erasure-Decodable Codes (LLEDs)). A family of codes  $\{C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N\}_{n \in \mathbb{N}}$  is  $(\alpha, q, L)$ -*locally list erasure-decodable* if there exists a randomized algorithm  $A$  such that, for every  $n \in \mathbb{N}$  and every  $w \in (\mathbb{F}_2 \cup \{\perp\})^N$  with at most an  $\alpha$  fraction of erasures, the algorithm  $A$  makes at most  $q$  queries to  $w$  and outputs a list of randomized algorithms  $\{T_1, T_2, \dots, T_L\}$  such that the following hold:

1. With probability at least  $2/3$ , for all  $x \in \mathbb{F}_2^n$  such that  $C_n(x)$  agrees with  $w$  on all nonerased bits, there exists an index  $j \in [L]$  such that  $T_j$  with oracle access to  $w$  implicitly computes  $x$ .
2. For all  $j \in [L]$  and  $i \in [n]$ , the expected number of queries that the algorithm  $T_j$  makes to  $w$  on input  $i$  is at most  $q$ .

The definition of an  $(\alpha, q, L)$ -LLDC is identical to Definition 1.2 except that the input word has no erasures, and the list is required to contain, with probability at least  $2/3$ , algorithms that implicitly compute messages corresponding to codewords disagreeing with the input word on at most an  $\alpha$  fraction of bits. The celebrated Goldreich-Levin theorem [19] states that the Hadamard code, defined next, is an LLDC that has an efficient decoder.

► **Definition 1.3** (Hadamard code). For  $a \in \mathbb{F}_2^n$ , let  $H_a : \mathbb{F}_2^n \rightarrow \mathbb{F}_2$  be defined as follows:  $H_a(x) = \bigoplus_{i \in [n]} a_i \cdot x_i$  for all  $x \in \mathbb{F}_2^n$ . The Hadamard code, denoted by  $\{\mathcal{H}_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^{2^n}\}_{n \in \mathbb{N}}$ , is such that for  $a \in \mathbb{F}_2^n$ , the encoding  $\mathcal{H}_n(a)$  is the string of evaluations of  $H_a$  over  $\mathbb{F}_2^n$ .

Our first result is about the local list erasure-decodability of the Hadamard code. It is an analogue of the Golreich-Levin Theorem [19] for corruptions in the form of erasures.

► **Theorem 1.4** (Local List Erasure-Decoder for Hadamard). *There is an  $(\alpha, \Theta(\frac{1}{1-\alpha}), \Theta(\frac{1}{1-\alpha}))$ -local list erasure-decoder for the Hadamard code that works for every  $\alpha \in [0, 1)$ .*

The Goldreich-Levin theorem holds for any fraction of errors in  $[0, 1/2)$ . In contrast, our local list erasure-decoder works for any fraction of erasures less than 1. However, it is impossible to decode the Hadamard code in the presence of  $1/2$  fraction of errors because every Hadamard codeword has relative distance at most  $1/2$  from the all-zero codeword. Another improvement in Theorem 1.4 as compared to Golreich-Levin is in the list size and the query complexity: from  $\Theta(\frac{1}{(1/2-\alpha)^2})$  to  $\Theta(\frac{1}{1-\alpha})$ . Such an improvement is impossible if we are decoding against errors as opposed to erasures. Specifically, for the list size, Blinovskiy [8] and Guruswami and Vadhan [26] show that every list decoder for every binary code that is list decodable in the presence of an  $\alpha$  fraction of errors must output lists of size  $\Omega(\frac{1}{(1/2-\alpha)^2})$ . Grinberg, Shaltiel, and Viola [21] show that the same lower bound holds for query complexity.

### Separation between Erasure-Resilient and Tolerant Testing

We first describe the erasure-resilient and tolerant models of testing. A *property*  $\mathcal{P}$  is a set of strings. Given  $\alpha \in [0, 1)$ , a string is  $\alpha$ -erased if at most an  $\alpha$  fraction of its values are erasures (denoted by  $\perp$ ). A *completion* of an  $\alpha$ -erased string  $x \in \{0, 1, \perp\}^n$  is a string  $y \in \{0, 1\}^n$  that agrees with  $x$  on all the positions where  $x$  is nonerased. An  $\alpha$ -erasure-resilient  $\varepsilon$ -tester [12] for a property  $\mathcal{P}$  is a randomized algorithm that, given parameters  $\alpha \in [0, 1), \varepsilon \in (0, 1)$  and oracle access to an  $\alpha$ -erased string  $x$ , accepts with probability at least  $2/3$  if  $x$  has a completion in  $\mathcal{P}$  and rejects with probability at least  $2/3$  if, in every completion of  $x$ , at least an  $\varepsilon$  fraction of the nonerased values has to be changed to get a string in  $\mathcal{P}$ . The property  $\mathcal{P}$  is  $\alpha$ -erasure-resiliently  $\varepsilon$ -testable if there exists an  $\alpha$ -erasure-resilient  $\varepsilon$ -tester for  $\mathcal{P}$  with query complexity that depends only on the parameters  $\alpha$  and  $\varepsilon$  (but not on  $n$ ).

A string  $x \in \{0, 1\}^n$  is  $\varepsilon'$ -far ( $\alpha$ -close) from (to, respectively) a property  $\mathcal{P}$ , if the normalized Hamming distance of  $x$  from  $\mathcal{P}$  is at least  $\varepsilon'$  (at most  $\alpha$ , respectively). An  $(\alpha, \varepsilon')$ -tolerant tester [34] for  $\mathcal{P}$  is a randomized algorithm that, given parameters  $\alpha \in (0, 1), \varepsilon' \in (\alpha, 1)$  and oracle access to a string  $x$ , accepts with probability at least  $\frac{2}{3}$  if  $x$  is  $\alpha$ -close to  $\mathcal{P}$  and rejects with probability at least  $\frac{2}{3}$  if  $x$  is  $\varepsilon'$ -far from  $\mathcal{P}$ . The property  $\mathcal{P}$  is  $(\alpha, \varepsilon')$ -tolerantly testable if there exists an  $(\alpha, \varepsilon')$ -tolerant tester for  $\mathcal{P}$  with query complexity that depends only on  $\alpha$  and  $\varepsilon'$  (but not  $n$ ).

**Comparison of parameters.** We remark that, while comparing the two models, it is appropriate to compare  $(\alpha, \alpha + \varepsilon(1 - \alpha))$ -tolerant testing of a property  $\mathcal{P}$  with  $\alpha$ -erasure-resilient  $\varepsilon$ -testing of  $\mathcal{P}$  for the same values of  $\alpha$  and  $\varepsilon$ . The parameter  $\alpha$  in both models is an upper bound on the fraction of corruptions (erasures, or errors) that an adversary can make to an input. An  $\alpha$ -erasure-resilient  $\varepsilon$ -tester rejects with probability at least  $\frac{2}{3}$  if, for every way of completing an input string, one needs to change at least an  $\varepsilon$  fraction of the remaining part of the input to make it satisfy  $\mathcal{P}$ . Similarly, an  $(\alpha, \alpha + \varepsilon(1 - \alpha))$ -tolerant tester rejects with probability at least  $\frac{2}{3}$  if, for every way of *correcting* an  $\alpha$  fraction of the input values, one needs to change at least an  $\varepsilon$  fraction of the remaining  $(1 - \alpha)$  fraction of the input to make it satisfy  $\mathcal{P}$ .

**Separation.** The following theorem states that there exists a property that is erasure-resiliently testable but is not tolerantly testable. This proves that tolerant testing is, in general, harder problem than erasure-resilient testing.

- **Theorem 1.5 (Separation).** *There exist a property  $\mathcal{P}$  and constants  $\varepsilon, \alpha \in (0, 1)$  such that*
- $\mathcal{P}$  is  $\alpha$ -erasure-resiliently  $\varepsilon$ -testable;
  - $\mathcal{P}$  is not  $(\alpha, \alpha + \varepsilon(1 - \alpha))$ -tolerantly testable.

**Approximate Local List Erasure-Decoding and Strengthened Separation.** We obtain a separation better than in Theorem 1.5 with the help of a variant of LLEDCs, called approximate locally list erasure-decodable codes (ALLEDC). An approximate local list erasure-decoder is identical to a local list erasure-decoder in all aspects except that the algorithms in its list are required to implicitly compute strings that are just “close” to the actual messages. More formally,  $(\alpha, \beta, q, L)$ -ALLEDCs are defined as  $(\alpha, q, L)$ -LLEDCs in Definition 1.2, except that we replace “implicitly computes  $x$ ” at the end of Item 1 with “implicitly computes a string  $x' \in \mathbb{F}_2^n$  that is  $\beta$ -close to  $x$ ”.

The definition of an  $(\alpha, \beta, q, L)$ -approximate locally list decodable code (ALLDC) is identical to that of an  $(\alpha, \beta, q, L)$ -ALLEDC except that the input word has no erasures, and the list is required to contain, with probability at least  $2/3$ , algorithms that implicitly compute strings that are  $\beta$ -close to messages corresponding to codewords which are  $\alpha$ -close to the input word. We observe (Observation 4.2) that every  $(\alpha, \beta, q, L)$ -ALLDC is also a  $(2\alpha, \beta, 4q, 4L)$ -ALLEDC, and combine this observation with existing constructions for ALLDCs [28, 4] to obtain efficient ALLEDCs. We use them and get our strengthened separation.

- **Theorem 1.6 (Strengthened Separation).** *There exist a property  $\mathcal{P}'$  and constants  $\varepsilon, \alpha \in (0, 1)$  such that*
- $\mathcal{P}'$  is  $\alpha$ -erasure-resiliently  $\varepsilon$ -testable;
  - every  $(\alpha, \alpha + \varepsilon(1 - \alpha))$ -tolerant tester for  $\mathcal{P}'$  makes  $n^{\Omega(1)}$  queries.

### Relationship between Local Erasure-Decoding and Local Decoding.

We investigate the general relationship between the erasures and errors in the context of local unique and list decoding. We show that local (unique) decoding from erasures implies local (unique) decoding from errors, up to some loss in parameters.

► **Definition 1.7 (Locally Erasure-Decodable Codes (LEDCs)).** A code family  $\{C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N\}_{n \in \mathbb{N}}$  is  $(\alpha, q)$ -locally erasure-decodable if there exists an algorithm  $A$  that, given an index  $i \in [n]$  and oracle access to an input word  $w \in (\{\perp\} \cup \mathbb{F}_2)^N$  with at most  $\alpha$  fraction of erasures, makes at most  $q$  queries to  $w$  and outputs  $x_i$  with probability at least  $\frac{2}{3}$ .

An  $(\alpha, q)$ -locally decodable code (LDC) is defined similarly to an  $(\alpha, q)$ -LEDC except that the input word  $w$  contains at most  $\alpha$  fraction of errors instead of erasures. We observe (Observation 6.4) that an LDC is also locally erasure-decodable from (nearly) twice as many erasures. We also show that constant-query LEDCs are constant-query locally decodable (up to constant loss in parameters).

► **Theorem 1.8.** *For every  $\alpha \in [0, 1)$ , if a code family  $\{C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N\}_{n \in \mathbb{N}}$  is  $(\alpha, q)$ -locally erasure-decodable, then it is  $(\frac{\alpha}{O(q^2 \cdot 81^q)}, O(q \cdot 9^q))$  locally decodable.*

We note that although our final code has small decoding radius (that is, it tolerates only a small fraction of errors), the decoding radius can be amplified to any constant arbitrarily close to  $1/4$  at the cost of increasing the query complexity and encoding length by a constant factor. Specifically, using a local version of the AEL transformation [1] (see [30, Lemma 3.1]), one can amplify the decoding radius to any constant arbitrarily close to  $1/2$  at the cost of increasing the query complexity, alphabet size, and length by constant factors. The alphabet then can be reduced back to binary by encoding the binary representation of each alphabet symbol with the Hadamard code. The length will grow by another constant factor, and using a local version of the GMD decoder [30, Corollary 3.9], one can show that final decoding radius is arbitrarily close to  $1/4$  and query complexity grows only by a constant factor.

## 1.2 Open Questions

The main open question raised by our work is whether local list decoding is significantly easier in terms of the query complexity, the list size, or the rate of codes when corruptions are in the form of erasures. The same question can be asked about approximate local list decoding. Our local list erasure-decoder for the Hadamard code shows that there is some advantage for having erasures over errors, in terms of the list size and query complexity, for some settings of parameters. A positive or negative answer to this question, combined with our result on the equivalence of errors and erasures in the local decoding regime, will enhance the understanding of whether local list decoding is an inherently more powerful model when compared to local decoding.

## 2 Local List Erasure-Decoding of the Hadamard Code

In this section, we describe a local list erasure-decoder for the Hadamard code and prove Theorem 1.4. We follow the style of the proof of the Goldreich-Levin theorem given in a tutorial by Luca Trevisan [39] on the applications of coding theory to complexity.

**Proof of Theorem 1.4.** For  $b_1, b_2 \in \mathbb{F}_2$ , let  $b_1 \oplus b_2$  denote the XOR of  $b_1$  and  $b_2$ . For vectors  $x, y \in \mathbb{F}_2^n$ , let  $x \odot y$  denote the bitwise XOR of  $x$  and  $y$ . Let  $e_k \in \mathbb{F}_2^n$  denote the  $k^{\text{th}}$  standard basis vector. A codeword of the Hadamard code  $\mathcal{H}_n$  (see Definition 1.3) is the string of all evaluations of a linear function mapping  $\mathbb{F}_2^n$  to  $\mathbb{F}_2$ . A function  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \cup \{\perp\}$  is  $\alpha$ -erased, if  $f$  evaluates to  $\perp$  on at most  $\alpha$  fraction of its domain. Our local list erasure-decoder, described in Algorithm 1, gets a parameter  $\alpha \in [0, 1)$  as its input and has oracle access to an  $\alpha$ -erased linear function  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \cup \{\perp\}$  (or, equivalently, oracle access to an  $\alpha$ -erased codeword of  $\mathcal{H}_n$ ).

Let  $t = \lceil \log_2(1 + \frac{12}{1-\alpha}) \rceil$ . Consider  $z_1, z_2, \dots, z_t \in \mathbb{F}_2^n$  sampled uniformly and independently at random. For a nonempty set  $S \subseteq [t]$ , let  $z_S$  denote  $\bigodot_{i \in S} z_i$ . Let  $z_\emptyset$  denote  $\vec{0}$ . For any two nonempty sets  $R, S \subseteq [t]$  such that  $R \neq S$ , the vectors  $z_R$  and  $z_S$  are independently and uniformly distributed in  $\mathbb{F}_2^n$ . Recall that for a string  $a \in \mathbb{F}_2^n$ , let  $H_a : \mathbb{F}_2^n \rightarrow \{0, 1\}$  denote the Hadamard encoding (see Definition 1.3) of  $a$ .

Let  $a \in \mathbb{F}_2^n$  be such that for all  $x \in \mathbb{F}_2^n$  where  $f(x) \neq \perp$ , the functions  $H_a$  and  $f$  agree with each other. There exists some iteration of Step 5 of Algorithm 1 such that  $b_i = H_a(z_i)$  for all  $i \in B$ . Let  $T$  and  $A$  denote the algorithms whose descriptions are generated in Steps 12 and 7 of this iteration respectively.

First, we show that for  $x$  distributed uniformly in  $\mathbb{F}_2^n$ , the algorithm  $A$  on input  $x$ , returns  $H_a(x)$  with probability at least  $\frac{2}{3}$ . Fix  $x \in \mathbb{F}_2^n$ . Consider a set  $S \subseteq [t]$  such that  $f(x \odot z_S) \neq \perp$ . According to the description of  $A$ , we get,  $A(x) = (\bigoplus_{j \in S \cap B} b_j) \oplus$

**Algorithm 1** Local List Erasure-Decoder for the Hadamard code.

---

**Input:**  $\alpha \in [0, 1)$ ; oracle access to  $\alpha$ -erased linear function  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \cup \{\perp\}$

- 1: Let  $t = \lceil \log_2(1 + \frac{12}{1-\alpha}) \rceil$ .
- 2: Choose  $z_1, z_2, \dots, z_t \in \mathbb{F}_2^n$  uniformly and independently at random.
- 3: Let  $z_S \leftarrow \bigodot_{i \in S} z_i$  for all nonempty  $S \subseteq [t]$ . Let  $z_\emptyset \leftarrow \vec{0}$ .
- 4: Set  $B \leftarrow \{i \in [t] : f(z_i) = \perp\}$ .
- 5: **for** all  $b_1, b_2, \dots, b_{|B|} \in \{0, 1\}$  **do** **define**
- 6: ▷ Description of the local decoder  $T_{b_1, \dots, b_{|B|}}$  follows.
- 7:     **function**  $A_{b_1, \dots, b_{|B|}}$
- 8:         **input:**  $x \in \mathbb{F}_2^n$ ; oracle access to  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \cup \{\perp\}$
- 9:         **for** all  $S \subseteq [t]$  **do**
- 10:             **if**  $f(x \odot z_S) \neq \perp$  **then return**  $(\bigoplus_{j \in S \cap B} b_j) \oplus (\bigoplus_{j \in S \cap ([t] \setminus B)} f(z_j)) \oplus f(x \odot z_S)$ .
- 11:         **Return**  $\perp$ .
- 12:     **function**  $T_{b_1, \dots, b_{|B|}}$
- 13:         **input:**  $k \in [n]$ ; oracle access to  $f : \mathbb{F}_2^n \rightarrow \mathbb{F}_2 \cup \{\perp\}$
- 14:         **repeat**
- 15:             Pick  $y \in \mathbb{F}_2^n$  uniformly and independently at random.
- 16:              $u \leftarrow A_{b_1, \dots, b_{|B|}}(y \odot e_k)$ ,  $v \leftarrow A_{b_1, \dots, b_{|B|}}(y)$ .
- 17:             **if**  $v \neq \perp$  and  $u \neq \perp$  **then return**  $u \oplus v$ .
- 18: **Return** the descriptions of  $T_{b_1, \dots, b_{|B|}}$  for all  $b_1, b_2, \dots, b_{|B|} \in \{0, 1\}$ .

---

$$\left(\bigoplus_{j \in S \cap ([t] \setminus B)} f(z_j)\right) \oplus f(x \odot z_S) = \left(\bigoplus_{j \in S \cap B} H_a(z_j)\right) \oplus \left(\bigoplus_{j \in S \cap ([t] \setminus B)} H_a(z_j)\right) \oplus H_a(x \odot z_S) = \left(\bigoplus_{j \in S} H_a(z_j)\right) \oplus H_a(x) = H_a(x).$$

Let  $\alpha^* \leq \alpha$  denote the fraction of erasures in  $f$ . For each  $S \subseteq [t]$  and  $x \in \mathbb{F}_2^n$ , we have that  $f(x \odot z_S) \neq \perp$  with probability equal to  $1 - \alpha^*$ , since  $x \odot z_S$  is uniformly distributed in  $\mathbb{F}_2^n$ . Define an indicator random variable  $Z_S = \mathbb{1}(f(x \odot z_S) \neq \perp)$ . Then  $\mathbb{E}[Z_S] = 1 - \alpha^*$  and  $\text{Var}(Z_S) = (1 - \alpha^*) \cdot \alpha^*$ . Note that the collection  $\{x \odot z_S | S \subseteq [t], S \neq \emptyset\}$  is pairwise independent, and hence the collection  $\{Z_S | S \subseteq [t], S \neq \emptyset\}$  is also pairwise independent.

Let  $Z = \sum_{S \subseteq [t], S \neq \emptyset} Z_S$ . The random variable  $Z$  denotes the number of nonerased values among  $f(x \odot z_S)$  over all nonempty  $S \subseteq [t]$ . The event that  $\forall S \subseteq [t], S \neq \emptyset, f(x \odot z_S) = \perp$  is equivalent to the event that  $Z < 1$ . Also,  $\mathbb{E}[Z] = \sum_{S \subseteq [t], S \neq \emptyset} \mathbb{E}[Z_S] = (1 - \alpha^*) \cdot (2^t - 1)$  and  $\text{Var}[Z] = \sum_{S \subseteq [t], S \neq \emptyset} \text{Var}[Z_S] = (2^t - 1) \cdot \alpha^*(1 - \alpha^*)$ . By Chebyshev's inequality,

$$\begin{aligned} \Pr[Z < 1] &= \Pr[\mathbb{E}[Z] - Z > \mathbb{E}[Z] - 1] \\ &\leq \Pr\left[\mathbb{E}[Z] - Z > \frac{(1 - \alpha^*) \cdot (2^t - 1)}{2}\right] \leq \frac{4\text{Var}(Z)}{(1 - \alpha^*)^2 \cdot (2^t - 1)^2} \leq \frac{1}{3}. \end{aligned}$$

The last inequality follows from our setting of  $t$ . Therefore, for  $x$  distributed uniformly in  $\mathbb{F}_2^n$ , the algorithm  $A$  on input  $x$ , returns  $H_a(x)$  with probability at least  $\frac{2}{3}$ .

We now prove that  $T$  implicitly computes  $a \in \mathbb{F}_2^n$  and that the expected number of queries that it makes to  $f$  is  $\Theta(\frac{1}{1-\alpha})$ . It is clear that the output of  $T$  on input  $k$  is always  $a[k] = H_a(y \odot e_k) \oplus H_a(y) = H_a(e_k)$ . The number of queries made by  $T$  to  $A$  is a geometric random variable with success probability  $\geq \frac{1}{3}$ . Hence, the expected number of queries made by  $T$  to  $A$  is at most 3. Since the query complexity of  $A$  is at most  $2^t$ , the expected number of queries made to  $f$  in one invocation of  $T$  is  $\Theta(2^t)$ , that is,  $\Theta(\frac{1}{1-\alpha})$ . The number of algorithms whose descriptions are generated is also at most  $2^t$ , which is,  $\Theta(\frac{1}{1-\alpha})$ . ◀

### 3 Separation

In this section, we describe a property  $\mathcal{P}$  that is erasure-resiliently testable using a constant number of queries, but not tolerantly testable using a constant number of queries, and prove Theorem 1.5. In fact, we prove the following (more general) statement and show that it implies Theorem 1.5.

► **Theorem 3.1.** *Let  $\varepsilon^* \in (0, \frac{1}{100})$  be a constant. There exists a property  $\mathcal{P} \subseteq \{0, 1\}^*$  such that*

- *for every  $\alpha \in [0, \frac{3\varepsilon^*}{16})$  and  $\varepsilon \in (\frac{3\varepsilon^*}{4(1-\alpha)}, 1)$ , the property  $\mathcal{P}$  can be  $\alpha$ -erasure-resiliently  $\varepsilon$ -tested using  $O(\frac{1}{\varepsilon(1-2\alpha)})$  queries.*
- *for all  $\alpha \in (\frac{\varepsilon^*}{8}, 1)$  and  $\varepsilon' \in (\alpha, \varepsilon^* - \frac{(\varepsilon^*)^2}{4})$ , the query complexity of  $(\alpha, \varepsilon')$ -tolerant testing  $\mathcal{P}$  on inputs of length  $N$  is  $\tilde{\Omega}(\log N)$ .*

#### 3.1 Description of the Separating Property $\mathcal{P}$

The property  $\mathcal{P}$  is defined in terms of a property  $\mathcal{R}$  that is hard to test in the standard property testing model [18, 37], a probabilistically checkable proof system (PCP of proximity [6, 11]<sup>2</sup>) for the problem of testing  $\mathcal{R}$ , and the Hadamard code. We discuss them below. The idea of using PCPs of proximity in separating property testing models comes from the work of Fischer and Fortnow [15]. Our contribution is to use locally list decodable codes in this context.

Given a Boolean formula  $\phi$  over  $n$  variables, let  $\mathcal{R}_\phi \subseteq \{0, 1\}^n$  denote the set of all satisfying assignments to  $\phi$ , represented as  $n$ -bit strings. Ben-Sasson, Harsha and Raskhodnikova [7] showed that for infinitely many  $n \in \mathbb{N}$ , there exists a 3CNF formula  $\phi_n$  on  $n$  variables such that every tester for  $\mathcal{R}_{\phi_n}$  requires  $\Omega(n)$  queries.

► **Lemma 3.2** ([7]). *There exists a parameter  $\varepsilon^* \in (0, 1)$  and a countably infinite set  $\aleph \subseteq \mathbb{N}$  such that for all  $n \in \aleph$ , there exists a 3CNF formula  $\phi_n$  with  $n$  variables and  $\Theta(n)$  clauses such that every  $\varepsilon^*$ -tester for  $\mathcal{R}_{\phi_n}$  has query complexity  $\Omega(n)$ .*

As mentioned before, another important ingredient in the description of the separating property  $\mathcal{P}$  is a probabilistically checkable proof system for property testing problems, called PCP of proximity, defined and studied independently by Ben-Sasson et al. [6] and Dinur and Reingold [11]. PCPs of proximity were further studied by Dinur [10] and Meir [32, 33].

► **Definition 3.3** (PCP of proximity [6, 11]). Given a property  $P_n \subseteq \{0, 1\}^n$ , the PCP of proximity (PCPP) for  $P_n$  is a randomized algorithm  $V$  that takes a parameter  $\varepsilon \in (0, 1]$  as input, gets oracle access to a string  $y \circ \pi$ , where  $y \in \{0, 1\}^n$  is the input and  $\pi \in \{0, 1\}^m$  is the proof, and satisfies the following:

- if  $y \in P_n$ , then, for some  $\pi$ , the algorithm  $V$  always accepts  $y \circ \pi$ ;
- if  $y$  is  $\varepsilon$ -far from  $P_n$ , then, for every  $\pi$ , the algorithm  $V$  rejects  $y \circ \pi$  with probability at least  $\frac{2}{3}$ .

A result by Dinur [10, Corollary 8.4] states that there are efficient PCPPs (over a small constant alphabet  $\Sigma$ ) for testing properties (over  $\Sigma$ ) that are decidable using polynomial-sized circuits. By representing the symbols in  $\Sigma$  using the binary alphabet, we obtain the following.

<sup>2</sup> PCPs of proximity are referred to as assignment testers by Dinur and Reingold [11]. Ben-Sasson et al. [6] and Dinur and Reingold [11] defined these objects concurrently and independently in order to obtain simpler and more efficient PCP constructions.

► **Lemma 3.4** ([10]). *If  $P_n \subseteq \{0,1\}^n$  is a property decidable by a circuit of size  $s(n)$ , then there exists a PCPP  $V$  that works for every  $\varepsilon \in (0,1]$ , uses a proof of length at most  $s(n) \cdot \text{polylog } s(n)$ , and has query complexity  $O(\frac{1}{\varepsilon})$ . Moreover, the queries of  $V$  are nonadaptive.*

► **Claim 3.5.** *There exists a constant  $c > 0$  such that for every large enough  $n \in \mathbb{N}$ , there exists a PCPP  $V$  for the property  $\mathcal{R}_{\phi_n}$  that works for all  $\varepsilon \in (0,1]$ , uses a proof of length at most  $cn \cdot \text{polylog } n$ , and has query complexity  $O(\frac{1}{\varepsilon})$ .*

The following is the definition of our separating property  $\mathcal{P}$ . At a high level, the definition says that, for all  $n \in \mathbb{N}$ , a string of length  $O(2^{n \cdot \text{polylog } n})$  satisfies  $\mathcal{P}$  if its first part is the repetition of a string  $y$  satisfying  $\mathcal{R}$ , and the second part is the encoding (by the Hadamard code) of  $y$  concatenated with a proof  $\pi$  that makes the algorithm  $V$  in Claim 3.5 accept.

► **Definition 3.6 (Separating Property  $\mathcal{P}$ ).** Let  $\varepsilon^* \in (0,1)$  be as in Lemma 3.2. For  $n \in \mathbb{N}$ , let  $p(n) \leq cn \cdot \text{polylog } n$  denote the length of proof that the algorithm  $V$  in Claim 3.5 has oracle access to. A string  $x \in \{0,1\}^N$  of length  $N = \frac{4}{\varepsilon^*} \cdot 2^{n+p(n)}$  satisfies  $\mathcal{P}$  if:

1. The first  $(\frac{4}{\varepsilon^*} - 1) \cdot 2^{n+p(n)}$  bits of  $x$  (called the *plain part* of  $x$ ) consist of  $(\frac{4}{\varepsilon^*} - 1) \cdot \frac{2^{n+p(n)}}{n}$  repetitions of a string  $y \in \mathcal{R}_{\phi_n}$  of length  $n$ , for  $\phi_n$  from Lemma 3.2.
2. The remaining bits of  $x$  (called the *encoded part* of  $x$ ) form the Hadamard encoding of a string  $y \circ \pi(y)$  of length  $n + p(n)$ , where  $\circ$  denotes the concatenation operation on strings. The string  $y \in \{0,1\}^n$  is the same as the one in the description of the plain part. The string  $\pi(y) \in \{0,1\}^{p(n)}$  is a proof such that the algorithm  $V$  (from Claim 3.5) accepts when given oracle access to  $y$  and  $\pi(y)$ .

## 3.2 Proof of Theorem 3.1

In this section, we prove Theorem 3.1, which in turn implies Theorem 1.5. Lemmas 3.7 and 3.10 prove the first and second parts of Theorem 3.1, respectively. The erasure-resilient tester for  $\mathcal{P}$  first obtains a list of (implicit) decodings of the encoded part (see Definition 3.6) of an input string  $x \in \{0,1\}^N$  using the local list erasure-decoder guaranteed by Theorem 1.4. If  $x \in \mathcal{P}$ , with high probability, at least one of the algorithms implicitly computes (see Definition 1.1) the string  $y \circ \pi(y)$ , where  $y$  is such that the plain part of  $x$  (see Definition 3.6) consists of repetitions of  $y$ , and  $\pi(y)$  is a proof string such that the algorithm  $V$  (from Claim 3.5) accepts upon oracle access to  $y \circ \pi(y)$ . In case  $x$  is  $\varepsilon$ -far from  $\mathcal{P}$  we show that for every algorithm  $T$  output by the local list erasure-decoder, the string  $y' \circ \pi(y')$  implicitly computed by  $T$  is such that, (1) either the plain part of  $x$  is far from being the repetitions of  $y'$ , (2) or  $y'$  is far from  $\mathcal{R}$  (in which case, the algorithm  $V$  from Claim 3.5 rejects when given oracle access to  $y' \circ \pi(y')$ ). To show that tolerant testing of  $\mathcal{P}$  is hard, we reduce  $\varepsilon^*$ -testing of  $\mathcal{R}_{\phi_n}$  to it. Specifically, given oracle access to a string  $y \in \{0,1\}^n$  that we want to  $\varepsilon^*$ -test, we simulate oracle access to a string  $x \in \{0,1\}^N$  such that the plain part of  $x$  consists of repetitions of  $y$ , and every bit in the encoded part of  $x$  is 0. Since every Hadamard codeword has an equal number of 0s and 1s, the string  $x$  can be thought of as having 0.5 fraction of “errors” in the encoded part. If  $y \in \mathcal{R}_{\phi_n}$ , then the string  $x$  is close to being in  $\mathcal{P}$ , as the errors are only in the encoded part of  $x$  and the length of the encoded part is a small fraction of the length of  $x$ . If  $y$  is far from  $\mathcal{R}_{\phi_n}$ , then  $x$  is also far from  $\mathcal{P}$ , since the plain part of  $x$ , whose length is a large fraction of the length of  $x$ , is the repetitions of  $y$ . Thus, the decision of a tolerant tester for  $\mathcal{P}$  on  $x$  can be used to test  $y$  for  $\mathcal{R}_{\phi_n}$ , implying that the complexity of tolerant testing of  $\mathcal{P}$  is equal to the complexity of testing  $\mathcal{R}_{\phi_n}$ .

