■ Contents

Preface	
<i>Dimitris Achlioptas and László A. Végh</i>	0:xi

APPROX

The Query Complexity of Mastermind with ℓ_p Distances	
<i>Manuel Fernández V, David P. Woodruff, and Taisuke Yasuda</i>	1:1–1:11
Tracking the ℓ_2 Norm with Constant Update Time	
<i>Chi-Ning Chou, Zhixian Lei, and Preetum Nakkiran</i>	2:1–2:15
Submodular Optimization with Contention Resolution Extensions	
<i>Benjamin Moseley and Maxim Sviridenko</i>	3:1–3:17
Prepare for the Expected Worst: Algorithms for Reconfigurable Resources Under Uncertainty	
<i>David Ellis Hershkowitz, R. Ravi, and Sahil Singla</i>	4:1–4:19
Streaming Hardness of Unique Games	
<i>Venkatesan Guruswami and Runzhou Tao</i>	5:1–5:12
On Strong Diameter Padded Decompositions	
<i>Arnold Filtser</i>	6:1–6:21
Max-Min Greedy Matching	
<i>Alon Eden, Uriel Feige, and Michal Feldman</i>	7:1–7:23
Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues	
<i>Gary L. Miller, Noel J. Walkington, and Alex L. Wang</i>	8:1–8:19
Improved 3LIN Hardness via Linear Label Cover	
<i>Prahladh Harsha, Subhash Khot, Euiwoong Lee, and Devanathan Thiruvengatachari</i>	9:1–9:16
Dynamic Pricing of Servers on Trees	
<i>Ilan Reuven Cohen, Alon Eden, Amos Fiat, and Łukasz Jeż</i>	10:1–10:22
Approximating the Norms of Graph Spanners	
<i>Eden Chlamtáč, Michael Dinitz, and Thomas Robinson</i>	11:1–11:22
Conditional Hardness of Earth Mover Distance	
<i>Dhruv Rohatgi</i>	12:1–12:17
Single-Elimination Brackets Fail to Approximate Copeland Winner	
<i>Reyna Hulett</i>	13:1–13:20
Routing Symmetric Demands in Directed Minor-Free Graphs with Constant Congestion	
<i>Timothy Carpenter, Ario Salmasi, and Anastasios Sidiropoulos</i>	14:1–14:15
Rainbow Coloring Hardness via Low Sensitivity Polymorphisms	
<i>Venkatesan Guruswami and Sai Sandeep</i>	15:1–15:17

Approximation, Randomization, and Combinatorial Optimization. Algorithms and Techniques (APPROX/RANDOM 2019).

Editors: Dimitris Achlioptas and László A. Végh

Leibniz International Proceedings in Informatics
LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Syntactic Separation of Subset Satisfiability Problems <i>Eric Allender, Martín Farach-Colton, and Meng-Tsung Tsai</i>	16:1–16:23
Malleable Scheduling Beyond Identical Machines <i>Dimitris Fotakis, Jannik Matuschke, and Orestis Papadigenopoulos</i>	17:1–17:14
On the Cost of Essentially Fair Clusterings <i>Ioana O. Bercea, Martin Groß, Samir Khuller, Aounon Kumar, Clemens Rösner, Daniel R. Schmidt, and Melanie Schmidt</i>	18:1–18:22
The Maximum Exposure Problem <i>Neeraj Kumar, Stavros Sintos, and Subhash Suri</i>	19:1–19:20
Small Space Stream Summary for Matroid Center <i>Sagar Kale</i>	20:1–20:22
Improved Bounds for Open Online Dial-a-Ride on the Line <i>Alexander Birx, Yann Disser, and Kevin Schewior</i>	21:1–21:22
Improved Online Algorithms for Knapsack and GAP in the Random Order Model <i>Susanne Albers, Arindam Khan, and Leon Ladewig</i>	22:1–22:23
Fast and Deterministic Approximations for k -Cut <i>Kent Quanrud</i>	23:1–23:20
Global Cardinality Constraints Make Approximating Some Max-2-CSPs Harder <i>Per Austrin and Aleksa Stanković</i>	24:1–24:17
Robust Appointment Scheduling with Heterogeneous Costs <i>Andreas S. Schulz and Rajan Udwani</i>	25:1–25:17
Collapsing Superstring Conjecture <i>Alexander Golovnev, Alexander S. Kulikov, Alexander Logunov, Ivan Mihajlin, and Maksim Nikolaev</i>	26:1–26:23
Improved Algorithms for Time Decay Streams <i>Vladimir Braverman, Harry Lang, Enayat Ullah, and Samson Zhou</i>	27:1–27:17
Approximation Algorithms for Partially Colorable Graphs <i>Suprovat Ghoshal, Anand Louis, and Rahul Raychaudhury</i>	28:1–28:20
Towards Optimal Moment Estimation in Streaming and Distributed Models <i>Rajesh Jayaram and David P. Woodruff</i>	29:1–29:21
The Complexity of Partial Function Extension for Coverage Functions <i>Umang Bhaskar and Gunjan Kumar</i>	30:1–30:21
Almost Optimal Classical Approximation Algorithms for a Quantum Generalization of Max-Cut <i>Sevag Gharibian and Ojas Parekh</i>	31:1–31:17
Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint <i>Chien-Chung Huang, Mathieu Mari, Claire Mathieu, Joseph S. B. Mitchell, and Nabil H. Mustafa</i>	32:1–32:21
Robust Correlation Clustering <i>Devrit, Ravishankar Krishnaswamy, and Nived Rajaraman</i>	33:1–33:18

RANDOM

Counting Independent Sets and Colorings on Random Regular Bipartite Graphs
Chao Liao, Jiabao Lin, Pinyan Lu, and Zhenyu Mao 34:1–34:12

The Expected Number of Maximal Points of the Convolution of Two 2-D Distributions
Josep Diaz and Mordecai Golin 35:1–35:14

On a Connectivity Threshold for Colorings of Random Graphs and Hypergraphs
Michael Anastos and Alan Frieze 36:1–36:10

Slow Mixing of Glauber Dynamics for the Six-Vertex Model in the Ordered Phases
Matthew Fahrbach and Dana Randall 37:1–37:20

Lifted Multiplicity Codes and the Disjoint Repair Group Property
Ray Li and Mary Wootters 38:1–38:18

Think Globally, Act Locally: On the Optimal Seeding for Nonsubmodular Influence Maximization
Grant Schoenebeck, Biaoshuai Tao, and Fang-Yi Yu 39:1–39:20

Direct Sum Testing: The General Case
Irit Dinur and Konstantin Golubev 40:1–40:11

Fast Algorithms at Low Temperatures via Markov Chains
Zongchen Chen, Andreas Galanis, Leslie Ann Goldberg, Will Perkins, James Stewart, and Eric Vigoda 41:1–41:14

Deterministic Approximation of Random Walks in Small Space
Jack Murtagh, Omer Reingold, Aaron Sidford, and Salil Vadhan 42:1–42:22

Two-Source Condensers with Low Error and Small Entropy Gap via Entropy-Resilient Functions
Avraham Ben-Aroya, Gil Cohen, Dean Doron, and Amnon Ta-Shma 43:1–43:20

Efficient Average-Case Population Recovery in the Presence of Insertions and Deletions
Frank Ban, Xi Chen, Rocco A. Servedio, and Sandip Sinha 44:1–44:18

Improved Pseudorandom Generators from Pseudorandom Multi-Switching Lemmas
Rocco A. Servedio and Li-Yang Tan 45:1–45:23

Unconstraining Graph-Constrained Group Testing
Bruce Spang and Mary Wootters 46:1–46:20

Near-Neighbor Preserving Dimension Reduction for Doubling Subsets of ℓ_1
Ioannis Z. Emiris, Vasilis Margonis, and Ioannis Psarros 47:1–47:13

Improved Strong Spatial Mixing for Colorings on Trees
Charilaos Efthymiou, Andreas Galanis, Thomas P. Hayes, Daniel Štefankovič, and Eric Vigoda 48:1–48:16

(Near) Optimal Adaptivity Gaps for Stochastic Multi-Value Probing
Domagoj Bradac, Sahil Singla, and Goran Zuzic 49:1–49:21

Testing Odd Direct Sums Using High Dimensional Expanders <i>Roy Gotlib and Tali Kaufman</i>	50:1–50:20
A Lower Bound for Sampling Disjoint Sets <i>Mika Göös and Thomas Watson</i>	51:1–51:13
Approximating the Noise Sensitivity of a Monotone Boolean Function <i>Ronitt Rubinfeld and Arsen Vasilyan</i>	52:1–52:17
Connectivity of Random Annulus Graphs and the Geometric Block Model <i>Sainyam Galhotra, Arya Mazumdar, Soumyabrata Pal, and Barna Saha</i>	53:1–53:23
A Local Stochastic Algorithm for Separation in Heterogeneous Self-Organizing Particle Systems <i>Sarah Cannon, Joshua J. Daymude, Cem Gökmen, Dana Randall, and Andréa W. Richa</i>	54:1–54:22
The Large-Error Approximate Degree of AC^0 <i>Mark Bun and Justin Thaler</i>	55:1–55:16
String Matching: Communication, Circuits, and Learning <i>Alexander Golovnev, Mika Göös, Daniel Reichman, and Igor Shinkar</i>	56:1–56:20
Efficient Black-Box Identity Testing for Free Group Algebras <i>V. Arvind, Abhranil Chatterjee, Rajit Datta, and Partha Mukhopadhyay</i>	57:1–57:16
The Maximum Label Propagation Algorithm on Sparse Random Graphs <i>Charlotte Knierim, Johannes Lengler, Pascal Pfister, Ulysse Schaller, and Angelika Steger</i>	58:1–58:15
Samplers and Extractors for Unbounded Functions <i>Rohit Agrawal</i>	59:1–59:21
Successive Minimum Spanning Trees <i>Svante Janson and Gregory B. Sorkin</i>	60:1–60:16
Simple Analysis of Sparse, Sign-Consistent JL <i>Meena Jagadeesan</i>	61:1–61:20
Streaming Coreset Constructions for M-Estimators <i>Vladimir Braverman, Dan Feldman, Harry Lang, and Daniela Rus</i>	62:1–62:15
Pairwise Independent Random Walks Can Be Slightly Unbounded <i>Shyam Narayanan</i>	63:1–63:19
Optimal Convergence Rate of Hamiltonian Monte Carlo for Strongly Logconcave Distributions <i>Zongchen Chen and Santosh S. Vempala</i>	64:1–64:12
Exploring Differential Obliviousness <i>Amos Beimel, Kobbi Nissim, and Mohammad Zaheri</i>	65:1–65:20
Thresholds in Random Motif Graphs <i>Michael Anastos, Peleg Michaeli, and Samantha Petti</i>	66:1–66:19

Random-Cluster Dynamics in \mathbb{Z}^2 : Rapid Mixing with General Boundary Conditions
Antonio Blanca, Reza Gheissari, and Eric Vigoda 67:1–67:19

On List Recovery of High-Rate Tensor Codes
Swastik Kopparty, Nicolas Resch, Noga Ron-Zewi, Shubhangi Saraf, and Shashwat Silas 68:1–68:22

Approximate \mathbb{F}_2 -Sketching of Valuation Functions
Grigory Yaroslavtsev and Samson Zhou 69:1–69:21

Streaming Verification of Graph Computations via Graph Structure
Amit Chakrabarti and Prantar Ghosh 70:1–70:20

Approximate Degree, Secret Sharing, and Concentration Phenomena
Andrej Bogdanov, Nikhil S. Mande, Justin Thaler, and Christopher Williamson .. 71:1–71:21

Improved Extractors for Recognizable and Algebraic Sources
Fu Li and David Zuckerman 72:1–72:22

■ Preface

This volume contains the papers presented at the 22nd International Conference on Approximation Algorithms for Combinatorial Optimization Problems (APPROX'2019) and the 23rd International Conference on Randomization and Computation (RANDOM'2019), which took place concurrently at the at Massachusetts Institute of Technology, USA during September 20–22, 2019.

APPROX focuses on algorithmic and complexity issues surrounding the development of efficient approximate solutions to computationally difficult problems, and was the 22nd in the series. RANDOM is concerned with applications of randomness to computational and combinatorial problems, and was the 23rd in the series. Prior to 2003, APPROX took place in Aalborg (1998), Berkeley (1999), Saarbrücken (2000), Berkeley (2001), and Rome (2002), while RANDOM took place in Bologna (1997), Barcelona (1998), Berkeley (1999), Geneva (2000), Berkeley (2001), and Harvard (2002). Since 2003, APPROX and RANDOM have been colocated, taking place in Princeton (2003), Cambridge (2004), Berkeley (2005), Barcelona (2006), Princeton (2007), Boston (2008), Berkeley (2009), Barcelona (2010), Princeton (2011), Boston (2012), Berkeley (2013), Barcelona (2014), Princeton (2015), Paris (2016), Berkeley (2017), and Princeton (2018).

Topics of interest for APPROX and RANDOM are: approximation algorithms, hardness of approximation, small space, sub-linear time and streaming algorithms, online algorithms, approaches that go beyond worst case analysis, distributed and parallel approximation, embeddings and metric space methods, mathematical programming methods, spectral methods, combinatorial optimization, algorithmic game theory, mechanism design and economics, computational geometric problems, approximate learning, design and analysis of randomized algorithms, randomized complexity theory, pseudorandomness and derandomization, random combinatorial structures, random walks/Markov chains, expander graphs and randomness extractors, probabilistic proof systems, random projections and embeddings, error-correcting codes, average-case analysis, smoothed analysis, property testing, and computational learning theory.

The volume contains 33 contributed papers, selected by the APPROX Program Committee out of 66 submissions, and 39 contributed papers, selected by the RANDOM Program Committee also out of 66 submissions. We would like to thank all of the authors who submitted papers, the invited speakers, the members of the Program Committees, and the external reviewers. We are grateful for the guidance of the steering committees: Klaus Jansen, Samir Khuller, and Monaldo Mastrolili for APPROX, and Oded Goldreich, Cris Moore, Anup Rao, Omer Reingold, Dana Ron, Ronitt Rubinfeld, Amit Sahai, Ronen Shaltiel, Alistair Sinclair, and Paul Spirakis for RANDOM.

September 2019

Dimitris Achlioptas and László A. Végh

■ Program Committees

APPROX

Nima Anari	Stanford University
Kristóf Bérczi	Eötvös University, Budapest
Deeparnab Chakrabarty	Dartmouth College
Karthekeyan Chandrasekaran	University of Illinois, Urbana-Champaign
Michael Dinitz	Johns Hopkins University
Leah Epstein	University of Haifa
Samuel Fiorini	Université libre de Bruxelles
Swati Gupta	Georgia Institute of Technology
Bundit Laekhanukit	Shanghai University of Finance and Economics
Joseph Seffi Naor	Technion
Huy Lê Nguyễn	Northeastern University
Kanstantsin Pashkovich	University of Ottawa
Barna Saha	University of Massachusetts Amherst
Bruce Shepherd	University of British Columbia
David B. Shmoys	Cornell University
He Sun	University of Edinburgh
László A. Végh (chair)	London School of Economics and Political Science

RANDOM

Dimitris Achlioptas (chair)	University of California Santa Cruz/Google
Nikhil Bansal	Eindhoven/Centrum Wiskunde & Informatica
Paul Beame	University of Washington
Ivona Bezakova	Rochester Institute of Technology
Klim Efremenko	Ben Gurion University
Uri Feige	Weizmann Institute of Science
Anna Gilbert	University of Michigan
Subhash Khot	New York University
Antonina Kolokova	Memorial University of Newfoundland
Ravi Kumar	Google
Or Meir	University of Haifa
Prasad Raghavendra	University of California Berkeley
Noga Ron-Zewi	University of Haifa
Sofya Raskhodnikova	Boston University
C. Seshadhri	University of California Santa Cruz
Devavrat Shah	Massachusetts Institute of Technology
Christian Sohler	Technical University of Dortmund/Google
Kunal Talwar	Google
Thomas Vidick	California Institute of Technology
Jan Vondrak	Stanford University
David Woodruff	Carnegie Mellon University

■ Subreviewers

Raghavendra Addanki
David Adjashvili
Saba Ahmadi
Matthew Aldridge
Zeyuan Allen-Zhu
Itai Arad
Sepehr Assadi

Abstract

Consider a variant of the Mastermind game in which queries are ℓ_p distances, rather than the usual Hamming distance. That is, a codemaker chooses a hidden vector $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ and answers to queries of the form $\|\mathbf{y} - \mathbf{x}\|_p$ where $\mathbf{x} \in \{-k, -k+1, \dots, k-1, k\}^n$. The goal is to minimize the number of queries made in order to correctly guess \mathbf{y} .

In this work, we show an upper bound of $O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ queries for any real $1 \leq p < \infty$ and $O(n)$ queries for $p = \infty$. To prove this result, we in fact develop a nonadaptive polynomial time algorithm that works for a natural class of separable distance measures, i.e., coordinate-wise sums of functions of the absolute value. We also show matching lower bounds up to constant factors, even for adaptive algorithms for the approximation version of the problem, in which the problem is to output \mathbf{y}' such that $\|\mathbf{y}' - \mathbf{y}\|_p \leq R$ for any $R \leq k^{1-\varepsilon} n^{1/p}$ for constant $\varepsilon > 0$. Thus, essentially any approximation of this problem is as hard as finding the hidden vector exactly, up to constant factors. Finally, we show that for the noisy version of the problem, i.e., the setting when the codemaker answers queries with any $q = (1 \pm \varepsilon)\|\mathbf{y} - \mathbf{x}\|_p$, there is no query efficient algorithm.