---

**Algorithm 2** Erasure-resilient tester for separating property  $\mathcal{P}$ .
 

---

**Input:**  $\alpha, \varepsilon \in (0, 1), N = \frac{4}{\varepsilon^*} \cdot 2^{(n+p(n))}$ ; oracle access to  $x \in \{0, 1, \perp\}^N$

- 1: Set  $s \leftarrow (\frac{4}{\varepsilon^*} - 1) \cdot 2^{(n+p(n))}/n$ ,  $\varepsilon' \leftarrow \varepsilon(1 - 2\alpha)/3$ .
- 2: Set  $Q \leftarrow C/(\varepsilon(1 - 2\alpha))$  for a large enough constant  $C$ .
- 3: **Accept** whenever the number of queries exceeds  $Q$ .
- 4: Let  $T_1, T_2, \dots, T_L$  be the list of algorithms returned by a  $(\frac{3}{4}, q, L)$ -local list erasure-decoder for the Hadamard code (Algorithm 1), given oracle access to  $x[sn + 1..N]$ , the encoded part of  $x$ .
- 5: **for** each  $k \in [L]$  **do**
- 6:    $\triangleright$  Check if the plain part of  $x$  is the repetition of  $y$ , where  $y$  denotes the first  $n$  bits of the decoding (given by  $T_k$ ) of the encoded part of  $x$ .
- 7:    **repeat**  $\lceil \frac{9 \log L}{\varepsilon(1-2\alpha)} \rceil$  times:
  - 8:      Pick  $a \in_R [n], i \in_R [s]$ .
  - 9:      **if**  $x[(i-1)n + a] \neq \perp$  and  $T_k(a) \neq x[(i-1)n + a]$  **then**
  - 10:        **Discard** the current  $k$
- 11:    $\triangleright$  Check if the string  $y \in \mathcal{R}_{\phi_n}$ , where  $y$  denotes the first  $n$  bits of the decoding (by  $T_k$ ) of the encoded part of  $x$ .
- 12:    **repeat**  $\lceil 4 \log L \rceil$  times:
  - 13:      Run  $V$ , from Claim 3.5, with input  $\varepsilon'$  and oracle access to  $T_k$ .
  - 14:      **Discard** the current  $k$  if  $V$  rejects.
- 15: **Reject** if every  $k \in [L]$  is **discarded**; otherwise, **accept**.

---

We first prove the existence of an efficient erasure-resilient tester for  $\mathcal{P}$ . An  $\alpha$ -erased string  $x$  is  $\varepsilon$ -far from a property  $\mathcal{P}$  if there is no way to complete  $x$  to a string that satisfies  $\mathcal{P}$  without changing at least an  $\varepsilon$  fraction of the nonerased values in  $x$ .

► **Lemma 3.7.** *Let  $\varepsilon^* \in (0, 1)$  be as in Lemma 3.2. For every  $\alpha \in [0, \frac{3\varepsilon^*}{16})$ , and every  $\varepsilon \in (\frac{3\varepsilon^*}{4(1-\alpha)}, 1)$ , the property  $\mathcal{P}$  can be  $\alpha$ -erasure-resiliently  $\varepsilon$ -tested using  $O(\frac{1}{\varepsilon(1-2\alpha)})$  queries.*

**Proof.** The erasure-resilient tester for  $\mathcal{P}$  is described in Algorithm 2. The query complexity of the tester is evident from its description. We now prove that the tester, with probability at least  $\frac{2}{3}$ , accepts strings in  $\mathcal{P}$  and rejects strings that are  $\varepsilon$ -far from  $\mathcal{P}$ .

Let  $\aleph, \varepsilon^* \in (0, 1)$  be as in Lemma 3.2. Fix  $n \in \aleph$  and let  $p(n)$  and  $N$  be as in Definition 3.6. Let  $s$  denote  $(\frac{4}{\varepsilon^*} - 1) \cdot \frac{2^{n+p(n)}}{n}$ . Consider a string  $x \in \{0, 1\}^N$  that we want to erasure-resiliently test for  $\mathcal{P}$ . As in Definition 3.6, we refer to the substring  $x[1 \dots sn]$  as the plain part of  $x$  and the substring  $x[sn + 1 \dots N]$  as the encoded part of  $x$ .

Assume that  $x \in \mathcal{P}$ . Since  $\alpha < 3\varepsilon^*/16$ , the fraction of erasures in the encoded part of  $x$  is at most  $3/4$ . Hence, by Theorem 1.4, with probability at least  $2/3$ , there exists an algorithm  $T_k$  computed in Step 4 of Algorithm 2, such that  $T_k$  implicitly computes the string  $y \circ \pi \in \{0, 1\}^{n+p(n)}$ , where  $y \in \mathcal{R}_{\phi_n}$ , the plain part of  $x$  can be completed to a repetition of  $y$ , and  $\pi$  is a proof such that the algorithm  $V$  (from Claim 3.5) accepts when given oracle access to  $y \circ \pi$ . Therefore  $k$  is not discarded in either Step 10 or Step 14. Thus, the tester will accept with probability at least  $2/3$ .

Now, assume that  $x$  is  $\varepsilon$ -far from  $\mathcal{P}$ . Let  $E$  denote the event that the number of queries made by the tester does not exceed its query budget. We will first show that, conditioned on  $E$ , the tester rejects  $x$  with probability at least  $4/5$ .

Let  $\mathcal{N}_1$  denote the set of nonerased points in the plain part of  $x$  and  $\mathcal{N}_2$  denote those in the encoded part and let  $\mathcal{N}$  denote the set of nonerased points in  $x$ . Even if all of at most  $N\alpha$  erased points in  $x$  are in the plain part of  $x$ , the total number of nonerased points

in plain part of  $x$ , which is  $|\mathcal{N}_1|$ , is at least  $sn - N\alpha$ . Since, for large enough  $n$ , we have  $N \leq 2sn$  by Definition 3.6, we can see that  $|\mathcal{N}_1| \geq sn(1 - 2\alpha)$ . We first prove two claims about the plain part of  $x$ , that is,  $x[1 \dots sn]$ .

► **Claim 3.8.** *The plain part of  $x$  is  $\frac{2\varepsilon}{3}$ -far from being  $s$  repetitions of a string  $y \in \mathcal{R}_{\phi_n}$ .*

From Claim 3.8, it follows that at least  $\frac{2\varepsilon \cdot |\mathcal{N}_1|}{3} \geq \frac{2\varepsilon \cdot sn(1-2\alpha)}{3}$  nonerased points need to be changed in the plain part of  $x$  for it to be  $s$  repetitions of a string  $y \in \mathcal{R}_{\phi_n}$ .

► **Claim 3.9.** *For every  $y \in \{0, 1\}^n$ , if the plain part of  $x$  can be changed to  $s$  repetitions of  $y$  by modifying less than  $\frac{\varepsilon \cdot sn(1-2\alpha)}{3}$  nonerased values, then  $y$  is  $\frac{\varepsilon(1-2\alpha)}{3}$ -far from  $\mathcal{R}_{\phi_n}$ .*

Fix  $k \in [L]$ . Let  $y' \in \{0, 1\}^n$  be the first  $n$  bits from the left in the decoding, using  $T_k$ , of the encoded part of  $x$ . We will show that the algorithm discards  $k$  with high probability. We split the analysis into two cases.

**Case I:** Suppose we need to change at least  $\frac{\varepsilon |\mathcal{N}_1|}{3} \geq \frac{\varepsilon \cdot sn(1-2\alpha)}{3}$  nonerased points in the plain part of  $x$  for it to become  $s$  repetitions of  $y'$ . We show that in this case, Steps 7-10 discard  $k$  with probability at least  $\frac{9}{10L}$ . A point  $(i-1)n + a$  for  $i \in [s]$  and  $a \in [n]$  is called a witness if  $x[(i-1)n + a] \neq \perp$  and  $x[(i-1)n + a] \neq y'[a]$ . Since we need to change at least  $\varepsilon \cdot sn(1-2\alpha)/3$  nonerased points in the plain part of  $x$  for it to become  $s$  repetitions of  $y'$ , there are at least  $\varepsilon \cdot sn(1-2\alpha)/3$  witnesses in the plain part of  $x$ . In each iteration of Steps 7-10, the point selected is a witness with probability at least  $\frac{\varepsilon \cdot sn(1-2\alpha)}{3sn} = \frac{\varepsilon(1-2\alpha)}{3}$ . Thus, in  $\lceil \frac{9 \log L}{\varepsilon(1-2\alpha)} \rceil$  iterations, Algorithm 2 finds a witness (and discards  $k$ ) with probability at least  $9/10L$ .

**Case II:** In this case, we assume that we can change less than  $\varepsilon \cdot sn(1-2\alpha)/3$  nonerased points in the plain part of  $x$  and make it  $s$  repetitions of  $y'$ . Then, by Claim 3.9,  $y'$  is  $\varepsilon \cdot (1-2\alpha)/3$ -far from  $\mathcal{R}_{\phi_n}$ . Let  $\varepsilon' = \frac{\varepsilon(1-2\alpha)}{3}$ . By Claim 3.5, for every proof  $\pi \in \{0, 1\}^{p(n)}$ , the algorithm  $V$  (from Claim 3.5), on input  $\varepsilon'$  and oracle access to  $y' \circ \pi$  (obtained via  $T_k$ ), rejects (causing  $k$  to be discarded) with probability at least  $2/3$ . Thus, the probability that tester fails to discard  $k$  in  $\lceil 4 \log L \rceil$  independent iterations of Steps 12-14 is at most  $1/16L$ .

Therefore, the probability that the tester fails to discard  $k$  is at most  $\frac{1}{10L} + \frac{1}{16L} < \frac{1}{5L}$ . By the union bound, the probability that Algorithm 2 fails to discard some  $k \in [L]$  is at most  $1/5$ . Thus, conditioned on the event  $E$  that the number of queries made by the tester does not exceed its query budget, with probability at least  $4/5$ , the tester rejects.

We bound the probability of  $E$  by first showing that the expected number of queries made by Algorithm 2 is  $O(\frac{1}{\varepsilon(1-2\alpha)})$  and then applying Markov's inequality. Hence, the probability that the tester accepts  $x$  that is  $\varepsilon$ -far from  $\mathcal{P}$  is at most  $1/3$ . ◀

► **Lemma 3.10.** *Let  $\varepsilon^* \in (0, 1)$  be as in Lemma 3.2. For every  $\alpha \in (\frac{\varepsilon^*}{8}, 1)$  and  $\varepsilon' \in (\alpha, \varepsilon^* - \frac{(\varepsilon^*)^2}{4})$ , the query complexity of  $(\alpha, \varepsilon')$ -tolerant testing  $\mathcal{P}$  on strings of length  $N$  is  $\tilde{\Omega}(\log N)$ .*

**Proof.** Let  $\aleph, \varepsilon^* \in (0, 1)$  be as in Lemma 3.2. We will prove the lemma by showing a reduction from  $\varepsilon^*$ -testing of  $\mathcal{R}_{\phi_n}$ . Fix  $n \in \aleph$  and let  $p(n)$  and  $N$  be as in Definition 3.6. Let  $s$  denote  $(\frac{4}{\varepsilon^*} - 1) \cdot \frac{2^{n+p(n)}}{n}$ .

Consider a string  $y \in \{0, 1\}^n$  that we want to  $\varepsilon^*$ -test for  $\mathcal{R}_{\phi_n}$ . Let  $x \in \{0, 1\}^N$  be the string where the first  $sn$  bits of  $x$  are  $s$  repetitions of  $y$  and the remaining bits are all 0s. We refer to the substring  $x[1 \dots sn]$  as the plain part of  $x$  and the substring  $x[sn + 1 \dots N]$  as the encoded part of  $x$ .

Assume that  $A$  is an  $(\alpha, \varepsilon')$ -tolerant tester for  $\mathcal{P}$ . We now describe an  $\varepsilon^*$ -tester  $A'$  for  $\mathcal{R}_{\phi_n}$  that has the same query complexity as  $A$ . Given oracle access to  $y \in \{0, 1\}^n$ , the tester  $A'$  runs the tester  $A$  on the string  $x \in \{0, 1\}^N$  and accepts if and only if  $A$  accepts, where  $x$  is constructed from  $y$  as described above. Observe that one can simulate a query to  $x$  by making at most one query to  $y$ .

If  $y \in \mathcal{R}_{\phi_n}$ , then  $x$  is  $\alpha$ -close to  $\mathcal{P}$ . Observe that the encoded part of  $x$  needs to be changed in at most  $1/2$  fraction of its positions in order to make it the encoding of a string  $y \circ \pi$ , where  $\pi$  is a proof that makes a PCP of proximity for testing  $\mathcal{R}_{\phi_n}$  accept. This follows from the fact that the normalized weight of every nonzero codeword in the Hadamard code is  $1/2$ . Thus, the fraction of bits in  $x$  that needs to be changed in order to make it satisfy  $\mathcal{P}$  is at most  $\frac{1}{2} \cdot \frac{N-sn}{N} = \frac{\varepsilon^*}{8}$ , which is less than  $\alpha$ . Therefore, by definition,  $A'$  will accept  $x$  with probability at least  $2/3$ .

If  $y$  is  $\varepsilon^*$ -far from  $\mathcal{R}_{\phi_n}$ , then  $x$  needs to be changed in at least  $\varepsilon^* \cdot sn$  positions to make it satisfy  $\mathcal{P}$ . From this, one can observe that  $x$  is  $(\varepsilon^* - \frac{(\varepsilon^*)^2}{4})$ -far from  $\mathcal{P}$ . Hence, for all  $\varepsilon' < \varepsilon^* - \frac{(\varepsilon^*)^2}{4}$ , we have that  $A$  will reject  $x$  with probability at least  $2/3$ , and therefore  $A'$  will reject  $y$  with probability at least  $2/3$ .

Thus, we have shown that the query complexity of  $(\alpha, \varepsilon')$ -tolerant testing  $\mathcal{P}$  is at least the query complexity of  $\varepsilon^*$ -testing  $\mathcal{R}_{\phi_n}$ . Hence, the query complexity of  $(\alpha, \varepsilon')$ -tolerant testing  $\mathcal{P}$  is  $\Omega(n)$ , which is equal to  $\tilde{\Omega}(\log N)$ . ◀

**Proof of Theorem 1.5.** For every  $0 < \varepsilon^* < 1/100$ , the system of constraints on  $\alpha, \varepsilon \in (0, 1)$  (by Theorem 3.1) has a feasible solution with  $\alpha = \varepsilon^*/6$  and  $\varepsilon = 4\varepsilon^*/5$ . ◀

## 4 Approximate Local List Erasure-Decoding

In this section, we prove the existence of an approximate locally list erasure-decodable code (ALLEDC) with inverse polynomial rate. Our starting point is an approximate locally list decodable code (ALLDC) due to Impagliazzo et al. [28]. To this code, we apply Observation 4.2 which states that every ALLDC that works in the presence of errors also works in the presence of twice as many erasures (with the same parameters up to constant factors).

► **Theorem 4.1** ([28] as restated by [4]). *For every  $\gamma, \beta > 0$ , there exists a number  $f(\gamma, \beta) > 0$  and a code family  $\{C_k : \mathbb{F}_2^k \rightarrow \mathbb{F}_2^{f(\gamma, \beta)k^5}\}_{k \in \mathbb{N}}$  that is a  $(\gamma, \beta, O(\frac{\log(1/\beta)}{(\frac{1}{2}-\gamma)^3}), O(\frac{1}{(\frac{1}{2}-\gamma)^2}))$ -ALLDC.*

► **Observation 4.2.** *If a code family  $\{C_k : \mathbb{F}_2^k \rightarrow \mathbb{F}_2^n\}_{k \in \mathbb{N}}$  is an  $(\alpha, \beta, q, L)$ -ALLDC, it is also a  $(2\alpha, \beta, 4q, 4L)$ -ALLEDC.*

Applying Observation 4.2 to Theorem 4.1, we get the ALLEDCs that we need.

► **Lemma 4.3.** *Let  $c_3 > 0$  be a constant. For every  $\gamma, \beta > 0$ , there exists a number  $f(\gamma, \beta) > 0$  and a code family  $\{C_k : \mathbb{F}_2^k \rightarrow \{0, 1\}^{f(\gamma, \beta)k^5}\}_{k \in \mathbb{N}}$  that is a  $(\gamma, \beta, \frac{c_3 \log(1/\beta)}{(1-\gamma)^3}, \frac{c_3}{(1-\gamma)^2})$ -ALLEDC.*

## 5 Strengthened Separation

In this section, we describe a property  $\mathcal{P}'$  that can be erasure-resiliently tested using a constant number of queries, but for which every tolerant tester has query complexity  $n^{\Omega(1)}$ , and prove Theorem 1.6. The following theorem implies Theorem 1.6.

- **Theorem 5.1.** *There exists a property  $\mathcal{P}'$  and constants  $\varepsilon^* \in (0, 1), c_2 > 1$  such that,*
- *For every  $\varepsilon \in \left(\frac{\varepsilon^*}{8}, 1\right)$  and  $\alpha \in \left(0, \frac{\varepsilon^*}{57600 \cdot c_2}\right)$ , property  $\mathcal{P}'$  can be  $\alpha$ -erasure-resiliently  $\varepsilon$ -tested using a constant number of queries,*
  - *For every  $\alpha \in \left(\frac{\varepsilon^*}{57600 \cdot c_2 + 2\varepsilon^*}, 1\right)$ , and  $\varepsilon' \in \left(\alpha, \frac{28800 \cdot c_2 \cdot \varepsilon^*}{28800 \cdot c_2 + \varepsilon^*}\right)$ , every  $(\alpha, \varepsilon')$ -tolerant tester for  $\mathcal{P}'$  on inputs of length  $N$  has query complexity  $N^{\Omega(1)}$ .*

## 5.1 Description of the Separating Property $\mathcal{P}'$

The property  $\mathcal{P}'$  is very similar to the property  $\mathcal{P}$  that we used in our first separation (see Definition 3.6). Like a string that satisfies  $\mathcal{P}$ , a string that satisfies  $\mathcal{P}'$  can also be thought of as consisting of a plain part (that contains the repetition of a string  $y \in \mathcal{R}_{\phi_n}$ ) and an encoded part. The encoded part of a string in  $\mathcal{P}$  is the Hadamard encoding of a string  $y \circ \pi$ , where  $\pi$  is a proof that makes the algorithm  $V$  from Claim 3.5 accept. However, the encoded part of a string satisfying  $\mathcal{P}'$  is the encoding of a string  $\pi'$ , where  $\pi'$  is a proof (whose length is asymptotically equal to  $|\pi|$ ) that makes a ‘smoothed’ PCPP accept. In addition, the encoding uses an ALLEDC (from Section 4) instead of the Hadamard code.

We first describe the ‘smoothed’ PCPP used in our construction. The following lemma by Ben-Sasson et al. [6] and Guruswami and Rudra [25] states that algorithms making nonadaptive queries can be transformed into algorithms that make nearly uniform queries.

- **Lemma 5.2** ([25, 6]). *For every nonadaptive algorithm  $T$ , there exists a mapping  $\varphi : \{0, 1\}^* \rightarrow \{0, 1\}^*$  and an algorithm  $T'$  satisfying the following:*
- *For every  $x \in \{0, 1\}^*$ , the decision of  $T$  with oracle access to  $x$  is identical to the decision of  $T'$  with oracle access to  $\varphi(x)$ . Moreover,  $3|x| < |\varphi(x)| \leq 4|x|$ , and the number of queries that  $T'$  makes to  $\varphi(x)$  is at most twice the number of queries that  $T$  makes to  $x$ .*
  - *Given oracle access to  $x' \in \{0, 1\}^n$ , each query of  $T'$  is to location  $j \in [n]$  with probability at most  $2/n$ .*

Combining Lemma 3.4 with Lemma 5.2 (along with the fact that  $\mathcal{R} = \{\mathcal{R}_{\phi_n}\}_{n \in \mathbb{N}}$  can be decided using linear-sized circuits), we get the required ‘smoothed’ PCPP for  $\mathcal{R}$ .

- **Lemma 5.3.** *Let  $c_1 > 0, c_2 > 1$  be constants. The property  $\mathcal{R}_{\phi_n}$  has a PCPP  $V$  that works for all  $\varepsilon \in (0, 1]$ , gets oracle access to an input  $y$  of length  $n$  and a proof  $\pi$  of length at most  $c_1 n \cdot \text{polylog } n$ , and makes at most  $\frac{c_2}{\varepsilon}$  queries. Moreover, the queries of  $V$  are nonadaptive and satisfy the following:*
- *Each query  $V$  makes to  $y$  is to any particular location of  $y$  with probability at most  $2/n$ .*
  - *Each query  $V$  makes to  $\pi$  is to any particular location of  $\pi$  with probability at most  $2/|\pi|$ .*

The following is the definition of our separating property  $\mathcal{P}'$ . Note that the encoded part of a string satisfying  $\mathcal{P}'$  contains the encoding of a proof as well as the complement of that encoding. This is done in order to equalize the number of 0s and 1s in the encoded part.

- **Definition 5.4** (Separating Property  $\mathcal{P}'$ ). Let  $\aleph$  and  $\varepsilon^* \in (0, 1)$  be as in Lemma 3.2. Let  $c_1 > 0, c_2 > 1$  be as in Lemma 5.3 and  $c_3 > 0$  be as in Lemma 4.3. Let  $m = \frac{28800 \cdot c_2}{\varepsilon^*}$ ,  $\gamma = \frac{1}{2} + \frac{\varepsilon^*}{57600 \cdot c_2}$  and  $\beta = \frac{\varepsilon^*}{9000c_2 \cdot \lceil \ln \frac{6c_3}{(1-\gamma)^2} \rceil}$ . For  $n \in \aleph$ , let  $p(n) \leq c_1 \cdot n \cdot \text{polylog } n$  denote the length of the proof that makes the algorithm  $V$  in Lemma 5.3 accept. Let  $f(\cdot, \cdot)$  be as in Lemma 4.3. Let  $\mathcal{C} = \{C_k\}_{k \in \mathbb{N}}$  be the  $(\gamma, \beta, \frac{c_3 \log(1/\beta)}{(1-\gamma)^3}, \frac{c_3}{(1-\gamma)^2})$ -ALLEDC from Lemma 4.3. A string  $x \in \{0, 1\}^N$  of length  $N = (m+1) \cdot 2f(\gamma, \beta) \cdot (p(n))^5$  satisfies  $\mathcal{P}'$  if the following conditions hold:

1. The first  $m \cdot 2f(\gamma, \beta) \cdot (p(n))^5$  bits of  $x$  (called the *plain part* of  $x$ ) consist of  $m \cdot \frac{2f(\gamma, \beta) \cdot (p(n))^5}{n}$  repetitions of a string  $y \in \mathcal{R}_{\phi_n}$  of length  $n$ , for  $\mathcal{R}_{\phi_n}$  from Lemma 3.2.
2. The remaining  $2f(\gamma, \beta) \cdot (p(n))^5$  bits of  $x$  is called the *encoded part*. Its first half is the encoding, using  $\mathcal{C}$ , of a string  $\pi \in \{0, 1\}^{p(n)}$  such that the PCPP  $V$  in Lemma 5.3 accepts when given oracle access to  $y \circ \pi$ . The second half of the encoded part is the complement of its first half.

## 5.2 Proof of Strengthened Separation

In this section, we prove Theorem 5.1. Lemmas 5.5 and 5.9 together imply the first and second parts of Theorem 5.1, respectively. The high level idea of the proof of Lemma 5.5 is very similar to that of Lemma 3.7. The differences arise mainly because of the way the encoded parts of strings satisfying  $\mathcal{P}$  and  $\mathcal{P}'$  differ. The erasure-resilient tester for  $\mathcal{P}$  could first check whether the plain part is a repetition of the ‘decoded input’, and then check whether the ‘decoded input’ is in  $\mathcal{R}$  with the help of the ‘decoded PCPP proof’. Since the encoded part of  $\mathcal{P}'$  is the encoding of just a PCPP proof, this is not possible. Instead, the erasure-resilient tester for  $\mathcal{P}'$  samples a uniformly random nonerased point  $u$  from the plain part and uses the ‘block’ from which  $u$  is obtained as a ‘candidate input’  $y$ . It then checks whether the plain part is a repetition of  $y$  and also checks whether  $y \in \mathcal{R}$  using the ‘approximately decoded proof’. In case a string is  $\alpha$ -erased and  $\varepsilon$ -far from  $\mathcal{P}'$ , we show that the ‘candidate input’  $y$  that we sample is  $c\alpha$ -erased and  $c'\varepsilon$ -far from  $\mathcal{R}$ , for some constants  $c, c'$ . Hence, the smoothed PCPP verifier rejects.

► **Lemma 5.5.** *Let  $\varepsilon^* \in (0, 1)$  be as in Lemma 3.2 and  $c_2 > 1$  be as in Lemma 5.3. For every  $\varepsilon \in \left(\frac{\varepsilon^*}{8}, 1\right)$  and  $\alpha \in \left(0, \frac{\varepsilon^*}{57600 \cdot c_2}\right)$ , the property  $\mathcal{P}'$  is  $\alpha$ -erasure-resiliently  $\varepsilon$ -testable using a constant number of queries.*

**Proof.** The erasure-resilient tester is presented in Algorithm 3. Let  $m$  denote  $28800 \cdot c_2 / \varepsilon^*$ . Let  $\gamma = 1/2 + \varepsilon^* / 57600 c_2$ ,  $\beta = \frac{\varepsilon^*}{9000 c_2 \cdot \lceil \ln \frac{6c_3}{(1-\gamma)^2} \rceil}$ ,  $q = \frac{c_3 \log(1/\beta)}{(1-\gamma)^3}$ , and  $L = c_3 / (1-\gamma)^2$ . For  $n \in \mathbb{N}$ , consider a string  $x \in \{0, 1\}^N$ , where  $N = (m+1) \cdot 2f(\gamma, \beta) \cdot (p(n))^5$ . The plain part of  $x$  is  $m$  times larger than the encoded part. Let  $s$  denote the number  $m \cdot 2f(\gamma, \beta) \cdot (p(n))^5 / n$ .

Assume that  $x$  satisfies  $\mathcal{P}'$ . Since  $x$  satisfies  $\mathcal{P}'$ , the plain part of  $x$  is completable to the repetitions of some  $y \in \mathcal{R}_{\phi_n}$ . Therefore, Steps 5-9 never reject. By definition of  $\mathcal{P}'$ , the first half of the encoded part of  $x$  is the encoding (using the  $(\gamma, \beta, q, L)$ -ALLED code  $\mathcal{C}$  from Lemma 4.3) of a proof  $\pi(y) \in \{0, 1\}^{p(n)}$  such that the PCPP  $V$  with oracle access to  $y \circ \pi(y)$  always accepts. The second half of the encoding is the complement of the first half. The fraction of erasures in the encoded part (even if all of the erasures were there) is at most  $(m+1)\alpha$ . Therefore, the fraction of erasures in either the first half or the second half of the encoded part is at most  $(m+1) \cdot \alpha = 1/2 + 1/2m = \gamma$ .

By the definition of a  $(\gamma, \beta, q, L)$ -ALLED code, with probability at least  $2/3$ , one of the algorithms  $T_1, T_2, \dots, T_L$  returned by the approximate local list decoder provides oracle access to  $\pi(y)$  with at most  $\beta$  fraction of errors. Let  $T_k$  be that algorithm. The tester discards this  $k$  only if an erroneous point is queried in some iteration of Steps 14-18. Since each proof query of  $V$  (in Step 17) is made to a specific index in the proof with probability at most  $2/|p(n)|$  and the string decoded by  $T_k$  is  $\beta$ -erroneous, by the union bound over queries of  $V$ , the probability of  $V$  querying an erroneous point is at most  $2\beta \cdot \frac{c_2 \cdot 75}{24\varepsilon}$ . Hence, by the union bound, the probability that the tester discards  $k$  is at most  $\frac{1}{3} + 2 \cdot 6 \cdot \lceil \ln 6L \rceil \cdot \frac{c_2 \cdot 75}{24\varepsilon} \cdot \beta \leq \frac{2}{5}$ , where the inequality follows from our setting of  $\beta$ . Hence, Step 19 does not reject with probability at least  $3/5$ . That is, the tester accepts  $x$  with probability at least  $3/5$ .

---

**Algorithm 3** Erasure-resilient tester for separating property  $\mathcal{P}'$ .
 

---

**Input:**  $\alpha, \varepsilon \in (0, 1), N = (m + 1) \cdot 2f(\gamma, \beta) \cdot (p(n))^5$ ; oracle access to  $x \in \{0, 1, \perp\}^N$

- 1: Set  $s \leftarrow m \cdot \frac{2f(\gamma, \beta) \cdot (p(n))^5}{n}$ ,  $q \leftarrow \frac{c_3 \log(1/\beta)}{(1-\gamma)^3}$ , and  $L \leftarrow \frac{c_3}{(1-\gamma)^2}$ .
- 2: Set the query budget  $Q \leftarrow 30 \cdot \left( \lceil \frac{432}{\varepsilon} \rceil \cdot \frac{2}{1-(m+1)\alpha} + L \lceil 6 \ln 6L \rceil \cdot \frac{c_2 \cdot 75}{24\varepsilon} \cdot q \right)$ .
- 3: **Accept** whenever the number of queries exceeds  $Q$ .
- 4:      $\triangleright$  Steps 5-9 check that the plain part of  $x$  is the repetition of a string  $y \in \{0, 1\}^n$ .
- 5: **repeat**  $\lceil \frac{432}{\varepsilon} \rceil$  times:
  - 6: Repeatedly sample a uniformly random point  $u$  from the plain part until  $x[u] \neq \perp$ .
  - 7: Let  $u$  be  $(i - 1)n + a$  for  $i \in [s]$  and  $a \in [n]$ .
  - 8: Repeatedly sample  $j \in [s]$  uniformly at random until  $x[(j - 1)n + a] \neq \perp$ .
  - 9: **Reject** if  $x[(i - 1)n + a] \neq x[(j - 1)n + a]$ .
- 10:  $\triangleright$  In order to query the  $i$ -th bit of the encoding, we query the  $i$ -th bits of both the first and second halves of the encoded part. We set the  $i$ -th bit of the encoding to the  $i$ -th bit of the first half if that is nonerased, and to the complement of the  $i$ -th bit of second half if that is nonerased. If both are erased, we set the  $i$ -th bit of the encoding to  $\perp$ .
- 11: Run the decoder for the  $(\gamma, \beta, q, L)$ -ALLED code (Lemma 4.3) with oracle access to the encoded part of  $x$ . Let  $A_1, A_2, \dots, A_L$  be the list of algorithms it returns.
- 12:      $\triangleright$  Steps 13-19 check that  $y \in \mathcal{R}_{\phi_n}$  using the PCPP  $V$  on decoded proofs.
- 13: **for** each  $k \in [L]$  **do**
- 14:     **repeat**  $\lceil 6 \ln 6L \rceil$  times:
  - 15: Repeatedly sample a uniformly random point  $u$  from the plain part until  $x[u] \neq \perp$ .
  - 16: Let  $u$  be  $(i - 1)n + a$  for  $i \in [s]$  and  $a \in [n]$ .
  - 17: Run the PCPP  $V$  (guaranteed by Lemma 5.3) with proximity parameter  $\frac{24\varepsilon}{75}$ , and oracle access to  $x[(i - 1)n + 1, \dots, (i - 1)n + n]$  as the input string and the string decoded by  $T_k$  as the proof.
  - 18:     **Discard** the current  $k$  if all query answers to  $V$  are nonerased and  $V$  rejects.
  - 19: **Reject** if every  $k \in [L]$  is **discarded**; otherwise, **accept**.

---

Assume now that  $x$  is  $\varepsilon$ -far from  $\mathcal{P}'$ . Let  $\mathcal{N}_{\text{pl}}$  denote the set of nonerased points in the plain part of  $x$ . Let  $\mathcal{N}_{\text{en}}$  denote the set of nonerased points in the encoded part of  $x$ . Let  $\alpha_{\text{pl}}$  denote the fraction (with respect to  $sn$ ) of erased points in the plain part. Let  $E$  denote the event that the number of queries made by the tester does not exceed the query budget  $Q$ .

► **Claim 5.6.** *The probability that Algorithm 3 exceeds its query budget is at most  $1/30$ .*

We now analyze the probability that Algorithm 3 rejects, conditioned on  $E$ .

**Case I:** the plain part of  $x$  is  $\varepsilon/144$ -far from being the repetitions of every  $y \in \{0, 1\}^n$ .

Let  $\varepsilon_{\text{pl}}$  denote the fraction of points (with respect to  $|\mathcal{N}_{\text{pl}}|$ ) in  $\mathcal{N}_{\text{pl}}$  whose values need to be changed in order to make the plain part a repetition of some string  $y \in \{0, 1\}^n$ . Let  $S_a = \{(i - 1)n + a : i \in [s]\}$  for all  $a \in [n]$ . We use the term  $a$ -th segment to refer to the set  $S_a$ . For all  $a \in [n]$ , we have  $|S_a| = s$ . For all  $a \in [n]$ , let  $\alpha_a = |\{u \in S_a : x[u] = \perp\}|/s$  denote the fraction of points in  $S_a$  that are erased. Let  $\mathcal{N}_a \subseteq S_a$  denote the set of nonerased points in the  $a$ -th segment. Let  $\varepsilon_a$  for all  $a \in [n]$  denote the fraction of points in  $\mathcal{N}_a$  whose values need to be changed in order to satisfy  $x[u] = x[v]$  for all  $u, v \in S_a$  such that both  $x[u]$  and  $x[v]$  are nonerased.

For every  $a \in [n]$  and  $u \in \mathcal{N}_a$ , the number of  $v \in \mathcal{N}_a$  such that  $x[u] \neq x[v]$ , is at least  $\varepsilon_a \cdot |\mathcal{N}_a|$ . Let  $G_a$  for all  $a \in [n]$  denote the (good) event that the tester samples a point from  $\mathcal{N}_a$  in Step 6. Let  $F$  denote the event that the tester rejects in a single iteration Steps 5-9. Hence,  $\Pr[F|E] = \sum_{a \in [n]} \Pr[G_a|E] \cdot \Pr[F|G_a, E] \geq \sum_{a \in [n]} \frac{|\mathcal{N}_a|}{|\mathcal{N}_{\text{pl}}|} \cdot \varepsilon_a = \varepsilon_{\text{pl}} \geq \varepsilon/144$ . Therefore, conditioned on  $E$ , in at least  $432/\varepsilon$  iterations, the tester will reject with probability at least  $19/20$ . Hence, the algorithm accepts with probability at most  $1/20 + \Pr[\overline{E}] \leq 1/20 + 1/30 \leq 2/5$ , since  $\Pr[\overline{E}] \leq 1/30$ . Thus, the algorithm rejects with probability at least  $3/5$ .

**Case II:** the plain part of  $x$  is  $\varepsilon/144$ -close to being repetitions of a string  $y^* \in \{0, 1\}^n$ .

► **Claim 5.7.** *The string  $y^*$  is  $\varepsilon/2$ -far from  $\mathcal{R}_{\phi_n}$ .*

Let  $B_i = \{(i-1)n + a : a \in [n]\}$  for all  $i \in [s]$ . We use the term  $i$ -th block to refer to the set  $B_i$ . For all  $i \in [s]$ , we have,  $|B_i| = n$ . Let  $\alpha_i = |\{u \in B_i : x[u] = \perp\}|/n$  for all  $i \in [s]$  denote the fraction of points in  $B_i$  that are erased. Let  $\mathcal{N}_i \subseteq S_i$  denote the set of nonerased points in the  $i$ -th block. Let  $\varepsilon_i$  for all  $i \in [s]$  denote the fraction of points in  $\mathcal{N}_i$  whose values need to be changed in order to satisfy  $x[(i-1)n + a] = y^*[a]$  for all  $a \in [n]$ .

Fix  $k \in [L]$ . We show that Algorithm 3 discards  $k$  with high probability. Consider a single iteration of Steps 15-18. Let  $y'$  denote the (partially erased) string represented by the block that Algorithm 3 samples in Step 15. Let  $G_1$  denote the (good) event that  $y'$  is  $\varepsilon/6$ -close to  $y^*$ . Let  $G_2$  denote the (good) event that  $y'$  has at most  $48\alpha$  fraction of erasures.

► **Claim 5.8.** *Conditioned on  $G_1$  and  $G_2$ , the string  $y'$  is  $24\varepsilon/75$ -far from  $\mathcal{R}_{\phi_n}$ .*

The PCPP  $V$ , with proximity parameter  $\frac{24\varepsilon}{75}$ , is run on  $y'$  and the proof decoded by  $T_k$ . Let  $B_1$  denote the (bad) event that the PCPP  $V$  obtains an erased bit as the answer to some query. Let  $B_2$  denote the (bad) event that  $V$  accepts. By Lemma 5.3, each query of  $V$  to the input part is made to each input index with probability at most  $\frac{2}{n}$  uniformly distributed among the  $n$  input indices. Hence  $\Pr[B_1|E, G_1, G_2]$ , the probability that some input query is made to an erased point, is at most  $\frac{\varepsilon_2 \cdot 75}{24\varepsilon} \cdot 96\alpha$ . The probability that the  $V$  accepts (even if there were no erased query answers) is  $\Pr[B_2|E, G_1, G_2]$  and is, by Definition 3.3, at most  $1/3$ . Thus, the probability that the PCPP accepts, conditioned on  $E$ ,  $G_1$ , and  $G_2$ , is by the union bound, at most  $\frac{\varepsilon_2 \cdot 75}{24\varepsilon} \cdot 96\alpha + \frac{1}{3} \leq \frac{1}{24} + \frac{1}{3}$ , where the inequality follows from our setting of  $\varepsilon$  and  $\alpha$ .

To bound the probability that the PCPP accepts in a single iteration of Steps 15-18, we now evaluate  $\Pr[\overline{G_1}]$  and  $\Pr[\overline{G_2}]$ . Let the random variable  $X$  denote the relative Hamming distance of  $y'$  from  $y^*$ . Then,  $\mathbb{E}[X] = \sum_{i \in [s]} \frac{|\mathcal{N}_i|}{|\mathcal{N}_{\text{pl}}|} \cdot \varepsilon_i = \varepsilon_{\text{pl}} \leq \frac{\varepsilon}{144}$ . By Markov's inequality,  $\Pr[\overline{G_1}] = \Pr[X \geq \frac{\varepsilon}{6}] \leq \mathbb{E}[X]/(\varepsilon/6) \leq 1/24$ . To bound  $\Pr[\overline{G_2}]$ , let the random variable  $Y$  denote the fraction of erasures in  $y'$ . We first show that  $\mathbb{E}[Y] = \alpha_{\text{pl}}$ . Even if all the erasures were in the plain part,  $\alpha_{\text{pl}} \leq \frac{\alpha N}{sn} \leq \alpha \cdot (1 + \frac{1}{m})$ . Again, by an application of Markov's inequality, we get  $\Pr[\overline{G_2}] = \Pr[Y > 48\alpha] \leq \frac{\mathbb{E}[Y]}{48\alpha} \leq \frac{1 + \frac{1}{m}}{48} \leq 1/24$ .

Therefore, conditioned on  $E$ , the probability that the PCPP accepts in one iteration of Steps 15-18 is at most  $\Pr[B_1|E, G_1, G_2] + \Pr[B_2|E, G_1, G_2] + \Pr[\overline{G_2}] + \Pr[\overline{G_1}] \leq \frac{1}{24} + \frac{1}{3} + \frac{1}{24} + \frac{1}{24} \leq \frac{2}{3}$ . That is, conditioned on  $E$ , for a fixed  $k \in [L]$ , in  $[6 \ln 6L]$  independent repetitions of Steps 15-18, the probability that the PCPP does not discard  $k$  is at most  $(1 - \frac{1}{3})^{[6 \ln 6L]} \leq \frac{1}{36L^2}$ . Hence, conditioned on  $E$ , the probability that for some  $k \in [L]$ , Steps 14-18 accepts is, by the union bound, at most  $1/36L$ . Thus, if  $x$  is in Case II, the probability that the tester accepts is at most,  $\frac{1}{36L} + \Pr[\overline{E}] \leq \frac{1}{36L} + \frac{1}{30} \leq \frac{2}{5}$ , where Claim 5.6 shows that  $\Pr[\overline{E}]$  is at most  $1/30$ . ◀

Next, we show that it is hard to tolerant test  $\mathcal{P}'$ . The proof of Lemma 5.9 is identical to the proof of Lemma 3.10 up to change in parameters and is hence omitted.

► **Lemma 5.9.** *Let  $\varepsilon^* \in (0, 1)$  be as in Lemma 3.2 and  $c_2 > 1$  be as in Lemma 5.3. For every  $\alpha \in (\frac{\varepsilon^*}{57600 \cdot c_2 + 2\varepsilon^*}, 1)$ , and  $\varepsilon' \in (\alpha, \frac{28800 \cdot c_2 \cdot \varepsilon^*}{28800 \cdot c_2 + \varepsilon^*})$ , every  $(\alpha, \varepsilon')$ -tolerant tester for  $\mathcal{P}'$  requires  $\tilde{\Omega}(N^{0.2})$  queries.*

**Proof of Theorem 1.6.** For sufficiently small  $\varepsilon^*$ , setting  $\alpha = \frac{\varepsilon^*}{57600 \cdot c_2 + \varepsilon^*}$  and  $\varepsilon = \frac{57599}{57600 \cdot c_2 + 2\varepsilon^*}$  satisfies all the constraints on  $\varepsilon$  and  $\alpha$  imposed by Theorem 5.1. ◀

## 6 Local Erasure-Decoding Versus Local Decoding

In this section, we prove Theorem 1.8 and an observation that if a code is locally decodable, it is also locally erasure-decodable up to (nearly) twice as many erasures. To prove Theorem 1.8, we first make the local erasure-decoder for  $\{C_n\}_{n \in \mathbb{N}}$  nonadaptive. We then show that every LEDC with a nonadaptive decoding algorithm is such that uncorrupted codewords can be locally decoded using an algorithm that queries nearly uniformly distributed codeword indices (Claim 6.2). We then use this ‘smoothness’ property (see Definition 6.1) to show that the code family is locally decodable from a smaller fraction of errors than erasures (Claim 6.3).

► **Definition 6.1** (Smooth Locally Decodable Codes). A code family  $\{C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N\}_{n \in \mathbb{N}}$  is  $(q, \eta)$ -smooth locally decodable if there exists a  $(0, q)$ -local erasure-decoder  $A$  (see Definition 1.7) that, given oracle access to an uncorrupted codeword  $w \in \mathbb{F}_2^N$ , and input  $i \in [n]$ , is such that for all  $j \in [N]$ , the probability that  $A$  queries  $j$  is at most  $\eta$ .

► **Claim 6.2.** *For every  $\alpha \in [0, 1)$ , if a code  $C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N$  is  $(\alpha, q)$ -locally erasure-decodable, then  $C_n$  is  $(q', \eta)$ -smooth locally decodable, where  $q' = 18q \cdot 9^{q-1}$ , and  $\eta = q'/\alpha N$ .*

► **Claim 6.3.** *For every  $\alpha \in [0, 1)$ , if a code  $C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N$  is  $(q, q/\alpha N)$ -smooth locally erasure-decodable, then  $C_n$  is  $(\alpha/12q^2, 72q)$ -locally decodable.*

**Proof of Claim 6.2.** Let  $A$  be an  $(\alpha, q)$ -local erasure-decoder for  $C_n$ . We first design a nonadaptive local erasure-decoder  $A_1$  for  $C_n$  that makes a higher number of queries than  $A$ . Consider a (partially erased) codeword  $w \in (\{\perp\} \cup \mathbb{F}_2)^N$  that has at most  $\alpha$  fraction of erasures. The algorithm  $A_1$ , on oracle access to  $w$  and an input  $i \in [n]$ , has  $18 \cdot 9^{q-1}$  independent iterations. In each iteration,  $A_1$  simulates  $A$ , guesses the answers to the first  $q-1$  queries made by  $A$ , and decides the  $q$ -th query of  $A$  based on these guesses.  $A_1$  then queries  $w$  on the  $q$  queries made by  $A$  in the simulation. If all the query answers agree with the guesses, the decoder  $A_1$  stores the output of  $A$  as the output of the current iteration. Otherwise, it stores a uniformly random bit as the output of the current iteration. Finally,  $A_1$  outputs the majority value output among all iterations.

In any particular iteration, the probability that  $A_1$  outputs the correct answer in that iteration, is at least  $\frac{3^{q-1}-1}{3^q-1} \cdot \frac{1}{2} + \frac{1}{3^q-1} \cdot \frac{2}{3}$ , which is equal to  $\frac{1}{2} + \frac{1}{6 \cdot 3^{q-1}}$ . Hence, using standard arguments, the probability that  $A_1$  outputs the correct answer after  $18 \cdot 9^{q-1}$  independent iterations, is at least  $2/3$ . The query complexity of  $A_1$  is  $18q \cdot 9^{q-1}$ , which we denote by  $q'$ .

We now use  $A_1$  to construct  $A_2$ , a  $(q', \frac{q'}{\alpha N})$ -smooth local decoder for  $C_n$ . Consider an uncorrupted codeword  $w = C_n(x)$  for  $x \in \mathbb{F}_2^n$ . For each  $i \in [n]$ , let  $S_i$  denote the set consisting of indices in  $[N]$  that get queried by  $A_1$  (on input  $i$ ) with probability more than  $\frac{q'}{\alpha N}$ . Since  $\sum_{j \in [N]} \Pr[A_1^{C_n(x)}(i) \text{ queries } j] = q'$ , we have  $|S_i| \leq \alpha \cdot N$ . On input  $i \in [n]$  and oracle access to  $w = C_n(x)$ , the algorithm  $A_2$  simulates  $A_1$  in the following way. If  $A_1$  queries  $j' \in S_i$ , the algorithm  $A_2$  does not query  $j'$  and assumes that  $w[j'] = \perp$ . Thus,  $A_2$  is a  $(q', \frac{q'}{\alpha N})$ -smooth local decoder for  $C_n$ . ◀

**Proof of Claim 6.3.** Consider a  $(q, \frac{q}{\alpha N})$ -smooth local decoder  $A$  for  $C_n$ . We will construct an  $(\frac{\alpha}{12q^2}, 72q)$ -local decoder  $A'$  for  $C_n$ . Algorithm  $A'$ , on input  $i \in [n]$  and oracle access to a word  $w$  with at most  $\frac{\alpha}{12q^2}$  fraction of errors, performs 72 independent repetitions of  $A$  and outputs the majority value output among all the iterations. Let  $x \in \mathbb{F}_2^n$  be such that  $y = C_n(x)$  is the codeword closest to  $w$ . If  $A$  is run on input  $i$  with oracle access to  $y$ , then for at least  $\frac{2}{3}$  fraction of the sequences of its random coin tosses,  $A$  returns  $x_i$  correctly. When  $A$  is run on input  $i$  with oracle access to  $w$ , by the union bound and the smoothness of  $A$ , at most  $q \cdot \frac{\alpha}{12q^2} \cdot N \cdot \frac{q}{\alpha N} = \frac{1}{12}$  fraction of sequences of its random coin tosses result in an erroneous position being queried. Hence, the probability that  $A$ , on input  $i$  and oracle access to  $w$ , returns  $x_i$  correctly is at least  $\frac{2}{3} - \frac{1}{12}$ . Hence, the probability that  $A'$  outputs  $x_i$  correctly is at least  $2/3$ . The query complexity of  $A'$  is  $72q$ . ◀

► **Observation 6.4.** Every  $(\alpha, q)$ -locally decodable code  $C_n : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^N$  is also  $(2\alpha - \rho, 72q)$ -locally erasure-decodable, where  $\rho = 2 \cdot \sqrt{\ln(12) \cdot \alpha/N}$ .

## Abstract

We introduce new models and new information theoretic measures for the study of communication complexity in the natural peer-to-peer, multi-party, number-in-hand setting. We prove a number of properties of our new models and measures, and then, in order to exemplify their effectiveness, we use them to prove two lower bounds. The more elaborate one is a tight lower bound of  $\Omega(kn)$  on the multi-party peer-to-peer randomized communication complexity of the  $k$ -player,  $n$ -bit function Disjointness,  $\text{Disj}_k^n$ . The other one is a tight lower bound of  $\Omega(kn)$  on the multi-party peer-to-peer randomized communication complexity of the  $k$ -player,  $n$ -bit bitwise parity function,  $\text{Par}_k^n$ . Both lower bounds hold when  $n = \Omega(k)$ . The lower bound for  $\text{Disj}_k^n$  improves over the lower bound that can be inferred from the result of Braverman et al. (FOCS 2013), which was proved in the coordinator model and can yield a lower bound of  $\Omega(kn/\log k)$  in the peer-to-peer model.

To the best of our knowledge, our lower bounds are the first tight (non-trivial) lower bounds on communication complexity in the natural *peer-to-peer* multi-party setting.

In addition to the above results for communication complexity, we also prove, using the same tools, an  $\Omega(n)$  lower bound on the number of random bits necessary for the (information theoretic) private computation of the function  $\text{Disj}_k^n$ .

## 1 Introduction

Communication complexity, first introduced by Yao [44], has become a major topic of research in Theoretical Computer Science, both for its own sake, and as a tool which has yielded important results (mostly lower bounds) in various theoretical computer science fields such as circuit complexity, streaming algorithms, or data structures (e.g., [34, 36, 24, 39, 23]). Communication complexity is a measure for the amount of communication needed in order to

---

<sup>2</sup> Research supported in part by ERC QCC and by ANR project RDAM.

solve a problem whose input is distributed among several players. The two-party case, where two players, usually called Alice and Bob, cooperate in order to compute a function of their respective inputs, has been widely studied with many important results; yet major questions in this area are still open today (e.g., the log-rank conjecture, see [34]). The multi-party case, where  $k \geq 3$  players cooperate in order to compute a function of their inputs, is much less understood.

A number of variants have been proposed in the literature to extend the two-party setting into the multi-party one. In this paper we consider the more natural *number-in-hand* (NIH) setting, where each player has its own input, as opposed to the so-called *number-on-forehead* (NOF) setting, where each player knows all pieces of the input except one, its own. Moreover, also the communication structure between the players in the multi-party setting was considered in the literature under a number of variants. For example, in the *blackboard* (or *broadcast*) model the communication between the players is achieved by each player writing, in turn, a message on the board, to be read by all other players. In the *coordinator* model, introduced in [20], there is an additional entity, the coordinator, and all players communicate back and forth only with the coordinator. The most natural setting is, however, the *peer-to-peer message-passing* model, where each pair of players is connected by a communication link, and each player can send a separate message to any other player. This latter setting has been studied, in the context of communication complexity, even less than the other multi-party settings, probably due to the difficulty in tracking the distributed communication patterns that occur during a run of a protocol in that setting. This setting is, however, not only the most natural one, and the one that occurs the most in real systems, but is the setting studied widely in the distributed algorithms and distributed computation communities, for complexity measures which are usually other than communication complexity.

In the present paper we attempt to fill this gap in the study of peer-to-peer communication complexity, and, further, to create a more solid bridge between the research field of communication complexity and the research field of distributed computation. We propose a computation model, together with an information theoretic complexity measure, for the analysis of the communication complexity of protocols in the asynchronous multi-party peer-to-peer (number-in-hand) setting. We argue that our model is, on the one hand, only a slight restriction over the asynchronous model usually used in the distributed computation literature, and, on the other hand, stronger than the models that have been previously suggested in order to study communication complexity in the peer-to-peer setting common in the distributed computation literature (e.g., [20, 42]). Furthermore, our model lends itself to the analysis of communication complexity, most notably using information theoretic tools.

Indeed, after defining our model and our information theoretic measure, that we call *Multi-party Information Cost* (MIC), we prove a number of properties of that measure, and then prove a number of fundamental properties of protocols in our model. We then exemplify the effectiveness of our model and information theoretic measure by proving two tight lower bounds. The more elaborate one is a tight lower bound of  $\Omega(kn)$ , when  $n = \Omega(k)$ , on the peer-to-peer randomized communication complexity of the function **set-disjointness** ( $\text{Disj}_k^n$ ). This function is a basic, important function, which has been the subject of a large number of studies in communication complexity, and is often seen as a test for our ability to give lower bounds in a given model (cf. [16]). We note that the communication complexity of Disjointness in the two-party case is well understood [29, 38, 3, 7, 9]. From a quantitative point of view, our result for peer-to-peer multi-party Disjointness improves by a  $\log k$  factor the lower bound that could be deduced for the peer-to-peer model from the lower bound on the communication complexity of Disjointness in the coordinator model [8]. The second lower

bound that we prove is a tight lower bound of  $\Omega(kn)$ , when  $n = \Omega(k)$ , on the peer-to-peer randomized communication complexity of the bitwise parity function  $\text{Par}_k^n$ . Both our lower bounds are obtained by giving a lower bound on the MIC of the function at hand, which yields the lower bound on the communication complexity of that function. We believe that our lower bounds are the first tight (non-trivial) lower bound on communication complexity in a peer-to-peer multi-party setting.<sup>3</sup>

It is important to note that, to the best of our knowledge, there is no known method to obtain tight lower bounds on multi-party communication complexity in a peer-to-peer setting via lower bounds in other known multi-party settings. Lower bounds obtained in the coordinator model can be transferred to the peer-to-peer model at the cost of a  $\log k$  factor, where  $k$  is the number of players, because any peer-to-peer protocol can be simulated in the coordinator model by having the players attach to every message the identity of the destination of that message [37, 21]. The loss of this factor in the lower bounds is unavoidable when the communication protocols can exploit a flexible communication pattern, since there are examples of functions where this factor in the communication complexity is necessary, while others, e.g., the parity function of single-bit inputs, have the same communication complexity in the coordinator and peer-to-peer settings (see a more detailed discussion on this point in Section 2.2). Therefore, one cannot prove tight lower bounds in the peer-to-peer setting by proving corresponding results in the coordinator model. Note that flexible communication configurations arise naturally for mobile communicating devices, for example, when these devices exchange information with the nearby devices. Constructions based on the pointer jumping problem also seem to be harder in the coordinator model, as solving the problem usually requires exchanging information in a specific order determined by the inputs of the players. It is thus important to develop lower bound techniques which apply directly in the peer-to-peer model, as we do in the present paper. Information theoretic tools seem, as we show, most suitable for this task.

**Information theoretic complexity measures.** As indicated above, our work makes use of information theoretic tools. Based on information theory, developed by Shannon [40], *Information Complexity* (IC), originally defined in [2, 14], is a powerful tool for the study of two-party communication protocols. Information complexity is a measure of how much *information*, about each other's input, the players must learn during the course of the protocol, if that protocol must compute the function correctly. Since IC can be shown to provide a lower bound on the communication complexity, this measure has proven to be a strong and useful tool for obtaining lower bounds on two-party communication complexity in a sequence of papers (e.g., [3, 4, 11, 7]). However, information complexity cannot be extended in a straightforward manner to the multi-party setting. This is because with three players or more, any function can be computed privately (cf. [5, 19]), i.e., in a way such that the players learn nothing but the value of the function to compute. This implies that the information complexity of any function is too low to provide a meaningful lower bound on the communication complexity in the natural peer-to-peer multi-party setting. Therefore, before the present paper, information complexity and its variants have been used to obtain lower bounds on multi-party communication complexity only in settings which do not allow for private protocols (and most notably not in the natural peer-to-peer setting), with the single

---

<sup>3</sup> Lower bounds in a seemingly peer-to-peer setting were given in [42]. However, in the model of that paper, the communication pattern is determined by an external view of the transcript, which makes the model equivalent to the coordinator model.

exception of [30]. For example, a number of lower bounds have been obtained via information complexity for a promise version of set-disjointness in the broadcast model [3, 13, 26] (also cf. [28]), and external information complexity was used in [10] for a lower bound on the general disjointness function, also in the broadcast model. In the coordinator model, lower bounds on the communication complexity of set-disjointness were given via variants of information complexity [8]. The latter result was extended in [15] to the function *Tribes*. A notion of external information cost in the coordinator model was introduced in [27] to study maximum matching in a distributed setting. We note that the study of communication complexity in number-in-hand multi-party settings via techniques other than those based on information theory is limited to very few papers. One such example is the technique of *symmetrization* that was introduced for the coordinator model in [37], and was shown to be useful to study functions such as the bitwise AND. That technique was further developed along with other reduction techniques in [41, 42, 43]. Another example is the notion of strong fooling sets, introduced in [12] to study deterministic communication complexity of discreet protocols, also defined in [12].

**Private computation.** It is well known that in the multi-party number-in-hand peer-to-peer setting, unlike in the two-party case, *any* function can be privately computed [5, 19]. The model that we define in the present paper does allow for (information theoretic) private computation of any function [5, 19, 1]. The minimum amount of private randomness needed in order to compute privately a given function is often referred to in this context as the *randomness complexity* of that function. Randomness complexity (in private computation) is of interest because true randomness is considered a costly resource, and since randomness complexity in private computation has been shown to be related to other complexity measures, such as the circuit size of the function or its sensitivity. For example, it has been shown [35] that a boolean function  $f$  has a linear size circuit if and only if  $f$  has constant randomness complexity. A small number of works [6, 33, 25, 30] prove lower bounds on the randomness complexity of the parity function. The parity and other modulo-sum functions are, to the best of our knowledge, the only functions for which randomness complexity lower bounds are known. Using the information theoretic results that we obtain in the present paper for the set-disjointness function, we are able to give a lower bound of  $\Omega(n)$  on the randomness complexity of  $\text{Disj}_k^n$ . The significance of this result lies in that it is the first such lower bound that grows with the size of the input (which is  $kn$ ), while the output remains a single bit, contrary to the sum function (see [6]) or the bitwise parity function (see [30]).

## 1.1 Our techniques and contributions

Our contribution in the present paper is twofold.

First, on the conceptual, modeling and definitions side we lay the foundations for proving lower bounds on (randomized) communication complexity in the natural peer-to-peer multi-party setting. Specifically, we propose a model that, on the one hand, is a very natural peer-to-peer model, and very close to the model used in the distributed computation literature, and, at the same time, does have properties that allow one to analyze protocols in terms of their information complexity and communication complexity. While at first sight the elaboration of such model does not seem to be a difficult task, many technical, as well as fundamental, issues render this task non-trivial. For example, one would like to define a notion of “transcript” that would guarantee both a relation between the length of the transcript and the communication complexity, and at the same time will contain *all* the information that the players get and use while running the protocol. The difficulty in elaborating such

model may be the reason for which, prior to the present paper, hardly any work studied communication complexity directly in a *peer-to-peer*, multi-party setting (cf. [21]), leaving the field with only the results that can be inferred from other models, hence suffering the appropriate loss in the obtained bounds. We propose our model (see Section 2.1) and prove a number of fundamental properties that allow one to analyze protocols in that model (see Section 3.2), as well as prove the accurate relationship between the entropy of the transcript and the communication complexity of the protocol (Proposition 2.4).

We then define our new information theoretic measure, that we call “Multi-party Information Cost” (MIC), intended to be applied to peer-to-peer multi-party protocols, and prove that it provides, for any (possibly randomized) protocol, a lower bound on the communication complexity of that protocol (Lemma 3.4). We further show that MIC has certain properties such as a certain direct-sum property (Theorem 3.5). We thus introduce a framework as well as tools for proving lower bounds on communication complexity in a peer-to-peer multi-party setting.