1 Introduction

Mastermind is a game played between two players, the *codemaker* and the *codebreaker*. In the 1970 original 4-position 6-color version of the game, the codemaker chooses 4 colored pegs, each taking one of 6 colors, and the codebreaker tries to guess the codemaker's 4 pegs by making queries to the codemaker by taking a guess at the sequence of the codemaker's 4 colored pegs. These guesses are answered by two numbers, the number of pegs guessed that are in the right position and the right color, indicated by black pegs, and the additional number of pegs of the right color but in the wrong position, indicated by white pegs.

Leibniz International Proceedings in Informatics

LIPICs Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

Ever since, this game and its generalizations and variants have been studied by many computer scientists. The original version was completely characterized by [7], who showed upper and lower bounds of 5 queries for deterministic strategies. The n -position k -color generalization of the game was studied in [4], which sparked a line of research that led to progressive improvement in upper and lower bounds for this problem, both in the original version of the game as well as in related variants of the game [2]. As these variants are not the focus of this work, we refer the reader to the expositions of [5, 2] for more details on this literature.

Note that in the variant that the codebreaker only receives the black peg answers, the problem can be phrased as guessing a hidden vector based on Hamming distance queries. One can then consider many variants of the Mastermind game in which the codebreaker guesses the codemaker's hidden vector based on other distance queries. For instance, motivated by the theory of black-box complexity, [1] recently studied the variant where the distance is the length of the longest common prefix with respect to an unknown permutation. In recreational mathematics, the ℓ_1 distance case has been studied under the name of "digit-distance" [6]. In this work, we study the case of ℓ_p distance queries. That is, the codemaker chooses a hidden vector $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ and answers to queries of the form $\|\mathbf{y} - \mathbf{x}\|_p$ where $\mathbf{x} \in \{-k, -k+1, \dots, k-1, k\}^n$.

1.1 Our contributions

On the algorithmic side, we present Theorem 9, in which we develop a very general nonadaptive algorithm that works for any separable distance measure, i.e., the distance between $\mathbf{x}, \mathbf{y} \in \mathbb{R}^n$ is given by $f(\mathbf{x} - \mathbf{y})$ where $f(\mathbf{x}) = \sum_{i=1}^n g_i(|x_i|)$. When we apply this to the case of $g_i(x) = x^p$ for any constant real $1 \leq p < \infty$, i.e., when f is the (p -th power of the) ℓ_p norm, we obtain a polynomial time algorithm making $O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ queries. For $p = \infty$, we give a simple algorithm achieving $O(n)$ queries. We also give lower bounds for any adaptive algorithm that match our upper bounds up to constant factors, for any constant integer $1 \leq p < \infty$ (Theorem 11) and for $p = \infty$ (Theorem 12). In fact, our lower bounds are for a weaker problem, the problem of outputting an approximation \mathbf{y}' such that its distance from the true hidden vector \mathbf{y} is at most $\|\mathbf{y}' - \mathbf{y}\|_p \leq R$, whenever the approximation radius satisfies $R \leq k^{1-\varepsilon} n^{1/p}$ (where we think of $n^{1/p} = 1$ when $p = \infty$) for constant $\varepsilon > 0$. Thus, approximation for this problem is hard, in the sense that finding the point exactly is optimal up to constant factors, even when the approximation radius is as large as $k^{1-\varepsilon} n^{1/p}$.

Our main algorithmic technique for obtaining Theorem 9 is a judicious application of a generalization of the Fourier-based detecting matrix construction of [3]. Our lower bounds are simply obtained by counting the number of lattice points in an ℓ_p ball.

Finally, we consider a noisy version of the above problem, where the codemaker is allowed to answer queries with any answer that is within $(1 \pm \varepsilon)\|\mathbf{y} - \mathbf{x}\|_p$. For this variant, we show that any algorithm must make $\Omega(\exp(\varepsilon^2 \Theta(k^p n)))$ queries in Theorem 13. That is, there is no query efficient algorithm for this problem.

2 Preliminaries

2.1 Notation

► **Definition 1** (ℓ_p norm). Let $1 \leq p \leq \infty$. Then, we endow \mathbb{R}^n with the ℓ_p norm $\|\cdot\|_p$, given by

$$\|\mathbf{x}\|_p := \left(\sum_{i=1}^n |x_i|^p \right)^{1/p} \quad (1)$$

if $p < \infty$ and

$$\|\mathbf{x}\|_\infty := \max_{i=1}^n |x_i| \tag{2}$$

if $p = \infty$.

► **Definition 2** (Weight of binary vector). *Let $a \in \{0, 1\}^\nu$. Then, $\text{wt}(a)$ is the number of 1s in a .*

► **Definition 3** (Even-odd decomposition). *Let $h : \mathbb{R} \rightarrow \mathbb{R}$ be any function. Then, the even-odd decomposition of h is given by*

$$\begin{aligned} h_{\text{even}}(x) &:= \frac{h(x) + h(-x)}{2} \\ h_{\text{odd}}(x) &:= \frac{h(x) - h(-x)}{2}. \end{aligned} \tag{3}$$

It is easy to see that $h = h_{\text{even}} + h_{\text{odd}}$ and that $h_{\text{even}}(-x) = h_{\text{even}}(x)$ and $h_{\text{odd}}(-x) = -h_{\text{odd}}(x)$ for all $x \in \mathbb{R}$.

2.2 Bshouty's detecting matrix

We very briefly review the construction of the detecting matrix of [3], as we build off of this result for our algorithms.

► **Definition 4** (Detecting matrix [3]). *A (d_1, d_2, \dots, d_n) -detecting matrix is a $\{0, 1\}$ -matrix such that for every $\mathbf{u}, \mathbf{v} \in \prod_{i=1}^n \{0, 1, \dots, d_i - 1\}$ with $\mathbf{u} \neq \mathbf{v}$, we have $M\mathbf{u} \neq M\mathbf{v}$.*

The theorem we use is the following:

► **Theorem 5** (Bshouty detecting matrix, Theorem 4/Corollary 5 of [3]). *Let $1 < d_1 \leq d_2 \leq \dots \leq d_n$ where $d_1 + d_2 + \dots + d_n = d$. There is a (d_1, d_2, \dots, d_n) -detecting matrix M of size $s \times n$ where*

$$s(\log s - 4) \leq 2n \log \frac{d}{n}. \tag{4}$$

Furthermore, for $\mathbf{u} \in \prod_{i=1}^n \{0, 1, \dots, d_i - 1\}$, there is a polynomial time algorithm for recovering \mathbf{u} given $M\mathbf{u}$.

We will only sketch the main idea behind the construction of the matrix and the decoding algorithm, and refer the reader to [3] for the proof of the bounds and the correctness.

2.2.1 Fourier representation [3]

We consider the Fourier basis on real-valued functions defined on the Boolean hypercube $\{-1, +1\}^\nu$, i.e., the basis

$$\mathcal{B} := \left\{ \chi_a(x) := \prod_{a_i=1} x_i \mid a \in \{0, 1\}^\nu \right\} \subseteq \{f : \{-1, +1\}^\nu \rightarrow \mathbb{R}\}. \tag{5}$$

It is known that \mathcal{B} is an orthonormal basis, and thus any $f : \{-1, +1\}^\nu \rightarrow \mathbb{R}$ can be uniquely represented as

$$f(x) = \sum_{a \in \{0, 1\}^s} \hat{f}(a) \chi_a(x) \tag{6}$$

1:4 The Query Complexity of Mastermind with ℓ_p Distances

where $\hat{f}(a)$ is the Fourier coefficient of χ_a given by

$$\hat{f}(a) = \frac{1}{2^\nu} \sum_{x \in \{-1, +1\}^\nu} f(x) \chi_a(x). \quad (7)$$

Using the fast Fourier transform, all the coefficients $\hat{f}(a)$ can be found from the values of $f(x)$, $x \in \{-1, +1\}^\nu$, and ordered according to lexicographic order of $a \in \{0, 1\}^\nu$ in time $O(\nu 2^\nu)$.

2.2.2 Detecting matrix construction

The overall idea is as follows. We choose s as in equation (4) and $\nu := \log_2 s$. Then, we view column vectors in \mathbb{R}^s with $s = 2^\nu$ rows as enumerations of the values of functions $f : \{-1, +1\}^\nu \rightarrow \mathbb{R}$. That is, for $x \in \{-1, +1\}^\nu$, the x th row of the column vector representing f is $f(x)$. We then view our detecting matrix $M \in \{0, 1\}^{s \times n}$ as a family of n $\{0, 1\}$ -valued functions defined on $\{-1, +1\}^\nu$ and Mu as a linear combination of functions from this family, where the coefficients of the linear combination are specified by the unknown vector $\mathbf{u} \in \prod_{i=1}^n \{0, 1, \dots, d_i - 1\}$. The n functions of M have a special structure in the Fourier basis, so that there is an efficient iterative algorithm for recovering the coordinates of u in batches from the Fourier coefficients of the function Mu .

We iteratively construct columns of M as follows. For each $a \in \{0, 1\}^\nu$, we will choose ℓ_a more columns to construct, so that in the end, we have $\sum_{a \in \{0, 1\}^\nu} \ell_a = n$ columns.

Suppose that columns 1 through r have already been constructed. Let $a \in \{0, 1\}^\nu$ and choose an integer ℓ_a such that

$$\begin{aligned} d_{r+1} d_{r+2} \dots d_{r+\ell_a} &\leq 2^{\text{wt}(a)} \\ d_{r+1} d_{r+2} \dots d_{r+\ell_a} d_{r+\ell_a+1} &> 2^{\text{wt}(a)-1}. \end{aligned} \quad (8)$$

We then construct ℓ_a more columns of M so that the i th new function $g_{a,i}$ has Fourier coefficient of χ_a as

$$\hat{g}_{a,i}(a) = d_{r+1} d_{r+2} \dots d_{r+i} / 2^{\text{wt}(a)} \quad (9)$$

and the Fourier coefficient of χ_b for any $b > a$ (in the usual ordering on the Boolean hypercube) as

$$\hat{g}_{a,i}(b) = 0. \quad (10)$$

The way we choose the column functions $g_{a,i}$ to have these properties is described in [3].

2.2.3 Decoding algorithm

We now show how to efficiently decode $M\mathbf{u}$. Essentially, we will decode ℓ_a of the entries of \mathbf{u} at a time, subtract them off, and recurse.

Note that column vector $M\mathbf{u}$ is the enumeration of the values of a linear combination f of the $g_{a,i}$ functions from above, where the row corresponding to $x \in \{-1, +1\}^\nu$ is $f(x)$. Then, using the fast Fourier transform, we find all the Fourier coefficients $\hat{f}(z)$ for $z \in \{0, 1\}^\nu$ and search for a maximal $a \in \{0, 1\}^\nu$ such that $\hat{f}(a) \neq 0$. For such an a , one can prove that its Fourier coefficient in f is

$$\hat{f}(a) = \frac{1}{2^{\text{wt}(a)}} (\lambda_{r+1} + \lambda_{r+2} d_{r+1} + \lambda_{r+3} d_{r+1} d_{r+2} + \dots + \lambda_{r+\ell_a+1} d_{r+1} d_{r+2} \dots d_{r+\ell_a}) \quad (11)$$

where r is the number of columns in M before the columns corresponding to a , and $\lambda_{r+i} = u_{r+i}$ (for sake of matching the notation in [3]). Since $\lambda_{r+i} \in \{0, 1, \dots, d_{r+i} - 1\}$ for all $i \in [\ell_a]$, we can recover all of the λ_{r+i} . Then, these coefficients can be subtracted off and we can recurse on the remaining entries of \mathbf{u} .

In our Theorem 9, we will modify the above algorithm to allow for non-integer values for the λ_{r+i} , as long as they are bounded and well-separated (to be made precise later).

3 Algorithms

We now describe our upper bounds. As a warm up, we start with algorithms for ℓ_1 , ℓ_2 , and ℓ_∞ . These will introduce some tricks that we exploit in our coordinate-wise sums algorithm. Then, we combine these tricks along with a modification of the Bshouty detecting matrix algorithm described above to obtain Theorem 9.

3.1 Algorithms for ℓ_1 , ℓ_2 , and ℓ_∞

Our algorithms will be based around the idea of applying the Bshouty detecting matrix M to the hidden vector \mathbf{y} . This can be most straightforwardly applied in the case of ℓ_2 , by expanding squared distances (equation (12)).

► **Theorem 6** (Algorithm for ℓ_2 queries). *Let $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ be an unknown vector, and suppose that we receive answers to s queries of the form $\|\mathbf{x} - \mathbf{y}\|_2$. Then, there is a polynomial time algorithm that recovers \mathbf{y} in $s = O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ queries.*

Proof. By first making the query with the $\mathbf{0}$ vector, we may find the norm $\|\mathbf{y}\|_2$ of the unknown vector. Now suppose we query for $\|\mathbf{x} - \mathbf{y}\|_2$. Note then that

$$\langle \mathbf{x}, \mathbf{y} \rangle = \frac{\|\mathbf{x}\|_2^2 + \|\mathbf{y}\|_2^2 - \|\mathbf{x} - \mathbf{y}\|_2^2}{2} \quad (12)$$

so we can compute the inner product between \mathbf{x} and \mathbf{y} . Thus by taking n queries to be the n standard basis vectors $\mathbf{x} = \mathbf{e}_i$ for $i \in [n]$, we can always recover \mathbf{y} in $n+1$ queries. To obtain $s = O\left(\frac{n \log k}{\log n}\right)$ for $k \leq n$, we can take our query vectors \mathbf{x} to be the rows of the detecting matrix of Theorem 4/Corollary 5 of [3] and recover \mathbf{y} by using the decoding algorithm as described in the proof. We thus conclude as desired. ◀

As shown above, if we can simulate computing inner products with binary vectors in $O(1)$ queries each, then we get an $O(n)$ algorithm by querying with the standard basis vectors or $O\left(\frac{n \log k}{\log n}\right)$ by using [3]. For ℓ_1 , we take a similar approach. This time, the way we extract the inner product is quite different from the case of ℓ_2 . This technique turns out to be much more flexible, and will allow us to generalize the result to coordinate-wise sums.

► **Theorem 7** (Algorithm for ℓ_1 queries). *Let $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ be an unknown vector, and suppose that we receive answers to s queries of the form $\|\mathbf{x} - \mathbf{y}\|_1$. Then, there is a polynomial time algorithm that recovers \mathbf{y} in $s = O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ queries.*

Proof. We will just show how to compute inner products in $O(1)$ queries, since the rest follows as in the ℓ_2 case. Let $\boldsymbol{\tau} \in \{0, 1\}^n$ be any binary vector and consider the sign vector $\boldsymbol{\sigma} \in \{\pm 1\}^n$ with $\sigma_i = (-1)^{\tau_i+1}$. Then for $\sigma_i \in \{\pm 1\}$ and $-k \leq y_i \leq k$, we have that

$$|k\sigma_i - y_i| = |k\sigma_i - \sigma_i^2 y_i| = |k - \sigma_i y_i| = k - \sigma_i y_i. \quad (13)$$

1:6 The Query Complexity of Mastermind with ℓ_p Distances

Thus,

$$\|k\boldsymbol{\sigma} - \mathbf{y}\|_1 = \sum_{i=1}^n |k\sigma_i - y_i| = \sum_{i=1}^n k - \sigma_i y_i = kn - \boldsymbol{\sigma} \cdot \mathbf{y} \quad (14)$$

so we may compute the quantity $\boldsymbol{\sigma} \cdot \mathbf{y} = kn - \|k\boldsymbol{\sigma} - \mathbf{y}\|_1$. We may then compute the desired inner product with binary vectors as $\boldsymbol{\tau} \cdot \mathbf{y} = (\boldsymbol{\sigma} \cdot \mathbf{y} + \mathbf{1}_n \cdot \mathbf{y})/2$. \blacktriangleleft

To conclude the section, we show an $O(n)$ algorithm for ℓ_∞ queries. This turns out to be optimal, as we show later.

► **Theorem 8** (Algorithm for ℓ_∞ queries). *Let $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ be an unknown vector, and suppose that we receive answers to s queries of the form $\|\mathbf{x} - \mathbf{y}\|_\infty$. Then, there is a polynomial time algorithm that recovers \mathbf{y} in $s = O(n)$ queries.*

Proof. For each $i \in [n]$, we make the query $q_i^+ = \|k\mathbf{e}_i - \mathbf{y}\|_\infty$ and $q_i^- = \|-k\mathbf{e}_i - \mathbf{y}\|_\infty$. Note that $y_i = 0$ if and only if these two are both equal to k . If $y_i > 0$, then $q_i^- = k + y_i > k$ and if $y_i < 0$, then $q_i^+ = k - y_i > k$. Thus, with these two queries, we can determine y_i . Thus, we recover \mathbf{y} in $O(n)$ queries. \blacktriangleleft

3.2 Algorithm for coordinate-wise sums

In the previous section, we obtained polynomial time algorithms with tight query complexity for ℓ_1 and ℓ_2 by simulating inner product computations between \mathbf{y} and binary vectors. We now generalize these ideas to an algorithm for any query given by sums along the coordinates. This in particular includes all (p -th powers of) ℓ_p norms, even for p not an integer.