Second, we exemplify the effectiveness of our conceptual contributions by proving, using the new tools that we define, two tight lower bounds on the randomized communication complexity of certain functions in the peer-to-peer multi-party setting. Both these lower bounds are proved by giving a lower bound on the Multi-party Information Complexity of the function at hand. The more elaborate lower bound is a tight lower bound of  $\Omega(nk)$  on the randomized communication complexity of the function  $\text{Disj}_k^n$  (under the condition that  $n = \Omega(k)$ ). The function Disjointness is a well studied function in communication complexity and is often seen as a test-case of one’s ability to give lower bounds in a given model (cf. [16]). While the general structure of the proof of this lower bound does have similarities to the proof of a lower bound for Disjointness in the coordinator model [8],<sup>4</sup> we do, even in the parts that bear similarities, have to overcome a number of technical difficulties that require new ideas and new proofs. For example, the very basic *rectangularity* property of communication protocols is, in the multi-party (peer-to-peer) setting, very sensitive to the details of the definition of the model and the notion of a transcript. We therefore need first to give a proof of this property in the peer-to-peer model (Lemma 3.6 and Lemma 3.7). We then use a distribution of the input which is a modification over the distributions used in [8, 15] (see Section 5). Our proof proceeds, as in [8], by proving a lower bound for the function AND, on a certain information theoretic measure that, in our proof, is called SMIC (for Switched Multi-party Information Cost), and then, by using a direct-sum-like lemma, to infer a lower bound on SMIC for Disjointness (we note that SMIC is an adaptation to the peer-to-peer model of a similar measure used in [8]). However, the lack of a “coordinator” in a peer-to-peer setting necessitates a definition of a more elaborate reduction protocol, and a more complicated proof for the direct-sum argument, inspired by classic secret-sharing primitives. See Lemma 6.1 for our construction and proof. We then show that SMIC provides a lower bound on MIC, which yields our lower bound on the communication complexity of Disjointness.

We further give a tight lower bound of  $\Omega(nk)$  on the randomized communication complexity of the function  $\text{Par}_k^n$  (bitwise parity) in the peer-to-peer multi-party setting (under the condition that  $n = \Omega(k)$ ). This proof proceeds by first giving a lower bound on MIC for the parity function  $\text{Par}_k^1$ , and then using a direct-sum property of MIC to get a lower bound on MIC for  $\text{Par}_k^n$ . The latter yields the lower bound of  $\Omega(nk)$  on the communication complexity of  $\text{Par}_k^n$ .

<sup>4</sup> The lower bound in [8] would yield an  $\Omega(\frac{1}{\log k} \cdot nk)$  lower bound in the peer-to-peer setting.

To the best of our knowledge, our lower bounds are the first tight (non-trivial) lower bound on communication complexity in a peer-to-peer multi-party setting.

In addition to our results on communication complexity, we analyze the number of random bits necessary for private computations [5, 19], making use of the model, tools and techniques we develop in the present paper. It has been shown [30] that the *public information cost* (defined also in [30]) can be used to derive a lower bound on the randomness complexity of private computations. In the present paper we give a lower bound on the public information cost of any synchronous protocol computing the Disjointness function by relating it to its Switched Multi-party Information Cost, which yields the lower bound on the randomness complexity of Disjointness.

**Organization.** Due to space limitation *all* proofs are deferred to the full version of the paper. Section 2 introduces our model. In Section 3 we define our new information theoretic measure, MIC, give some of its properties, and give a number of fundamental properties of protocols in our model. In Section 4 we give the lower bound for the bitwise parity function. In Section 5 we prove a lower bound on the switched multi-party information cost of  $\text{AND}_k$ , and in Section 6, we prove, using the results of Section 5, the lower bound on the communication complexity of  $\text{Disj}_k^n$ . In Section 7 we apply our information theoretic lower bounds in order to give a lower bound on the number of random bits necessary for the private computation of  $\text{Disj}_k^n$ . Last, in Section 8 we discuss some open questions.

## 2 Multi-party communication protocols

We start with our model, and, to this end, give a number of notations.

**Notations.** We denote by  $k$  the number of players. We often use  $n$  to denote the size (in bits) of the input to each player. Calligraphic letters will be used to denote sets. Upper case letters will be used to denote random variables, and given two random variables  $A$  and  $B$ , we will denote by  $AB$  the joint random variable  $(A, B)$ . Given a string (of bits)  $s$ ,  $|s|$  denotes the length of  $s$ . Using parentheses we denote an ordered set (family) of items, e.g.,  $(Y_i)$ . Given a family  $(Y_i)$ ,  $Y_{-i}$  denotes the sub-family which is the family  $(Y_i)$  *without* the element  $Y_i$ . The letter  $X$  will usually denote the input to the players, and we thus use the shortened notation  $X$  for  $(X_i)$ , i.e., the input to all players. A protocol will usually be denoted by  $\pi$ .

We now define a natural communication model which is a slight restriction of the general asynchronous peer-to-peer model. The restriction of our model compared to the general asynchronous peer-to-peer model is that for a given player at a given time, the set of players from which that player waits for a message before sending any message of its own is determined by that player's own local view, i.e., from that player's input and the messages it has read so far, as well as its private randomness, and the public randomness. This allows us to define information theoretic tools that pertain to the transcripts of the protocols, and at the same time to use these tools as lower bounds for communication complexity. This restriction however does not exclude the existence of private protocols, as other special cases of the general asynchronous model do. We observe that practically all multi-party protocols in the literature are implicitly defined in our model, and that without such restriction, one bit of communication can bring  $\log k$  bits of information, because not only the content of the message, but also the identity of the sender may reveal information. To exemplify why the general asynchronous model is problematic consider the following simple example (that we borrow from our work in [30]).

► **Example 2.1.** There are 4 players  $A$ ,  $B$  and  $C$ ,  $D$ . The protocol allows  $A$  to transmit to  $B$  its input bit  $x$ . But all messages sent in the protocol are the bit 0, and the protocol generates only a single transcript over all possible inputs. The protocol works as follows:

**A:** If  $x = 0$  send 0 to  $C$ ; after receiving 0 from  $C$ , send 0 to  $D$ .

If  $x = 1$  send 0 to  $D$ ; after receiving 0 from  $D$ , send 0 to  $C$

**B:** After receiving 0 from a player, send 0 back to that player.

**C,D:** After receiving 0 from  $A$  send 0 to  $B$ . After receiving 0 from  $B$  send 0 to  $A$ .

It is easy to see that  $B$  learns the value of  $x$  from the order of the messages it gets.

In what follows we formally define our model, compare it to the general one and to other restricted ones, and explain the usefulness and logic of our specific model.

## 2.1 Definition of the model

We work in a *multi-party, number-in-hand, peer-to-peer* setting. Each player  $1 \leq i \leq k$  has unbounded local computation power and, in addition to its input  $X_i$ , has access to a source of private randomness  $R_i$ . We will use the notation  $R$  for  $(R_i)$ , i.e., the private randomness of all players. A source of public randomness  $R^p$  is also available to all players. We will call a protocol with no private randomness a public-coins protocol. The system consists of  $k$  players and a family of  $k$  functions  $f = (f_i)_{i \in [1, k]}$ , with  $\forall i \in [1, k]$ ,  $f_i : \prod_{\ell=1}^k \mathcal{X}_\ell \rightarrow \mathcal{Y}_i$ , where  $\mathcal{X}_\ell$  denotes the set of possible inputs of player  $\ell$ , and  $\mathcal{Y}_i$  denotes the set of possible outputs of player  $i$ . The players are given some input  $x = (x_i) \in \prod_{i=1}^k \mathcal{X}_i$ , and for every  $i$ , player  $i$  has to compute  $f_i(x)$ .

We define the communication model as follows, which is the asynchronous setting, with some restrictions. To make the discussion simpler we assume a global time which is *unknown* to the players. Every pair of players is connected by a bidirectional communication link that allows them to send messages to each other. There is no bound on the delivery time of a message, but every message is delivered in finite time, and the communication link maintains FIFO order in each of the two directions. Given a specific time we define the *view* of player  $i$  as the input of this player,  $X_i$ , its private randomness,  $R_i$ , the public randomness,  $R^p$ , and the messages read so far by player  $i$ . After the protocol has started, each player runs the protocol in *local rounds*. In each round, player  $i$  sends messages to some subset of the other players. The identity of these players, as well as the content of these messages, depend on the current view of player  $i$ . The player also decides whether it should stop, and output (or “return”) the result of the function  $f_i$ . Then (if player  $i$  did not stop and return the output), the player waits for messages from a certain subset of the other players, this subset being also determined by the current view of the player. Then the (local) round of player  $i$  terminates.<sup>5</sup> To make it possible for the player to identify the arrival of the *complete* message that it waits for, we require that each message sent by a player in the protocol is self-delimiting.

Denote by  $\mathcal{D}_i^\ell$  the set of possible views of player  $i$  at the end of local round  $\ell$ ,  $\ell \geq 0$ , where the beginning of the protocol is considered round 0.

Formally, a **protocol**  $\pi$  is defined by a set of local programs, one for each player  $i$ , where the local program of player  $i$  is defined by a sequence of functions, parametrized by the index of the *local* round  $\ell$ ,  $\ell \geq 1$ :

<sup>5</sup> The fact that the receiving of the incoming messages comes as the last step of the (local) round comes only to emphasize that the sending of the messages and the output are a function of only the messages received in previous (local) rounds.

- $S_i^{\ell,s} : \mathcal{D}_i^{\ell-1} \rightarrow 2^{\{1,\dots,k\}\setminus\{i\}}$ , defining the set of players to which player  $i$  sends the messages.
- $m_{i,j}^\ell : \mathcal{D}_i^{\ell-1} \rightarrow \{0,1\}^*$ , such that for any  $D_i^{\ell-1} \in \mathcal{D}_i^{\ell-1}$ , if  $j \in S_i^{\ell,s}(D_i^{\ell-1})$ , then  $m_{i,j}^\ell(D_i^{\ell-1})$  is the content of the message player  $i$  sends to player  $j$ . Each such message is self-delimiting.
- $O_i^\ell : \mathcal{D}_i^{\ell-1} \rightarrow \{0,1\}^* \cup \{\perp\}$ , defining whether or not the local program of player  $i$  stops and the player returns its output, and what is that output. If the value is  $\perp$  then no output occurs. If the value is  $y \in \{0,1\}^*$ , then the local program stops and the player returns the value  $y$ .
- $S_i^{\ell,r} : \mathcal{D}_i^{\ell-1} \rightarrow 2^{\{1,\dots,k\}\setminus\{i\}}$ , defining the set of players from which player  $i$  waits to receive a message.

To define the **transcript** of a protocol we proceed as follows. We first define  $k(k-1)$  basic transcripts  $\Pi_{i,j}^r$ , denoting the transcript of the messages read by player  $i$  from its link from player  $j$ , and another  $k(k-1)$  basic transcripts  $\Pi_{i,j}^s$ , denoting the transcript of the messages sent by player  $i$  on its link to player  $j$ .

We then define the transcript of player  $i$ ,  $\Pi_i$ , as the  $2(k-1)$ -tuple of the  $2(k-1)$  basic transcripts  $\Pi_{i,j}^r, \Pi_{i,j}^s, j \in [1, k] \setminus \{i\}$ . The transcript of the whole protocol  $\Pi$  is defined as the  $k$ -tuple of the  $k$  player transcripts  $\Pi_i, i \in [1, k]$ . We denote by  $\Pi_i(x, r)$  the transcript of player  $i$  when protocol  $\pi$  is run on input  $x$  and on randomness (public and private of all players)  $r$ . By  $\Pi_i^\ell(x, r)$  we denote  $\Pi_i(x, r)$  modified such that all the messages that player  $i$  sends in local rounds  $\ell' > \ell$ , and all the messages that player  $i$  reads in local rounds  $\ell' > \ell$  are eliminated from the transcript. Observe that while  $\Pi_{i,j}^r$  is always a prefix of  $\Pi_{j,i}^s$ , the definition of a protocol does not imply that they are equal. Further observe that each bit sent in  $\pi$  appears in  $\Pi$  at most twice.

We note that while seemingly the model that we introduce here is the same as the one used in [30], there are important differences between the models, and that these differences are crucial for the properties that we prove in the present paper to hold. See Section 2.2 for a comparison.

For a  $k$ -party protocol  $\pi$  we denote the set of possible inputs as  $\mathcal{X}$ , and denote the projection of this set on the  $i$ 'th coordinate (i.e., the set of possible inputs for player  $i$ ) by  $\mathcal{X}_i$ . Thus  $\mathcal{X} \subseteq \mathcal{X}_1 \times \dots \times \mathcal{X}_k$ . The set of possible transcripts for a protocol is denoted  $\mathcal{T}$ , and the projection of this set on the  $i$ 'th coordinate (i.e., the set of possible transcripts of player  $i$ ) is denoted  $\mathcal{T}_i$ . Observe that  $\mathcal{T} \subseteq \mathcal{T}_1 \times \dots \times \mathcal{T}_k$ .

Furthermore, in the course of the proofs, we sometimes consider a protocol that does *not* have access to public randomness (but may have private randomness). We call such protocol a *private-coins protocol*.

We now formally define the notion of a protocol computing a given function with certain bounded error. We will give most of the following definitions for the case where all functions  $f_i$  are the same function, that we denote by  $f$ . The definitions in the case of family of functions are similar.

► **Definition 2.2.** For a given  $0 \leq \epsilon < 1$ , a protocol  $\pi$   $\epsilon$ -computes a function  $f$  if for all  $x \in \Pi_{i=1}^k \mathcal{X}_i$ :

- For all possible assignments for the random sources  $R_i, 1 \leq i \leq k$ , and  $R^p$ , every player eventually stops and returns an output.
- With probability at least  $1 - \epsilon$  (over all random sources) the following event occurs: each player  $i$  outputs the value  $f(x)$ , i.e., the correct value of the function.

We also consider the notion of *external computation*.

► **Definition 2.3.** For a given  $0 \leq \epsilon < 1$ , a protocol  $\pi$  *externally*  $\epsilon$ -computes  $f$  if there exists a deterministic function  $\theta$  taking as input the possible transcripts of  $\pi$  and verifying  $\forall x \in \mathcal{X}$ ,  $\Pr[\theta(\Pi(x)) = f(x)] \geq 1 - \epsilon$ .

The **communication complexity** of a protocol is defined as the worst case, over the possible inputs and the possible randomness, of the number of bits sent by all players. For a protocol  $\pi$  we denote its communication complexity by  $\text{CC}(\pi)$ . For a given function  $f$  and a given  $0 \leq \epsilon < 1$ , we denote by  $\text{CC}^\epsilon(f)$  the  $\epsilon$ -error communication complexity of  $f$ , i.e.,  $\text{CC}^\epsilon(f) = \inf_{\pi \text{ } \epsilon\text{-computing } f} \text{CC}(\pi)$ .

Finally, we give a proposition that relates the communication complexity of a  $k$ -party protocol  $\pi$  to the entropy of the transcripts of the protocol  $\pi$ .

► **Proposition 2.4.** *Let the input to a  $k$ -party protocol  $\pi$  be distributed according to an arbitrary distribution. Then,  $\sum_{i=1}^k H(\Pi_i) \leq 4 \cdot \text{CC}(\pi) + 4k^2$ , where the entropy is according to the input distribution and the randomization of protocol  $\pi$ .*

## 2.2 Comparison to other models

The somewhat restricted model (compared to the general asynchronous model) that we work with allows us to use information theoretic tools for the study of protocols in this model, and in particular to give lower bounds on the multi-party communication complexity. Notice that the general asynchronous model is problematic in this respect since one bit of communication can bring  $\log k$  bits of information, because not only the content of the message, but also the identity of the sender may reveal information. Thus, information cannot be used as a lower bound on communication. In our case, the sets  $S_i^{l,r}$  and  $S_i^{l,s}$  are determined by the current view of the player,  $\Pi$  contains only the content of the messages, and thus the desirable relation between the communication and the information is maintained. On the other hand, our restriction is natural, does not seem to be very restrictive (practically all protocols in the literature adhere to our model), and does not exclude the existence of private protocols. To exemplify why the general asynchronous model is problematic see Example 2.1.

While the model that we introduce in the present paper bears some similarities to the model used in [30], there are a number of important differences between them. First, the definition of the transcript is different, resulting in a different relation between the entropy of the transcript and the communication complexity. More important is the natural property of the model in the present paper that the local program of a protocol in a given node ends its execution when it locally gives its output. It turns out that the very basic rectangularity property of protocols, used in many papers, holds in this case (and when the transcript is defined as we define in the present paper), while if the local protocol may continue to operate after output, there are examples where this property does not hold. Thus, we view the introduction of the present model also as a contribution towards identifying the necessary features of a peer-to-peer model so that basic and useful properties of protocols hold in the peer-to-peer setting.

There has been a long series of works about multi-party communication protocols in different variants of models, for example [20, 13, 26, 28, 37, 17, 18] (see [21] for a comparison of a few of these models). In the *coordinator model* (cf. [20, 37, 8]), an additional player (the coordinator) with no input can communicate privately with each player, and the players can only communicate with the coordinator. We first note that the coordinator model does not yield exact bounds for the multi-party communication complexity in the peer-to-peer setting (neither in our model nor in the most general one). Namely, any protocol in the peer-to-peer model can be transformed into a protocol in the coordinator model with an

$O(\log k)$  multiplicative factor in the communication complexity, by sending each message to the coordinator with an  $O(\log k)$ -bit label indicating its destination. This factor is sometimes necessary, e.g., for the **permutation** functional defined as follows: Given a permutation  $\sigma : \llbracket 1, k \rrbracket \rightarrow \llbracket 1, k \rrbracket$ , each player  $i$  has as input a bit  $b_i$  and  $\sigma^{-1}(\sigma(i) - 1)$  and  $\sigma^{-1}(\sigma(i) + 1)$  (i.e., each player has as input the indexes of the players before and after itself in the permutation).<sup>6</sup> For player  $i$  the function  $f_i$  is defined as  $f_i = b_{\sigma^{-1}(\sigma(i)+1)}$  (i.e., the value of the input bit of the next player in the permutation  $\sigma$ ). Clearly in our model the communication complexity of this function is  $k$  (each player sends its input bit to the correct player), and the natural protocol is valid in our model. On the other hand, in the coordinator model  $\Omega(k \log k)$  bits of communication are necessary. But this multiplicative factor between the complexities in the two models is not always necessary: the communication complexity of the parity function **Par** is  $\Theta(k)$  both in the peer-to-peer model and in the coordinator model.

Moreover, when studying private protocols in the multi-party setting, the coordinator model does not offer any insight. In the coordinator model, described in [20] and used for instance in [8], if one does not impose any privacy requirement with respect to the coordinator, it is trivial to have a private protocol by all players sending their input to the coordinator, and the coordinator returning the results to the players. If there is a privacy requirement with respect to the coordinator, then if there is a random source shared by all the players (but not the coordinator), privacy is always possible using the protocol of [22]. If no such source exists, privacy is impossible in general. This follows from the results of Braverman et al. [8] who show a non-zero lower bound on the total internal information complexity of all parties (including the coordinator) for the function *Disjointness* in that model. Our model, on the other hand, does allow for the private computation of any function [5, 19, 1].

It is worthwhile to contrast our model, and the communication complexity measure that we are concerned with, with work in the so-call congested-clique model that has gained increasing attention in the distributed computation literature (cf. [31, 32]). While both models are based on a communication network in the form of a complete graph (i.e., every player can send messages to any other player, and these messages can be different) there are two significant differences between them. Most of the works in the congested clique model deal with graph-theoretic problems and the input to each player is related to the adjacency list of a node (identified with that player) in the input graph, while in our model the input is not associated in any way with the communication graph. More importantly, the congested clique model is a *synchronous* model while ours is an asynchronous one. This brings about a major difference between the complexity measures studied in each of the models. Work in the congested clique model is concerned with giving bounds on the number of rounds necessary to fulfill a certain task under the condition that in each round each player can send to any other player a limited number of bits (usually  $O(\log k)$  bits). The measure of communication complexity, that is of interest to us in the present paper, deals with the total number of communication bits necessary to fulfill a certain task in an asynchronous setting without any notion of global rounds.<sup>7</sup>

<sup>6</sup> All additions are modulo  $k$ . This is a promise problem.

<sup>7</sup> Any function can be computed in the congested clique model with  $O(k)$  communication complexity (at a cost of having many rounds) by each player, having input  $x$ , sending a single bit to player 1 only at round number  $x$ . On the other hand, in the asynchronous model any function can be computed in a single “round” (at a cost of high communication complexity) by each player sending its whole input to player 1.

### 3 Tools for the study of multi-party communication protocols

In this section we consider two important tools for the study of peer-to-peer multi-party communication protocols. First, we define and introduce an information theoretic measure that we call *Multi-party Information Cost* (MIC); we later use it to prove our lower bounds. Then, we prove, in the peer-to-peer multi-party model that we define, the so-called rectangularity property of communication protocols, that we also use in our proofs.

#### 3.1 Multi-party Information Cost

We now introduce an information theoretic measure for multi-party peer-to-peer protocols that we later show to be useful for proving lower bounds on the communication complexity of multi-party peer-to-peer protocols. We note that a somewhat similar measure was proposed in [8] for the coordinator model, but, to the best of our knowledge, never found an application as a tool in a proof of a lower bound.

► **Definition 3.1.** For any  $k$ -player protocol  $\pi$  and any input distribution  $\mu$ , we define the *multi-party information cost* of  $\pi$ :

$$\text{MIC}_\mu(\pi) = \sum_{i=1}^k (I(X_{-i}; \Pi_i | X_i R_i) + I(X_i; \Pi_i | X_{-i} R_{-i})) .$$

Observe that the second part of each of the  $k$  summands can be interpreted as the information that player  $i$  “leaks” to the other players on its input. While the “usual” intuitive interpretation of two-party IC is “what Alice learns on Bob’s input plus what Bob learns on Alice’s input”, one can also interpret two-party IC as “what Alice learns on Bob’s input plus what Alice leaks on her input”. Thus, MIC can be interpreted as summing over all players  $i$  of “what player  $i$  learns on the other players’ inputs, plus what player  $i$  leaks on its input.” Indeed, the expression defining MIC is equal to the sum, over all players  $i$ , of the two-party IC for the two-party protocol that results from collapsing all players, except  $i$ , into one virtual player. Thus, for number of players  $k = 2$ ,  $\text{MIC} = 2 \cdot \text{IC}$ . We note that defining our measure without the private randomness in the condition of the mutual information expressions would yield the exact same measure (as is the case for 2-party IC); we prefer however to define MIC with the randomness in the conditions, as we believe that it allows one to give shorter, but still clear and accurate, proofs.

On the other hand observe that the second of the two mutual information expressions has  $X_{-i}$  in the condition, contrary to a seemingly similar measure used in [8] (Definition 3 in [8]). Our measure is thus “internal” in nature, while the one of [8] has an “external” component. The fact that MIC is “internal” allows us to give lower bounds on MIC, and thus to use it for lower bounds on the communication complexity, contrary to the measure of [8].

Further observe that the summation, over all players, of each one of the two mutual information expressions alone would not yield a measure useful for proving lower bounds on the communication complexity of functions. The first mutual information expression would yield a measure for functions that would never be higher than the entropy of the function at hand, due to the existence of private protocols for all functions [5, 19]. For the second mutual information expression there are functions for which that measure would be far too low compared to the communication complexity: e.g., the function  $f = x_1$ ,  $x \in \{0, 1\}^n$  (i.e., the value of the function is the input of player 1); in that case the measure would equal only  $n$ , while the communication complexity of that function is  $\Omega(kn)$ .

We now define the multi-party information complexity of a function.

► **Definition 3.2.** For any function  $f$ , any input distribution  $\mu$ , and any  $0 \leq \epsilon \leq 1$ , we define the quantity

$$\text{MIC}_\mu^\epsilon(f) = \inf_{\pi \text{ } \epsilon\text{-computing } f} \text{MIC}_\mu(\pi) .$$

► **Definition 3.3.** For any  $f$ , and any  $0 \leq \epsilon \leq 1$ , we define the quantity

$$\text{MIC}^\epsilon(f) = \inf_{\pi \text{ } \epsilon\text{-computing } f} \sup_{\mu} \text{MIC}_\mu(\pi) .$$

We now claim that the multi-party information cost and the communication complexity of a protocol are related, as formalized by the following lemma.

► **Lemma 3.4.** For any  $k$ -player protocol  $\pi$ , and for any input distribution  $\mu$ ,

$$\text{CC}(\pi) \geq \frac{1}{8} \text{MIC}_\mu(\pi) - k^2 .$$

We now show that the multi-party information cost satisfies a direct sum property for product distributions. In what follows, the notation  $f^{\otimes n}$  denotes the task of computing  $n$  instances of  $f$ , where the requirement from an  $\epsilon$ -computing protocol is that each instance is computed correctly with probability at least  $1 - \epsilon$  (as opposed to the stronger requirement that the whole vector of instances is computed correctly with probability at least  $1 - \epsilon$ ).

► **Theorem 3.5.** For any protocol  $\pi$  (externally)  $\epsilon$ -computing a function  $f^{\otimes n}$ , there exists a protocol  $\pi'$  (externally)  $\epsilon$ -computing  $f$  such that, for any product distribution  $\mu$  for the input, it holds that

$$\text{MIC}_{\mu^n}(\pi) \geq n \cdot \text{MIC}_\mu(\pi') .$$

## 3.2 The rectangularity property

The *rectangularity property* (or *Markov property*) is one of the key properties that follow from the structure and definition of (some) protocols. For randomized protocols it was introduced in the two-party setting and in the multi-party blackboard model in [3], and in the coordinator model in [8]. We prove a similar rectangularity property in the peer-to-peer model that we consider in the present paper.

We note that the proof of this property in the peer-to-peer model makes explicit use of the specific properties of the model we defined: the proof that follows explicitly uses the definition of the transcript on an edge by edge basis as in our model, as well as the fact that a player returns and stops as one operation. One can build examples where if any of these two properties does not hold, then the rectangularity property of protocols does not hold. Thus we view the following proof of rectangularity in our model also as an identification of model properties needed for the useful rectangularity property of multiparty peer-to-peer protocols to hold.

To define this property, for any transcript  $\bar{\tau} \in \mathcal{T}_i$ , let  $\mathcal{A}_i(\bar{\tau}) = \{(x, r) \mid \Pi_i(x, r) = \bar{\tau}\}$  (i.e., the set of input, randomness pairs that lead to transcript  $\bar{\tau}$ ), and define the projection of  $\mathcal{A}_i(\bar{\tau})$  on coordinate  $i$  as  $\mathcal{I}_i(\bar{\tau}) = \{(x', r'), \exists (x, r) \in \mathcal{A}_i(\bar{\tau}), x' = x_i \ \& \ r' = r_i\}$ , and the projection of  $\mathcal{A}_i(\bar{\tau})$  on the complement of coordinate  $i$  as  $\mathcal{J}_i(\bar{\tau}) = \{(x', r'), \exists (x, r) \in \mathcal{A}_i(\bar{\tau}), x' = x_{-i} \ \& \ r' = r_{-i}\}$ . Similarly, for any transcript  $\tau \in \mathcal{T}$ , let  $\mathcal{B}(\tau) = \{(x, r) \mid \Pi(x, r) = \tau\}$ , and for any player  $i$ , let  $\mathcal{H}_i(\tau) = \{(x', r'), \exists (x, r) \in \mathcal{B}(\tau), x' = x_{-i} \ \& \ r' = r_{-i}\}$ .

We start by proving a combinatorial property of transcripts of communication protocols, which intuitively follows from the fact that each player has access to only its own input and private randomness. The proof of this property is technically more involved compared to the analogous property in other settings, since the structure of protocols and the manifestation of the transcripts in the peer-to-peer setting are more flexible than in the other settings.

► **Lemma 3.6.** *Let  $\pi$  be a  $k$ -player private-coins protocol with inputs from  $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_k$ . Let  $\mathcal{T}$  denote the set of possible transcripts of  $\pi$ , and for  $i \in \llbracket 1, k \rrbracket$  let  $\mathcal{T}_i$  denote the set of possible transcript observed by player  $i$ , so that  $\mathcal{T} \subseteq \mathcal{T}_1 \times \dots \times \mathcal{T}_k$ . Then,  $\forall i \in \llbracket 1, k \rrbracket$ :*

- $\forall \bar{\tau} \in \mathcal{T}_i, \mathcal{A}_i(\bar{\tau}) = \mathcal{I}_i(\bar{\tau}) \times \mathcal{J}_i(\bar{\tau})$ .
- $\forall \tau \in \mathcal{T}, \mathcal{B}(\tau) = \mathcal{I}_i(\tau_i) \times \mathcal{H}_i(\tau)$ .

We now prove the *rectangularity property of randomized protocols* in the peer-to-peer setting.

► **Lemma 3.7.** *Let  $\pi$  be a  $k$ -player private-coins protocol with inputs from  $\mathcal{X} = \mathcal{X}_1 \times \dots \times \mathcal{X}_k$ . Let  $\mathcal{T}$  denote the set of possible transcripts of  $\pi$ , and for  $i \in \llbracket 1, k \rrbracket$  let  $\mathcal{T}_i$  denote the set of possible transcript observed by player  $i$ , so that  $\mathcal{T} \subseteq \mathcal{T}_1 \times \dots \times \mathcal{T}_k$ . Then for every  $i \in \llbracket 1, k \rrbracket$ , there exist functions  $q_i : \mathcal{X}_i \times \mathcal{T}_i \rightarrow [0, 1]$ ,  $q_{-i} : \mathcal{X}_{-i} \times \mathcal{T}_i \rightarrow [0, 1]$  and  $p_{-i} : \mathcal{X}_{-i} \times \mathcal{T} \rightarrow [0, 1]$  such that  $\forall x \in \mathcal{X}, \forall \tau = (\tau_1, \dots, \tau_k) \in \mathcal{T}, \Pr[\Pi_i(x) = \tau_i] = q_i(x_i, \tau_i)q_{-i}(x_{-i}, \tau_i)$ , and  $\forall x \in \mathcal{X}, \forall \tau = (\tau_1, \dots, \tau_k) \in \mathcal{T}, \Pr[\Pi(x) = \tau] = q_i(x_i, \tau_i)p_{-i}(x_{-i}, \tau)$ .*

## 4 The function parity

We now prove a lower bound on the multi-party peer-to-peer randomized communication complexity of the  $k$ -party  $n$ -bit parity function  $\text{Par}_k^n$ , defined as follows: each player  $i$  receives  $n$  bits  $(x_i^p)_{p \in \llbracket 1, n \rrbracket}$  and player 1 has to output the bitwise sum modulo 2 of the inputs, i.e.,  $\text{Par}_k^n(x) = (\oplus_{i=1}^k x_i^1, \oplus_{i=1}^k x_i^2, \dots, \oplus_{i=1}^k x_i^n)$  (the case where all  $k$  players compute the function is trivial). To start, we prove a lower bound on the multi-party information complexity of the parity function, where each player has a single input bit. For simplicity we denote this function  $\text{Par}_k$ , rather than  $\text{Par}_k^1$ .