► **Theorem 9** (Algorithm for coordinate-wise sums). *Let $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ be an unknown vector, and suppose that we receive answers to s queries of the form $f(\mathbf{y} - \mathbf{x})$, where $f(\mathbf{x}) = \sum_{i=1}^n g_i(|x_i|)$. For each $i \in [n]$, define the function $h_i(x) = g_i(k - x)$ and consider the even-odd decomposition $h_i = (h_i)_{\text{even}} + (h_i)_{\text{odd}}$ (see Definition 3). Also consider the following quantities:*

$$\begin{aligned} M_i^{\min} &:= \min_{x \in \{-k, -k+1, \dots, k-1, k\}} (h_i)_{\text{odd}}(x) \\ M_i^{\max} &:= \max_{x \in \{-k, -k+1, \dots, k-1, k\}} (h_i)_{\text{odd}}(x) \\ \Delta_i &:= \min_{\substack{x_1, x_2 \in \{-k, -k+1, \dots, k-1, k\} \\ x_1 \neq x_2}} |(h_i)_{\text{odd}}(x_1) - (h_i)_{\text{odd}}(x_2)| \\ \Delta &:= \min_{i=1}^n \Delta_i \\ d_i &:= \left\lceil \frac{M_i^{\max} - M_i^{\min}}{\Delta} \right\rceil + 1 \end{aligned} \quad (15)$$

If $\Delta > 0$, then there is a polynomial time algorithm that recovers \mathbf{y} with $s = O\left(\min\left\{n, \frac{\log \prod_{i=1}^n d_i}{\log n}\right\}\right)$ queries.

Proof. Let \mathbf{h}_{even} and \mathbf{h}_{odd} be the functions that apply $(h_i)_{\text{even}}$ and $(h_i)_{\text{odd}}$ on the i th coordinate, respectively. We will show that we can recover $\mathbf{h}_{\text{odd}}(\mathbf{y})$ in $O\left(\min\left\{n, \frac{\log \prod_{i=1}^n d_i}{\log n}\right\}\right)$ queries. Note that since $\min_{i=1}^n \Delta_i > 0$, $(h_i)_{\text{odd}}$ is injective for each i and thus we can recover \mathbf{y} from $\mathbf{h}_{\text{odd}}(\mathbf{y})$ in polynomial time using a lookup table for the values of $(h_i)_{\text{odd}}$.

3.2.1 Inner products with binary vectors

We first show that we can compute the inner product between $\mathbf{h}_{\text{odd}}(\mathbf{y})$ and any binary vector $\boldsymbol{\tau} \in \{0, 1\}^n$. To do this, consider the sign vector $\boldsymbol{\sigma} \in \{\pm 1\}^n$ with $\sigma_i = (-1)^{\tau_i+1}$. Note that for $\sigma_i \in \{\pm 1\}$ and $-k \leq y_i \leq k$, we have $|k\sigma_i - y_i| = |k - \sigma_i y_i| = k - \sigma_i y_i$. Then, by querying vectors of the form $\mathbf{x} = k\boldsymbol{\sigma}$, we obtain

$$f(k\boldsymbol{\sigma} - \mathbf{y}) = \sum_{i=1}^n g_i(k - \sigma_i y_i) = \sum_{i=1}^n h_i(\sigma_i y_i). \quad (16)$$

Then using the even/oddness of $(h_i)_{\text{even}}/(h_i)_{\text{odd}}$, we have

$$\sum_{i=1}^n h_i(\sigma_i y_i) = \left(\sum_{i=1}^n (h_i)_{\text{even}}(y_i) \right) + \left(\sum_{i=1}^n \sigma_i (h_i)_{\text{odd}}(y_i) \right) = \mathbf{1}_n \cdot \mathbf{h}_{\text{even}}(\mathbf{y}) + \boldsymbol{\sigma} \cdot \mathbf{h}_{\text{odd}}(\mathbf{y}). \quad (17)$$

Note also that by querying for $k\mathbf{1}_n$ and $-k\mathbf{1}_n$, we also obtain

$$\begin{aligned} \frac{f(k\mathbf{1}_n - \mathbf{y}) + f(-k\mathbf{1}_n - \mathbf{y})}{2} &= \sum_{i=1}^n (h_i)_{\text{even}}(y_i) = \mathbf{1}_n \cdot \mathbf{h}_{\text{even}}(\mathbf{y}) \\ \frac{f(k\mathbf{1}_n - \mathbf{y}) - f(-k\mathbf{1}_n - \mathbf{y})}{2} &= \sum_{i=1}^n (h_i)_{\text{odd}}(y_i) = \mathbf{1}_n \cdot \mathbf{h}_{\text{odd}}(\mathbf{y}). \end{aligned} \quad (18)$$

Using these, we may compute $\boldsymbol{\tau} \cdot \mathbf{h}_{\text{odd}}(\mathbf{y}) = \frac{1}{2}(\boldsymbol{\sigma} + \mathbf{1}_n) \cdot \mathbf{h}_{\text{odd}}(\mathbf{y})$ and thus we are able to compute dot products of arbitrary binary vectors with $\mathbf{h}_{\text{odd}}(\mathbf{y})$. At this point, we can obtain $O(n)$ queries just by taking the binary vectors to be the standard basis vectors, so we focus on obtaining an algorithm making at most $O\left(\frac{\log \prod_{i=1}^n d_i}{\log n}\right)$ queries.

3.2.2 Modification of the Bshouty detecting matrix decoding [3]

Recall the detecting matrix of [3] for integer vectors in $\prod_{i=1}^n \{0, 1, \dots, d_i - 1\}$ for $d_i \in \mathbb{N}$ for $i \in [n]$. If $\mathbf{h}_{\text{odd}}(\mathbf{y})$ took integer values, then we could just directly use this theorem to conclude with the desired query complexity. However, this is not true of $\mathbf{h}_{\text{odd}}(\mathbf{y})$, and so we need to show how to modify the [3] construction to handle our setting.

We first shift and scale our vector $\mathbf{h}_{\text{odd}}(\mathbf{y})$. Let \mathbf{M}^{\min} be the vector with M_i^{\min} in the i th coordinate. Note that we can easily compute $\boldsymbol{\tau} \cdot \mathbf{M}^{\min}$. Thus, we are able to compute dot products of arbitrary binary vectors with the vector $(\mathbf{h}_{\text{odd}}(\mathbf{y}) - \mathbf{M}^{\min})$. By dividing by Δ , we have dot products of arbitrary binary vectors with $\frac{1}{\Delta}(\mathbf{h}_{\text{odd}}(\mathbf{y}) - \mathbf{M}^{\min})$. We now define this as

$$\begin{aligned} \varphi_i(y) &:= \frac{1}{\Delta}((h_i)_{\text{odd}}(y) - M_i^{\min}) \\ \boldsymbol{\varphi}(\mathbf{y}) &:= \frac{1}{\Delta}(\mathbf{h}_{\text{odd}}(\mathbf{y}) - \mathbf{M}^{\min}) \end{aligned} \quad (19)$$

Note then that $0 \leq \varphi_i \leq d_i - 1$ (see equation (15)) and that $y_1 \neq y_2 \implies |\varphi(y_1) - \varphi(y_2)| \geq 1$.

Now consider the detecting matrix construction of Theorem 4 in [3]. Recall that we may extract the Fourier coefficient of χ_a for some maximal a in our unknown vector $\boldsymbol{\varphi}(\mathbf{y})$ viewed as a function, which gives us

$$\lambda_{r+1} + \lambda_{r+2}d_{r+1} + \lambda_{r+3}d_{r+1}d_{r+2} + \dots + \lambda_{r+\ell_a+1}d_{r+1}d_{r+2} \dots d_{r+\ell_a} \quad (20)$$

1:8 The Query Complexity of Mastermind with ℓ_p Distances

which in our case we set $\lambda_j = \varphi_j(y_j)$. Now let $\mathcal{X} := \prod_{j=r+1}^{r+\ell_a+1} \varphi_j(\{-k, -k+1, \dots, k-1, k\})$ be the image of our original points in a subset of $\ell_a + 1$ coordinates starting at $r + 1$ under the corresponding φ_j . Consider the function $\psi : \mathcal{X} \rightarrow \mathbb{R}^+$ defined via

$$\psi(\mathbf{z}) = \sum_{i=0}^{\ell_a} z_{i+1} \prod_{j=1}^i d_{r+j}. \quad (21)$$

It is easy to see that when we endow \mathcal{X} with the lexicographical ordering, then ψ is increasing. Thus, given the Fourier coefficient as in equation (20), we can do binary search on the at most k^n values in \mathcal{X} to extract the values λ_{r+i} in time $O(n \log k)$. Given this step of recovering ℓ_a of the coordinates, we can proceed as in the rest of [3] by subtracting these coordinates of the unknown vector and recursing. Hence, we conclude that we may recover $\varphi(\mathbf{y})$ efficiently and thus $\mathbf{h}(\mathbf{y})$, as claimed. \blacktriangleleft

3.2.3 Reconstruction with ℓ_p queries

As a corollary of the above result, we obtain an algorithm for recovering $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ from $s = O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ distance queries in ℓ_p .

► Corollary 10 (Algorithm for ℓ_p queries). *Let $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ be an unknown vector, and suppose that we receive answers to s queries of the form $\|\mathbf{x} - \mathbf{y}\|_p$ for p a constant. Then, there is a polynomial time algorithm that recovers \mathbf{y} in $s = O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right)$ queries.*

Proof. We are in the setting to use Theorem 9, with $g_i(x) = x^p$ for all $i \in [n]$ and $h_{\text{odd}}(x) = \frac{1}{2}((k-x)^p - (k+x)^p)$. Recall that we have efficient algorithms with the desired guarantees when $p \in \{1, 2\}$ so we dismiss these cases. In the remaining range of p , we just need to compute $\prod_{i=1}^n d_i$.

Note that

$$h'_{\text{odd}}(x) = -\frac{p}{2}((k-x)^{p-1} + (k+x)^{p-1}) < 0 \quad (22)$$

on $x \in [-k, k]$ so h_{odd} is decreasing on this interval. Then, $(2k)^p/2 = h_{\text{odd}}(-k) \geq h_{\text{odd}}(x) \geq h_{\text{odd}}(k) = -(2k)^p/2$. Furthermore, note that

$$h''_{\text{odd}}(x) = \frac{p(p-1)}{2}((k-x)^{p-2} - (k+x)^{p-2}). \quad (23)$$

If $p > 2$, then this is negative on $x \geq 0$, so $|h'_{\text{odd}}(x)|$ is smallest at $x = 0$ and thus $|h'_{\text{odd}}(x)| \geq |h'_{\text{odd}}(0)| = pk^{p-1}$ for all x . If $1 < p < 2$, then this is positive on $x \geq 0$, so $|h'_{\text{odd}}(x)|$ is smallest at $x = k$ and thus $|h'_{\text{odd}}(x)| \geq |h'_{\text{odd}}(k)| = (p/2)(2k)^{p-1}$ for all x . In either case, we have that $\Delta = \Omega(pk^{p-1})$ and the range is $M^{\max} - M^{\min} = O(k^p)$ and thus $d_i = O((M^{\max} - M^{\min})/\Delta) = O(k)$. Thus, the query complexity is

$$O\left(\min\left\{n, \frac{\log \prod_{i=1}^n d_i}{\log n}\right\}\right) = O\left(\min\left\{n, \frac{n \log k}{\log n}\right\}\right) \quad (24)$$

as desired. \blacktriangleleft

4 Lower Bounds

In this section, we complement our algorithms with matching lower bounds, for integer p . Our lower bounds work even for the problem of approximating the hidden vector and for adaptive randomized algorithms with constant success probability.

► **Theorem 11** (Lower bound for integer ℓ_p). *Let $1 \leq p < \infty$ be a constant integer and let $R \in (0, kn^{1/p}]$ be an approximation radius. Suppose there exists an algorithm \mathcal{A} such that for all unknown vectors $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$, \mathcal{A} outputs a vector $\mathbf{y}' \in \{-k, -k+1, \dots, k-1, k\}^n$ such that*

$$\|\mathbf{y}' - \mathbf{y}\|_p \leq R \tag{25}$$

in s possibly adaptive ℓ_p queries with probability at least $2/3$ over the algorithm's random coin tosses. Then

$$s = \Omega\left(\frac{n \log(kn^{1/p}/R)}{\log k + \log n}\right). \tag{26}$$

In particular, if $R \leq k^{1-\varepsilon}n^{1/p}$ for some constant $\varepsilon > 0$, then

$$s = \Omega\left(\frac{n \log k}{\log k + \log n}\right), \tag{27}$$

which is $\Omega\left(\frac{n \log k}{\log n}\right)$ if $k < n$ and $\Omega(n)$ if $k \geq n$.

Proof. By Yao's minimax principle [9], it suffices to show the lower bound for all deterministic algorithms \mathcal{A} that correctly approximates a uniformly random $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ with probability at least $2/3$.

Note that each query $\|\mathbf{x} - \mathbf{y}\|_p^p$ results in a nonnegative integer that is at most $(2k)^pn$. Thus, there are at most $((2k)^pn + 1)^s$ possible sequences of answers. Now let Q be the set of all sequence of answers that \mathcal{A} can observe, and for each sequence of answers $\mathbf{q} \in Q$, let $S_{\mathbf{q}}$ denote the set of vectors $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$ such that the deterministic algorithm \mathcal{A} observes \mathbf{q} on input \mathbf{y} . Then, $S_{\mathbf{q}}$ partitions the unknown vectors \mathbf{y} into $|Q|$ disjoint sets. Then, the probability that $|S_{\mathbf{q}}|$ has size at most $\frac{1}{100} \frac{(2k+1)^n}{|Q|}$ is

$$\begin{aligned} \Pr_{\mathbf{y}}\left(|S_{\mathbf{q}}| \leq \frac{1}{100} \frac{(2k+1)^n}{|Q|}\right) &= \sum_{\substack{\mathbf{q} \in Q \\ |S_{\mathbf{q}}| \leq \frac{1}{100} \frac{(2k+1)^n}{|Q|}}} \Pr_{\mathbf{y}}(\mathcal{A} \text{ queries the sequence } \mathbf{q}) \\ &= \sum_{\substack{\mathbf{q} \in Q \\ |S_{\mathbf{q}}| \leq \frac{1}{100} \frac{(2k+1)^n}{|Q|}}} \frac{|S_{\mathbf{q}}|}{(2k+1)^n} \\ &\leq \sum_{\substack{\mathbf{q} \in Q \\ |S_{\mathbf{q}}| \leq \frac{1}{100} \frac{(2k+1)^n}{|Q|}}} \frac{1}{100} \frac{(2k+1)^n}{|Q|} \frac{1}{(2k+1)^n} \\ &\leq \sum_{\mathbf{q} \in Q} \frac{1}{100|Q|} = \frac{1}{100}. \end{aligned} \tag{28}$$

Thus with probability at least $99/100$, $|S_{\mathbf{q}}|$ has size at least $\frac{1}{100} \frac{(2k+1)^n}{|Q|}$.

Note that by [8], the volume of a unit ℓ_p ball is $2^n \Gamma(1 + 1/p)^n / \Gamma(1 + n/p)$, so the volume of a ball of radius R in ℓ_p is

$$V := R^n 2^n \frac{\Gamma(1 + 1/p)^n}{\Gamma(1 + n/p)} = \left(\Theta\left(\frac{R}{n^{1/p}}\right)\right)^n. \tag{29}$$

Now suppose that \mathbf{q} is a sequence of queries such that $|S_{\mathbf{q}}| > 2V$ and let \mathbf{z} be the output of the deterministic algorithm \mathcal{A} on the sequence of queries \mathbf{q} . Then, at most V of the points

1:10 The Query Complexity of Mastermind with ℓ_p Distances

in S can be in the ℓ_p ball of radius R centered at \mathbf{z} . Thus, with probability at least $1/2$ over the random hidden vector \mathbf{y} , we output a point \mathbf{z} such that $\|\mathbf{z} - \mathbf{y}\|_p \geq R$. Thus, if

$$\frac{1}{100} \frac{(2k+1)^n}{|Q|} > 2V, \quad (30)$$

then our probability of success is at most $1/2 + 1/100$ and thus we do not have a correct algorithm. Thus, it must be that

$$\frac{1}{100} \frac{(2k+1)^n}{|Q|} \leq 2V \implies \frac{(2k+1)^n}{200V} \leq |Q| \leq ((2k)^p n + 1)^s. \quad (31)$$

Rearranging, we have that

$$s \geq \frac{\log \frac{(2k+1)^n}{200V}}{\log((2k)^p n + 1)} = \Omega\left(\frac{n \log(kn^{1/p}/R)}{\log k + \log n}\right), \quad (32)$$

as claimed. \blacktriangleleft

For $p = \infty$, we have a lower bound of $\Omega(n)$ regardless of k .

► Theorem 12 (Lower bound for ℓ_∞). *Let $R \in (0, k]$ be an approximation radius. Suppose there exists an algorithm \mathcal{A} such that for all unknown vectors $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$, \mathcal{A} outputs a vector $\mathbf{y}' \in \{-k, -k+1, \dots, k-1, k\}^n$ such that*

$$\|\mathbf{y}' - \mathbf{y}\|_\infty \leq R \quad (33)$$

in s possibly adaptive ℓ_∞ queries with probability at least $2/3$ over the algorithm's random coin tosses. Then

$$s = \Omega\left(\frac{n \log(k/R)}{\log k}\right). \quad (34)$$

In particular, if $R \leq k^{1-\varepsilon}$ for a constant $\varepsilon > 0$, then $s = \Omega(n)$.

Proof. By the same argument as the finite ℓ_p case, we use Yao's minimax principle to reduce the argument to a lower bound for all deterministic algorithms \mathcal{A} on uniformly random inputs \mathbf{y} succeeding with probability at least $2/3$. Furthermore, by the same partition argument as before, we have that $|S_{\mathbf{q}}|$ is at least $\frac{1}{100} \frac{(2k+1)^n}{|Q|}$ with probability at least $99/100$.

The volume of an ℓ_∞ ball of radius R is $(2R)^n$, so as before, we must have

$$\frac{1}{100} \frac{(2k+1)^n}{|Q|} \leq 2(2R)^n. \quad (35)$$

When $p = \infty$, there are only $(2k+1)^s$ possible sequences of answers, so we instead have the bound

$$\frac{(2k+1)^n}{(2R)^n} \leq 200(2k+1)^s \quad (36)$$

By rearranging, we obtain the bound $s = \Omega\left(\frac{n \log(k/R)}{\log k}\right)$ as desired. \blacktriangleleft

4.1 Lower bound for the noisy problem

Finally, we show that in the noisy version of the problem, i.e., the setting where the codemaker is allowed to answer the queries \mathbf{x} with any $q = (1 \pm \varepsilon)\|\mathbf{y} - \mathbf{x}\|_p$, there is no good algorithm.

► **Theorem 13** (Lower bound for the noisy problem). *Let $1 \leq p < \infty$ be a constant and let $0 < R < kn^{1/p}$ be an approximation radius. Suppose there exists an algorithm \mathcal{A} such that for all unknown vectors $\mathbf{y} \in \{-k, -k+1, \dots, k-1, k\}^n$, \mathcal{A} outputs a vector $\mathbf{y}' \in \{-k, -k+1, \dots, k-1, k\}^n$ such that*

$$\|\mathbf{y}' - \mathbf{y}\|_p \leq R \quad (37)$$

in s possibly adaptive $(1 \pm \varepsilon)$ -noisy ℓ_p queries, i.e., answers with adversarially chosen $q_{\mathbf{x}} = (1 \pm \varepsilon)\|\mathbf{y} - \mathbf{x}\|_p$, with probability at least $2/3$ over the algorithm's random coin tosses. Then

$$s = \Omega(\exp(\varepsilon^2 \Theta(k^p n))). \quad (38)$$

Proof. By Yao's minimax principle, we can take the algorithm to be deterministic by taking our hidden vector \mathbf{y} to be drawn uniformly from $\{-k, -k+1, \dots, k-1, k\}^n$. Now fix any query $\mathbf{x} \in \{-k, -k+1, \dots, k-1, k\}^n$ and let $\mu = \mathbf{E}_{\mathbf{z}}(\|\mathbf{x} - \mathbf{z}\|_p^p) = \Theta(k^p n)$. Then by Chernoff bounds,

$$\Pr_{\mathbf{y}}\left(\left|\|\mathbf{x} - \mathbf{y}\|_p^p - \mu\right| \geq \varepsilon \mu\right) \leq 2 \exp(-\varepsilon^2 \mu). \quad (39)$$

Thus, if the number of queries s is less than $\exp(\varepsilon^2 \Theta(k^p n))/200$, then by the union bound over the s queries, with probability at least $99/100$ over the choice of \mathbf{y} , the codemaker can just return $\mathbf{E}_{\mathbf{z}}(\|\mathbf{x} - \mathbf{z}\|_p^p)$ for any query \mathbf{x} . Thus, the deterministic codebreaker algorithm sees the same sequence of answers with probability at least $99/100$ and so the algorithm cannot be correct. Hence, we conclude that $s = \Omega(\exp(\varepsilon^2 \Theta(k^p n)))$. ◀

Abstract

The ℓ_2 tracking problem is the task of obtaining a streaming algorithm that, given access to a stream of items a_1, a_2, a_3, \dots from a universe $[n]$, outputs at each time t an estimate to the ℓ_2 norm of the frequency vector $f^{(t)} \in \mathbb{R}^n$ (where $f_i^{(t)}$ is the number of occurrences of item i in the stream up to time t). The previous work [Braverman-Chestnut-Ivkin-Nelson-Wang-Woodruff, PODS 2017] gave a streaming algorithm with (the optimal) space using $O(\epsilon^{-2} \log(1/\delta))$ words and $O(\epsilon^{-2} \log(1/\delta))$ update time to obtain an ϵ -accurate estimate with probability at least $1 - \delta$. We give the first algorithm that achieves update time of $O(\log 1/\delta)$ which is independent of the accuracy parameter ϵ , together with the nearly optimal space using $O(\epsilon^{-2} \log(1/\delta))$ words. Our algorithm is obtained using the Count Sketch of [Charlkar-Chen-Farach-Colton, ICALP 2002].

1 Introduction

The *streaming model* considers the following setting. One is given a list $a_1, a_2, \dots, a_m \in [n]$ as input where we think of n as extremely large. The algorithm is only allowed to read the input once in a stream and the goal is to answer some predetermined queries using space of size logarithmic in n . For each $i \in [n]$ and time $t \in [m]$, define $f_i^{(t)} = |\{1 \leq j \leq t : a_j = i\}|$ as the frequency of i at time t . Many classical streaming problems are concerned with approximating statistics of $f^{(m)}$ such as the distinct element problem (*i.e.*, $\|f^{(m)}\|_0$). One of

the most well-studied problems is the one-shot ℓ_2 estimation problem where the goal is to estimate $\|f^{(m)}\|_2^2$ within multiplicative error $(1 \pm \epsilon)$ and had been achieved by the seminal AMS sketch by Alon et al. [1].

We consider a streaming algorithm A that maintains some logarithmic space and outputs an estimation σ_t at the t^{th} step of the computation. A achieves ℓ_2 (ϵ, δ) -tracking if for every input stream $a_1, a_2, \dots, a_m \in [n]$

$$\Pr \left[\exists_{t \in [m]} |\sigma_t - \|f^{(t)}\|_2^2| > \epsilon \Delta_t \right] \leq \delta$$

where the “normalization factor” Δ_t differs between *strong* tracking and *weak* tracking. For (ϵ, δ) -*strong tracking*, $\Delta_t = \|f^{(t)}\|_2^2$ is the norm squared of the frequency vector up to the time t , while for (ϵ, δ) -*weak tracking*, $\Delta_t = \|f^{(m)}\|_2^2$ is the norm squared of the overall frequency vector. Note that strong tracking implies weak tracking and weak tracking implies one-shot approximation. In this work, we focus on ℓ_2 tracking via linear sketching, where we specify a distribution D on matrices $\Pi \in \mathbb{R}^{k \times n}$, and maintain a sketch vector at time t as $\tilde{f}^{(t)} \triangleq \Pi f^{(t)}$. Then the estimate σ_t is defined as $\|\tilde{f}^{(t)}\|_2^2$. The space complexity of A is the number of machine words¹ required by A . The update time complexity of A is the time to update σ_t , in terms of number of arithmetic operations.

Both weak tracking and strong tracking have been studied in different context [11, 5, 4] and the focus of this paper is on the *update time complexity*. Specifically, we are interested in the dependency of update time on the approximation factor ϵ . The state-of-the-art result prior to our work is by Braverman et al. [4] showing that AMS provides weak tracking with $O(\epsilon^{-2} \log(1/\delta))$ update time and $O(\epsilon^{-2} \log(1/\delta))$ words of space.

Apart from tracking, there have been several sketching algorithms for one-shot approximation that have faster update time. Dasgupta et al. [8] and Kane and Nelson [16] showed that sparse JL achieves $O_\delta(\epsilon^{-1})^2$ update time for ℓ_2 one-shot approximation. Charikar, Chen, and Farach-Colton [6] designed the CountSketch algorithm for the heavy hitter problem and Thorup and Zhang [23] showed that it achieve $O_\delta(1)$ update time for ℓ_2 one-shot approximation.

Update time

Unlike the space complexity in streaming model, there have been less studies in the update time complexity though it is of great importance in applications. For example, the *packet passing problem* [21] requires the ℓ_2 estimation in the streaming model with input arrival rate as high as 7.75×10^6 packets³ per second. Thorup and Zhang [24] improved the update time from 182 nanoseconds to 50 nanoseconds and made the algorithm more practical.

While some streaming problems have algorithms with constant update time (*e.g.*, distinct elements [19] and ℓ_2 estimation [24]), some other important problems do not (ℓ_p estimation for $p \neq 2$ [17], heavy hitters problems⁴ [6, 7], and tracking problems [4]). Larsen et al. [22] systematically studies the update time complexity and showed lower bounds against heavy hitters, point query, entropy estimation, and moment estimation in the non-adaptive turnstile streaming model. In particular, they show that $O(\epsilon^{-2})$ -space algorithms for ℓ_2 estimation of vectors over \mathbb{R}^n , with failure probability δ , must have update time roughly $\Omega(\log(1/\delta)/\sqrt{\log n})$. Note that their lower bound does not depend on ϵ .

¹ Following convention, we assume the size of a machine word is at least $\Omega(\max(\log n, \log m))$ bits.

² $O_\delta(\cdot)$ is the same as the usual big O notation except treating δ as a constant.

³ Each packet has 40 bytes (320 bits).

⁴ There is a memory and update time tradeoff for heavy hitter from space $O(\epsilon^{-2} \log(n/\delta))$ to $O(\epsilon^{-2}(n/\delta))$ to get constant update time. However, achieving constant update time and logarithmic space simultaneously is unknown.

Space lower bounds

For one-shot estimation of the ℓ_2 norm, Kane et al. [20] showed that $\Theta(\epsilon^{-2} \log m + \log \log n)$ bits of space are required, for any streaming algorithm. This space lower bound is tight due to the AMS sketch. However, this only applies in the constant failure probability regime.

In the regime of sub-constant failure probability δ , known tight lower-bounds on Distributional JL [15, 14] imply that $\Omega(\epsilon^{-2} \log(1/\delta))$ rows are necessary for the special case of linear sketching algorithms.⁵ For linear sketches, this lower bound on number of rows is equivalent to a lower bound on the words of space.

For the regime of faster update time, Kane and Nelson [16] shows that CountSketch-type of constructions (with the optimal $\Omega(\epsilon^{-2} \log(1/\delta))$ rows) require sparsity i.e. number of non-zero elements $\tilde{\Omega}(\epsilon^{-1} \log(1/\delta))$ ⁶ per column to achieve distortion ϵ and failure probability δ . But, this does not preclude a sketch with suboptimal dependency on δ in the number of rows from having constant sparsity, for example a sketch with $\Omega_\delta(\epsilon^{-2})$ rows and constant sparsity – indeed, this is what CountSketch achieves. Note that in our setting, we can boost constant-failure probability to arbitrarily small failure probability by taking medians of estimators.⁷ Thus, we may be able to bypass the lower-bounds for linear sketches.

To summarize the situation: for constant failure probability, it is only known that linear sketches require dimension $\Omega(\epsilon^{-2})$, and it is not known if super-constant sparsity is required for tracking with this optimal dimension. In particular, it was not known how to achieve say $(\epsilon, O(1))$ -weak tracking for ℓ_2 , with $O(\epsilon^{-2})$ words of space and constant update time.

Our contributions

In this paper, we show that there is a streaming algorithm with $O(\log(1/\delta))$ update time and space using $O(\epsilon^{-2} \log(1/\delta))$ words that achieves ℓ_2 (ϵ, δ) -weak tracking.

► **Theorem 1 (informal).** *For any $\epsilon > 0$, $\delta \in (0, 1)$, and $n \in \mathbb{N}$. For any insertion-only stream over $[n]$ with frequencies $f^{(1)}, f^{(2)}, \dots, f^{(m)}$, there exists a streaming algorithm providing ℓ_2 (ϵ, δ) -weak tracking with space using $O(\epsilon^{-2} \log(1/\delta))$ words and $O(\log(1/\delta))$ update time.*

Further, by applying a standard union bound argument in Lemma 13, the same algorithm can achieve ℓ_2 strong tracking as well.

► **Corollary 2.** *For any $\epsilon > 0$, $\delta \in (0, 1)$, and $n \in \mathbb{N}$. For any insertion-only stream over $[n]$ with frequencies $f^{(1)}, f^{(2)}, \dots, f^{(m)}$, there exists a streaming algorithm providing ℓ_2 (ϵ, δ) -strong tracking with $O(\epsilon^{-2} \log(1/\delta) \log \log m)$ words and $O(\log(1/\delta) \log \log m)$ update time.*

The algorithm in the main theorem is obtained by running $O(\log(1/\delta))$ many copies of CountSketch and taking the median.

The main techniques used in the proof are the chaining argument and Hansen-Wright inequality which are also used in [4] to show the tracking properties of AMS. However, direct applications of these tools on the CountSketch algorithm would not give the desired bounds due to the sparse structure of the sketching matrix. To overcome this issue, we have to dig into the structure of sketching matrix of CountSketch. We will compare the difference between our techniques and that in [4] after presenting the proof of Theorem 1 (see Remark 12).

⁵ Note that an (ϵ, δ) -weak tracking via linear sketch defines a distribution over matrices that satisfies the Distributional JL guarantee, with distortion $(1 \pm \epsilon)$ and failure probability δ .

⁶ $\tilde{\Omega}(\cdot)$ is the same as the $\Omega(\cdot)$ notation by ignoring extra logarithmic factor.

⁷ This is not immediate for weak tracking.

The rest of the paper is organized as follows. Some preliminaries are provided in Section 2. In Section 3, we prove our main theorem showing that CountSketch with $O(\epsilon^{-2})$ rows achieves ℓ_2 $(\epsilon, O(1))$ -weak tracking with constant update time. As for the ℓ_2 strong tracking, we discuss some upper and lower bounds in Section 4. In Section 5, we discuss some future directions and open problems.

2 Preliminaries

In the following, $n \in \mathbb{N}$ denotes the size of the universe, k denotes the number of rows of the sketching matrix, t denotes the time, and m denote the final time. We let $[n] = \{1, 2, \dots, n\}$ and use $\tilde{O}(\cdot)$ and $\tilde{\Omega}(\cdot)$ to denote the usual $O(\cdot)$ and $\Omega(\cdot)$ with some extra poly-logarithmic factor.

The input of the streaming algorithm is a list $a_1, a_2, \dots, a_m \in [n]$. For each $i \in [n]$ and time $t \in [m]$, define $f_i^{(t)} = |\{1 \leq j \leq t : a_j = i\}|$ as the frequency of i at time t . The one-shot ℓ_2 approximation problem is to produce an estimate for $\|f^{(m)}\|_2^2$ with $(1 \pm \epsilon)$ multiplicative error and success probability at least $1 - \delta$ for $\epsilon > 0$ and $\delta \in (0, 1)$.

2.1 ℓ_2 tracking

Here, we give the formal definition of ℓ_2 tracking for sketching algorithm.

► **Definition 3** (ℓ_2 tracking). *For any $\epsilon > 0, \delta \in (0, 1)$, and $n, m \in \mathbb{N}$. Let $f^{(1)}, f^{(2)}, \dots, f^{(m)}$ be the frequency of an insertion-only stream over $[n]$ and $\tilde{f}^{(1)}, \tilde{f}^{(2)}, \dots, \tilde{f}^{(m)}$ be its (randomized) approximation produced by a sketching algorithm. We say the algorithm provides ℓ_2 (ϵ, δ) -strong tracking if*

$$\Pr \left[\exists_{t \in [m]}, \left| \|\tilde{f}^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 \right| > \epsilon \|f^{(t)}\|_2^2 \right] \leq \delta.$$

We say the algorithm provides ℓ_2 (ϵ, δ) -weak tracking if

$$\Pr \left[\exists_{t \in [m]}, \left| \|\tilde{f}^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 \right| > \epsilon \|f^{(m)}\|_2^2 \right] \leq \delta.$$

Note that the difference between the two tracking guarantee is that in strong tracking we bound the deviation of the estimate from the true norm squared by $\epsilon \|f^{(t)}\|_2^2$ while in the weak tracking we bound this deviation by $\epsilon \|f^{(m)}\|_2^2$.

2.2 AMS sketch and CountSketch

Alon *et al.* [1] proposed the seminal AMS sketch for ℓ_2 approximation in the streaming model. In AMS sketch, consider $\Pi \in \mathbb{R}^{k \times n}$ where $\Pi_{j,i} = \sigma_{j,i}/\sqrt{k}$ and $\sigma_{j,i}$ is i.i.d. Rademacher for each $j \in [k], i \in [n]$. When $k = O(\epsilon^{-2})$, AMS sketch approximates ℓ_2 norm within $(1 \pm \epsilon)$ multiplicative error. Note that the update time of AMS sketch is k since the matrix Π is dense.