► **Theorem 4.1.** *Let  $\mu$  be the uniform distribution on  $\{0, 1\}^k$ . Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , for any protocol  $\pi$   $\epsilon$ -computing  $\text{Par}_k$ , it holds that  $\text{MIC}_\mu(\pi) = \Omega(k)$ .*

The next theorem follows immediately from Theorem 4.1 and Theorem 3.5.

► **Theorem 4.2.** *Let  $\mu$  be the uniform distribution on  $\{0, 1\}^k$ . Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , for any protocol  $\pi$   $\epsilon$ -computing  $\text{Par}_k^n$ , it holds that  $\text{MIC}_{\mu^n}(\pi) = \Omega(kn)$ .*

We can now prove a lower bound on the communication complexity of  $\text{Par}_k^n$ . Note that the lower bound for  $\text{Par}_k^n$  given in [30] is valid only for a restricted class of protocols, called “oblivious” in [30].

► **Theorem 4.3.** *Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , there is a constant  $\alpha$  such that for  $n \geq \frac{1}{\alpha}k$ ,*

$$\text{CC}^\epsilon(\text{Par}_k^n) = \Omega(kn) .$$

## 5 The function AND

In this section we consider an arbitrary  $k$ -party protocol,  $\pi$ , where each player has an input bit  $x_i$ , and where  $\pi$  has to compute the AND of all the input bits. We prove a lower bound on a certain information theoretic measure (that we define below) for  $\pi$ . The proof makes use of the following input distribution.

**Input distribution.** Consider the distribution  $\mu$  defined as follows. Draw a bit  $M \sim \text{Ber}(\frac{2}{3}, \frac{1}{3})$ , and a uniformly random index  $Z \in \llbracket 1, k \rrbracket$ . Assign 0 to  $X_Z$ . If  $M = 0$ , sample  $X_{-Z}$  uniformly in  $\{0, 1\}^{k-1}$ ; if  $M = 1$ , assign  $1^{k-1}$  to  $X_{-Z}$ . We will also work with the product distribution  $\mu^n$ . Our distribution is similar to the ones of [8, 15] in that it leads to a high information cost (or similar measures) for the function  $\text{AND}_k$ . The distribution that we use has the property that the AND of any input in the support of  $\mu$  is 0. This allows us to prove lower bounds for the Disjointness function without the constraint that  $k = \Omega(\log n)$  which was necessary in [8] (but not in [15]).

### 5.1 Switched multi-party information cost of $\text{AND}_k$

We propose the following definition, which is an adaptation of the switched information cost of [8]. We call it Switched Multi-party Information Cost (SMIC).

► **Definition 5.1.** For a  $k$ -player protocol  $\pi$  with inputs drawn from  $\mu^n$  let

$$\text{SMIC}_{\mu^n}(\pi) = \sum_{i=1}^k (I(X_i; \Pi_i \mid MZ) + I(M; \Pi_i \mid X_i Z)) .$$

Note that the notion of SMIC is only defined with respect to the distribution  $\mu^n$  that we defined, and we may thus omit the distribution from the notation. We note that in order to simplify the expressions we often consider the public randomness as implicit in the information theoretic expressions we use below. It can be materialized either as part of the transcript or in the conditioning of the information theoretic expressions.

We can now prove the main result of this section.

► **Theorem 5.2.** For any fixed  $0 \leq \epsilon < \frac{1}{2}$ , for any protocol  $\pi$  externally  $\epsilon$ -computing  $\text{AND}_k$ ,

$$\text{SMIC}_{\mu}(\pi) = \Omega(k) .$$

## 6 The function Disjointness

In the  $k$  players  $n$ -bit disjointness function  $\text{Disj}_k^n$ , every player  $i \in \llbracket 1, k \rrbracket$  has an  $n$ -bit string  $(x_i^\ell)_{\ell \in \llbracket 1, n \rrbracket}$ , and the players have to output 1 if and only if there exists a coordinate  $\ell$  where all players have the bit 1. Formally,  $\text{Disj}_k^n(x) = \bigvee_{\ell=1}^n \bigwedge_{i=1}^k x_i^\ell$ .

### 6.1 Switched multi-party information cost of $\text{Disj}_k^n$

We first prove a direct-sum-type property which allows us to make the link between the functions  $\text{AND}_k$  and  $\text{Disj}_k^n$ . A similar property was proved in [8] in the coordinator model; our peer-to-peer model requires a different, more involved, construction, since we do not have the coordinator, and moreover no player can act as the coordinator since it would get too much information. Since  $\text{Disj}_k^n$  is the disjunction of  $n$   $\text{AND}_k$  functions, we analyze the switched multi-party information cost of  $\text{Disj}_k^n$  using the distribution  $\mu^n$ .

► **Lemma 6.1.** Let  $k > 3$ . For any protocol  $\pi$  externally  $\epsilon$ -computing  $\text{Disj}_k^n$ , there exists a protocol  $\pi'$  externally  $\epsilon$ -computing  $\text{AND}_k$  such that

$$\text{SMIC}_{\mu^n}(\pi) \geq n \cdot \text{SMIC}_{\mu}(\pi') .$$

Coupled with the lower bound on  $\text{SMIC}(\pi')$  for any protocol  $\pi'$  that computes  $\text{AND}_k$  (Section 5), the above lemma gives us a lower bound on  $\text{SMIC}(\pi)$  for any protocol that computes the function  $\text{Disj}_k^n$ :

► **Theorem 6.2.** *Let  $k > 3$ . Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , for any protocol  $\pi$  externally  $\epsilon$ -computing  $\text{Disj}_k^n$  it holds that*

$$\text{SMIC}_{\mu^n}(\pi) = \Omega(kn) .$$

## 6.2 Multi-party information complexity and communication complexity of $\text{Disj}_k^n$

The next lemma is key to our argument. The theorem that follows is a consequence of it and of Theorem 6.2.

► **Lemma 6.3.** *For any  $k$ -player protocol  $\pi$ ,  $\text{SMIC}_{\mu^n}(\pi) \leq \text{MIC}_{\mu^n}(\pi)$ .*

The next theorem follows immediately from Theorem 6.2 and Lemma 6.3.

► **Theorem 6.4.** *Let  $k > 3$ . Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , for any protocol  $\pi$  externally  $\epsilon$ -computing  $\text{Disj}_k^n$ , it holds that*

$$\text{MIC}_{\mu^n}(\pi) = \Omega(kn) .$$

We now conclude with a lower bound on the randomized communication complexity of the disjointness function.

► **Theorem 6.5.** *Given any fixed  $0 \leq \epsilon < \frac{1}{2}$ , there is a constant  $\alpha$  such that for  $n \geq \frac{1}{\alpha}k$ ,*

$$\text{CC}^\epsilon(\text{Disj}_k^n) = \Omega(kn) .$$

We note that our tight lower bound holds also for protocols where only one player is required to output the value of the function.

## 7 Randomness complexity of private protocols

A protocol  $\pi$  is said to *privately* compute a function  $f$  if, at the end of the execution of the protocol, the players have learned nothing but the value of that function. We now prove that the (information theoretic) private computation of  $\text{Disj}_k^n$  requires  $\Omega(n)$  random bits. We prove this result using the information theoretic results for  $\text{Disj}_k^n$  of the previous sections. The definitions and the details of the proof are deferred to the full version of the paper.

► **Theorem 7.1.** *Let  $k > 3$ . Then  $\mathcal{R}(\text{Disj}_k^n) = \Omega(n)$ , where  $\mathcal{R}(f)$  is the minimum number of random bits necessary for a protocol to privately compute  $f$ .*

## 8 Conclusions and open problems

We introduce new models and new information theoretic tools for the study of communication complexity, and other complexity measures, in the natural peer-to-peer, multi-party, number-in-hand setting. We prove a number of properties of our new models and measures, and exemplify their effectiveness by proving two lower bounds on communication complexity, as well as a lower bound on the amount of randomness necessary for certain private computations.

To the best of our knowledge, our lower bounds on communication complexity are the first tight (non-trivial) lower bounds on communication complexity in the natural *peer-to-peer* multi-party setting, and our lower bound on the randomness complexity of private computations is the first that grows with the size of the input, while the computed function is a boolean one (i.e., the size of the output does not grow with the size of the input).

We believe that our models and tools may find additional applications and may open the way to further study of the natural peer-to-peer setting and to the building of a more solid bridge between the the fields of communication complexity and of distributed computation.

Our work raises a number of questions. First, how can one relax the restrictions that we impose on the general asynchronous model and still prove communication complexity lower bounds in a peer-to-peer setting? Our work seems to suggest that novel techniques and ideas, possibly not based on information theory, are necessary for this task, and it would be most interesting to find those. Second, it would be interesting to identify the necessary and sufficient conditions that guarantee the “rectangularity” property of communication protocols in a peer-to-peer setting. While this property is fundamental to the analysis of two-party protocols, it turns out that once one turns to the multi-party peer-to-peer setting, not only does this property become subtle to prove, but also this property does not always hold. Given the central (and sometimes implicit) role of the rectangularity property in the literature, it would be interesting to identify when it holds in the multi-party peer-to-peer number-in-hand setting.

# A Schur Complement Cheeger Inequality

Aaron Schild<sup>1</sup>

University of California, Berkeley, CA, USA  
aschild@berkeley.edu

---

## Abstract

Cheeger’s inequality shows that any undirected graph  $G$  with minimum normalized Laplacian eigenvalue  $\lambda_G$  has a cut with conductance at most  $O(\sqrt{\lambda_G})$ . Qualitatively, Cheeger’s inequality says that if the mixing time of a graph is high, there is a cut that certifies this. However, this relationship is not tight, as some graphs (like cycles) do not have cuts with conductance  $o(\sqrt{\lambda_G})$ .

To better approximate the mixing time of a graph, we consider a more general object. Specifically, instead of bounding the mixing time with cuts, we bound it with cuts in graphs obtained by Schur complementing out vertices from the graph  $G$ . Combinatorially, these Schur complements describe random walks in  $G$  restricted to a subset of its vertices. As a result, all Schur complement cuts have conductance at least  $\Omega(\lambda_G)$ . We show that unlike with cuts, this inequality is tight up to a constant factor. Specifically, there is a Schur complement cut with conductance at most  $O(\lambda_G)$ .

## 1 Introduction

In this paper, we give a constant-factor approximation for the minimum ratio of electrical conductance to volume of any pair of sets  $S_1, S_2$ . When  $S_1$  is the complement of  $S_2$ , for example, this quantity is what is classically called the *conductance* of the set  $S_1$ , so the ratio that we consider is less than conductance of the graph  $G$ . We obtain this constant-factor approximation by showing that the minimum electrical conductance-to-volume ratio is approximated within a constant factor by  $\lambda_G$ . Thus, our quantity closes the classical  $\sqrt{\lambda_G}$  gap present between the upper and lower bounds in Cheeger’s inequality.

In particular, we prove the following partitioning result, which relates  $1/\lambda_G$  to effective resistances between sets in the graph  $G$ . Think of the weighted graph  $G$  as an electrical network, where each edge represents a conductor with electrical conductance equal to its weight. For two sets of vertices  $S_1$  and  $S_2$ , obtain a graph  $H$  by contracting all vertices in  $S_1$  to a single vertex  $s_1$  and all vertices in  $S_2$  to a single vertex  $s_2$ . Let  $\text{Reff}_G(S_1, S_2)$  denote the effective resistance between the vertices  $s_1$  and  $s_2$  in the graph  $H$ . Then, we show the following in Appendix A:

► **Theorem 1.** *In any weighted graph  $G$ , there are two sets of vertices  $S_1$  and  $S_2$  for which  $\text{Reff}_G(S_1, S_2) \geq 1/(25600\lambda_G \min(\text{vol}_G(S_1), \text{vol}_G(S_2)))$ . Furthermore, for any pair of sets  $S'_1, S'_2$ ,  $\text{Reff}_G(S'_1, S'_2) \leq 2/(\lambda_G \min(\text{vol}_G(S'_1), \text{vol}_G(S'_2)))$ .*

## 1.1 Relationship to Cheeger's Inequality

For a set of vertices  $S$ , let  $\phi_S$  denote the total weight of edges leaving  $S$  divided by the total degree of the vertices in  $S$ . Throughout the literature, this quantity is often called the conductance of  $S$ . To avoid confusion with electrical conductance, we call this quantity the *fractional conductance* of  $S$ . Let  $\phi_G$  denote the minimum fractional conductance of any set  $S$  with at most half of the volume (total vertex degree). Cheeger's inequality for graphs [3, 2] is as follows:

► **Theorem 2** (Cheeger's Inequality). *For any weighted graph  $G$ ,  $\lambda_G/2 \leq \phi_G \leq \sqrt{2\lambda_G}$ .*

Cheeger's inequality was originally introduced in the context of manifolds [6]. It is a fundamental primitive in graph partitioning [20, 15] and for upper bounding the mixing time of Markov chains [19]. Motivated by spectral partitioning, much work has been done on higher-order generalizations of Cheeger's inequality [13, 14]. The myriad of applications for Cheeger's inequality and generalizations of it [4, 21], along with the  $\sqrt{\lambda_G}$  gap between the upper and lower bounds, have led to a long line of work that seeks to improve the quality of the partition found when the spectrum has certain properties (for example, bounded eigenvalue gap [11] or when the graph has special structure [10].)

Here, we get rid of the  $\sqrt{\lambda_G}$  gap by taking a different approach. Instead of assuming special combinatorial or spectral structure of the input graph to obtain a tighter relationship between conductance and  $\lambda_G$ , we introduce a more general object than graph cuts that enable a tighter approximation to  $\lambda_G$ . Instead of just considering cuts in the given graph  $G$ , we consider cuts obtained by picking two disjoint sets of vertices  $S_1$  and  $S_2$ , computing the Schur complement of  $G$  onto  $S_1 \cup S_2$ , and looking at the cut consisting of all edges between  $S_1$  and  $S_2$  in that Schur complement. Let  $\rho_G$  be the minimum conductance of any such cut (defined formally in Section 2). We show that the minimum conductance of any such cut is a constant factor approximation to  $\lambda_G$ :

► **Theorem 3.** *Let  $G$  be a weighted graph. Then*

$$\lambda_G/2 \leq \rho_G \leq 25600\lambda_G$$

## 1.2 Graph Partitioning

Effective resistance in spectral graph theory has been used several times recently (for example [16, 1]) to obtain improved graph partitioning results.  $1/\lambda_G$  may not yield a good approximation to the effective resistance between pairs of vertices [5]. For example, on an  $n$ -vertex grid graph  $G$ , all effective resistances are between  $\Omega(1)$  and  $O(\log n)$ , but  $\lambda_G = \Theta(1/n)$ . Theorem 1 closes this gap by considering pairs of *sets* of vertices, not just pairs of vertices.

Cheeger's inequality is the starting point for analysis of spectral partitioning. In some partitioning tasks, cutting the graph does not make sense. For example, spectral partitioning is an important tool in image segmentation [18, 17]. Graph partitioning makes the most sense in image segmentation when one wants to find an object with a sharp boundary. However, in many images, like the one in Figure 1 on the right, objects may have fuzzy boundaries. In these cases, it is not clear which cut an image segmentation algorithm should return.

Considering cuts in Schur complements circumvents this ambiguity. Think of an image as a graph by making a vertex for each pixel and making an edge between adjacent pixels, where the weight on an edge is inversely related to the disparity between the colors of the endpoint pixels for the edge. An optimal segmentation in our setting would consist of the

■ **Figure 1** Spectral partitioning finds the  $S_1$ - $S_2$  cut in the left image, but may not in the right due to the presence of many equal weight cuts. The minimum fractional conductance Schur complement cut is displayed in both images.

■ **Figure 2** A tight example for the upper bound in Cheeger's inequality. The minimum fractional conductance of any cut in this graph is  $1/8$ , while the fractional conductance of the illustrated Schur complement cut on the right is  $2(1/4)/(2(1/4) + 8(1)) = 1/17 < 1/8$ .

two sets  $S_1$  and  $S_2$  corresponding to pixels on either side of the fuzzy boundary. Computing the Schur complement of the graph onto  $S_1 \cup S_2$  eliminates all vertices corresponding to pixels in the boundary.

Some examples in which Cheeger's inequality is not tight illustrate a similar phenomenon in which there are many equally good cuts. For example, let  $G$  be an unweighted  $n$ -vertex cycle. This is a tight example for the upper bound in Cheeger's inequality, as no cut has fractional conductance smaller than  $O(1/n)$  despite the fact that  $\lambda_G = \Theta(1/n^2)$ . Instead, divide the cycle into four equal-sized quarters and let  $S_1$  and  $S_2$  be two opposing quarters. The Schur complement cut between  $S_1$  and  $S_2$  has fractional conductance at most  $O(1/n^2)$ , which matches  $\lambda_G$  up to a constant factor.

### 1.3 Mixing Times of Markov Chains

Cheeger's inequality and variants of it can be used to upper bound the relaxation time of reversible Markov chains. The *relaxation time* of a reversible Markov chain is defined to be  $1/\lambda_G$  and approximates the mixing time of a chain up to a  $\log(1/\pi_{\min})$  factor, where  $\pi_{\min}$  is the minimum stationary distribution probability. To do this, one finds a fractional multicommodity flow that routes the demand  $\text{degree}(u)\text{degree}(v)$  for every pair of vertices

$u, v \in V(G)$ . The relevant quantity is the *congestion* of this flow. Specifically, view a multicommodity flow as a collection of paths  $\mathcal{P}$ , where a flow path has flow value  $f_p$ . The congestion of the flow is defined to be

$$\max_{e \in E(G)} \sum_{p \in \mathcal{P}: e \in p} |f_p|$$

The fractional conductance of any cut can be lower bounded using the the congestion of the flow. By the upper bound in Theorem 2, we get a lower bound on  $\lambda_G$  as well, which in turn yields an upper bound on the relaxation time of  $G$ . However, the congestion of the optimal fractional multicommodity flow is not a close approximation to the relaxation time of the graph, due to the loss in both Cheeger's inequality and in the gap between fractional multicommodity flows and sparsest cuts. One can improve upon this by considering a length-weighted form of congestion instead:

$$\max_{e \in E(G)} \sum_{p \in \mathcal{P}: e \in p} |f_p| |p|$$

The length-weighted congestion of any multicommodity flow in  $G$  routing the right demand is an upper bound on the relaxation time of  $G$ . For a precise statement of this, see Theorem 4.6 of [8]. This overcomes the square root present in the upper bound in Cheeger's inequality. However, this approach does not overcome the multicommodity flow-cut gap. In particular, any multicommodity flow in a constant-degree random Erdos-Renyi graph has length-weighted congestion at least  $\Omega(\log^2 n)$  (see, for example, Section 4.1 of [9]), despite the fact that these graphs have constant relaxation time.

Theorem 3 yields a upper lower bound on the relaxation time of a reversible Markov chain. Unlike the bounds discussed in the previous paragraph, it is tight up to a constant factor on all graphs. We do not know of a lower bound for Schur complement cut fractional conductance analogous to multicommodity flows for standard cuts.

## 2 Preliminaries

**Graph theory.** Consider an undirected, connected graph  $H$  with edge weights  $\{c_e^H\}_{e \in E(H)}$ ,  $m$  edges, and  $n$  vertices. Let  $V(H)$  and  $E(H)$  denote the vertex and edge sets of  $H$  respectively. For two sets of vertices  $A, B \subseteq V(H)$ , let  $E_H(A, B)$  denote the set of edges in  $H$  incident with one vertex in  $A$  and one vertex in  $B$  and let  $c^H(A, B) := \sum_{e \in E_H(A, B)} c_e^H$ . For a set of edges  $F \subseteq E(H)$ , let  $c^H(F) := \sum_{e \in F} c_e^H$ . For a set of vertices  $A \subseteq V(H)$ , let  $\partial_H A := E_H(A, V(H) \setminus A)$ . For a vertex  $v \in V(H)$ , let  $\partial_H v := \partial_H \{v\}$  denote the edges incident with  $v$  in  $H$  and let  $c_v^H := \sum_{e \in \partial_H v} c_e^H$ . For a set of vertices  $A \subseteq V(H)$ , let  $\text{vol}_H(A) := \sum_{v \in A} c_v^H$ . When  $A$  and  $B$  are disjoint, let  $H/(A, B)$  denote the graph with all vertices in  $A$  identified to one vertex  $a$  and all vertices in  $B$  identified to one vertex  $b$ . Formally, let  $H/(A, B)$  be the graph with  $V(H/(A, B)) = (V(H) \setminus (A \cup B)) \cup \{a, b\}$ , embedding  $f : V(H) \rightarrow V(H/(A, B))$  with  $f(u) := a$  if  $u \in A$ ,  $f(u) := b$  if  $u \in B$ , and  $f(u) := u$  otherwise, and edges  $\{f(u), f(v)\}$  for all  $\{u, v\} \in E(H)$ . Let  $H/A := H/(A, \emptyset)$ .

**Laplacians.** Let  $D_H$  be the  $n \times n$  diagonal matrix with rows and columns indexed by vertices in  $H$  and  $D_H(v, v) = c_v^H$  for all  $v \in V(H)$ . Let  $A_H$  be the adjacency matrix of  $H$ ; that is the matrix with  $A_H(u, v) = c_{uv}^H$  for all  $u, v \in V(H)$ . Let  $L_H := D_H - A_H$  be the Laplacian matrix of  $H$ . Let  $N_H := D_H^{-1/2} L_H D_H^{-1/2}$  denote the normalized Laplacian matrix

of  $H$ . For a matrix  $M$ , let  $M^\dagger$  denote the Moore-Penrose pseudoinverse of  $M$ . For subsets  $A$  and  $B$  of rows and columns of  $M$  respectively, let  $M[A, B]$  denote the  $|A| \times |B|$  submatrix of  $M$  restricted to those rows and columns. For a set of vertices  $S \subseteq V(H)$ , let  $\mathbf{1}_S$  denote the indicator vector for the set  $S$ . For two vertices  $u, v \in \mathbb{R}^n$ , let  $\chi_{uv} := \mathbf{1}_{\{u\}} - \mathbf{1}_{\{v\}}$ . When the graph is clear from context, we omit  $H$  from all of the subscripts and superscripts of  $H$ . For a vector  $x \in \mathbb{R}^n$ , let  $x_S \in \mathbb{R}^S$  denote the restriction of  $x$  to the coordinates in  $S$ .

Let  $\lambda_H$  denote the smallest nonzero eigenvalue of  $N_H$ . Equivalently,

$$\lambda_H := \min_{x \in \mathbb{R}^n: x^T D_H^{1/2} \mathbf{1}_{V(H)} = 0} \frac{x^T N_H x}{x^T x}$$

For any set of vertices  $X \subseteq V(H)$ , let

$$L_{\text{Schur}(H, X)} := L_H[X, X] - L_H[X, V(H) \setminus X] L_H[V(H) \setminus X, V(H) \setminus X]^{-1} L_H[V(H) \setminus X, X]$$

where brackets denote submatrices with the indexed rows and columns. The following fact applies specifically to Laplacian matrices:

► **Remark (Fact 2.3.6 of [12]).** For any graph  $H$  and any  $X \subseteq V(H)$ ,  $L_{\text{Schur}(H, X)}$  is the Laplacian matrix of an undirected graph.

Let  $\text{Schur}(H, X)$  denote the graph referred to in Remark 2. Schur complementation commutes with edge contraction and deletion and is associative:

► **Theorem 4** (Lemma 4.1 of [7], statement from [12]). *Given  $H$ ,  $S \subseteq V(H)$ , and any edge  $e$  with both endpoints in  $S$ ,*

$$\text{Schur}(H \setminus e, S) = \text{Schur}(H, S) \setminus e$$

and, for any pair of vertices  $x, y \in S$ ,

$$\text{Schur}(H/\{x, y\}, S) = \text{Schur}(H, S)/\{x, y\}$$

► **Theorem 5.** *Given  $H$  and two sets of vertices  $X \subseteq Y \subseteq V(H)$ ,  $\text{Schur}(\text{Schur}(H, Y), X) = \text{Schur}(H, X)$ .*

The following property follows from the definition of Schur complements:

► **Remark.** Let  $H$  be a graph and  $S \subseteq V(H)$ . Let  $I := \text{Schur}(H, S)$ . For any  $x \in \mathbb{R}^{V(H)}$  that is supported on  $S$  with  $x^T \mathbf{1}_{V(H)} = 0$ ,

$$x^T L_H^\dagger x = x_S^T L_I^\dagger x_S$$

The weight of edges in this graph can be computed using the following folklore fact, which we prove for completeness:

► **Theorem 6.** *For two disjoint sets  $C, D \subseteq V(H)$ , let  $I := \text{Schur}(H, C \cup D)$ . Then*

$$c^I(C, D) = \frac{1}{\chi_{cd}^T L_{H/(C, D)}^\dagger \chi_{cd}}$$

**Proof.** By definition,  $c^I(C, D) = c^{I/(C, D)}(\{c\}, \{d\})$ . By Theorem 4,  $I/(C, D) = \text{Schur}(H/(C, D), \{c, d\})$ . By Remark 2,  $c^{\text{Schur}(H/(C, D), \{c, d\})}(\{c\}, \{d\}) = \frac{1}{\chi_{cd}^T L_{H/(C, D)}^\dagger \chi_{cd}}$ . Combining these equalities gives the desired result. ◀

## 65:6 A Schur Complement Cheeger Inequality

We also use the following folklore fact about electrical flows, which we prove for the sake of completeness:

► **Theorem 7.** For two vertices  $s, t \in V(H)$ ,

$$\chi_{st}^T L_H^\dagger \chi_{st} = \frac{1}{\min_{p \in \mathbb{R}^{V(H)}: p_s \leq 0, p_t \geq 1} p^T L_H p}$$

**Proof.** We first show that

$$\chi_{st}^T L_H^\dagger \chi_{st} = \frac{1}{\min_{p \in \mathbb{R}^{V(H)}: p_s = 0, p_t = 1} p^T L_H p}$$

Taking the gradient of the objective  $p^T L_H p$  shows that that the optimal  $p$  are the potentials for an electrical flow with flow conservation at all vertices besides  $s$  and  $t$ . Therefore,  $p$  is proportional to  $L_H^\dagger \chi_{st} + \gamma \mathbf{1}$  for some  $\gamma \in \mathbb{R}$ . The constant of proportionality is  $\chi_{st}^T L_H^\dagger \chi_{st}$  since the  $s$ - $t$  potential drop in  $p$  is 1. Therefore,

$$\begin{aligned} \min_{p \in \mathbb{R}^{V(H)}: p_s = 0, p_t = 1} p^T L_H p &= \left( \frac{L_H^\dagger \chi_{st}}{\chi_{st}^T L_H^\dagger \chi_{st}} \right)^T L_H \left( \frac{L_H^\dagger \chi_{st}}{\chi_{st}^T L_H^\dagger \chi_{st}} \right) \\ &= \frac{1}{\chi_{st}^T L_H^\dagger \chi_{st}} \end{aligned}$$

The desired result follows from the fact that in the optimal  $p$ , all potentials are between 0 and 1 inclusive. ◀

**Notions of fractional conductance.** For a set of vertices  $A \subseteq V(H)$ , let

$$\phi_A^H := \frac{c^H(\partial_H(A))}{\min(\text{vol}_H(A), \text{vol}_H(V(H) \setminus A))}$$

be the *fractional conductance* of  $A$ . Let

$$\phi_H := \min_{A \subseteq V(H): A \neq \emptyset} \phi_A^H$$

be the *fractional conductance* of  $H$ .

For two disjoint sets of vertices  $A, B \subseteq V(H)$ , let  $I := \text{Schur}(H, A \cup B)$  and

$$\rho_{A,B}^H := \frac{c^I(A, B)}{\min(\text{vol}_I(A), \text{vol}_I(B))}$$

be the *Schur complement fractional conductance* of the pair of sets  $(A, B)$ . Define the *Schur complement fractional conductance* of the graph  $H$  to be

$$\rho_H := \min_{A, B \subseteq V(H): A \cap B = \emptyset, A \neq \emptyset, B \neq \emptyset} \rho_{A,B}^H$$

It will be helpful to deal with the quantities

$$\sigma_{A,B}^H := \frac{c^I(A, B)}{\min(\text{vol}_H(A), \text{vol}_H(B))}$$

and

$$\sigma_H := \min_{A, B \subseteq V(H): A \cap B = \emptyset, A \neq \emptyset, B \neq \emptyset} \sigma_{A,B}^H$$

as well, which we call the *mixed fractional conductances* of  $(A, B)$  and  $H$  respectively.

The following will be useful in relating  $\rho_{A,B}^H$  to  $\sigma_{A,B}^H$ :

► **Proposition 8.** *For any two sets  $X \subseteq Y \subseteq V(H)$ , let  $I := \text{Schur}(H, Y)$ . Then,*

$$\text{vol}_I(X) \leq \text{vol}_H(X)$$

**Proof.** It suffices to show this result when  $|X| = 1$  because  $\text{vol}$  is a sum of volumes (degrees) of vertices in the set. Furthermore, by Theorem 5, it suffices to show the result when  $|Y| = |V(H)| - 1$ . Let  $v$  be the unique vertex in  $H$  outside of  $Y$  and let  $u$  be the unique vertex in  $X$ . Then, by definition of the Schur complement,

$$\begin{aligned} \text{vol}_I(X) &= c_u^I \\ &= \sum_{w \in V(I)} c_{uw}^I \\ &= \sum_{w \in V(I)} \left( c_{uw}^H + \frac{c_{uv}^H c_{vw}^H}{c_v^H} \right) \\ &= \left( \sum_{w \in V(I)} c_{uw}^H \right) + \frac{c_{uv}^H}{c_v^H} \left( \sum_{w \in V(I)} c_{vw}^H \right) \\ &\leq \left( \sum_{w \in V(I)} c_{uw}^H \right) + c_{uv}^H \\ &= c_u^H \\ &= \text{vol}_H(X) \end{aligned}$$

as desired. ◀

To prove the upper bound, we given an algorithm for constructing a low fractional conductance Schur complement cut. The following result is helpful for making this algorithm take near-linear time:

► **Theorem 9** (Theorem 8.2 of [23]). *Given a graph  $H$ , there is a  $\tilde{O}(m)$ -time algorithm that produces a vector  $x \leftarrow \text{ApxFiedler}(H) \in \mathbb{R}^{V(H)}$  with  $x^T D_H^{1/2} \mathbf{1}_{V(H)} = 0$  for which*

$$x^T N_H x \leq 2\lambda_H x^T x$$

### 3 Lower bound

We now show the first inequality in Theorem 3, which follows from the following lemma by Proposition 8, which implies that  $\sigma_G \leq \rho_G$ .