Charikar, Chen, and Farach-Colton [6] proposed the following CountSketch algorithm for the heavy hitter problem and Thorup and Zhang [23] showed that CountSketch is also able to solve the ℓ_2 approximation. Here, consider $\Pi \in \mathbb{R}^{k \times n}$ where we denote the i^{th} column of Π as Π_i for each $i \in [n]$. Π_i is defined as follows. First, pick $j \in [k]$ uniformly and set $\Pi_{j,i}$ to be an independent Rademacher. Next, set the other entries in Π_i to be 0. Note that unlike AMS sketch, the normalization term in CountSketch is 1 since there is exactly one non-zero entry in each column. [6] showed that CountSketch provides one-shot ℓ_2 approximation with $O(\epsilon^{-2})$ rows.

► **Lemma 4** ([6, 23]). *Let $\epsilon > 0$, $\delta \in (0, 1)$, and $n \in \mathbb{N}$. Pick $k = \Omega(\epsilon^{-2}\delta^{-1})$, we have for any $x \in \mathbb{R}^n$,*

$$\Pr_{\Pi} [|\|\Pi x\|_2^2 - \|x\|_2^2| > \epsilon \|x\|_2^2] \leq \delta.$$

Implement CountSketch in logarithmic space

Previously, we defined CountSketch using uniformly independent randomness, which requires space $\Omega(nk)$. However, one could see that in the proof of Theorem 8 we actually only need 8-wise independence. Thus, the space required can be reduced to $O(\log n)$ for each row. It is well known that CountSketch with k rows can be implemented with 8-wise independent hash family using $O(k)$ words. We describe the whole implementation in Appendix A for completeness.

2.3 ϵ -net for insertion-only stream

In our analysis, we will use the following existence of a small ϵ -net for insertion-only streams.

► **Definition 5** (ϵ -net). *Let $S \subseteq \mathbb{R}^n$ be a set of vectors. For any $\epsilon > 0$, we say $E \subseteq \mathbb{R}^n$ is an ϵ -net for S with respect to ℓ_2 norm if for any $x \in S$, there exists $y \in E$ such that $\|x - y\|_2 \leq \epsilon$.*

► **Lemma 6** ([5]). *Let $\{x^{(t)}\}_{t \in [m]}$ be an insertion-only stream. For any $\epsilon > 0$, there exists a size $(1 + \epsilon^{-2} \cdot \|x^{(m)}\|_2)$ ϵ -net for $\{x^{(t)}\}_{t \in [m]}$ with respect to ℓ_2 norm. Moreover, the elements in the net are all from $\{x^{(t)}\}_{t \in [m]}$.*

Proof Sketch. The idea is to use a greedy algorithm, by scanning through the stream from the beginning and adding an element $x^{(t)}$ into the net if there does not already exist an element in the net that is ϵ -close to $x^{(t)}$. ◀

2.4 Concentration inequalities

Our analysis crucially relies on the following Hanson-Wright inequality [10].

► **Lemma 7** (Hanson-Wright inequality [10]). *For any symmetric $B \in \mathbb{R}^{n \times n}$, $\sigma \in \{\pm 1\}^n$ being independent Rademacher vector, and integer $p \geq 1$, we have*

$$\|\sigma^\top B \sigma - \mathbb{E}_\sigma[\sigma^\top B \sigma]\|_p \leq O(\sqrt{p}\|B\|_F + p\|B\|) = O(p\|B\|_F),$$

where $\|X\|_p$ is defined as $\mathbb{E}[|X|^p]^{1/p}$ and $\|\cdot\|_F$ is the Frobenius norm.

Note that the only randomness in $\sigma^\top B \sigma - \mathbb{E}_\sigma[\sigma^\top B \sigma]$ is the Rademacher vector σ .

3 CountSketch with $O(\epsilon^{-2})$ rows provides ℓ_2 weak tracking

In this section we will show that CountSketch with $O(\epsilon^{-2})$ rows provides $(\epsilon, O(1))$ -weak tracking.

► **Theorem 8** (CountSketch with $O(\epsilon^{-2})$ rows provides ℓ_2 weak tracking). *For any $\epsilon > 0$, $\delta \in (0, 1)$, and $n \in \mathbb{N}$. Pick $k = \Omega(\epsilon^{-2}\delta^{-1})$. For any insertion-only stream over $[n]$ with frequency $f^{(1)}, f^{(2)}, \dots, f^{(m)}$, the CountSketch algorithm with k rows provides ℓ_2 (ϵ, δ) -weak tracking.*

2:6 Tracking the ℓ_2 Norm with Constant Update Time

► **Remark.** Note that for linear sketches, the dependency of number of rows on ϵ is tight in Theorem 8. This is implied by known lower-bounds on Distributional JL [15, 14], which imply lower-bounds on one-shot ℓ_2 approximation.

► **Remark.** Recall that the number of rows in linear sketches is proportional to the number of words needed in the algorithm.

Using the standard median trick, we can run $O(\log(1/\delta))$ copies of `CountSketch` with $k = O(\epsilon^{-2})$ in parallel and output the median. With this, Theorem 8 immediately gives the following corollary with better dependency on δ .

► **Corollary 9.** *For any $\epsilon > 0$, $\delta \in (0, 1)$, and $n \in \mathbb{N}$. For any insertion-only stream over $[n]$ with frequency $f^{(1)}, f^{(2)}, \dots, f^{(m)}$, there exists a streaming algorithm providing ℓ_2 (ϵ, δ) -weak tracking with $k = O(\epsilon^{-2} \log(1/\delta))$ rows and update time $O(\log(1/\delta))$.*

The proof of Theorem 8 uses the Dudley-like chaining technique similar to other tracking proofs [4]. However, direct application of the chaining argument would not suffice and we have to utilize the structure of the sketching matrix of `CountSketch` (see Remark 12 for comparison). We will prove Theorem 8 in Subsection 3.1.

3.1 Proof of Theorem 8

In this subsection, we give a formal proof for our main theorem. Let us start with some notations for `CountSketch`. Recall that for any $i \in [n]$, the i^{th} column of Π is defined by (i) picking $j \in [k]$ uniformly and set $\Pi_{j,i}$ to be a Rademacher random variable and (ii) set the other entries in Π_i to be 0. Denote $\Pi_{j,i} = \sigma_{j,i} \eta_{j,i}$, where $\sigma_{j,i}$ is a Rademacher random variable, and $\eta_{j,i}$ is the indicator for choosing the j^{th} row in the i^{th} column. Note that there is exactly one non-zero entry in each column and the probability distribution is uniform. The approximation error of Π for a vector $\mathbf{x} \in \mathbb{R}^n$ is denoted as $\gamma(\mathbf{x}) := \left| \|\Pi \mathbf{x}\|_2^2 - \|\mathbf{x}\|_2^2 \right|$. To show weak tracking, it suffices to upper bound the supremum of $\gamma(f^{(t)})$.

$$\mathbb{E}_\Pi \sup_{t \in [m]} \gamma(f^{(t)}) = \mathbb{E}_\Pi \sup_{t \in [m]} \left| \|\Pi f^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 \right|. \quad (1)$$

The first observation⁸ is that one can rewrite the error $\gamma(\mathbf{x})$ as follows.

$$\gamma(\mathbf{x}) = |\mathbf{x}^\top \Pi^\top \Pi \mathbf{x} - \mathbf{x}^\top \mathbf{x}| = |\sigma^\top B_{\eta, \mathbf{x}} \sigma - \mathbf{x}^\top \mathbf{x}| = |\sigma^\top \tilde{B}_{\eta, \mathbf{x}} \sigma|,$$

where $\sigma \in \{-1, 1\}^n$ is an independent Rademacher random vector and for any $i, i' \in [n]$,

$$(\tilde{B}_{\eta, \mathbf{x}})_{i, i'} = \begin{cases} \mathbf{x}_i \mathbf{x}_{i'}, & i \neq i' \text{ and } \exists j \in [k], \eta_{j,i} = \eta_{j,i'} = 1 \\ 0, & \text{else.} \end{cases}$$

Note that the diagonals of $\tilde{B}_{\eta, \mathbf{x}}$ are all zero as follow.

$$\tilde{B}_{\eta, \mathbf{x}} = \begin{pmatrix} 0 & \mathbf{x}_1 \mathbf{x}_2 \langle \Pi_1, \Pi_2 \rangle & \cdots & \mathbf{x}_1 \mathbf{x}_n \langle \Pi_1, \Pi_n \rangle \\ \mathbf{x}_2 \mathbf{x}_1 \langle \Pi_2, \Pi_1 \rangle & 0 & \cdots & \mathbf{x}_2 \mathbf{x}_n \langle \Pi_2, \Pi_n \rangle \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{x}_n \mathbf{x}_1 \langle \Pi_n, \Pi_1 \rangle & \mathbf{x}_n \mathbf{x}_2 \langle \Pi_n, \Pi_2 \rangle & \cdots & 0 \end{pmatrix}.$$

⁸ Note that the matrix $\tilde{B}_{\mathbf{x}}$ we are using is different from the matrix used in the previous analysis of [4]. This difference is crucial since the matrix of [4] does not work for `CountSketch`.

For convenience, for any matrix $B \in \mathbb{R}^{n \times n}$, we overload the notation γ by denoting $\gamma(B) = \sigma^\top B \sigma$. That is, $\gamma(\tilde{B}_{\eta, \mathbf{x}}) = \gamma(\mathbf{x})$. One benefit of writing ℓ_2 weak tracking error into the above quadratic form is that Hanson-Wright inequality (see Lemma 7) is now applicable.

The lemma below shows that the expectation of the weak tracking error is upper bounded by the Frobenius norm of $\tilde{B}_{\eta, f^{(m)}}$.

► **Lemma 10.** *Let $\{f^{(t)}\}_{t \in [m]}$ be the frequencies of an insertion-only stream. We have*

$$\mathbb{E} \left[\sup_{t \in [m]} \gamma(f^{(t)}) \mid \eta \right] = O(\|\tilde{B}_{\eta, f^{(m)}}\|_F).$$

The proof of Lemma 10 uses the Dudley-like chaining argument. For the smooth of presentation, we postpone the details to Subsection 3.2. Next, the following lemma shows that for any vector $x \in \mathbb{R}^n$, with high probability, $\|\tilde{B}_{\eta, x}\|_F = O(\|x\|_2^2/\sqrt{k})$.

► **Lemma 11.** *For any $\delta \in (0, 1)$ and $x \in \mathbb{R}^n$,*

$$\Pr \left[\|\tilde{B}_{\eta, x}\|_F > \frac{\sqrt{2}\|x\|_2^2}{\sqrt{\delta \cdot k}} \right] \leq \frac{\delta}{2}.$$

Lemma 11 has similar flavor as Lemma 4. The proof can be found in Subsection 3.2. Finally, Theorem 8 is an immediate corollary of Lemma 10 and Lemma 11. Here we provide a proof for completeness.

Proof of Theorem 8. Recall that to prove Theorem 8, it suffices to show that with probability at least $1 - \delta$ over η , $\sup_{t \in [m]} \gamma(f^{(t)}) \leq \epsilon$. From Lemma 10, for a fixed η , we have $\Pr \left[\sup_{t \in [m]} \gamma(f^{(t)}) > C_1 \|\tilde{B}_{\eta, f^{(m)}}\|_F \right] \leq \delta/2$ for some constant $C_1 > 0$. Next, from Lemma 11, we have $\|\tilde{B}_{\eta, f^{(m)}}\|_F \leq \|f^{(m)}\|_2^2 \cdot k^{-1/2} \cdot \delta^{-1/2}$ with probability at least $1 - \delta/2$ over the randomness in η for some constant $C_2 > 0$. Pick $m \geq C_1 C_2 \cdot \epsilon^{-2} \cdot \delta^{-1}$, we have $\Pr \left[\sup_{t \in [m]} \gamma(f^{(t)}) > \epsilon \|f^{(m)}\|_2^2 \right] \leq \delta$ and complete the proof. ◀

3.2 Proof of the two key lemmas

In this subsection, we provide the proofs for Lemma 10 and Lemma 11. Let us start with Lemma 10 which shows that the tracking error can be upper bounded by the Frobenius norm of $\tilde{B}_{\eta, f^{(m)}}$.

Proof of Lemma 10. Recall that we define $\tilde{B}_{\eta, x}$ such that $\gamma(x) = \sigma^\top \tilde{B}_{\eta, x} \sigma$ where σ is 8-wise independent Rademacher random vector. An important trick here is that we think of *fixing*⁹ η in the following.

The starting point of chaining argument is constructing a sequence of ϵ -nets with exponentially decreasing error for $\{\tilde{B}_{\eta, f^{(t)}}\}_{t \in [m]}$. Note that here $\{\tilde{B}_{\eta, f^{(t)}}\}_{t \in [m]}$ are matrices but one can view it as a vector and apply Lemma 6 where ℓ_2 norm for a vector becomes Frobenius norm for a matrix. Namely, for any non-negative integer ℓ , let $T_{\eta, \ell}$ be the $(\|\tilde{B}_{\eta, f^{(m)}}\|_F/2^\ell)$ -net for $\{\tilde{B}_{\eta, f^{(t)}}\}_{t \in [m]}$ under Frobenius norm where $|T_{\eta, \ell}| \leq 1 + 2^{2\ell}$. Note that here we fixed η first and then constructed the nets. Thus, for each $t \in [m]$, one can rewrite $\tilde{B}_{\eta, f^{(t)}}$ into a *chain* as follows.

$$\tilde{B}_{\eta, f^{(t)}} = B_{\eta, 0}^{(t)} + \sum_{\ell=1}^{\infty} B_{\eta, \ell}^{(t)} - B_{\eta, \ell-1}^{(t)}, \quad (2)$$

⁹ We do this by conditioning on η .

2:8 Tracking the ℓ_2 Norm with Constant Update Time

where $B_{\eta,\ell}^{(t)} \in T_{\eta,\ell}$ and $\|\tilde{B}_{\eta,f^{(t)}} - B_{\eta,\ell}^{(t)}\|_F \leq 2^{-\ell} \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F$. Moreover, from Equation 2 we have

$$\mathbb{E} \sup_{t \in [m]} \gamma(f^{(t)}) \leq \mathbb{E} \sup_{t \in [m]} \gamma(B_{\eta,0}^{(t)}) + \sum_{\ell=1}^{\infty} \mathbb{E} \sup_{t \in [m]} \gamma(B_{\eta,\ell}^{(t)} - B_{\eta,\ell-1}^{(t)}). \quad (3)$$

To bound the first term of Equation 3, observe that $T_{\eta,0} = \{\tilde{B}_{\eta,f^{(1)}}\}$ where $\tilde{B}_{\eta,f^{(1)}}$ is the all zero matrix. Namely, the first term of Equation 3 is zero. As for the second term of Equation 3, we apply the chaining argument as follows. For any positive integer ℓ , denote $\mathcal{A}_\ell = \{B_{\eta,\ell}^{(t)} - B_{\eta,\ell-1}^{(t)}\}_{t \in [m]}$. Note that from the construction of ϵ -net in Lemma 6, we have $|\mathcal{A}_\ell| \leq 2|T_{\eta,\ell}| \leq 2^{2\ell+2}$ by triangle inequality.

$$\begin{aligned} \mathbb{E} \left[\sup_{t \in [m]} \gamma(B_{\eta,\ell}^{(t)} - B_{\eta,\ell-1}^{(t)}) \right] &= \int_0^\infty \Pr \left[\sup_{A \in \mathcal{A}_\ell} \gamma(A) > u \right] du \\ &\leq u_\ell^* + \int_{u_\ell^*}^\infty \Pr \left[\sup_{A \in \mathcal{A}_\ell} \gamma(A) > u \right] du, \end{aligned} \quad (4)$$

where $u_\ell^* > 0$ will be chosen later. For any $A \in \mathcal{A}_\ell$ and integer $p \geq 2$, by Markov's inequality and Hanson-Wright inequality, we have

$$\Pr[\gamma(A) > u] \leq \frac{\mathbb{E}[\gamma(A)^p]}{u^p} = \frac{\|\sigma^\top A \sigma\|_p^p}{u^p} \leq \frac{(C \cdot \sqrt{p} \|A\|_F + C \cdot p \|A\|)^p}{u^p}$$

for some constant $C > 0$. Note that the randomness here is only in σ and thus we can apply the Hanson-Wright inequality. Let $R_\ell = \sup_{A \in \mathcal{A}_\ell} (C \cdot \sqrt{p} \|A\|_F + C \cdot p \|A\|) \leq C' p \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F \cdot 2^{-\ell}$ for some $C' > 0$. The last inequality holds because of $\|\cdot\| \leq \|\cdot\|_F$ and the choice of ϵ -net. Now, choose $u_\ell^* = 2S_\ell \cdot R_\ell$ where S_ℓ will be decided later, Equation 4 becomes

$$\begin{aligned} \mathbb{E} \left[\sup_{t \in [m]} \gamma(B_{\eta,\ell}^{(t)} - B_{\eta,\ell-1}^{(t)}) \right] &\leq u_\ell^* + \int_{u_\ell^*}^\infty |\mathcal{A}_\ell| \cdot \frac{R_\ell^p}{u^p} du \\ &\leq 2S_\ell R_\ell + |\mathcal{A}_\ell| \cdot \frac{R_\ell^p}{(2S_\ell R_\ell)^{p-1}} \\ &\leq 2S_\ell C' p \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F \cdot 2^{-\ell} + |\mathcal{A}_\ell| \cdot \frac{C' p \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F}{S_\ell^{p-1}} \cdot 2^{-\ell} \end{aligned} \quad (5)$$

where the second term of Equation 5 is due to union bound. Now, Equation 3 becomes

$$\begin{aligned} \mathbb{E} \sup_{t \in [m]} \gamma(f^{(t)}) &\leq \sum_{\ell=1}^{\infty} 2S_\ell C' p \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F \cdot 2^{-\ell} + |\mathcal{A}_\ell| \cdot \frac{C' p \cdot \|\tilde{B}_{\eta,f^{(m)}}\|_F}{S_\ell^{p-1}} \cdot 2^{-\ell} \\ &\leq \|\tilde{B}_{\eta,f^{(m)}}\|_F \cdot \left(\sum_{\ell=1}^{\infty} 2C' p S_\ell \cdot 2^{-\ell} + \frac{2^\ell C' p}{S_\ell^{p-1}} \right). \end{aligned} \quad (6)$$

Choose $S_\ell = 2^{3\ell/4}$ and $p \geq 4$, the summation term in Equation 6 can thus be upper bounded by a constant. We conclude that

$$\mathbb{E} \sup_{t \in [m]} \gamma(f^{(t)}) = O(\|\tilde{B}_{\eta,f^{(m)}}\|_F).$$

Note that this also means that 8-wise independence suffices and thus the sketching matrix can be efficiently stored (see Appendix A for more details). \blacktriangleleft

Next, we prove Lemma 11 which upper bounds the expectation of $\|\tilde{B}_{\eta,\mathbf{x}}\|$ for any $\mathbf{x} \in \mathbb{R}^n$.

Proof of Lemma 11. We first show that $\mathbb{E}_\eta \|\tilde{B}_{\eta,\mathbf{x}}\|_F^2 \leq \frac{\|\mathbf{x}\|_2^4}{k}$ and the lemma immediately holds due to Markov's inequality.

Let $\mathbf{1}_{ii'}$ be the indicator for whether there exists $j \in [k]$ such that $\eta_{ij} = \eta_{i'j} = 1$. Note that for $i \neq i'$, $\mathbb{E}[\mathbf{1}_{ii'}] = 1/k$ and the only randomness here is in η .

$$\begin{aligned} \mathbb{E}\|\tilde{B}_{\eta,\mathbf{x}}\|_F^2 &= \mathbb{E} \sum_{i,i' \in [n]} (\tilde{B}_{\eta,\mathbf{x}})_{i,i'}^2 = \mathbb{E} \sum_{(i,i') \in [n]^2, i \neq i'} x_i^2 x_{i'}^2 \mathbf{1}_{ii'} \\ &= \frac{1}{k} \sum_{(i,i') \in [n]^2, i \neq i'} x_i^2 x_{i'}^2 \leq \frac{\|\mathbf{x}\|_2^4}{k}, \end{aligned}$$

where the last inequality is by Cauchy-Schwarz. Note that 8-wise independence is sufficient in the above argument. \blacktriangleleft

► **Remark 12.** Here, let us briefly compare the difference between our techniques and that in [4]. There are two key observations on the structure of the sketching matrix of **CountSketch**. First, we observe that the Frobenius norm of $\Pi^\top \Pi$ is dominated by its diagonal and thus *removing* the diagonal would give us a more accurate analysis on the contribution from the off-diagonal term. However, removing the diagonal of $\Pi^\top \Pi$ destroys the symmetric structure and thus the standard ϵ -net argument (e.g., in [4]) would not work. To overcome this, we observe that one can directly construct ϵ -net for the matrix obtained by removing the diagonal from $\Pi^\top \Pi$. Combining these two observations and standard chaining argument, we are able to show that **CountSketch** provides ℓ_2 weak tracking.

4 Strong tracking of AMS sketch and CountSketch

In this section, we are going to discuss the strong tracking of AMS sketch and **CountSketch**. We start with a standard reduction from weak tracking to strong tracking via union bound. This gives us an $O(\log m)$ blow-up in the dependency on δ . Next, we show that this is essentially tight for both AMS sketch and **CountSketch** up to a logarithmic factor.

► **Lemma 13** (folklore). *For any $\epsilon > 0$, $\delta \in (0, 1)$, and $n, m \in \mathbb{N}$. If a linear sketch provides (ϵ, δ) weak tracking for length m inputs having value from $[n]$, then it also provides $(2\epsilon, \delta')$ strong tracking where $\delta' = \min\{1, (\log m) \cdot \delta\}$.*

Proof. See Subsection B.1 for details. \blacktriangleleft

From Lemma 13, we immediately have the following corollaries.

► **Corollary 14.** *For any $\epsilon > 0$ and $\delta \in (0, 1)$, AMS sketch with $O(\epsilon^{-2}(\log \log m + \log(1/\delta)))$ rows provides $\ell_2(\epsilon, \delta)$ -strong tracking.*

► **Corollary 15.** *For any $\epsilon > 0$ and $\delta \in (0, 1)$, CountSketch with $O(\epsilon^{-2}\delta^{-1} \log m)$ rows provides $\ell_2(\epsilon, \delta)$ -strong tracking.*

► **Remark.** After applying median trick on **CountSketch**, the dependency of the number of rows on δ becomes $O(\log(1/\delta))$ and thus $O(\epsilon^{-2}(\log \log m + \log(1/\delta)))$ rows suffices to achieve $\ell_2(\epsilon, \delta)$ -strong tracking.

In the following, we are going to show that the above two upper bounds are essentially tight for these two algorithms.

► **Theorem 16.** *There exists constants $C > 0$ such that for any $\epsilon \in (0, 0.1)$ and $\delta \in (0, 1)$, there exists $N_0 \in \mathbb{N}$ such that if $k < C \cdot \left(\log \frac{\log m}{\log(1/\epsilon)} + \log(1/\delta)\right)$ and $N_0 \leq n \leq m$, then fully independent AMS sketch with k rows does not provide ℓ_2 (ϵ, δ) -strong tracking.*

That is, AMS sketch requires $\tilde{\Omega}(\epsilon^{-2}(\log \log m + \log(1/\delta)))$ rows to achieve ℓ_2 (ϵ, δ) -strong tracking. Interestingly, the hard instance for AMS sketch to achieve strong tracking is simply the stream consisting all distinct elements. See Subsection B.2 for details.

► **Theorem 17.** *There exists a constant $C > 0$ such that for any $\epsilon \in (0, 0.5)$, and $\delta \in (0, 1)$, there exists $N_0 \in \mathbb{N}$ such that if $k \leq C \cdot \epsilon^{-2} \delta^{-1} \frac{\log m}{\log(1/\epsilon)}$ and $N_0 \leq n \leq O(\log m)$, then CountSketch with k rows does not provide ℓ_2 (ϵ, δ) -strong tracking.*

That is, CountSketch requires $\tilde{\Omega}(\epsilon^{-2} \delta^{-1} \log m)$ rows to achieve ℓ_2 (ϵ, δ) -strong tracking. The hard instance for CountSketch is more complicated than that of AMS sketch. See Subsection B.3 for details.

5 Conclusion

In this work, we showed that CountSketch provides ℓ_2 weak tracking with update time having no dependence on the error parameter ϵ . We also give almost tight ℓ_2 strong tracking lower bounds for AMS sketch and CountSketch.

An immediate open problem after this work would be tracking ℓ_p with faster update time for $0 < p < 2$. The ℓ_p estimation problem had been solved by Indyk [12] via p -stable sketch and was proven to provide weak tracking by Błasiok et al. [3]. However, same as AMS sketch, the p -stable sketch is dense and has update time $\Omega(\epsilon^{-2})$. Nevertheless, Kane et al. [18] gave a space-optimal algorithm for ℓ_p estimation problem with update time $O(\log^2(1/\epsilon) \log \log(1/\epsilon))$. It would be interesting to see if their algorithm also provides ℓ_p weak tracking.

A Implementation of CountSketch

Here, we present the implementation of CountSketch for the completeness. Note that the construction is standard and not new.

Algorithm 1 Constructing CountSketch.

-
- 1: $k \leftarrow \lceil \frac{c}{\epsilon^2} \rceil$ for some constant $c > 0$.
 - 2: $\tilde{f} \in \mathbb{Z}^k$ vector with initial value 0.
 - 3: Sample $h : [n] \rightarrow [k]$ from a 8-wise independent hash family.
 - 4: Sample $g : [n] \rightarrow \{\pm 1\}$ from a 8-wise independent hash family.
 - 5: **for** $t = 1, 2, \dots, m$ **do**
 - 6: On input $a_t = i$, set $\tilde{f}_{h(i)} = \tilde{f}_{h(i)} + g(i)$.
-

Note that both h and g can be stored in space $O(\log n + \log(1/\epsilon))$ and be evaluated in $O(1)$ many arithmetic operations. \tilde{f} can be stored in space $O(\epsilon^{-2} \log m)$ bits. For the convenience of analysis, we define the sketching matrix $\Pi \in \{0, \pm 1\}^{k \times n}$ of CountSketch by $\Pi_{h(i), i} = g(i)$ for all $i \in [n]$.

B Proofs for strong tracking

B.1 From weak tracking to strong tracking

After applying union bound on all points $t = 1, 2, \dots, m$, a streaming algorithm provides ℓ_2 (ϵ, δ) -approximation also provides ℓ_2 (ϵ, δ') -strong tracking where $\delta' = \min\{1, m\delta\}$. However, the blow-up in δ is m , which is undesirable. The following lemma shows that with a more delicate union bound argument, the reduction from weak tracking to strong tracking only has $O(\log m)$ blow-up in δ . Note that the lemma is a folklore and we provide a proof for completeness.

Proof. Let $\{f^{(t)}\}_{t \in [m]}$ be the frequency of an insertion-only stream and let $\{\tilde{f}^{(t)}\}_{t \in [m]}$ be its (randomized) approximations produced by the linear sketch. Let $w = \lfloor \log m \rfloor + 1$ and $t_i = 2^i - 1$ for each $i \in [w]$. Note that for each $i \in [w]$ and $t_{i-1} < t \leq t_i$, $\frac{1}{2} \|f^{(t_i)}\|_2^2 \leq \|f^{(t)}\|_2^2 \leq \|f^{(t_i)}\|_2^2$. Define the event

$$E_i := \left\{ \left| \|\tilde{f}^{(t_i)}\|_2^2 - \|f^{(t_i)}\|_2^2 \right| > \epsilon \|f^{(t_i)}\|_2^2 \right\}.$$

Observe that for each $t_{i-1} < t \leq t_i$, $\left| \|\tilde{f}^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 \right| > 2\epsilon \cdot \|f^{(t)}\|_2^2$ would imply $\neg E_i$. Namely, $\neg \cup_{i \in [w]} E_i$ implies strong tracking.

By the ℓ_2 (ϵ, δ) -weak tracking property of the streaming algorithm, for each $i \in [w]$, we have $\Pr[E_i] \leq \delta$ and thus $\Pr[\cup_{i \in [w]} E_i] \leq w\delta$. We conclude that the streaming algorithm provides ℓ_2 $(2\epsilon, w\delta)$ -strong tracking. \blacktriangleleft

B.2 Strong tracking lower bound for AMS sketch

The hard instance is simply the stream of all distinct elements, *i.e.*, $i_t = t$ for all $t \in [m]$.

Proof of Theorem 16. Consider the stream of all distinct elements as the hard instance, *i.e.*, $i_t = t$ for all $t \in [m]$. Thus, $\|f^{(t)}\|_2^2 = t$ and $\|\Pi f^{(t)}\|_2^2 = \sum_{i \in [k]} \left(\sum_{j \in [t]} \Pi_{i,j} \right)^2$ for all $t \in [m]$.

Define a sequence of time $\{t_j\}$ as follows. $t_0 = 0$ and $t_j = \sum_{i \in [j]} \Delta_i$ where $\Delta_i = \lceil 10/\epsilon \rceil^i$. Pick ℓ and m properly such that $t_\ell \leq m$. Some quick facts about the choice of parameters here: (i) $|t_j - \Delta_j| \leq \frac{\epsilon}{5} \cdot t_j$. (ii) $\ell = \Theta\left(\frac{\log m}{\log(1/\epsilon)}\right)$.

To show AMS sketch does not provide (ϵ, δ) -strong tracking for $\epsilon \in (0, 0.1)$ and $\delta \in (0, 1)$, it suffices to show that with probability at least δ there exists $j \in [\ell]$ such that $\|\Pi f^{(t_j)}\|_2^2 - t_j > (1 + \epsilon) \cdot t_j$.

For the convenience of the analysis, for any $i \in [k]$ and $j \in [\ell]$, let $X_i^{(t_j)} = \sum_{s=t_{j-1}+1}^{t_j} \Pi_{i,s}$ which is the sum of Δ_j independent Rademacher random variables divided by \sqrt{k} . Also let $Z_j = \sum_{i \in [k]} (X_i^{(t_j)})^2$. Note that $\mathbb{E}[Z_j] = \Delta_j / \sqrt{k}$ and

$$\begin{aligned} \|\Pi f^{(t_j)}\|_2^2 &= \sum_{i \in [k]} \left(\sum_{j' \in [j]} X_i^{(t_{j'})} \right)^2 \\ &= Z_j + \sum_{i \in [k]} \left(\sum_{j' \in [j-1]} X_i^{(t_{j'})} \right)^2 + 2 \sum_{i \in [k]} \langle X_i^{(t_j)}, \sum_{j' \in [j-1]} X_i^{(t_{j'})} \rangle. \end{aligned} \quad (7)$$

Define an event $E_j := \{Z_j \geq (1 + 2\epsilon) \cdot \mathbb{E}[Z_j]\}$ for each $j \in [\ell]$. Observe that when conditioning on $\cap_{j' \in [j-1]} \neg E_{j'}$, the second term of Equation 7 is bounded by $O(t_{j-1})$ and the third term is bounded by $O(\sqrt{t_{j-1} Z_j})$ due to Cauchy-Schwarz. By the choice of parameters, both term can be bounded by $0.1 t_j$. Furthermore, E_j implies $\|\Pi f^{(t_j)}\|_2^2 - t_j > (1 + \epsilon) \cdot t_j$. Note that E_j is independent to E_1, \dots, E_{j-1} . The following lemma lower bound the probability of E_j to happen.

► **Lemma 18.** *There exists a constant $c > 0$ such that $\Pr[E_j] \geq e^{-c\epsilon^2 k}$ for any $j = \Omega(\log \log k)$.*

Proof of Lemma 18. From the seminal *Berry-Esseen theorem* [2, 9], we know that when $t_j = e^{\Omega(k)} = \Omega\left(\frac{\log m}{\delta}\right)$ then $X^{(t_j)}$ is point-wisely $e^{-\Omega(k)}$ -close to a normal distribution with zero mean and variance Δ_j . That is, $\frac{k Z_j}{\Delta_j}$ is also point-wisely $e^{-\Omega(k)}$ -close to a *chi-square* distribution $\chi_{\Delta_j}^2$ with mean Δ_j and Δ_j degree of freedom¹⁰.

Inglot and Ledwina [13] showed that the tail of chi-square random distribution can be lower bounded as $\Pr[\chi_k^2 \geq (1 + 2\epsilon) \cdot k] \geq \frac{1}{2} e^{-\epsilon^2 k/10}$ when k large enough. Combine with the Berry-Esseen theorem, we have $\Pr[E_j] \geq e^{-c\epsilon^2 k}$ for some constant $c > 0$. ◀

Note that as $\{Z_j\}_{j \in [\ell]}$ are mutually independent, the events $\{E_j\}_{j \in [\ell]}$ are also mutually independent. That is,

$$\begin{aligned} \Pr \left[\exists t \in [m], \left| \|\Pi f^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 \right| > 2\epsilon \|f^{(t)}\|_2^2 \right] &\geq \Pr \left[\cup_{j \in [\ell]} E_j \right] \\ &\geq 1 - \prod_{j \in [\ell]} \Pr[\neg E_j \mid \neg E_{j'}, \forall j' \in [j-1]] \\ &\geq 1 - \left(1 - e^{-c\epsilon^2 k} \right)^\ell \geq \ell e^{-c\epsilon^2 k}. \end{aligned}$$

Namely, there exists another constant $C > 0$ such that if $k < C\epsilon^{-2} \left(\log \frac{\log m}{\log(1/\epsilon)} + \log(1/\delta) \right) \leq \frac{1}{\epsilon} \epsilon^{-2} \log \frac{\ell}{\delta}$. Thus, AMS sketch does not provide (ϵ, δ) -strong tracking for all $\epsilon \in (0, 0.1)$.

¹⁰ Recall that a *chi-square random variable* of d degree of freedom is equivalent to the sum of d squares of the standard normal random variable.

B.3 Strong tracking lower bound for CountSketch

To prove Theorem 17, we are going to construct a stream such that any CountSketch does not provide strong tracking. Let's start from some observation. For any $i \neq i' \in [n]$ and $a > 0$, let $\mathbf{x} = a(\mathbf{e}_i + \mathbf{e}_{i'})$ such that $\|\mathbf{x}\|_2^2 = 2a^2$. Now, observe that if $\Pi_i = \Pi_{i'}$, then we have $\|\Pi\mathbf{x}\|_2^2 = 4a^2$. If $\Pi_i = -\Pi_{i'}$, then we have $\|\Pi\mathbf{x}\|_2^2 = 0$. Note that in both cases, the approximation $\|\Pi\mathbf{x}\|_2^2$ and the correct answer $\|\mathbf{x}\|_2^2$ has a huge gap $2a^2$, *i.e.*, $|\|\Pi\mathbf{x}\|_2^2 - \|\mathbf{x}\|_2^2| \geq \|\mathbf{x}\|_2^2$.