► **Lemma 10.**

$$\lambda_G \leq 2\sigma_G$$

**Proof.** We lower bound the Schur complement fractional conductance of any pair of disjoint sets  $A, B \subseteq V(G)$ . Let  $I := \text{Schur}(G, A \cup B)$ . Let  $P$  be the  $(A \cup B) \times (A \cup B)$  diagonal matrix with  $P(u, u) = c_u^G$  for each  $u \in A \cup B$ . We start by lower bounding the minimum nonzero eigenvalue  $\lambda$  of the matrix  $P^{-1/2} L_I P^{-1/2}$ . Let  $\lambda_{\max}(M)$  denote the maximum eigenvalue of a symmetric matrix  $M$ . By definition of the Moore-Penrose pseudoinverse,

$$1/\lambda = \lambda_{\max}(P^{1/2} L_I^\dagger P^{1/2})$$

## 65:8 A Schur Complement Cheeger Inequality

By Remark 2,

$$\lambda_{\max}(P^{1/2}L_I^\dagger P^{1/2}) \leq \lambda_{\max}(N_G^\dagger) = 1/\lambda_G$$

Therefore,  $\lambda \geq \lambda_G$ . We now plug in a test vector. Let

$$z := P^{1/2} \left( \frac{\mathbf{1}_A}{\text{vol}_G(A)} - \frac{\mathbf{1}_B}{\text{vol}_G(B)} \right)$$

$z^T(P^{1/2}\mathbf{1}_{V(I)}) = 0$ , so

$$\begin{aligned} \lambda_G &\leq \lambda \\ &= \min_{x \in \mathbb{R}^{A \cup B}: x^T P^{1/2} \mathbf{1}_{V(I)} = 0} \frac{x^T (P^{-1/2} L_I P^{-1/2}) x}{x^T x} \\ &\leq \frac{z^T (P^{-1/2} L_I P^{-1/2}) z}{z^T z} \\ &= \frac{c^I(A, B) ((1/\text{vol}_G(A)) + (1/\text{vol}_G(B)))^2}{(\text{vol}_G(A)/\text{vol}_G(A)^2) + (\text{vol}_G(B)/\text{vol}_G(B)^2)} \\ &= \frac{c^I(A, B) \text{vol}_G(A \cup B)}{\text{vol}_G(A) \text{vol}_G(B)} \\ &\leq 2\sigma_{A, B}^G \end{aligned}$$

### 4 Upper bound

We now show the second inequality in Theorem 3:

► **Lemma 11.**

$$\rho_G \leq 25600\lambda_G$$

To prove this lemma, we need to find a pair of sets  $A$  and  $B$  with low Schur complement fractional conductance:

► **Lemma 12.** *There is a near-linear time algorithm  $\text{SweepCut}(G)$  that takes in a graph  $G$  with  $\lambda_G \leq 1/25600$  and outputs a pair of nonempty sets  $A$  and  $B$  with the following properties:*

- (Low Schur complement fractional conductance)  $\sigma_{A, B}^G \leq 640\lambda_G$
- (Large interior)  $\phi_A^G \leq 1/4$  and  $\phi_B^G \leq 1/4$

We now prove Lemma 11 given Lemma 12:

**Proof of Lemma 11 given Lemma 12.** Let  $I := \text{Schur}(G, A \cup B)$ . For any two vertices  $u, v \in A \cup B$ ,  $c_{uv}^I \geq c_{uv}^G$ . Therefore,  $\text{vol}_I(A) \geq 2 \sum_{u, v \in A} c_{uv}^G$  and  $\text{vol}_I(B) \geq 2 \sum_{u, v \in B} c_{uv}^G$ . By the “Large interior” guarantee of Lemma 12,  $2 \sum_{u, v \in A} c_{uv}^G \geq (3/4)\text{vol}_G(A)$  and  $2 \sum_{u, v \in B} c_{uv}^G \geq (3/4)\text{vol}_G(B)$ . Therefore,

$$\rho_{A, B}^G \leq 4/3\sigma_{A, B}^G \leq 1280\lambda_G$$

by the “Low Schur complement weight” guarantee when  $\lambda_G \leq 1/25600$ , as desired. When  $\lambda_G > 1/25600$ , the lemma is trivially true, as desired. ◀

Now, we implement **SweepCut**. The standard Cheeger sweep examines all thresholds  $q \in \mathbb{R}$  and for each threshold, computes the fractional conductance of the cut  $\partial S_{\leq q}$  of edges from vertices with eigenvector coordinate at most  $q$  to ones greater than  $q$ . Instead, the algorithm **SweepCut** examines all thresholds  $q \in \mathbb{R}$  and computes an upper bound (a proxy) for the  $\sigma_{S_{\leq q/2}, S_{\geq q}}^G$  for each positive  $q$  and  $\sigma_{S_{\leq q}, S_{\geq q/2}}^G$  for each negative  $q$ . Let  $I_q := \text{Schur}(G, S_{\geq q} \cup S_{\leq q/2})$  for  $q > 0$  and  $I_q := \text{Schur}(G, S_{\leq q} \cup S_{\geq q/2})$ . Let  $\kappa_q(y) := \min(q, \max(q/2, y))$  for  $q > 0$  and  $\kappa_q(y) = \min(q/2, \max(q, y))$  for  $q \leq 0$ . The proxy is the following quantity, which is defined for a specific shift of the Rayleigh quotient minimizer  $y \in \mathbb{R}^{V(G)}$ .

$$\widehat{c}^{I_q}(S_{\geq q}, S_{\leq q/2}) := \frac{4}{q^2} \sum_{e=uv \in E(G)} c_e^G (\kappa_q(y_u) - \kappa_q(y_v))^2$$

for  $q > 0$  and

$$\widehat{c}^{I_q}(S_{\leq q}, S_{\geq q/2}) := \frac{4}{q^2} \sum_{e=uv \in E(G)} c_e^G (\kappa_q(y_u) - \kappa_q(y_v))^2$$

for  $q \leq 0$ . We now show that this is indeed an upper bound:

► **Proposition 13.** *For all  $q > 0$ ,*

$$c^{I_q}(S_{\leq q/2}, S_{\geq q}) \leq \widehat{c}^{I_q}(S_{\leq q/2}, S_{\geq q})$$

For all  $q \leq 0$ ,

$$c^{I_q}(S_{\leq q}, S_{\geq q/2}) \leq \widehat{c}^{I_q}(S_{\leq q}, S_{\geq q/2})$$

**Proof.** We focus on the  $q > 0$ , as the reasoning for the  $q \leq 0$  case is the same. By Theorems 6 and 7,

$$c^{I_q}(S_{\leq q/2}, S_{\geq q}) = \min_{p \in \mathbb{R}^{V(G)}: p_a \leq 0 \forall a \in S_{\leq q/2}, p_a \geq 1 \forall a \in S_{\geq q}} p^T L_G p$$

The vector  $p$  with  $p_a := \frac{2}{q} \kappa_q(y_a) - 1$  for all vertices  $a \in V(G)$  is a feasible solution to the above optimization problem with objective value  $\widehat{c}^{I_q}(S_{\leq q/2}, S_{\geq q})$ . This is the desired result. ◀

This proxy allows us to relate Schur complement conductances together across different thresholds  $q$  in a similar proof to the proof of the upper bound of Cheeger's inequality given in [22]. One complication in our case is that Schur complements for different values of  $q$  overlap in their eliminated vertices. Our choice of  $\leq q/2, \geq q$  plays a key role here (as opposed to  $\leq 0, \geq q$ , for example) in ensuring that the overlap is small. We now give the algorithm **SweepCut**:

**Algorithm 1:** SweepCut( $G$ ).

---

**Input:** A graph  $G$  with  $\lambda_G \leq 1/25600$   
**Output:** Two sets of vertices  $A$  and  $B$  satisfying the guarantees of Lemma 12

- 1  $z \leftarrow$  vector with  $z^T N_G z \leq 2\lambda_G z^T z$  and  $z^T (D_G^{1/2} \mathbf{1}_{V(G)}) = 0$
- 2  $x \leftarrow D_G^{-1/2} z$
- 3  $y \leftarrow x - \alpha \mathbf{1}_{V(G)}$  for a value  $\alpha$  such that  $\text{vol}_G(\{v : y_v \leq 0\}) \geq \text{vol}_G(V(G))/2$  and  $\text{vol}_G(\{v : y_v \geq 0\}) \geq \text{vol}_G(V(G))/2$
- 4 **foreach**  $q \in \mathbb{R}$  **do**
- 5      $S_{\geq q} \leftarrow$  vertices with  $y_v \geq q$
- 6      $S_{\leq q} \leftarrow$  vertices with  $y_v \leq q$
- 7 **end**
- 8 **foreach**  $q > 0$  **do**
- 9     **if** (1)  $\widehat{c}^{I_q}(S_{\leq q/2}, S_{\geq q}) \leq 640\lambda_G \min(\text{vol}_G(S_{\leq q/2}), \text{vol}_G(S_{\geq q}))$ , (2)  $c^G(\partial S_{\geq q/2}) \leq 1/4 \text{vol}_G(S_{\geq q})$ , and (3)  $\phi_{S_{\geq q}} \leq 1/4$  **then**
- 10         **return**  $(S_{\leq q/2}, S_{\geq q})$
- 11     **end**
- 12 **end**
- 13 **foreach**  $q \leq 0$  **do**
- 14     **if** (1)  $\widehat{c}^{I_q}(S_{\geq q/2}, S_{\leq q}) \leq 640\lambda_G \min(\text{vol}_G(S_{\geq q/2}), \text{vol}_G(S_{\leq q}))$ , (2)  $c^G(\partial S_{\geq q/2}) \leq 1/4 \text{vol}_G(S_{\leq q})$ , and (3)  $\phi_{S_{\leq q}} \leq 1/4$  **then**
- 15         **return**  $(S_{\leq q}, S_{\geq q/2})$
- 16     **end**
- 17 **end**

---

Our analysis relies on the following key technical result, which we prove in Appendix B:

► **Proposition 14.** For any  $a, b \in \mathbb{R}$ ,

$$\int_0^\infty \frac{(\kappa_q(a) - \kappa_q(b))^2}{q} dq \leq 10(a - b)^2$$

**Proof of Lemma 12.**

**Algorithm well-definedness.** We start by showing that SweepCut returns a pair of sets.

Assume, for the sake of contradiction, that SweepCut does not return a pair of sets. Let  $I_q := \text{Schur}(G, S_{\geq q} \cup S_{\leq q/2})$  for  $q > 0$  and  $I_q := \text{Schur}(G, S_{\leq q} \cup S_{\geq q/2})$  for  $q \leq 0$ . By the contradiction assumption, for all  $q > 0$ ,

$$\text{vol}_G(S_{\geq q}) \leq \frac{\widehat{c}^{I_q}(S_{\geq q}, S_{\leq q/2})}{640\lambda_G} + 4c^G(\partial S_{\geq q}) + 4c^G(\partial S_{\leq q/2})$$

and for all  $q < 0$ ,

$$\text{vol}_G(S_{\leq q}) \leq \frac{\widehat{c}^{I_q}(S_{\leq q}, S_{\geq q/2})}{640\lambda_G} + 4c^G(\partial S_{\leq q}) + 4c^G(\partial S_{\geq q/2})$$

Since  $\sum_{v \in V(G)} c_v^G x_v = 0$ ,

$$\sum_{v \in V(G)} c_v^G x_v^2 \leq \sum_{v \in V(G)} c_v^G y_v^2$$

Now, we bound the positive  $y_v$  and negative  $y_v$  parts of this sum separately. Negating  $y$  shows that it suffices to bound the positive part. Order the vertices in  $S_{\geq 0}$  in decreasing order by  $y_v$  value. Let  $v_i$  be the  $i$ th vertex in this ordering, let  $k := |S_{\geq 0}|$ ,  $y_{k+1} := 0$ ,  $y_i := y_{v_i}$ ,  $c_i := c_{v_i}^G$ , and  $S_i := \{v_1, v_2, \dots, v_i\}$  for each integer  $i \in [k]$ . Then

$$\begin{aligned} \sum_{v \in S_{\geq 0}} c_v^G y_v^2 &= \sum_{i=1}^k c_i y_i^2 \\ &= \sum_{i=1}^k (\text{vol}_G(S_i) - \text{vol}_G(S_{i-1})) y_i^2 \\ &= \sum_{i=1}^k \text{vol}_G(S_i) (y_i^2 - y_{i+1}^2) \\ &= 2 \int_0^\infty \text{vol}_G(S_{\geq q}) q dq \end{aligned}$$

By our volume upper bound from up above,

$$\begin{aligned} 2 \int_0^\infty \text{vol}_G(S_{\geq q}) q dq &\leq 2 \int_0^\infty \frac{\widehat{c}^I q(S_{\geq q}, S_{\leq q/2})}{640 \lambda_G} q dq + 8 \int_0^\infty c^G(\partial S_{\geq q}) q dq + 8 \int_0^\infty c^G(\partial S_{\leq q/2}) q dq \\ &= 2 \int_0^\infty \frac{\widehat{c}^I q(S_{\geq q}, S_{\leq q/2})}{640 \lambda_G} q dq + 8 \int_0^\infty c^G(\partial S_{\geq q}) q dq + 8 \int_0^\infty c^G(\partial S_{> q/2}) q dq \\ &= 2 \int_0^\infty \frac{\widehat{c}^I q(S_{\geq q}, S_{\leq q/2})}{640 \lambda_G} q dq + 40 \int_0^\infty c^G(\partial S_{\geq q}) q dq \end{aligned}$$

Substitution and Proposition 14 show that

$$\begin{aligned} 2 \int_0^\infty \text{vol}_G(S_{\geq q}) q dq &\leq 8 \sum_{e=uv \in E(G)} c_e^G \int_0^\infty \left( \frac{(\kappa_q(y_u) - \kappa_q(y_v))^2}{640 \lambda_G q} + 5 \mathbb{1}_{q \in [y_u, y_v]} q \right) dq \\ &\leq 8 \sum_{e=uv \in E(G)} c_e^G \left( \frac{10}{640 \lambda_G} (y_u - y_v)^2 + 5 |y_u^2 - y_v^2| \right) \end{aligned}$$

By Cauchy-Schwarz,

$$\begin{aligned} 8 \sum_{e=uv \in E(G)} c_e^G \left( \frac{10}{640 \lambda_G} (y_u - y_v)^2 + 5 |y_u^2 - y_v^2| \right) &\leq \frac{1}{8 \lambda_G} \sum_{e=uv \in E(G)} c_e^G (y_u - y_v)^2 \\ &\quad + 40 \sqrt{\sum_{e=uv \in E(G)} c_e^G (y_u - y_v)^2} \sqrt{\sum_{e=uv \in E(G)} c_e^G (y_u + y_v)^2} \\ &\leq \frac{1}{4} \sum_{v \in V(G)} c_v^G x_v^2 \\ &\quad + 80 \sqrt{\lambda_G} \sqrt{\sum_{v \in V(G)} c_v^G x_v^2} \sqrt{\sum_{v \in V(G)} c_v^G y_v^2} \end{aligned}$$

But since  $\sum_{v \in V(G)} c_v^G x_v^2 \leq \sum_{v \in V(G)} c_v^G y_v^2$  and  $\lambda_G < 1/25600$ ,

$$\frac{1}{4} \sum_{v \in V(G)} c_v^G x_v^2 + 80\sqrt{\lambda_G} \sqrt{\sum_{v \in V(G)} c_v^G x_v^2} \sqrt{\sum_{v \in V(G)} c_v^G y_v^2} < \frac{1}{2} \sum_{v \in V(G)} c_v^G y_v^2.$$

Negating  $y$  shows that  $\sum_{v \in S_{\leq 0}} c_v^G y_v^2 < 1/2 \sum_{v \in V(G)} c_v^G y_v^2$  as well. But these statements cannot both hold; a contradiction. Therefore, **SweepCut** must output a pair of sets.

**Runtime.** Computing  $z$  takes  $\tilde{O}(m)$  time by Theorem 9. Therefore, it suffices to show that the foreach loops can each be implemented in  $O(m)$  time. This implementation is similar to the  $O(m)$ -time implementation of the Cheeger sweep.

We focus on the first foreach loop, as the second is the same with  $q$  negated. First, note that the functions  $\phi_{S_{\geq q}}$ ,  $c^G(\partial S_{\geq q/2})$ , and  $\text{vol}_G(S_{\geq q})$  of  $q$  are piecewise constant, with breakpoints at  $q = y_u$  and  $q = 2y_u$  for each  $u \in V(G)$ . Furthermore, these functions can be computed for all values in  $O(m)$  time using an  $O(m)$ -time Cheeger sweep for each function.

Therefore, it suffices to compute the value of  $\tilde{c}^{Iq}(S_{\leq q/2}, S_{\geq q})$  for all  $q \geq 0$  that are local minima in  $O(m)$  time. Let  $h(q) := \tilde{c}^{Iq}(S_{\leq q/2}, S_{\geq q})$ . Notice that the functions  $h(q)$  and  $h'(q)$  are piecewise quadratic and linear functions of  $q$  respectively, with breakpoints at  $q = y_u$  and  $q = 2y_u$ . Using five  $O(m)$ -time Cheeger sweeps, one can compute the  $q^2$ ,  $q$  and 1 coefficients of  $h(q)$  and the  $q$  and 1 coefficients of  $h'(q)$  between all pairs of consecutive breakpoints. After computing these coefficients, one can compute the value of each function at a point  $q$  in  $O(1)$  time. Furthermore, given two consecutive breakpoints  $a$  and  $b$ , one can find all points  $q \in (a, b)$  with  $h'(q) = 0$  in  $O(1)$  time. Each local minimum for  $h$  is either a breakpoint or a point with  $h'(q) = 0$ . Since  $h$  and  $h'$  have  $O(n)$  breakpoints, all local minima can be computed in  $O(n)$  time.  $h$  can be evaluated at all of these points in  $O(n)$  time. Therefore, all local minima of  $h$  can be computed in  $O(m)$  time. Since the algorithm does return a  $q$ , some local minimum for  $h$  also suffices, so this implementation produces the desired result in  $O(m)$  time.

**Low Schur complement fractional conductance.** By Proposition 13,

$$c^{Iq}(S_{\geq q}, S_{\leq q/2}) \leq \tilde{c}^{Iq}(S_{\geq q}, S_{\leq q/2})$$

Therefore,  $c^{Iq}(S_{\geq q}, S_{\leq q/2}) \leq 640\lambda_G \min(\text{vol}_G(S_{\geq q}), \text{vol}_G(S_{\leq q/2}))$  for  $q \geq 0$  by the foreach loop if condition. Repeating this reasoning for  $q < 0$  yields the desired result.

**Large interior.** By definition of  $\alpha$ ,  $\text{vol}_G(S_{\geq q}) \leq \text{vol}_G(S_{\leq q/2})$  for  $q > 0$ . Since  $c^G(\partial S_{\leq q/2}) \leq 1/4\text{vol}_G(S_{\geq q})$ ,  $\phi_{S_{\leq q/2}} \leq 1/4$ , as desired.  $\blacktriangleleft$

### A Proof of Theorem 1

**Proof of Theorem 1.** For any two sets of vertices  $S_1, S_2$  in a graph  $G$ ,

$$\text{Reff}_G(S_1, S_2) \min(\text{vol}_G(S_1), \text{vol}_G(S_2)) = \frac{1}{\sigma_{S_1, S_2}^G}$$

Therefore, the desired result follows from Lemmas 11 and 10. ◀

### B Proof of Proposition 14

**Proof of Proposition 14.** Without loss of generality, suppose that  $a \leq b$ . We break the analysis up into cases:

**Case 1:  $a \leq 0$ .** In this case,  $\kappa_q(a) = q/2$  for all  $q \geq 0$ , so

$$\begin{aligned} \int_0^\infty \frac{(\kappa_q(a) - \kappa_q(b))^2}{q} dq &= \int_0^b \frac{(q/2 - q)^2}{q} dq \\ &\quad + \int_b^{2b} \frac{(q/2 - b)^2}{q} dq \\ &\quad + \int_{2b}^\infty \frac{(q/2 - q/2)^2}{q} dq \\ &= \frac{b^2}{8} + \int_b^{2b} (q/4 - b + b^2/q) dq \\ &= \frac{b^2}{2} - b^2 + b^2(\ln 2) \\ &\leq 10(a - b)^2 \end{aligned}$$

as desired.

Case 2:  $a > 0$  and  $b \leq 2a$ . In this case,

$$\begin{aligned}
 \int_0^\infty \frac{(\kappa_q(a) - \kappa_q(b))^2}{q} dq &= \int_0^a \frac{(q-q)^2}{q} dq \\
 &+ \int_a^b \frac{(a-q)^2}{q} dq \\
 &+ \int_b^{2a} \frac{(a-b)^2}{q} dq \\
 &+ \int_{2a}^{2b} \frac{(q/2-b)^2}{q} dq \\
 &+ \int_{2b}^\infty \frac{(q/2-q/2)^2}{q} dq \\
 &\leq \int_a^{2b} \frac{(a-b)^2}{q} dq \\
 &= (a-b)^2 \ln(2b/a) \\
 &\leq (a-b)^2 \ln 4 \leq 10(a-b)^2
 \end{aligned}$$

as desired.

Case 3:  $a > 0$  and  $b > 2a$ . In this case,

$$\begin{aligned}
 \int_0^\infty \frac{(\kappa_q(a) - \kappa_q(b))^2}{q} dq &= \int_0^a \frac{(q-q)^2}{q} dq \\
 &+ \int_a^{2a} \frac{(a-q)^2}{q} dq \\
 &+ \int_{2a}^b \frac{(q/2-q)^2}{q} dq \\
 &+ \int_b^{2b} \frac{(q/2-b)^2}{q} dq \\
 &+ \int_{2b}^\infty \frac{(q/2-q/2)^2}{q} dq \\
 &\leq \int_a^{2b} \frac{(q/2-q)^2}{q} dq \\
 &\leq b^2/2 \\
 &\leq 2(a-b)^2 \leq 10(a-b)^2
 \end{aligned}$$

as desired. ◀

# Game Efficiency Through Linear Programming Duality

## Abstract

The efficiency of a game is typically quantified by the price of anarchy (PoA), defined as the worst ratio of the value of an equilibrium – solution of the game – and that of an optimal outcome. Given the tremendous impact of tools from mathematical programming in the design of algorithms and the similarity of the price of anarchy and different measures such as the approximation and competitive ratios, it is intriguing to develop a duality-based method to characterize the efficiency of games.

In the paper, we present an approach based on linear programming duality to study the efficiency of games. We show that the approach provides a general recipe to analyze the efficiency of games and also to derive concepts leading to improvements. The approach is particularly appropriate to bound the PoA. Specifically, in our approach the dual programs naturally lead to competitive PoA bounds that are (almost) optimal for several classes of games. The approach indeed captures the smoothness framework and also some current non-smooth techniques/concepts. We show the applicability to the wide variety of games and environments, from congestion games to Bayesian welfare, from full-information settings to incomplete-information ones.

## 1 Introduction

Algorithmic Game Theory – a domain at the intersection of Game Theory and Algorithms – has been extensively studied in the last two decades. The development of the domain, as well as those of many other research fields, have witnessed a common phenomenon: interesting notions, results have been flourished at the early stage, then deep methods, techniques have been established at a more mature stage leading to further achievements. In Algorithmic Game Theory, a representative illustration is the notion and results on the price of anarchy and the smoothness argument method [24]. In a game, the price of anarchy (PoA) [15] is defined as the worst ratio between the cost of a Nash equilibrium and that of an optimal solution. The PoA is now considered as standard and is the most popular

measure to characterize the inefficiency of Nash equilibria – solutions of a game – in the same sense of approximation ratio in Approximation Algorithms and competitive ratio in Online Algorithms.

Mathematical programming in general and linear programming in particular are powerful tools in many research fields. Among others, linear programming has a tremendous impact on the design of algorithms. Linear programming and duality play crucial and fundamental roles in several elegant methods such as primal-dual and dual-fitting in Approximation Algorithms [34] and online primal-dual framework [6] in Online Algorithms. Given the similarity of the notions of PoA, approximation and competitive ratios, it is intriguing and also desirable to develop a method based on duality to characterize the PoA of games. In this paper, we present and aim at developing a framework based on linear programming duality to study the efficiency of games.

### 1.1 A primal-dual approach

In high-level, the approach follows the standard primal-dual or dual-fitting techniques in approximation/online algorithms. The approach consists of associating a game to an underlying optimization problem and formulate an integer program corresponding to the optimization problem. Next consider the linear program by relaxing the integer constraints and its dual LP. Note that until this step, no notion of game has been intervened. Then given a Nash equilibrium, construct dual variables in such a way that one can relate the dual objective to the cost of the Nash equilibrium. The PoA is then bounded by the ratio between the primal objective (essentially, the cost of the Nash equilibrium) and the dual objective (a lower bound of the optimum cost by weak duality). This approach has been considered by Kulkarni and Mirrokni [17] for full-information games with convex objectives.

There are two crucial steps in the approach. First, by this method, the bound of PoA is at least as large as the integrality gap of the formulation. Hence, to prove optimal PoA one has to derive a formulation (of the corresponding optimization problem) whose the integrality gap matches to the optimal PoA. This is very similar to the issue of linear-programming-based approaches in Approximation/Online Algorithms. Note that this issue is a main obstacle in [17] in order to study non-convex objectives (see discussion in Section 1.3). The second crucial step is the construction of dual variables. The dual variables need to reflect the notion of Nash equilibria as well as their properties in order to relate to the costs of equilibria. Intuitively, to prove optimal bound on the PoA, the constructed dual variables must constitute an optimal dual solution.

To overcome these obstacles, in the paper we systematically consider *configuration* linear programs and a primal-dual approach. Given a problem (game), we first consider a natural formulation of the problem. Then, the approach consists of introducing exponential variables and constraints to the natural formulation to get a configuration LP. The additional constraints have intuitive and simple interpretations: one constraint guarantees that the game admits exactly one outcome and the other constraint ensures that if a player uses a strategy then this strategy must be a component of the outcome. As the result, the configuration LPs significantly improve the integrality gap over that of the natural formulations.

The configuration LPs have been considered in approximation algorithms and to the best of our knowledge, the main approach is rounding. Here, to study the efficiency of games, we consider a primal-dual approach. The primal-dual approach is very appropriate to study the PoA through the mean of configuration LPs. In the dual of the configuration programs, the dual constraints naturally lead to the construction of dual variables and the

PoA bounds. Intuitively, one dual constraint corresponds exactly to the definition of Nash equilibrium and the other dual constraint settles the PoA bounds. Note that our approach gives stronger formulations and leads to more general results than that in [17] (see Section 1.3 for a discussion in more details).

## 1.2 Overview of Results

We illustrate the potential and the wide applicability of the approach throughout various results in the contexts of complete and incomplete-information environments, from the settings of congestion games to welfare maximization. The approach allows us to unify several previous results and establish new ones beyond the current techniques. It is worthy to note that the analyses are simple and are guided by dual LP very much in the sense of primal-dual methods in designing algorithms. Moreover, under the lens of LP duality, the notion of smooth games in both full-information settings [24] and incomplete-information settings [25, 31], the recent notion of no-envy learning [10] and the new notion of dual smooth (in this paper) can be naturally derived, which lead to the optimal bounds of the PoA of several games.

### 1.2.1 Smooth Games in Full-Information Settings

We first revisit smooth games by the primal-dual approach and show that the primal-dual approach captures the smoothness framework [24]. Roughgarden [24] has introduced the smoothness framework, which became quickly a standard technique, and showed that every  $(\lambda, \mu)$ -smooth game has a PoA of at most  $\lambda/(1 - \mu)$ . Through the duality approach, we show that in terms of techniques to study the PoA for complete information settings, the LP duality and the smoothness framework are exactly the same thing. Specifically, one of the dual constraint corresponds exactly to the definition of smooth games given in [24].

► **Informal Theorem 1.** *The primal-dual approach captures the smoothness framework in full-information settings.*

### 1.2.2 Congestion Games

We consider fundamental classes of *congestion games* in which we revisit and unify results in the atomic, non-atomic congestion games and prove the optimal PoA bound of coarse correlated equilibria in splittable congestion games.

**Atomic congestion games.** In this class, although the PoA bound follows the results for smooth games (Informal Theorem 1), we provide another configuration formulation and a similar primal-dual approach. The purpose of this formulation is twofold. First it shows the flexibility of the primal-dual approach. Second, it sets up the ground for an unified approach to other classes of congestion games.

**Non-atomic congestion games.** In this class, we re-prove the *optimal* PoA bound [29]. Along the line toward the optimal PoA bound for non-atomic congestion games, the equilibrium characterization by a variational inequality is at the core of the analyses [29, 9, 8]. In our proof, we establish the optimal PoA directly by the means of LP duality. By the LP duality as the unified approach, one can clearly observe that the non-atomic setting is a version of the atomic setting in large games (in the sense of [12]) in which each player weight becomes negligible (hence, the PoA of the atomic congestion games tend to that of

non-atomic ones). Besides, an advantage with LP approaches is that one can benefit from powerful techniques that have been developing for linear programming. Concretely, using the general framework on resource augmentation and primal-dual recently presented [19], we manage to recover and extend a resource augmentation result related to non-atomic setting [28].

► **Informal Theorem 2.** *In every non-atomic congestion game, for any constant  $r > 0$ , the cost of an equilibrium is at most  $1/r$  the optimum of the underlying optimization problem in which each demand is multiplied by a factor  $(1 + r)$ .*

**Splittable congestion games.** Roughgarden and Schoppmann [26] has presented a *local* smoothness property, a refinement of the smoothness framework, and proved that every  $(\lambda, \mu)$ -local-smooth splittable game has a PoA of  $\lambda/(1 - \mu)$ . This bound is tight for a large class of scalable cost functions in splittable games and holds for PoA of pure, mixed, correlated equilibria. However, this bound does not hold for coarse correlated equilibria and it remains an intriguing open question raised in [26]. Building upon the resilient ideas of non-atomic and atomic settings, we define a notion, called *dual smoothness*, which is inspired by the dual constraints. This new notion indeed leads to the *tight* PoA bound for coarse correlated equilibria in splittable games for a large class of cost functions; that answers the question in [26]. Note that the matching lower bound is given in [26] and that holds even for pure equilibria.