With the above observation, one can see that a collision (either $\Pi_i = \Pi_{i'}$ or $\Pi_i = -\Pi_{i'}$) is a sufficient condition for an estimation error. As a result, to show CountSketch does not provide strong tracking, it suffices to show the following two things: (i) there will be some collision with constant probability and (ii) construct a stream such that once a collision happens, the estimation error is large.

Note that (ii) is very specific to tracking since unlike ℓ_2 estimation which only cares about the final estimation, we need to keep track of the estimation at any time. Thus, to show the impossibility of tracking, we have to show that the estimation fails at least once at some point.

Proof of Theorem 17. Let n be the number of elements and k be the number of rows of CountSketch. Let $\Delta = \lceil 100/\epsilon \rceil$ and $w = \lceil 1/\epsilon \rceil$. For any $j \in [\ell]$, define $t_j = \sum_{j' \in [j]} \Delta^{j'+1} = \frac{\Delta^{j+1} - \Delta^1}{\Delta - 1}$ and the stream at time t_j as follows.

$$f^{(t_j)} = \left(\underbrace{\Delta, \dots, \Delta}_w, \underbrace{\Delta^2, \dots, \Delta^2}_w, \underbrace{\Delta^j, \dots, \Delta^j}_w, 0, \dots, 0 \right).$$

We have $\|f^{(t_j)}\|_2^2 = \sum_{j' \in [j]} w \cdot \Delta^{2j'+1} = \frac{w \cdot \Delta^{2j+2} - w \cdot \Delta^2}{\Delta^2 - 1}$. Note that one can easily complete rest of the stream $\{f^{(t)}\}_{t \in [m]}$ for any $m \geq t_\ell$. Note that here we can pick $\ell = \Theta\left(\frac{\log m}{\log(1/\epsilon)}\right)$.

Define the event $E_j := \{\|\Pi f^{(t_j)}\|_2^2 - \|f^{(t_j)}\|_2^2 > \epsilon \cdot \|f^{(t_j)}\|_2^2\}$. To show that COUNTSKETCH does not provide $w_2(\epsilon, \delta)$ -strong tracking, it suffices to prove $\Pr[\cup_{j \in [\ell]} E_j] > \delta$. The following lemma lower bounds the probability of single E_j .

► **Lemma 19.** For each $j \in \ell$, we have $\Pr[E_j \mid \neg \cup_{j' \in [j]} E_{j'}] \geq \frac{1}{10k\epsilon^2}$.

Proof. First, let $\bar{f}^{(t_j)} = f^{(t_j)} - f^{(t_{j-1})}$ for each $j \in \ell$ where we define $f^{(0)} = \mathbf{0}$. Observe that

$$\begin{aligned} \|\Pi f^{(t_j)}\|_2^2 - \|f^{(t_j)}\|_2^2 &= \|\Pi \bar{f}^{(t_j)} + \Pi f^{(t_{j-1})}\|_2^2 - \|\bar{f}^{(t_j)} + f^{(t_{j-1})}\|_2^2 \\ &= \|\Pi \bar{f}^{(t_j)}\|_2^2 - \|\bar{f}^{(t_j)}\|_2^2 + \|\Pi f^{(t_{j-1})}\|_2^2 - \|f^{(t_{j-1})}\|_2^2 \\ &\quad + 2\langle \Pi \bar{f}^{(t_j)}, \Pi f^{(t_{j-1})} \rangle - 2\langle \bar{f}^{(t_j)}, f^{(t_{j-1})} \rangle. \end{aligned}$$

Further, condition on $\neg \cup_{j' \in [j-1]} E_{j'}$, we have $\|f^{(t_{j-1})}\|_2^2$, $\|\Pi f^{(t_{j-1})}\|_2^2$, $|\langle \Pi \bar{f}^{(t_j)}, \Pi f^{(t_{j-1})} \rangle|$, and $|\langle \bar{f}^{(t_j)}, f^{(t_{j-1})} \rangle|$ are all at most $(\epsilon/10) \cdot \|f^{(t_j)}\|_2^2$ by the choice of Δ . Namely,

$$\|\Pi f^{(t_j)}\|_2^2 - \|f^{(t_j)}\|_2^2 \geq \|\Pi \bar{f}^{(t_j)}\|_2^2 - \|\bar{f}^{(t_j)}\|_2^2 - \frac{\epsilon}{2} \cdot \|f^{(t_j)}\|_2^2. \quad (8)$$

► **Lemma 20.** $\Pr[\|\Pi \bar{f}^{(t_j)}\|_2^2 - \|\bar{f}^{(t_j)}\|_2^2 > 3\epsilon \cdot \|f^{(t_j)}\|_2^2] > \frac{1}{10k\epsilon^2}$.

Proof. Let us consider the columns of Π that correspond to the non-zero entries of $\bar{f}^{(t_j)}$. That is, column $\Delta \cdot (j-1) + 1$ to $\Delta \cdot j$. Note that once there are exactly one collision happens among these columns and the both the value are the same, then $\|\Pi \bar{f}^{(t_j)}\|_2^2 - \|f^{(t_j)}\|_2^2 > 3\epsilon \cdot \|f^{(t_j)}\|_2^2$. The probability of the above to happen is at least the following.

$$\frac{1}{2} \cdot \frac{k \cdot \binom{w}{2} \cdot (k-1) \cdot (k-2) \cdots (k-w+2)}{k^w} \geq \frac{w^2}{5k} > \frac{1}{10k\epsilon^2}. \quad \blacktriangleleft$$

Now, Lemma 19 immediately follows from Equation 8 and Lemma 20. \blacktriangleleft

Let us wrap up the proof of Theorem 17 as follows.

$$\begin{aligned} \Pr \left[\exists t \in [m], \left| \|\Pi f^{(t)}\|_2^2 - \|f^{(t)}\|_2^2 > \epsilon \|f^{(t)}\|_2^2 \right] \right] &\geq \Pr \left[\cup_{j \in [\ell]} E_j \right] \\ &= \prod_{j \in [\ell]} \Pr \left[E_j \mid \neg \cup_{j' \in [j-1]} E_{j'} \right] \\ &\geq \left(1 - \frac{1}{10k\epsilon^2} \right)^\ell \geq 1 - \frac{\ell}{k\epsilon^2}. \end{aligned}$$

By the choice of parameters, the last quantity would be greater than δ and thus COUNTSKETCH with $k \leq C \cdot \epsilon^{-2} \delta^{-1} \frac{\log(m)}{\log(1/\epsilon)}$ rows does not provide $\ell_2(\epsilon, \delta)$ -strong tracking. \blacktriangleleft

Submodular Optimization with Contention Resolution Extensions

Abstract

This paper considers optimizing a submodular function subject to a set of downward closed constraints. Previous literature on this problem has often constructed solutions by (1) discovering a fractional solution to the multi-linear extension and (2) rounding this solution to an integral solution via a contention resolution scheme. This line of research has improved results by either optimizing (1) or (2).

Diverging from previous work, this paper introduces a principled method called contention resolution extensions of submodular functions. A contention resolution extension combines the contention resolution scheme into a continuous extension of a discrete submodular function. The contention resolution extension can be defined from effectively any contention resolution scheme. In the case where there is a loss in both (1) and (2), by optimizing them together, the losses can be combined resulting in an overall improvement. This paper showcases the concept by demonstrating that for the problem of optimizing a non-monotone submodular subject to the elements forming an independent set in an interval graph, the algorithm gives a .188-approximation. This improves upon the best known $\frac{1}{2e} \simeq .1839$ approximation.

1 Introduction

Submodular function maximization has numerous applications and there has been a rich theory developed on the topic. See [9] for pointers to relevant work. In this problem, the input consists of a universe of n elements U and a submodular set function $f : 2^U \rightarrow \mathbb{R}^+$. A function is submodular if for all sets $A, B \subseteq U$ where $A \subseteq B$ and any element $e \in U \setminus B$ it is the case that $f(A \cup \{e\}) - f(A) \geq f(B \cup \{e\}) - f(B)$.¹ Submodular functions are a general class of functions that capture the concept of diminishing returns. Natural occurrences of submodular functions include the cut function [8] and the coverage function [3]. Due to their generality, submodular functions capture many common objective functions. For example, submodular functions are frequently used in machine learning for problems such as document summarization [18], exemplar clustering [12], influence in social networks [13] and other problems [15].

¹ Equivalently, a function is submodular if for all sets $A, B \subseteq U$ it is the case that $f(A) + f(B) \geq f(A \cup B) + f(A \cap B)$.

The submodular maximization problem is to select a set S maximizing $f(S)$ such that $S \in \mathcal{I}$ where \mathcal{I} is a family of sets of feasible solutions. The set \mathcal{I} is usually assumed to be downward closed.² The set of feasible solutions \mathcal{I} is defined based on the constraints of the given problem. Prior work has focused on two cases. In one, the function f is additionally assumed to be *monotone* and in the other the function f is *non-monotone*. A submodular function is monotone if $f(S \cup \{e\}) \geq f(S)$ for all $S \subseteq U$ and $e \in U$. The function f is said to be non-monotone if there is no monotonicity restriction.

Optimizing a submodular function subject to classes of downward closed constraints has been extensively studied [7, 11, 4, 1, 10]. The most widely considered classes of constraints are a cardinality constraint [3], matroid constraints [17], knapsack constraints [16], and interval constraints [9]. Through this line of research, a general algorithmic method has emerged. The method consists of two parts. (1) Find a fractional solution to the multilinear extension, and then (2) use a contention resolution scheme or techniques like pipage rounding [5] to round the fractional solution to a feasible integral solution. The *multilinear extension* is an extension of a discrete submodular set function f to the fractional continuous setting. This algorithmic method is general enough to give strong results for numerous problems, including the best known results for monotone and non-monotone submodular maximization under a single matroid constraint [3, 7, 1].

Several past works have focused on optimizing either steps (1) or (2) to improve state-of-the-art methods. Generally, past work has focused on improving (1), the procedure to construct a fractional solution. This is because [6] gave general methods for converting fractional solutions to the multilinear extension to an integral solution. The algorithm typically used in (1) is the *continuous greedy* algorithm and its variants [2, 4, 19, 11, 7].

The Multi-Linear Extension, Continuous Greedy, and Contention Resolution Schemes.

Let F be the multilinear extension of f . The **multilinear extension** F is a continuous function that extends f to the fractional domain $[0, 1]^{|U|}$. The input to F is a vector \mathbf{x} where $0 \leq x_i \leq 1$ for all i . Let S contain each element U with probability x_i . The value of $F(\mathbf{x})$ is $\mathbb{E}[f(S)]$. It is important to note that S may not be in \mathcal{I} . Past work uses the continuous greedy framework to discover a vector \mathbf{x} such that $F(\mathbf{x})$ is close to the optimal solution. Then, this is rounded to an integral solution using a contention resolution scheme $\mathcal{C}(\mathbf{x})$. The idea is to first construct the set S at random, as is done in the computation of $F(\mathbf{x})$. Then some elements from S are dropped to find a set $S' \subseteq S$ such that $S' \in \mathcal{I}$. Key is showing that $\mathbb{E}[f(S')]$ is close to $F(\mathbf{x})$, and thereby bounding $\mathbb{E}[f(S')]$ by the optimal solution.

The **continuous greedy algorithm** iteratively builds a fractional solution \mathbf{x} . The algorithm adds a small fractional amount \mathbf{x}^* of some elements to \mathbf{x} such that it greedily increases $F(\mathbf{x} + \mathbf{x}^*)$. Past work has focused on the optimizing the greedy choice of \mathbf{x}^* .

This line of work has mostly focused on optimizing (1). This is due to (1) is being the core part of the algorithm where there is loss in the approximation factor. In many cases though, there is additionally loss when performing (2) as well [6, 9].

Contention Resolution Extensions. As mentioned, past work has focused on optimizing (1) and (2) in isolation. This paper for the first time considers optimizing (1) and (2) together to combine the losses in the two procedures and show overall improved results. Our main results are enabled by a principled algorithmic method called *contention resolution extensions*, going beyond optimizing the multi-linear extension.

² A set \mathcal{I} is said to be downward closed if $S \in \mathcal{I}$ implies $S' \in \mathcal{I}$ for all $S' \subseteq S$.

The framework takes as input a (randomized) contention resolution scheme $\mathcal{C}(\mathbf{x})$. The contention resolution scheme takes as input a fractional solution and returns a feasible integral solution. Past work constructs \mathbf{x} and then produces the final solution using \mathcal{C} only in the last step. Instead, this paper uses \mathcal{C} to construct \mathbf{x} . At each step the new method greedily selects a small fractional amount of each element \mathbf{x}^* to maximize the expected value of $\mathcal{C}(\mathbf{x} + \mathbf{x}^*)$. When the algorithm terminates, it simply returns $\mathcal{C}(\mathbf{x})$ for the final vector \mathbf{x} computed. In this way, the algorithm's greedy choices at each step are closely connected to the final solution that the algorithm will return.

Improved results can be shown using this framework because the loss in step (1) and (2) can be combined in the analysis. Further, the loss in the contention resolution scheme is optimized over in each step, allowing the algorithm to converge to a fractional solution that is chosen directly to optimize the final solution.

1.1 Applications of the Contention Resolution Extension Framework

This paper shows how contention resolution extensions can be used to improve state-of-the-art results for optimizing submodular functions.

The paper considers the problem of optimizing a submodular function over independent sets in an interval graph. In this problem, each element is associated with an interval. The goal is to select a set of intervals that do not intersect to maximize a non-monotone submodular function. The best known previous result is a $\frac{1}{2e} \simeq .1839$ -approximation [9].

► **Theorem 1.** *For any non-monotone submodular function where $f(\emptyset) = 0$ there is a .188-approximation algorithm for maximizing the function subject to an interval constraint.*

Overview of the Improved Analysis. To describe how our analysis improves over previous work, first consider the unified continuous greedy algorithm of [11]. Let \mathcal{C} be a contention resolution scheme and OPT denote the value of the optimal solution. As discussed, the algorithm greedily builds a fractional solution \mathbf{x} . At each step, an amount \mathbf{x}^* is added to \mathbf{x} where \mathbf{x}^* contains a small amount of some of the elements. Past analysis of the continuous greedy framework proves that in each step $F(\mathbf{x})$ increases by an amount proportional to $(1 - \|\mathbf{x}\|_\infty)\text{OPT}$. That is, the incremental improvement of $F(\mathbf{x})$ at each step is proportional to OPT multiplied by an amount that depends on the most any element is fractionally selected in \mathbf{x} . The analysis crucially relies on a bound on $\|\mathbf{x}\|_\infty$ at each step. The algorithm arrives at the final solution using \mathcal{C} on the vector \mathbf{x} at the end of the continuous greedy procedure. For many contention resolution schemes, the expected value of the solution returned is bounded by $F(\mathbf{x})$ multiplied by the minimum probability an element is not discarded by the contention resolution scheme.

Following the above, notice that improving the bound on $\|\mathbf{x}\|_\infty$ in each step will improve the overall analysis. Our algorithmic framework will allow us to achieve better bounds on $\|\mathbf{x}\|_\infty$. In particular, we know that the final solution returned is obtained by running \mathcal{C} , which increases the probability that an element is not included in the final solution. If somehow the probability an element is discarded by \mathcal{C} could be incorporated into each step of the algorithm to ensure $\|\mathbf{x}\|_\infty$ is small, then this would improve the overall analysis.

Our algorithm uses \mathcal{C} at each step in the continuous process of constructing \mathbf{x} . In particular, by using \mathcal{C} there is less of a chance an element is selected. For this reason, the analysis effectively gets a tighter bound on $\|\mathbf{x}\|_\infty$, resulting in an overall improved analysis.

A challenge in this approach is that no prior analysis has considered optimizing $\mathcal{C}(\mathbf{x})$ and have always used $F(\mathbf{x})$. Consequently, our analysis introduces new techniques for optimizing over contention resolutions extensions.

2 Preliminaries

Let f be a non-monotone submodular function. The input to the problem is a universe of n elements S . The goal is to select a set of elements $S' \subseteq \mathcal{I}$ such that $f(S')$ is maximized where \mathcal{I} is a set of feasible solution sets. Let $f_R(S') := f(R \cup S') - f(R)$ be the value of adding elements in the set S' to the set R . In this paper it is assumed that $f(\emptyset) = 0$.

The paper considers a hereditary set system defined by independent sets in interval graphs. In this problem, each element $i \in U$ is an interval $(s_i, d_i]$. A set S' is in \mathcal{I} if no two intervals in S' intersect.

The analysis framework in this paper builds on previous submodular optimization work. The next lemma follows from the contention resolution framework of [6]. It is not proven explicitly, but follows from the proof in the paper. Consider a contention resolution scheme that takes as input a set S' and returns a set $D(S') \subseteq S'$. The scheme is said to be monotonic if the probability an element $i \in D(S'')$ is only greater than the probability $i \in D(S')$ for $S'' \subseteq S'$ and $\{i\} \in S''$.