► **Definition 3.** A cost function  $\ell : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  is  $(\lambda, \mu)$ -dual-smooth if for every vectors  $\mathbf{u} = (u_1, \dots, u_n)$  and  $\mathbf{v} = (v_1, \dots, v_n)$ ,

$$v\ell(u) + \sum_{i=1}^n u_i(v_i - u_i) \cdot \ell'(u) \leq \lambda \cdot v\ell(v) + \mu \cdot u\ell(u)$$

where  $u = \sum_{i=1}^n u_i$  and  $v = \sum_{i=1}^n v_i$ . A splittable congestion game is  $(\lambda, \mu)$ -dual-smooth if for every resource  $e$  in the game, function  $\ell_e$  is  $(\lambda, \mu)$ -dual-smooth.

► **Informal Theorem 4.** *The price of anarchy of coarse correlated equilibria of a splittable congestion game  $G$  is at most  $\inf_{(\lambda, \mu)} \lambda/(1 - \mu)$  where the infimum is taken over  $(\lambda, \mu)$  such that  $G$  is  $(\lambda, \mu)$ -dual-smooth. This bound is tight for the class of scalable cost functions.*

### 1.2.3 Welfare Maximization

We next consider the inefficiency of Bayes-Nash equilibria in the context of welfare maximization in incomplete-information environments.

**Smooth Auctions.** The notion of smooth auctions in incomplete-information settings, inspired by the original smoothness framework [24], has been introduced by Roughgarden [25], Syrgkanis and Tardos [31]. This powerful notion has been widely used to study the PoA of Bayes-Nash equilibria (see the recent survey [27]). We show that the primal-dual approach captures the smoothness framework in incomplete-information settings. In other words, the notion of smooth auctions can be naturally derived from dual constraints in the primal-dual approach.

► **Informal Theorem 5.** *The primal-dual approach captures the smoothness framework in incomplete-information settings.*

**Simultaneous Item-Bidding Auctions: Beyond Smoothness.** Many PoA bounds in auctions are settled by smoothness-based proofs. However, there are PoA bounds for auctions proved via non-smooth techniques and these techniques seem more powerful than the smoothness framework in such auctions. Representative examples are the simultaneous first- and second-price auctions where players' valuations are sub-additive. Feldman et al. [11] have proved that the PoA is constant while the smooth argument gives only logarithmic guarantees. We show that in this context, our approach is beyond the smoothness framework and also captures the non-smooth arguments in [11] by re-establishing their results. Specifically, a main step in our analysis – proving the feasibility of a dual constraint – corresponds exactly to a crucial claim in [11]. From this point of view, the primal-dual approach helps to identify the key steps in settling the PoA bounds.

► **Informal Theorem 6** ([11]). *Assume that players have independent distributions over sub-additive valuations. Then, every Bayes-Nash equilibrium of a first-price auction and of a second price auction has expected welfare at least  $1/2$  and  $1/4$  of the maximal welfare, respectively.*

Subsequently, we illuminate the potential of the primal-dual approach in formulating new concepts. Concretely, Daskalakis and Syrgkanis [10] have very recently introduced *no-envy learning dynamic* – a novel concept of learning in auctions. Note that when players have fractionally sub-additive (XOS) valuations<sup>1</sup>, no-envy outcomes are a relaxation of no-regret outcomes. No-envy dynamics have advantages over no-regret dynamics. In particular, no-envy outcomes maintain the approximate welfare optimality of no-regret outcomes while ensuring the computational tractability. Perhaps surprisingly, there is a connection between the primal-dual approach and no-envy dynamics. Indeed, the latter can be naturally derived from the dual constraints very much in the same way as the smoothness argument is. We show this connection by revisiting the following theorem by the means of the primal-dual approach.

► **Informal Theorem 7** ([10]). *Assume that players have XOS valuations. Then, every no-envy dynamic has the average welfare at least half the expected optimal welfare.*

**Sequential Auctions.** To illustrate the applicability of the primal-dual approach, we consider thereafter another format of auctions – sequential auctions. In a simple model of sequential auctions, items are sold one-by-one via single-item auctions. Sequential auctions has a long and rich literature [16] and sequentially selling items leads to complex issues in analyzing PoA. Leme et al. [18], Syrgkanis and Tardos [30] have studied sequential auctions for matching markets and matroid auctions in complete and incomplete-information settings in which at each step, an item is sold via the first-price auctions. In this paper, we consider the sequential auctions for sponsored search via the second-price auctions. Informally, auctioneer sells advertising slots one-by-one in the non-increasing order of click-through-rates (from the most attractive to the least one). At each step, players submit bid for the currently-selling slot and the highest-bid player receives the slot and pays the second highest bid. In the auction, we study the PoA of perfect Bayesian equilibria and show the following PoA bound for the sponsored search problem.

<sup>1</sup> A valuation  $v(\cdot)$  is XOS if there exists a family of vectors  $\mathcal{W} = (w^\ell)_\ell$  where  $w^\ell \in \mathbb{R}_+^m$  such that  $v(S) = \max_{w^\ell \in \mathcal{W}} \sum_{j \in S} w_j^\ell \forall S \subset [m]$ . The class XOS is a subset of sub-additive functions and is a superset of sub-modular functions.

► **Informal Theorem 8.** *The PoA of sequential second-price auctions for the sponsored search problem is at most 2.*

Note that among all auction formats for the sponsored search problem, the best known PoA guarantee [7] is 2.927 which has been achieved in generalized second price (GSP) auctions. An observation is that although the behaviour of players in sequential auctions might be complex, the performance guarantee is better than the currently best-known one in GSP auctions for the sponsored search problem. Consequently, this result shows that the efficiency of sequential auctions is not necessarily worse than the GSP ones and using primal-dual approach, analyzing sequential auctions is not necessarily harder than analyzing GSP ones neither.

Building upon the resilient ideas for the sponsored search problem, we provide an improved PoA bound of 2 for the matching market problem where the best known PoA bound is  $2e/(e-1) \approx 3.16$  due to Syrgkanis and Tardos [30]. That also answers a question raised in [30] whether the PoA in the incomplete-information settings must be strictly larger than the best-known PoA bound (which is 2) in the full-information settings.

► **Informal Theorem 9.** *The PoA of sequential first-price auctions for the matching market problem is at most 2.*

Due to the space limit, the results in sequential auctions can be found in the full paper available online [32].

### 1.3 Related works

As the main point of the paper is to emphasize the primal-dual approach to study game efficiency, in this section we mostly concentrate on currently existing methods. Results related to specific problems will be summarized in the corresponding sections.

The most closely related to our work is a recent result [17]. In their approach, Kulkarni and Mirrokni [17] considered a convex formulation of a given game and its dual program based on Fenchel duality. Then, given a Nash equilibrium, the dual variables are constructed by relating the cost of the Nash equilibrium to that of the dual objective. In high-level, our approach has the same idea as [17] and both approaches indeed have inspired by the standard primal-dual and dual-fitting in the design of algorithms. Our approach is distinguished to that in [17] in the two following aspects. First, we consider arbitrary (non-decreasing) objective functions and make use of configuration LPs in order to reduce substantially the integrality gap while the approach in [17] needs convex objective functions. In term of approaches based on mathematical programs in approximation algorithms, we have come up with stronger formulations than those in [17] – a crucial point toward optimal bounds. Second, we have shown a wide applicability of our approach from full-information environments to incomplete-information ones while the approach in [17] dealt only with full-information settings. A question has been raised in a the recent survey [27] is whether the framework in [17] could be extended to incomplete-information settings. Our primal-dual approach tends to answer that question.

The connection between LP duality and the PoA have been previously considered by Nadav and Roughgarden [22] and Bilo [5]. Both papers follow an approach which is different to ours. Roughly speaking, given a game they consider corresponding natural formulations and incorporate the equilibrium constraint directly to the primal (whereas in our approach the equilibrium constraint appears naturally in the dual). However, this approach encounters also the integrality-gap obstacle when one considers pure Nash equilibria and the objectives are non-linear or non-convex.

For the problems studied in the paper, we systematically strengthen natural LPs by the construction of configuration LPs presented in [20]. Makarychev and Sviridenko [20] propose a scheme that consists in solving the new LPs (with exponential number of variables) and rounding the fractional solutions to integer ones using decoupling inequalities for optimization problems. Instead of rounding techniques, we consider a primal-dual approach which is more adequate to studying game efficiency.

The smoothness framework has been introduced by Roughgarden [24]. This simple, elegant framework gives tight bounds for many classes of games in full-information settings including the celebrated atomic congestion games (and others in [24, 2]). Subsequently, Roughgarden and Schoppmann [26] presented a similar notion, called local-smoothness, to study the PoA of splittable games in which players can split their flow to arbitrarily small amounts and route the amounts in different manners. The local-smoothness is also powerful. It has been used to settle the PoA for a large class of cost functions in splittable games [26] and in opinion formation games [3].

The smoothness framework has been extended to incomplete-information environments by Roughgarden [25], Syrgkanis and Tardos [31]. It has successfully yielded tight PoA bounds for several widely-used auction formats. We recommend the reader to a very recent survey [27] for applications of the smoothness framework in incomplete-information settings. However, the smoothness argument has its limit. As mentioned earlier, the most illustrative examples are the simultaneous first and second price auctions where players' valuations are sub-additive. Feldman et al. [11] have proved that the PoA is constant while the smooth argument gives only logarithmic guarantees. An interesting open direction, as raised in [27], is to develop new approaches beyond the smoothness framework.

Linear programming (and mathematical programming in general) has been a powerful tool in the development of game theory. There is a vast literature on this subject. One of the most interesting recent treatments on the role of linear programming in game theory is the book [33]. Vohra [33] revisited fundamental results in mechanism design in an elegant manner by the means of linear programming and duality. It is surprising to see that many results have been shaped nicely by LPs.

## 2 Smooth Games under the Lens of Duality

In this section, we consider smooth games [24] in the point of view of configuration LPs and duality. In a game, each player  $i$  selects a strategy  $s_i$  from a set  $\mathcal{S}_i$  for  $1 \leq i \leq n$  and that forms a *strategy profile*  $\mathbf{s} = (s_1, \dots, s_n)$ . The cost  $C_i(\mathbf{s})$  of player  $i$  is a function of the strategy profile  $\mathbf{s}$  – the chosen strategies of all players. A *pure Nash equilibrium* is a strategy profile  $\mathbf{s}$  such that no player can decrease its cost via a unilateral deviation; that is, for every player  $i$  and every strategy  $s'_i \in \mathcal{S}_i$ ,  $C_i(\mathbf{s}) \leq C_i(s'_i, \mathbf{s}_{-i})$  where  $\mathbf{s}_{-i}$  denotes the strategies chosen by all players other than  $i$  in  $\mathbf{s}$ . The notion of Nash equilibrium is extended to the following more general equilibrium concepts.

A *mixed Nash equilibrium* [23] of a game is a product distribution  $\sigma = \sigma_1 \times \dots \times \sigma_n$  where  $\sigma_i$  is a probability distribution over the strategy set of player  $i$  such that no player can decrease its expected cost under  $\sigma$  via a unilateral deviation:  $\mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s})] \leq \mathbb{E}_{\mathbf{s}_{-i} \sim \sigma_{-i}} [C_i(s'_i, \mathbf{s}_{-i})]$  for every  $i$  and  $s'_i \in \mathcal{S}_i$ , where  $\sigma_{-i}$  is the product distribution of all  $\sigma_{i'}$ 's other than  $\sigma_i$ . A *correlated equilibrium* [1] of a game is a joint probability distribution  $\sigma$  over the strategy profile of the game such that  $\mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s}) | s_i] \leq \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(s'_i, \mathbf{s}_{-i}) | s_i]$  for every  $i$  and  $s_i, s'_i \in \mathcal{S}_i$ . Finally, a *coarse correlated equilibrium* [21] of a game is a joint probability distribution  $\sigma$

over the strategy profile of the game such that  $\mathbb{E}_{\mathbf{s} \sim \sigma}[C_i(\mathbf{s})] \leq \mathbb{E}_{\mathbf{s} \sim \sigma}[C_i(s'_i, \mathbf{s}_{-i})]$  for every  $i$  and  $s'_i \in \mathcal{S}_i$ . These notions of equilibria are presented in the order from the least to the most general ones and a notion captures the previous one as a strict subset.

The notion of smooth games and robust price of anarchy are given in [24]. A game with a joint cost objective function  $C(\mathbf{s}) = \sum_{i=1}^n C_i(\mathbf{s})$  is  $(\lambda, \mu)$ -smooth if for every two outcomes  $\mathbf{s}$  and  $\mathbf{s}^*$ ,

$$\sum_{i=1}^n C_i(s_i^*, \mathbf{s}_{-i}) \leq \lambda \cdot C(\mathbf{s}^*) + \mu \cdot C(\mathbf{s})$$

The *robust price of anarchy* of a game  $G$  is

$$\rho(G) := \inf \left\{ \frac{\lambda}{1 - \mu} : \text{the game is } (\lambda, \mu)\text{-smooth where } \mu < 1 \right\}$$

► **Theorem 10** ([24]). *For every game  $G$  with robust PoA  $\rho(G)$ , every coarse correlated equilibrium  $\sigma$  of  $G$  and every strategy profile  $\mathbf{s}^*$ ,*

$$\mathbb{E}_{\mathbf{s} \sim \sigma}[C(\mathbf{s})] \leq \rho(G) \cdot C(\mathbf{s}^*)$$

Until the end of the section, we revisit this theorem by our primal-dual approach.

**Formulation.** Given a game, we formulate the corresponding optimization problem by a configuration LP. Let  $x_{ij}$  be variable indicating whether player  $i$  chooses strategy  $s_{ij} \in \mathcal{S}_i$ . Informally, a *configuration*  $A$  in the formulation is a strategy profile of the game. Formally, a configuration  $A$  consists of pairs  $(i, j)$  such that  $(i, j) \in A$  means that in configuration  $A$ ,  $x_{ij} = 1$ . (In other words, in this configuration, player  $i$  selects strategy  $s_{ij} \in \mathcal{S}_i$ .) For every configuration  $A$ , let  $z_A$  be a variable such that  $z_A = 1$  if and only if  $x_{ij} = 1$  for all  $(i, j) \in A$ . Intuitively,  $z_A = 1$  if configuration  $A$  is the outcome of the game. For each configuration  $A$ , let  $c(A)$  be the cost of the outcome (strategy profile) corresponding to configuration  $A$ . Consider the following formulation and the dual of its relaxation.

$$\begin{array}{ll} \min \sum_A c(A)z_A & \max \sum_i \alpha_i + \beta \\ \sum_{j: s_{ij} \in \mathcal{S}_i} x_{ij} \geq 1 & \forall i \\ \sum_A z_A = 1 & \\ \sum_{A: (i,j) \in A} z_A = x_{ij} & \forall i, j \\ x_{ij}, z_A \in \{0, 1\} & \forall i, j, A \end{array} \quad \begin{array}{ll} & \alpha_i \leq \gamma_{ij} \quad \forall i, j \\ \beta + \sum_{(i,j) \in A} \gamma_{ij} \leq c(A) & \forall A \\ & \alpha_i \geq 0 \quad \forall i \end{array}$$

In the formulation, the first constraint ensures that a player  $i$  chooses a strategy  $s_{ij} \in \mathcal{S}_i$ . The second constraint means that there must be an outcome of the game. The third constraint guarantees that if a player  $i$  selects some strategy  $s_{ij}$  then the outcome configuration  $A$  must contain  $(i, j)$ .

**Construction of dual variables.** Assuming that the game is  $(\lambda, \mu)$ -smooth. Fix the parameters  $\lambda$  and  $\mu$ . Given a (arbitrary) coarse correlated equilibrium  $\sigma$ , define dual variables as follows:

$$\alpha_i := \frac{1}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s})], \quad \beta := -\frac{\mu}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C(\mathbf{s})], \quad \gamma_{ij} := \frac{1}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(s_{ij}, \mathbf{s}_{-i})].$$

Informally, up to some constant factors depending on  $\lambda$  and  $\mu$ ,  $\alpha_i$  is the cost of player  $i$  in equilibrium  $\sigma$ ,  $-\beta$  stands for the cost of the game in equilibrium  $\sigma$  and  $\gamma_{ij}$  represents the cost of player  $i$  if player  $i$  uses strategy  $s_{ij}$  while other players  $i' \neq i$  follows strategies in  $\sigma$ . We notice that  $\beta$  has negative value.

**Feasibility.** We show that the constructed dual variables form a feasible solution. The first constraint follows exactly the definition of (coarse correlated) equilibrium. The second constraint is exactly the smoothness definition. Specifically, let  $\mathbf{s}^*$  be the strategy profile corresponding to configuration  $A$ . Note that  $\mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s}^*)] = C_i(\mathbf{s}^*)$ . The dual constraint reads

$$-\frac{\mu}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C(\mathbf{s})] + \sum_i \frac{1}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(s_i^*, \mathbf{s}_{-i})] \leq \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s}^*)]$$

which is the definition of  $(\lambda, \mu)$ -smoothness by arranging the terms and removing the expectation.

**Price of Anarchy.** By weak duality, the optimal cost among all outcomes of the problem (strategy profiles of the game) is at least the dual objective of the constructed dual variables. Hence, in order to bound the PoA, we will bound the ratio between the cost of an (arbitrary) equilibrium  $\sigma$  and the dual objective of the corresponding dual variables. The cost of equilibrium  $\sigma$  is  $\mathbb{E}_{\mathbf{s} \sim \sigma} [C(\mathbf{s})]$  while the dual objective of the constructed dual variables is

$$\sum_{i=1}^n \frac{1}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C_i(\mathbf{s})] - \frac{\mu}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C(\mathbf{s})] = \frac{1-\mu}{\lambda} \mathbb{E}_{\mathbf{s} \sim \sigma} [C(\mathbf{s})]$$

Therefore, for a  $(\lambda, \mu)$ -smooth game, the PoA is at most  $\lambda/(1-\mu)$ .

**Remark.** Having shown in [24], Theorem 10 applies also to outcome sequences generated by repeated play such as vanishing average regret. By the same duality approach, we can also recover this result (by setting dual variables related to the average cost during the play).

### 3 Splittable Congestion Games

**Model.** In this section we consider the splittable congestion games in discrete setting. Fix a constant  $\epsilon > 0$  (arbitrarily small). In a splittable congestion game, there is a set  $E$  of resources, each resource is associated to a non-decreasing differentiable cost function  $\ell_e : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  such that  $x\ell_e(x)$  is convex. There are  $n$  players, a player  $i$  has a set of strategies  $\mathcal{S}_i$  and has weight  $w_i$ , a multiple of  $\epsilon$ . A strategy of player  $i$  is a distribution  $u^i$  of its weight  $w_i$  among strategies  $s_{ij}$  in  $\mathcal{S}_i$  such that  $\sum_{s_{ij} \in \mathcal{S}_i} u_{s_{ij}}^i = w_i$  and  $u_{s_{ij}}^i \geq 0$  is a multiple of  $\epsilon$ . A strategy profile is a vector  $\mathbf{u} = (u^1, \dots, u^n)$  of all players' strategies. We abuse notation and define  $u_e^i = \sum_{e \in s_{ij}} u_{s_{ij}}^i$  as the load player  $i$  distributes on resource  $e$  and

$u_e = \sum_{i=1}^n u_e^i$  the total load on  $e$ . Given a strategy profile  $\mathbf{u}$ , the cost of player  $i$  is defined as  $C_i(\mathbf{u}) := \sum_e u_e^i \cdot \ell_e(u_e)$ . A strategy profile  $\mathbf{u}$  is a pure Nash equilibrium if and only if for every player  $i$  and all  $s_{ij}, s_{ij'} \in \mathcal{S}_i$  with  $u_{s_{ij}}^i > 0$ :

$$\sum_{e \in s_{ij}} (\ell_e(u_e) + u_e^i \cdot \ell'_e(u_e)) \leq \sum_{e \in s_{ij'}} (\ell_e(u_e) + u_e^i \cdot \ell'_e(u_e))$$

The proof of this equilibrium characterization can be found in [13]. Again, the more general concepts of mixed, correlated and coarse correlated equilibria are defined similarly as in Section 2. In the game, the social cost is defined as  $C(\mathbf{u}) := \sum_{i=1}^n C_i(\mathbf{u}) = \sum_e u_e \ell_e(u_e)$ .

The PoA bounds has been recently established for a large class of cost functions by Roughgarden and Schoppmann [26]. The authors proposed a *local smoothness* framework and showed that the local smoothness arguments give optimal PoA bounds for a large class of cost functions in splittable congestion games. Prior to Roughgarden and Schoppmann [26], the works of Cominetti et al. [8] and Harks [13] have also the flavour of local smoothness though their bounds are not tight. The local smooth arguments extends to the correlated equilibria of a game but not to the coarse correlated equilibria. Motivating by the duality approach, we define a new notion of smoothness and prove a bound on the PoA of coarse correlated equilibria. It turns out that this PoA bound for coarse correlated equilibria is indeed *tight* for all classes of scale-invariant cost functions by the lower bound given by Roughgarden and Schoppmann [26, Section 5]. A class of cost function  $\mathcal{L}$  is *scale-invariant* if  $\ell \in \mathcal{L}$  implies that  $a \cdot \ell(b \cdot x) \in \mathcal{L}$  for every  $a, b > 0$ .

**Formulation.** Given a splittable congestion game, we formulate the problem by the same configuration program for non-atomic congestion game. Denote a finite set of multiples of  $\epsilon$  as  $\{a_0, a_1, \dots, a_m\}$  where  $a_k = k \cdot \epsilon$  and  $m = \max_{i=1}^n w_i / \epsilon$ . We say that  $T_e$  is a *configuration* of a resource  $e$  if  $T_e = \{(i, k) : 1 \leq i \leq n, 0 \leq k \leq m\}$  in which a couple  $(i, k)$  specifies the player ( $i$ ) and the amount  $a_k$  of the weight  $w_i$  that player  $i$  distributes to some strategy  $s_{ij} \in \mathcal{S}_i$  where  $e \in s_{ij}$ . Intuitively, a configuration of a resource is a strategy profile of a game restricted on the resource. Let  $x_{ijk}$  be variable indicating whether player  $i$  distributes an amount  $a_k$  of its weight to strategy  $s_{ij} \in \mathcal{S}_i$ . For every resource  $e$  and a configuration  $T_e$  on resource  $e$ , let  $z_{e, T_e}$  be a variable such that  $z_{e, T_e} = 1$  if and only if for  $(i, k) \in T_e$ ,  $x_{ijk} = 1$  for some  $s_{ij} \in \mathcal{S}_i$  such that  $e \in s_{ij}$ . For a configuration  $T_e$  of resource  $e$ , denote  $w(T_e)$  the total amount distributed by players in  $T_e$  to  $e$ .

$$\begin{array}{ll} \min \sum_{e, T_e} w(T_e) \ell_e(w(T_e)) z_{e, T_e} & \max \sum_i w_i \alpha_i + \sum_e \beta_e \\ \sum_{j, k} a_k x_{ijk} = w_i & \forall i \\ \sum_{T_e} z_{e, T_e} = 1 & \forall e \\ \sum_{T_e: (i, k) \in T_e} z_{e, T_e} = \sum_{j: e \in s_{ij}} x_{ijk} & \forall (i, k), e \\ x_{ij}, z_{e, T_e} \in \{0, 1\} & \forall i, j, e, T_e \end{array} \quad \begin{array}{l} a_k \alpha_i \leq \sum_{e: e \in s_{ij}} \gamma_{i, k, e} \\ \forall i, k, j \\ \beta_e + \sum_{(i, k) \in T_e} \gamma_{i, k, e} \leq w(T_e) \ell_e(w(T_e)) \\ \forall e, T_e \end{array}$$

Again, in the primal, the first constraint says that a player  $i$  distributes the total weight  $w_i$  among its strategies. The second constraint means that a resource  $e$  is always associated to a

configuration (possibly empty). The third constraint guarantees that if a player  $i$  distributes an amount  $a_k$  to some strategy  $s_{ij}$  containing resource  $e$  then there must be a configuration  $T_e$  such that  $(i, k) \in T_e$  and  $z_{e, T_e} = 1$ .

All previous duality proofs have the same structure: in the dual LP, the first constraint gives the characterization of an equilibrium and the second one settles the PoA bounds. Following this line, we give the following definition.

► **Definition 11.** A cost function  $\ell : \mathbb{R}^+ \rightarrow \mathbb{R}^+$  is  $(\lambda, \mu)$ -dual-smooth if for every vectors  $\mathbf{u} = (u_1, \dots, u_n)$  and  $\mathbf{v} = (v_1, \dots, v_n)$ ,

$$v\ell(u) + \sum_{i=1}^n u_i(v_i - u_i) \cdot \ell'(u) \leq \lambda \cdot v\ell(v) + \mu \cdot u\ell(u)$$

where  $u = \sum_i u_i$  and  $v = \sum_i v_i$ . A splittable congestion game is  $(\lambda, \mu)$ -dual-smooth if every resource  $e$  in the game, function  $\ell_e$  is  $(\lambda, \mu)$ -dual-smooth.

► **Theorem 12.** For every  $(\lambda, \mu)$ -dual-smooth splittable congestion game  $G$ , the price of anarchy of coarse correlated equilibria of  $G$  is at most  $\lambda/(1 - \mu)$ . This bound is tight for the class of scalable cost functions.

**Proof.** The proof follows the duality scheme.

**Dual Variables.** Fix parameter  $\lambda$  and  $\mu$ . Given a coarse correlated equilibrium  $\sigma$ , define corresponding dual variables as follows.

$$\begin{aligned} \alpha_i &= \frac{1}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} \left[ \sum_{e \in s_{ij}} \ell_e(u_e) + u_e^i \ell'_e(u_e) \right] \text{ for some } s_{ij} \in \mathcal{S}_i : u_{s_{ij}}^i > 0, \\ \beta_e &= -\frac{1}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} \left[ \mu \cdot u_e \ell_e(u_e) + \sum_i (u_e^i)^2 \cdot \ell'_e(u_e) \right], \\ \gamma_{i,k,e} &= \frac{1}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} [a_k (\ell_e(u_e) + u_e^i \ell'_e(u_e))]. \end{aligned}$$

The dual variables have similar interpretations as previous analysis. Up to some constant factors, variable  $\alpha_i$  is the marginal cost of a strategy used by player  $i$  in the equilibrium; and  $\gamma_{i,k,e}$  represents an estimation of the cost of player  $i$  on resource  $e$  if player  $i$  distributes an amount  $a_k$  of its weight to some strategy containing  $e$  while players  $i'$  other than  $i$  follows their strategies in the equilibrium.

**Feasibility.** By this definition of dual variables, the first dual constraint holds since it is the definition of coarse correlated equilibrium. Rearranging the terms, the second dual constraint for a resource  $e$  and a configuration  $T_e$  reads

$$\frac{1}{\lambda} \sum_{(i,k) \in T_e} \mathbb{E}_{\mathbf{u} \sim \sigma} [a_k \cdot \ell_e(u_e) + u_e^i (a_k - u_e^i) \ell'_e(u_e)] \leq w(T_e) \ell_e(w(T_e)) + \frac{\mu}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} [u_e \ell_e(u_e)]$$

This inequality follows directly from the definition of  $(\lambda, \mu)$ -dual-smoothness and linearity of expectation (and note that  $w(T_e) \ell_e(w(T_e)) = \mathbb{E}_{\mathbf{u} \sim \sigma} [w(T_e) \ell_e(w(T_e))]$  and  $w(T_e) = \sum_{(i,k) \in T_e} a_k$ ).

**Bounding primal and dual.** By the definition of dual variables, the dual objective is

$$\begin{aligned}
 \sum_i w_i \alpha_i + \sum_e \beta_e &= \sum_e \left( \sum_i u_e^i \alpha_i + \beta_e \right) \\
 &= \frac{1}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} \left[ \sum_e u_e \ell_e(u_e) + \sum_i (u_e^i)^2 \cdot \ell'_e(u_e) \right] - \frac{1}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} \left[ \mu \cdot \sum_e u_e \ell_e(u_e) + \sum_i (u_e^i)^2 \cdot \ell'_e(u_e) \right] \\
 &= \frac{1 - \mu}{\lambda} \mathbb{E}_{\mathbf{u} \sim \sigma} \left[ \sum_e u_e \ell_e(u_e) \right]
 \end{aligned}$$

while the cost of the equilibrium  $\sigma$  is  $\mathbb{E}_{\mathbf{u} \sim \sigma} [\sum_e u_e \ell_e(u_e)]$ . The theorem follows.  $\blacktriangleleft$

#### 4 Efficiency in Welfare Maximization

In a general mechanism design setting, each player  $i$  has a set of actions  $\mathcal{A}_i$  for  $1 \leq i \leq n$ . Given an action  $a_i \in \mathcal{A}_i$  chosen by each player  $i$  for  $1 \leq i \leq n$ , which lead to the action profile  $\mathbf{a} = (a_1, \dots, a_n) \in \mathcal{A} = \mathcal{A}_1 \times \dots \times \mathcal{A}_n$ , the auctioneer decides an outcome  $o(\mathbf{a})$  among the set of feasible outcomes  $\mathcal{O}$ . Each player  $i$  has a *private valuation* (or *type*)  $v_i$  taking values in a parameter space  $\mathcal{V}_i$ . For each outcome  $o \in \mathcal{O}$ , player  $i$  has *utility*  $u_i(o, v_i)$  depending on the outcome of the game and its valuation  $v_i$ . Since the outcome  $o(\mathbf{a})$  of the game is determined by the action profile  $\mathbf{a}$ , the utility of a player  $i$  is denoted as  $u_i(\mathbf{a}; v_i)$ . We are interested in auctions that in general consist of an allocation rule and a payment rule. Given an action profile  $\mathbf{a} = (a_1, \dots, a_n)$ , the auctioneer decides an allocation and a payment  $p_i(\mathbf{a})$  for each player  $i$ . Then, the *utility* of player  $i$  with valuation  $v_i$ , following the quasi-linear utility model, is defined as  $u_i(\mathbf{a}; v_i) = v_i - p_i(\mathbf{a})$ . The *social welfare* of an auction is defined as the total utility of all participants (the players and the auctioneer):  $\text{SW}(\mathbf{a}; \mathbf{v}) = \sum_{i=1}^n u_i(\mathbf{a}; v_i) + \sum_{i=1}^n p_i(\mathbf{a})$ .

In the paper, we consider incomplete-information settings. In contrast to the full-information settings where private valuations are deterministically determined, in incomplete-information settings the valuation vectors  $\mathbf{v}$  (in which each component is the valuation of a player) is drawn from a publicly known distribution  $\mathbf{F}$  with density function  $\mathbf{f}$ . Let  $\Delta(\mathcal{A}_i)$  be the set of probability distributions over the actions in  $\mathcal{A}_i$ . A strategy of a player is a mapping  $\sigma_i : \mathcal{V}_i \rightarrow \Delta(\mathcal{A}_i)$  from a valuation  $v_i \in \mathcal{V}_i$  to a distribution over actions  $\sigma_i(v_i) \in \Delta(\mathcal{A}_i)$ .

► **Definition 13** (Bayes-Nash equilibrium). A strategy profile  $\sigma = (\sigma_1, \dots, \sigma_n)$  is a *Bayes-Nash equilibrium* (BNE) if for every player  $i$ , for every valuation  $v_i \in \mathcal{V}_i$ , and for every action  $a'_i \in \mathcal{A}_i$ :

$$\mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}(v_i)} [\mathbb{E}_{\mathbf{a} \sim \sigma(\mathbf{v})} [u_i(\mathbf{a}; v_i)]] \geq \mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}(v_i)} [\mathbb{E}_{\mathbf{a}_{-i} \sim \sigma_{-i}(\mathbf{v}_{-i})} [u_i(a'_i, \mathbf{a}_{-i}; v_i)]]$$

For a vector  $\mathbf{w}$ , we use  $\mathbf{w}_{-i}$  to denote the vector  $\mathbf{w}$  with the  $i$ -th component removed. Besides,  $\mathbf{F}_{-i}(v_i)$  stands for the probability distribution over all players other than  $i$  conditioned on the valuation  $v_i$  of player  $i$ .

The price of anarchy of Bayes-Nash equilibria of an auction is defined as

$$\inf_{\mathbf{F}, \sigma} \frac{\mathbb{E}_{\mathbf{v} \sim \mathbf{F}} [\mathbb{E}_{\mathbf{a} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{a}; \mathbf{v})]]}{\mathbb{E}_{\mathbf{v} \sim \mathbf{F}} [\text{OPT}(\mathbf{v})]}$$

where the infimum is taken over Bayes-Nash equilibria  $\sigma$  and  $\text{OPT}(\mathbf{v})$  is the optimal welfare with valuation profile  $\mathbf{v}$ .

In the paper, we consider discrete settings of valuations and payments, i.e., there are only a finite (large) number of possible valuations and payments. The main purpose of restricting to discrete settings is that we can use tools from linear programming. The continuous settings can be done by considering successively finer discrete spaces.

## 4.1 Smooth Auctions

In this section, we show that the primal-dual approach also captures the smoothness framework in studying the inefficiency of Bayes-Nash equilibria in incomplete-information settings. Smooth auctions have been defined by Roughgarden [25] and Syrgkanis and Tardos [31]. The definitions are slightly different but both are inspired by the original smoothness argument [24] and all known smoothness-based proofs can be equivalently analyzed by one of these definitions. In this section, we consider the definition of smooth auctions in [25] and revisit the price of anarchy bound of smooth auctions. In the end of the section, we show that a similar proof carries through the smooth auctions defined by Syrgkanis and Tardos [31].

► **Definition 14** ([25]). For parameters  $\lambda, \mu \geq 0$ , an auction is  $(\lambda, \mu)$ -smooth if for every valuation profile  $\mathbf{v} = (v_1, \dots, v_n)$ , there exists action distribution  $D_1^*(\mathbf{v}), \dots, D_n^*(\mathbf{v})$  over  $\mathcal{A}_1, \dots, \mathcal{A}_n$  such that, for every action profile  $\mathbf{a}$ ,

$$\sum_i \mathbb{E}_{a_i^* \sim D_i^*(\mathbf{v})} [u_i(a_i^*, \mathbf{a}_{-i}; v_i)] \geq \lambda \cdot \text{SW}(\mathbf{a}^*; \mathbf{v}) - \mu \cdot \text{SW}(\mathbf{a}; \mathbf{v}) \quad (1)$$

► **Theorem 15** ([25]). *If an auction is  $(\lambda, \mu)$ -smooth and the distributions of player valuations are independent then every Bayes-Nash equilibrium has expected welfare at least  $\frac{\lambda}{1+\mu}$  times the optimal expected welfare.*

**Proof.** Given an auction, we formulate the corresponding optimization problem by a configuration LP. A *configuration*  $A$  consists of pairs  $(i, a_i)$  such that  $(i, a_i) \in A$  means that in configuration  $A$ , player  $i$  chooses action  $a_i$ . Intuitively, a configuration is an action profile of players. For every player  $i$ , every valuation  $v_i \in \mathcal{V}_i$  and every action  $a_i \in \mathcal{A}_i$ , let  $x_{i,a_i}(v_i)$  be the variable representing the probability that player  $i$  chooses action  $a_i$ . Besides, for every valuation profile  $\mathbf{v}$ , let  $z_A(\mathbf{v})$  be the variable indicating the probability that the chosen configuration (action profile) is  $A$ . For each configuration  $A$  and valuation profile  $\mathbf{v}$ , the auctioneer outcomes an allocation and a payment and that results in a social welfare denoted as  $c_A(\mathbf{v})$ . In the other words, if  $\mathbf{a}$  is the action profile corresponding to the configuration  $A$  then  $c_A(\mathbf{v})$  is in fact  $\text{SW}(\mathbf{a}; \mathbf{v})$ . Consider the following formulation and its dual.

$$\begin{aligned} \max \quad & \sum_{\mathbf{v}} c_A(\mathbf{v}) z_A(\mathbf{v}) \\ & \sum_{a_i \in \mathcal{A}_i} x_{i,a_i}(v_i) \leq f_i(v_i) \quad \forall i, v_i \\ & \sum_A z_A(\mathbf{v}) \leq f(\mathbf{v}) \quad \forall \mathbf{v} \\ & \sum_{A: (i,a_i) \in A} z_A(v_i, \mathbf{v}_{-i}) \leq f_{-i}(\mathbf{v}_{-i}) \cdot x_{i,a_i}(v_i) \\ & \quad \quad \quad \forall i, a_i, v_i, \mathbf{v}_{-i} \\ & x_{i,a_i}(v_i), z_A(\mathbf{v}) \geq 0 \quad \forall i, a_i, A, v_i, \mathbf{v} \end{aligned} \quad \begin{aligned} \min \quad & \sum_{i, v_i} f_i(v_i) \cdot \alpha_i(v_i) + \sum_{\mathbf{v}} f(\mathbf{v}) \cdot \beta(\mathbf{v}) \\ & \alpha_i(v_i) \geq \sum_{\mathbf{v}_{-i}} f_{-i}(\mathbf{v}_{-i}) \cdot \gamma_{i,a_i}(v_i, \mathbf{v}_{-i}) \\ & \quad \quad \quad \forall i, a_i, v_i \\ & \beta(\mathbf{v}) + \sum_{(i,a_i) \in A} \gamma_{i,a_i}(\mathbf{v}) \geq c_A(\mathbf{v}) \quad \forall A, \mathbf{v} \\ & \alpha_i(v_i), \beta(\mathbf{v}), \gamma_{i,a_i}(\mathbf{v}) \geq 0 \quad \forall i, v_i, \mathbf{v} \end{aligned}$$

In the primal, the first and second constraints guarantee that variables  $x$  and  $z$  represent indeed the probability distribution of each player and the joint distribution, respectively. The third constraint makes the connection between variables  $x$  and  $z$ . It ensures that if a player  $i$  with valuation  $v_i$  selects some action  $a_i$  then in the valuation profile  $(v_i, \mathbf{v}_{-i})$ , the probability that the configuration  $A$  contains  $(i, a_i)$  must be  $f_{-i}(\mathbf{v}_{-i}) \cdot x_{i, a_i}(v_i)$ . The primal objective is the expected welfare of the auction.

**Construction of dual variables.** Assuming that the auction is  $(\lambda, \mu)$ -smooth. Fix the parameters  $\lambda$  and  $\mu$ . Given an arbitrary Bayes-Nash equilibrium  $\sigma$ , define dual variables as follows.

$$\begin{aligned}\alpha_i(v_i) &:= \frac{1}{\lambda} \mathbb{E}_{\mathbf{v}_{-i}} [\mathbb{E}_{\mathbf{b} \sim \sigma(v_i, \mathbf{v}_{-i})} [u_i(\mathbf{b}; v_i)]], \\ \beta(\mathbf{v}) &:= \frac{\mu}{\lambda} \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{b}; \mathbf{v})], \\ \gamma_{i, a_i}(\mathbf{v}) &:= \frac{1}{\lambda} \mathbb{E}_{\mathbf{b}_{-i} \sim \sigma_{-i}(\mathbf{v}_{-i})} [u_i(a_i, \mathbf{b}_{-i}; v_i)].\end{aligned}$$

Informally, up to some constant factors depending on  $\lambda$  and  $\mu$ ,  $\alpha_i(v_i)$  is the expected utility of player  $i$  in equilibrium  $\sigma$ ;  $\beta(\mathbf{v})$  stands for the social welfare of the auction where the valuation profile is  $\mathbf{v}$  and players follow the equilibrium actions  $\sigma(\mathbf{v})$ ; and  $\gamma_{i, a_i}(\mathbf{v})$  represents the utility of player  $i$  in valuation profile  $\mathbf{v}$  if player  $i$  chooses action  $a_i$  while other players  $i' \neq i$  follows their equilibrium strategies  $\sigma_{-i}(\mathbf{v}_{-i})$ .

**Feasibility.** We show that the constructed dual variables form a feasible solution. By the definition of dual variables, the first dual constraint reads

$$\begin{aligned}\frac{1}{\lambda} \mathbb{E}_{\mathbf{v}_{-i}} [\mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [u_i(\mathbf{b}; v_i)]] &\geq \frac{1}{\lambda} \sum_{\mathbf{v}_{-i}} f_{-i}(\mathbf{v}_{-i}) \cdot \mathbb{E}_{\mathbf{b}_{-i} \sim \sigma_{-i}(\mathbf{v}_{-i})} [u_i(a_i, \mathbf{b}_{-i}; v_i)] \\ &= \frac{1}{\lambda} \mathbb{E}_{\mathbf{v}_{-i}} [\mathbb{E}_{\mathbf{b}_{-i} \sim \sigma_{-i}(\mathbf{v}_{-i})} [u_i(a_i, \mathbf{b}_{-i}; v_i)]]\end{aligned}$$

This is exactly the definition that  $\sigma$  is a Bayes-Nash equilibrium.

For every valuation profile  $\mathbf{v} = (v_1, \dots, v_n)$  and for any configuration  $A$  (corresponding action profile  $\mathbf{a} = (a_1, \dots, a_n)$ ), the second constraint reads:

$$\frac{\mu}{\lambda} \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{b}; \mathbf{v})] + \sum_{(i, a_i) \in A} \frac{1}{\lambda} \mathbb{E}_{\mathbf{b}_{-i} \sim \sigma_{-i}(\mathbf{v}_{-i})} [u_i(a_i, \mathbf{b}_{-i}; v_i)] \geq \text{SW}(\mathbf{a}; \mathbf{v}). \quad (2)$$

Note that we can write  $\text{SW}(\mathbf{a}; \mathbf{v}) = \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{a}; \mathbf{v})]$ . For any fixed realization  $\mathbf{b}$  of  $\sigma(\mathbf{v})$ , by  $(\lambda, \mu)$ -smoothness  $\frac{\mu}{\lambda} \text{SW}(\mathbf{b}; \mathbf{v}) + \sum_i \frac{1}{\lambda} u_i(a_i, \mathbf{b}_{-i}; v_i) \geq \text{SW}(\mathbf{a}; \mathbf{v})$ . Hence, by taking expectation over  $\sigma(\mathbf{v})$ , Inequality (2) follows.

**Price of Anarchy.** The welfare of equilibrium  $\sigma$  is  $\mathbb{E}_{\mathbf{v}} \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{b}; \mathbf{v})]$  while the dual objective of the constructed dual variables is

$$\sum_{i, v_i} f_i(v_i) \cdot \frac{1}{\lambda} \mathbb{E}_{\mathbf{v}_{-i}} [\mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [u_i(\mathbf{b}; v_i)]] + \sum_{\mathbf{v}} f(\mathbf{v}) \cdot \frac{\mu}{\lambda} \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{b}; \mathbf{v})]$$

which is bounded by  $\frac{1+\mu}{\lambda} \cdot \mathbb{E}_{\mathbf{v}} \mathbb{E}_{\mathbf{b} \sim \sigma(\mathbf{v})} [\text{SW}(\mathbf{b}; \mathbf{v})]$ . Therefore, the PoA is at most  $\lambda/(1+\mu)$ . ◀

## 4.2 Simultaneous Item-Bidding Auctions

**Model.** In this section, we consider the following Bayesian combinatorial auctions. In the setting, there are  $m$  items to be sold to  $n$  players. Each player  $i$  has a private monotone valuation  $v_i : 2^{[m]} \rightarrow \mathbb{R}^+$  over different subsets of items  $S \subset 2^{[m]}$ . For simplicity, we denote  $v_i(S)$  as  $v_{iS}$ . The valuation profile  $\mathbf{v} = (v_1, \dots, v_n)$  is drawn from a *product* distribution  $\mathbf{F}$ . In other words, the probability distributions  $F_i$  of valuations  $v_i$  are independent. Designing efficient combinatorial auctions are in general complex and a major direction in literature is to seek simple and efficient auctions in term of PoA. Among others, simultaneous item-bidding auctions are of particular interest. We consider two forms of simultaneous item-bidding auctions: *simultaneous first-price auctions (S1A)* and *simultaneous second-price auctions (S2A)*. In the auctions, each player submits simultaneously a vector of bids, one for each item. A typical assumption is *non-overbidding* property in which each player submits a vector  $b_i$  of bids such that for any set of items  $S$ ,  $\sum_{j \in S} b_{ij} \leq v_{iS}$ . Given the bid profile, each item is allocated to the player with highest bid. In a simultaneous first-price auction, the payment of the winner of each item is its bid on the item; while in a simultaneous second-price auction, the winner of each item pays the second highest bid on the item.

### 4.2.1 Connection between Primal-Dual and Non-Smooth Techniques

In this section, we consider the setting in which all player valuations are *sub-additive*. That is,  $v_i(S \cup T) \leq v_i(S) + v_i(T)$  for every player  $i$  and every subsets  $S, T \subset 2^{[m]}$ . The PoA of simultaneous item-bidding auctions has been widely studied in this setting. Using smoothness framework in auctions, logarithmic bounds on PoA for S1A and S2A are given by Hassidim et al. [14] and Bhawalkar and Roughgarden [4], respectively. Recently, Feldman et al. [11] presented a significant improvement by establishing the PoA bounds 2 and 4 for S1A and S2A, respectively. Their proof arguments go beyond the smoothness framework. In the following, we revisit the results of Feldman et al. [11] and show that the duality approach captures the non-smooth technique in [11].

**Formulation.** Given a valuation profile  $\mathbf{v}$ , let  $\bar{x}_{ij}(\mathbf{v})$  be the variable indicating whether player  $i$  receives item  $j$  in valuation profile  $\mathbf{v}$ . Let  $\bar{z}_{iS}(\mathbf{v})$  be the variable indicating whether player  $i$  receives a set of items  $S$ . Then for any profile  $\mathbf{v}$  and for any item  $j$ ,  $\sum_i \bar{x}_{ij}(\mathbf{v}) \leq 1$ , meaning that an item  $j$  is allocated to at most one player. Moreover,  $\sum_{S: j \in S} \bar{z}_{iS}(\mathbf{v}) = \bar{x}_{ij}(\mathbf{v})$ , meaning that if player  $i$  receives item  $j$  then some subset of items  $S$  allocated to  $i$  must contain  $j$ . Besides,  $\sum_S \bar{z}_{iS}(\mathbf{v}) = 1$  since some subset of items (possibly empty) is allocated to  $i$ .

Let  $x_{ij}(v_i)$  and  $z_{iS}(v_i)$  be *interim* variables corresponding to  $\bar{x}_{ij}(\mathbf{v})$  and  $\bar{z}_{iS}(\mathbf{v})$  and are defined as follows:  $x_{ij}(v_i) := \mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}} [\bar{x}_{ij}(v_i, \mathbf{v}_{-i})]$  and  $z_{iS}(v_i) := \mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}} [\bar{z}_{iS}(v_i, \mathbf{v}_{-i})]$  where  $\mathbf{F}_{-i}$  is the product distribution of all players other than  $i$ . Consider the following relaxation with interim variables and its dual. The constraints in the primal follow the relationship between the interim variables  $x_{ij}(v_i)$ ,  $z_{iS}(v_i)$  and variables  $\bar{x}_{ij}(\mathbf{v})$ ,  $\bar{z}_{iS}(\mathbf{v})$ .

$$\begin{array}{ll}
 \max & \sum_{i,S} \sum_{v_i} f_i(v_i) [v_{iS} \cdot z_{iS}(v_i)] \\
 & \sum_i \sum_{v_i \in V_i} f_i(v_i) x_{ij}(v_i) \leq 1 \quad \forall j \\
 & \sum_S z_{iS}(v_i) = 1 \quad \forall i, v_i \\
 & \sum_{S:j \in S} z_{iS}(v_i) = x_{ij}(v_i) \quad \forall i, j, v_i \\
 & x_{ij}(v_i), z_{iS}(v_i) \geq 0 \quad \forall i, j, S, v_i \\
 \min & \sum_{i,v_i} \alpha_i(v_i) + \sum_j \beta_j \\
 & f_i(v_i) \cdot \beta_j \geq \gamma_{i,j}(v_i) \quad \forall i, j, v_i \\
 & \alpha_i(v_i) + \sum_{j \in S} \gamma_{i,j}(v_i) \geq f_i(v_i) \cdot v_{iS} \quad \forall i, S, v_i \\
 & \alpha_i(v_i) \geq 0 \quad \forall i, v_i
 \end{array}$$

**Dual Variables.** Fix a Bayes-Nash equilibrium  $\sigma$ . Given a valuation  $\mathbf{v}$ , denote  $\mathbf{b} = (b_1, \dots, b_n) = \sigma(\mathbf{v})$  as the bid equilibrium. Let  $\mathbf{B}$  be the distribution of  $\mathbf{b}$  over the randomness of  $\mathbf{v}$  and  $\sigma$ . Let  $\mathbf{B}(v_i)$  be the distribution of  $\mathbf{b}$  over the randomness of  $\mathbf{v}$  and  $\sigma$  while the valuation  $v_i$  of player  $i$  is fixed. Since  $v_i$  and  $\mathbf{v}_{-i}$  are independent and each  $\sigma_i$  is a mapping  $\mathcal{V}_i \rightarrow \Delta(\mathcal{A}_i)$ , strategy  $b_i$  is independent of  $\mathbf{b}_{-i}$ . Let  $\mathbf{B}_{-i}$  be the distribution of  $\mathbf{b}_{-i}$ . We define dual variables as follows.

Let  $\alpha_i(v_i)$  be proportional to the expected utility of player  $i$  with valuation  $v_i$ , over the randomness of valuations  $\mathbf{v}_{-i}$  of other players. Specifically,

$$\alpha_i(v_i) := 2f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}} [\mathbb{E}_{\sigma} [u_i(\sigma(v_i, \mathbf{v}_{-i}), v_i)]] = 2f_i(v_i) \cdot \mathbb{E}_{\mathbf{b} \sim \mathbf{B}(v_i)} [u_i(\mathbf{b}, v_i)]$$

Besides, let  $\gamma_{i,j}(v_i)$  be proportional to the expected value of the bid on item  $j$  if player  $i$  with valuation  $v_i$  wants to win item  $j$  while other players follow the equilibrium strategies. Formally,  $\gamma_{i,j}(v_i) := 2f_i(v_i) \cdot \mathbb{E}_{\mathbf{b}_{-i} \sim \mathbf{B}_{-i}} [\max_{k \neq i} b_{kj}]$ . Finally, define  $\beta_j := 2 \max_i \mathbb{E}_{\mathbf{b}_{-i} \sim \mathbf{B}_{-i}} [\max_{k \neq i} b_{kj}]$ .

The following lemma shows the feasibility of the variables. The main core of the proof relies on an argument in [11].

► **Lemma 16.** *The dual vector  $(\alpha, \beta, \gamma)$  defined above constitutes a dual feasible solution.*

► **Theorem 17 ([11]).** *If player valuations are sub-additive then every Bayes-Nash equilibrium of a S1A (or S2A) has expected welfare at least 1/2 (or 1/4, resp) of the optimal one.*

**Proof.** For an item  $j$ , let  $i^*(j) \in \arg \max_i \mathbb{E}_{\mathbf{v}_{-i} \sim \mathbf{F}_{-i}} [\max_{k \neq i} b_{kj}]$ . Hence,

$$\begin{aligned}
 \beta_j &= 2 \mathbb{E}_{\mathbf{v}_{-i^*(j)} \sim \mathbf{F}_{-i^*(j)}} \mathbb{E}_{\sigma} \left[ \max_{k \neq i^*(j)} b_{kj} \right] = 2 \mathbb{E}_{v_{i^*(j)} \sim F_{i^*(j)}} \mathbb{E}_{\mathbf{v}_{-i^*(j)} \sim \mathbf{F}_{-i^*(j)}} \mathbb{E}_{\sigma} \left[ \max_{k \neq i^*(j)} b_{kj} \right] \\
 &= 2 \mathbb{E}_{\mathbf{v} \sim \mathbf{F}} \mathbb{E}_{\sigma} \left[ \max_{k \neq i^*(j)} b_{kj} \right]
 \end{aligned}$$

where the second equality is due to the fact that the term  $\mathbb{E}_{\mathbf{v}_{-i^*(j)} \sim \mathbf{F}_{-i^*(j)}} \mathbb{E}_{\sigma} [\max_{k \neq i^*(j)} b_{kj}]$  is independent of  $v_{i^*(j)}$ . Therefore, the dual objective is

$$\sum_{i,v_i} \alpha_i(v_i) + \sum_j \beta_j = 2 \mathbb{E}_{\mathbf{v} \sim \mathbf{F}} \mathbb{E}_{\sigma} \left[ \sum_i u_i(\mathbf{b}, v_i) + \sum_j \max_{k \neq i^*(j)} b_{kj} \right]$$

Fix a random choice of profile  $\mathbf{v}$  and  $\sigma$  (so the bid profile  $\mathbf{b}$  is fixed). We bound the dual objective, i.e., the right-hand side of the above equality, in S1A and S2A. Note that the utility of a player winning no item is 0.

**First Price Auction.** Partition the set of items into the winning items of each player. Consider a player  $i$  with the set of winning items  $S$ . The utility of this player  $i$  is  $v_{iS} - \sum_{j \in S} \max_k b_{kj}$ . Hence,  $v_{iS} - \sum_{j \in S} b_{ij} + \sum_{j \in S} \max_{k \neq i^*(j)} b_{kj} \leq v_{iS}$  since by the allocation rule,  $b_{ij} = \max_k b_{kj}$  for every  $j \in S$ . Hence, summing over all players, the dual objective is bounded by twice the total expected valuation of winning players, which is the primal. So the price of anarchy is at most 2.

**Second Price Auction.** Similarly, consider a player  $i$  with the set of winning items  $S$ . The utility of player  $i$  as well as its payment (by no-overbidding) are at most  $v_{iS}$ . Therefore, summing over all players, the dual objective is bounded by four times the total expected valuation of winning players. Hence, the price of anarchy is at most 4. ◀

## 4.2.2 Connection between Primal-Dual and No-Envy Learning

Very recently, Daskalakis and Syrgkanis [10] have introduced *no-envy learning* – a novel concept of learning in auctions. The notion is inspired by the concept of Walrasian equilibrium and it is motivated by the fact that no-regret learning algorithms (which converge to coarse correlated equilibria) for the simultaneous item-bidding auctions are computationally inefficient as the number of player actions are exponential. When the players have fractionally sub-additive (XOS) valuation, Daskalakis and Syrgkanis [10] showed that no-envy outcomes are a relaxation of no-regret outcomes. Moreover, no-envy outcomes maintain the approximate welfare optimality of no-regret outcomes while ensuring the computational tractability. In this section, we explore the connection between the no-envy learning and the primal-dual approach. Indeed, the notion of no-envy learning would be naturally derived from the dual constraints very much in the same way as the smoothness argument is.

We recall the notion of no-envy learning algorithms [10]. We first define the *online learning problem*. In the online learning problem, at each step  $t$ , the player chooses a bid vector  $b^t = (b_1^t, \dots, b_m^t)$  where  $b_j^t$  is the bid on item  $j$  for  $1 \leq j \leq m$ ; and the adversary picks adaptively (depending on the history of the play but not on the current bid  $b^t$ ) a threshold vector  $\theta^t = (\theta_1^t, \dots, \theta_m^t)$ . The player wins the set  $S^*(b^t, \theta^t) = \{j : b_j^t \geq \theta_j^t\}$  and gets reward:

$$u(b^t, \theta^t) := v(S^*(b^t, \theta^t)) - \sum_{j \in S^*(b^t, \theta^t)} \theta_j^t$$

where  $v : 2^{[m]} \rightarrow \mathbb{R}$  is the valuation of the player.

► **Definition 18** ([10]). An algorithm for the online learning problem is *r-approximate no-envy* if, for any adaptively chosen sequence of (random) threshold vector  $\theta^{1:T}$  by the adversary, the (random) bid vector  $b^{1:T}$  chosen by the algorithm satisfies:

$$\frac{1}{T} \sum_{t=1}^T \mathbb{E}[u(b^t, \theta^t)] \geq \max_{S \subseteq [m]} \left( \frac{1}{r} \cdot v(S) - \sum_{j \in S} \frac{1}{T} \sum_{t=1}^T \mathbb{E}[\theta_j^t] \right) - \epsilon(T) \quad (3)$$

where the *no-envy rate*  $\epsilon(T) \rightarrow 0$  while  $T \rightarrow \infty$ . An algorithm is *no-envy* if it is 1-approximate no-envy.

Now we show the connection between primal-dual and no-envy learning by revisiting the following theorem. As we will see, the notion of no-envy learning corresponds exactly to a constraint of the dual program.

► **Theorem 19** ([10]). *If  $n$  players in a S2A use a  $r$ -approximate no-envy learning algorithm with envy rate  $\epsilon(T)$  then in  $T$  steps, the average welfare is at least  $\frac{1}{2r} \text{OPT} - n \cdot \epsilon(T)$  where  $\text{OPT}$  is the expected optimal welfare.*

**Proof.** Let  $b_i^t$  be the bid vector of player  $i$  where  $b_{ij}^t$  is the bid of player  $i$  on item  $j$  in step  $t$ . In a S2A the threshold  $\theta_{ij}^t = \max_{k \neq i} b_{kj}^t$ . Consider the same primal and dual LPs in Section 4.2.1.

**Dual variables.** Recall that  $r$  is the approximation factor and  $\epsilon(T)$  the no-envy rate of the learning algorithm. Define dual variables (similar to the ones in Section 4.2.1) as follows.

$$\begin{aligned} \alpha_i(v_i) &:= r \cdot f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(v_i, \mathbf{v}_{-i})} [u_i(b_i^t, \theta_i^t)] \right] + r \cdot \epsilon(T) \\ \gamma_{i,j}(v_j) &:= r \cdot f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(v_i, \mathbf{v}_{-i})} [\theta_{ij}^t] \right] = r \cdot f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}_{-i}^t(\mathbf{v}_{-i})} [\theta_{ij}^t] \right] \\ \beta_j &:= r \cdot \max_i \max_{v_i} \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(v_i, \mathbf{v}_{-i})} [\theta_{ij}^t] \right] = r \cdot \max_i \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}_{-i}^t(\mathbf{v}_{-i})} [\theta_{ij}^t] \right] \end{aligned}$$

where the second equalities in the definitions of  $\gamma$  and  $\beta$  follow the fact that player valuations are independent and  $\theta_{ij}^t$  does not depend on  $b_{ij}^t$  for every  $i, j$ .

**Feasibility.** The first dual constraint follows immediately by the definitions of dual variables  $\beta$  and  $\gamma$ . For a fixed set  $S$  and a player  $i$  with valuation  $v_i$ , the second dual constraint reads

$$\begin{aligned} r \cdot f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(v_i, \mathbf{v}_{-i})} [u_i(b_i^t, \theta_i^t)] \right] + r \cdot \epsilon(T) \\ + r \cdot \sum_{j \in S} f_i(v_i) \cdot \mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}_{-i}^t(\mathbf{v}_{-i})} [\theta_{ij}^t] \right] \geq f_i(v_i) \cdot v_{iS} \end{aligned}$$

This inequality follows immediately from the definition of  $r$ -approximate no-envy learning algorithms (specifically, Inequality (3)) by simplifying and rearranging terms. (Note that  $\mathbb{E}_{\mathbf{v}_{-i} \sim \mathcal{F}_{-i}} [f_i(v_i) \cdot v_{iS}] = f_i(v_i) \cdot v_{iS}$ ).

**Bounding the cost.** In  $T$  steps, the average welfare is

$$\mathbb{E}_{\mathbf{v}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(\mathbf{v})} [v_i(b_i^t, \theta_i^t)] \right] = \mathbb{E}_{\mathbf{v}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(\mathbf{v})} [v_i(S^*(b_i^t, \theta_i^t))] \right].$$

Besides, in the dual objective,

$$\begin{aligned} \sum_{i, v_i} \alpha_i(v_i) &\leq r \cdot \mathbb{E}_{\mathbf{v}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(\mathbf{v})} [v_i(S^*(b_i^t, \theta_i^t))] \right] + n \cdot r \cdot \epsilon(T), \\ \sum_j \beta_j &\leq r \cdot \mathbb{E}_{\mathbf{v}} \left[ \frac{1}{T} \sum_{t=1}^T \mathbb{E}_{\mathbf{b}^t(\mathbf{v})} [v_i(S^*(b_i^t, \theta_i^t))] \right] \end{aligned}$$

where the last inequality is due to the non-overbidding property. Hence, the theorem follows by weak duality. ◀

## 5 Conclusion

In the paper, we have presented a primal-dual approach to study the efficiency of games. We have shown the applicability of the approach on a wide variety of settings and have given simple and improved analyses for several problems in settings of different natures. Beyond concrete results, the main point of the paper is to illuminate the potential of the primal-dual approach. In this approach, the PoA-bound analyses now can be done similarly as the analyses of LP-based algorithms in Approximation/Online Algorithms. We hope that linear programming and duality would bring new ideas and techniques, from well-developed domains such as approximation, online algorithms, etc to algorithmic game theory, not only for the analyses and the understanding of current games but also for the design of new games (auctions) and new concepts leading to improved efficiency.