► **Theorem 2** ([6]). *Let S' be a set constructed using a randomized procedure. Consider a deterministic monotonic contention resolution scheme that given a set S' of elements constructs a set $D(S') \subseteq S'$ such that $\Pr[i \in D(S') \mid i \in S'] \geq c$ for all S' and i . Further, there exists an ordering of elements e_1, e_2, \dots in $D(S')$ such that $f_{e_1, e_2, \dots, e_i}(\{e_{i+1}\}) > 0$ for all $0 \leq i < |D(S')|$. Then it is the case that $c\mathbb{E}[f(S')] \leq \mathbb{E}[f(D(S'))]$.*

The following lemma is implied by a well known relationship between the Lovasz extension and multilinear extension of submodular functions. See [9] and [20]. We prove this here for completeness.

► **Theorem 3.** *Let f be a non-negative submodular function with $f(\emptyset) = 0$. Fix any set O . Let R be a set of elements constructed at random where element i is in R with probability p_i . Say that $p_i \leq \alpha$ for all $i \notin O$. It is the case that $\mathbb{E}[f(R \cup O)] \geq (1 - \alpha)f(O)$.*

Proof. Let p_i be the probability that i is in R for $i \notin O$ and let $p_i = 1$ for $i \in O$. Consider ordering all of the intervals so that $p_1 \geq p_2 \geq \dots \geq p_n$. For notational convenience, assume $p_{n+1} = 0$. Recall that for any sets S' and S'' we set $f_{S'}(S'') = f(S' \cup S'') - f(S')$. In the following $[k]$ is the set $\{1, 2, \dots, k\}$. Let $R' = R \cup O$ in the following. We see the following.

$$\begin{aligned}
\mathbb{E}[f(R')] &= f(\emptyset) + \sum_{k=1}^n \mathbb{E}[f(R' \cap [k]) - f(R' \cap [k-1])] \\
&= \sum_{k=1}^n \mathbb{E}[f_{R' \cap [k-1]}(R' \cap \{k\})] \geq \sum_{k=1}^n \mathbb{E}[f_{[k-1]}(R' \cap \{k\})] \quad [f(\emptyset) = 0 \text{ and submodularity}] \\
&= \sum_{k=1}^n p_k f_{[k-1]}(k) = \sum_{k=1}^n p_k (f([k]) - f([k-1])) = \sum_{k=1}^n (p_k - p_{k+1}) f([k]) \\
&\geq (1 - \alpha)f(O) \quad [f \text{ is positive and } p_i \leq (1 - \alpha) \text{ for all } i \notin O \text{ by assumption}] \quad \blacktriangleleft
\end{aligned}$$

3 Non-Monotone Function Subject to an Interval Constraint

In this section, we consider the problem of optimizing a non-monotone submodular function f subject to an interval scheduling constraint. In this problem, there is a set S of possible intervals $(s_i, d_i]$. We note that the intervals do not contain their starting point. This is

simply for notational purposes and is without loss of generality. A set S' of intervals is feasible (in \mathcal{I}) if no two intersect and the goal is to maximize $f(S')$. It is said that two intervals intersect if they both include a common point.

The algorithm maintains a vector y of size n . Let y^i denote the i th entry in the vector. Intuitively, one can think of the entry y^i as the probability of selecting interval i . The vector y will be chosen such that the following holds. Fix any point t . It is the case that $\sum_{i:t \in (s_i, d_i]} y^i \leq 1$. That is, the total weight of intervals intersecting point t is at most one.

The Function $F(y)$. The function F is defined as follows. A set R of intervals is selected by choosing each interval i with probability y^i . The function $F(y) = \mathbb{E}[f(R)]$. This function is the multi-linear extension. Notice that R may not be in the set of feasible solutions \mathcal{I} .

The Function $G(y)$. The function G is constructed similarly to F , but it removes additional intervals from R to get a set $D(R)$. The value of $G(y)$ is set to $\mathbb{E}[f(D(R))]$. Intervals are removed from R so that $D(R)$ forms a feasible solution. In this way, G acts as a contention resolution scheme. Each interval i in R is added to $D(R)$ if there is no other interval in R that intersects the start point s_i of i . This function is a *contention resolution extension*³ of the set function $f(S)$. Notice that the set $D(R)$ is a feasible solution.

Formally, each interval i is in R with probability y^i . Given R let $D(R) = \{i \in R \mid \forall j \in R, s_i \notin (s_j, d_j]\}$. Set $G(y) = \mathbb{E}[f(D(R))]$.

The Algorithm. The algorithm works as follows. The algorithm continuously optimizes G . At time t a vector y_t has been constructed. Let δ be very small, $\frac{1}{\text{poly}(n)}$. The algorithm initializes $y_{t+\delta}$ to y_t and then increases some of the entries. Pseudocode can be found in Algorithm 1. In the following description, for any vector v let $v + 1_i$ denote the vector v except that the coordinate of i is fixed to 1.

Separately for each element i , the algorithm finds the value of $\gamma_i = \sum_{S' \subseteq S} \Pr[R = S'] f(D(S' \cup \{i\}))$, equivalently the value of $G(y_t + 1_i)$. This can be estimated to high accuracy following sampling techniques used in previous work [6, 9, 7] and for ease of explanation we assume that it can be computed exactly. Let $\beta_i := \delta e^{-y_t^i} (1 - y_t^i)$ and $w_i = \beta_i (\gamma_i - G(y_t)) = \beta_i (G(y_t + 1_i) - G(y_t))$. The value of w_i is precisely the change in $G(y_t)$ if y_t^i is increased to 1 and then scaled by β_i .

The algorithm finds a maximum weight independent set I over all intervals where an interval i is given weight w_i . It is well known that such a solution can be found in polynomial time using dynamic programming [14]. For each interval $i \in I$, $y_{t+\delta}^i$ is increased by an additive β_i .

The procedure can stop at any time t where $0 \leq t \leq 1$.⁴ When the procedure stops, the final solution is produced by constructing $D(R)$ as in the description of G . This set is returned as the solution. This is a feasible solution by construction and the expected value of the algorithm's solution will be $G(y_t)$.

³ We note that this is not the only contention resolution extension and there are other natural contention resolution schemes that could be used.

⁴ One could stop at $t > 1$ so long as the contention resolution scheme constructs a feasible solution. This did not result in improvement in our analysis.

■ **Algorithm 1** Computing $y_{t+\delta}$ from y_t .

```

1: for  $i \in U$  do
2:    $\gamma_i \leftarrow G(y_t + 1_i)$ 
3:    $\beta_i \leftarrow \delta e^{-y_t^i} (1 - y_t^i)$ 
4:    $w_i \leftarrow \beta_i (\gamma_i - G(y_t))$  //  $= \beta_i (G(y_t + 1_i) - G(y_t))$ 
5: end for
6: Give each interval  $i$  a weight of  $w_i$ . Using these weights, find a maximum weight subset
   of intervals  $I$  that do not intersect.
7: for  $i \in U$  do
8:   if  $i \in I$  then
9:      $y_{t+\delta}^i = y_t^i + \beta_i$ 
10:  else
11:     $y_{t+\delta}^i = y_t^i$ 
12:  end if
13: end for
14: Output  $y_{t+\delta}$ 

```

3.1 Analysis

Let O denote the intervals in a fixed optimal solution. For each interval i , let E_i be the set of intervals at or before s_i that intersect i and let i be in E_i . The analysis begins by showing that any single interval is selected with at most a small probability.

► **Lemma 4.** *The maximum value an entry in y_t can have is $\alpha(t) := \frac{100(e^{37t/100}-1)}{100e^{37t/100}-63} + 2\delta \leq 1 - e^{-t} + 2\delta t$ for any $0 \leq t \leq 1$.*

Proof. In each step, an interval i chosen to be in I has its probability of selection increased by the algorithm. This increase is at most $\delta(1 - y_t^i)e^{-y_t^i}$ at time t . In the worst case, y_t^i is increased at each time step t . The proof will assume that this is the case for element i . For all $y_t^i \leq 1$, from convexity of $e^{-y_t^i}$ we derive,

$$e^{-y_t^i} \leq 1 - (1 - e^{-1})y_t^i \leq 1 - 0.63y_t^i.$$

We now define a function $\rho^i(t)$ which is a piecewise linear version of y_t^i over times t . Define the function $\rho^i(t)$ for any integer $j \geq 2$ and $t \in [0, 1]$ as follows: for each $t \in [(j-1)\delta, j\delta]$ let $\rho^i(t) = \delta \sum_{\tau=0}^{j-2} (1 - y_{\tau\delta}^i)(1 - 0.63y_{\tau\delta}^i) + (t - (j-1)\delta)(1 - y_{(j-1)\delta}^i)(1 - 0.63y_{(j-1)\delta}^i)$. Set $\rho^i(0) = 0$. Obviously $y_{\tau\delta}^i \leq \rho^i(t)$ when $t \leq \tau\delta$ and $y_{(\tau+1)\delta}^i \leq y_{\tau\delta}^i + \delta$ for all τ . Moreover,

$$\begin{aligned} \frac{d\rho^i(t)}{dt} &= (1 - y_{(j-1)\delta}^i)(1 - 0.63y_{(j-1)\delta}^i) \leq (1 - y_{j\delta}^i + \delta)(1 - 0.63y_{j\delta}^i + \delta) \\ &\leq (1 - \rho^i(t))(1 - 0.63\rho^i(t)) + 4\delta \end{aligned}$$

Consider setting up a new function $\alpha(t)$ where $\alpha(0) = 0$ and $\frac{d\alpha}{dt} = (1 - \alpha(t))(1 - 0.63\alpha(t)) + 4\delta$. Solving this differential equation gives that $\alpha(t) = \frac{100(e^{37t/100}-1)}{100e^{37t/100}-63} + 4\delta t$. We know that $\rho^i(0) = \alpha(0) = 0$. The function $\alpha(t)$ is continuous and the function $\rho(t)$ is piecewise linear. Further, for any $0 \leq t \leq 1$ whenever $\rho^i(t) = \alpha(t)$ the derivative of $\alpha(t)$ is larger than $\rho^i(t)$. This gives that $\rho^i(t) \leq \alpha(t)$ for all $0 \leq t \leq 1$.

Thus, we have that $y_t^i \leq \rho^i(t) \leq \alpha(t)$ for all $0 \leq t \leq 1$, proving the lemma. ◀

We will begin by relating the functions G and F . To do this, we will use Theorem 2. This theorem requires that we bound the probability an interval in R is in $D(R)$. We do this in the following lemma.

► **Lemma 5.** *For any time $0 \leq t \leq 1$ it is the case that $\Pr[i \in D(R) \mid i \in R] = \Pr[R \cap (E_i \setminus \{i\}) = \emptyset] \geq e^{-(t-y_i^i)} \geq e^{-t}$.*

Proof. Fix an interval $i = (s_i, d_i]$. If this interval is in R , then the only reason it is not in $D(R)$ is because there is another interval $j \in R$ such that j intersects the start point of i . That is if $j \in E_i \cap R$ and $j \neq i$ then in this case i will not be in $D(R)$; otherwise, if $R \cap (E_i \setminus \{i\}) = \emptyset$ then i is in $D(R)$ when $i \in R$. Thus, it suffices to bound the probability any interval is sampled to be in R which intersects s_i . The probability no interval in $E_i \setminus \{i\}$ is sampled is $\prod_{j \neq i, s_i \in (s_j, d_j]} (1 - y_t^j) \geq e^{-t+y_i^i}$. Where the inequality follows from the fact that $\sum_{j: s_i \in (s_j, d_j]} y_t^j \leq t$ for any step of the algorithm, i.e. any time t where $0 \leq t \leq 1$. ◀

Now we show two key lemmas. The first shows a relationship between G and F .

► **Lemma 6.** *$G(y) \geq \frac{1}{e^t} F(y)$ for all vectors y .*

Proof. We utilize Theorem 2. First notice that the procedure to construct $D(R)$ in the definition of G is a monotonic scheme. This is because the probability an interval is in $D(R)$ only decreases if intervals are added to R . Lemma 5 and Theorem 2 give the lemma. ◀

The next lemma is the key technical lemma that bounds the increase in the G at each step of the algorithm.

► **Lemma 7.** *It is the case that $G(y_{t+\delta}) \geq (1 - \delta)G(y_t) + \frac{\delta}{e^t} \mathbb{E} [\sum_{i \in O} (f(R \cup \{i\}) - f(R))] - O(n^2 \delta^2) f(O)$ for all $t \leq \ln 2 - \delta$.*

We defer the proof of the lemma and first show how this can be used to construct our result. Using the previous two lemma, we can bound the total increase in the function by the optimal solution.

► **Lemma 8.** *It is the case that $G(y_{t+\delta}) \geq (1 - \delta)G(y_t) + \frac{\delta}{e^t} ((1 - \alpha(t)) f(O) - e^t G(y_t)) - O(n^2 \delta^2) f(O)$ for all $t \leq \ln 2 - \delta$.*

Proof. Lemma 7 says that $G(y_{t+\delta}) \geq (1 - \delta)G(y_t) + \frac{\delta}{e^t} \mathbb{E} [\sum_{i \in O} f(R \cup \{i\}) - f(R)] - O(n^2 \delta^2) f(O)$. By definition, $\mathbb{E}[f(R)] = F(y_t)$ and Lemma 6 states that $F(y_t) \leq e^t G(y_t)$. This gives the following. The first inequality follows from submodularity.

$$\begin{aligned} & (1 - \delta)G(y_t) + \frac{\delta}{e^t} \mathbb{E} [\sum_{i \in O} f(R \cup \{i\}) - f(R)] - O(n^2 \delta^2) f(O) \\ \geq & (1 - \delta)G(y_t) + \frac{\delta}{e^t} \mathbb{E} [f(R \cup O) - f(R)] - O(n^2 \delta^2) f(O) \\ \geq & (1 - \delta)G(y_t) + \frac{\delta}{e^t} (\mathbb{E}[f(R \cup O)] - e^t G(y_t)) - O(n^2 \delta^2) f(O). \end{aligned} \tag{1}$$

Notice that $\mathbb{E}[f(R \cup O)] \geq (1 - \alpha(t)) f(O)$ by Theorem 3 because Lemma 4 gives that the maximum probability any interval is in R is bounded by $\alpha(t)$. Combining this with equation (1) gives the lemma. ◀

Using the two above lemmas, we can show our main result.

Proof of Theorem 1. Lemma 8 states that $G(y_{t+\delta}) \geq (1 - \delta)G(y_t) + \frac{\delta}{e^t}((1 - \alpha(t))f(O) - e^t G(y_t)) - O(n^2 \delta^2)f(O)$ wherever $t \leq \ln 2 - \delta$. This implies that $G(y_{t+\delta}) - G(y_t) \geq -2\delta G(y_t) + \frac{\delta}{e^t}((1 - \alpha(t))f(O)) - O(n^2 \delta^2)f(O)$ for $t \leq \ln 2 - \delta$.

By choosing δ to be sufficiently small, $G(y_{t+\delta})$ can be bounded using a differential equation. Consider a function $g(t)$ where $g(0) = 0$ and for any $t \in [(j - 1)\delta, j\delta]$ it is the case that

$$g(t) = \delta \sum_{\tau=0}^{j-2} \left(-2G(y_{\tau\delta}) + \frac{f(O)}{e^{\tau\delta}}(1 - \alpha(\tau\delta)) \right) + (t - (j - 1)\delta) \left(-2G(y_{(j-1)\delta}) + \frac{f(O)}{e^{(j-1)\delta}}(1 - \alpha((j - 1)\delta)) \right).$$

Inductively, notice that $G(y_t) + O(n^2 \delta^2 \cdot \frac{t}{\delta})f(O) \geq g(t)$ for any t divisible by δ and t less than $\ln 2 - \delta$. Further, $\frac{dg}{dt} = -2G(y_{(j-1)\delta}) + \frac{f(O)}{e^{(j-1)\delta}}(1 - \alpha((j - 1)\delta)) \geq -2g(t) + \frac{f(O)}{e^t}(1 - \alpha(t)) - 2\delta f(O)$. Consider a new function $h(t)$ where $h(0) = 0$ and $\frac{dh}{dt} = -2h(t) + \frac{f(O)}{e^t}(1 - \alpha(t)) - 2\delta f(O)$. Solving this differential equation results in $h(.54) > .188f(O)^5$. Note that $.54 \leq \ln 2 - \delta$ for sufficiently small δ .

We know that $h(0) = g(0) = 0$. We also know that $h(t)$ is a continuous function and $g(t)$ is piecewise linear. Further, for any $0 \leq t \leq 1$ whenever $h(t) = g(t)$ the derivative of $g(t)$ is only larger than that of $h(t)$. Thus, we have that $h(t) \leq g(t)$ for all t . Knowing that $g(t) \leq G(y_t) + O(n^2 \delta^2 \frac{t}{\delta})f(O) \leq G(y_t) + O(n^2 \delta)f(O)$ for $t \leq \ln n - \delta$, it is the case that $.188f(O) < h(.54) \leq g(.54) \leq G(y_{.54}) + O(n^2 \delta)f(O)$, proving the theorem for $\delta \leq \frac{1}{n^3}$. ◀

It only remains to prove Lemma 7. The proof can be found in Section 4.

4 Proof of Lemma 7

For this section, let y be the current solution computed by our algorithm at some fixed stage t . Throughout the section all lemmas and proofs will assume that $t \leq \ln 2 - \delta$, an assumption in the statement of Lemma 7. Let v be a vector equal to $y_{t+\delta} - y_t$. For simplicity, we drop the index t and throughout this section we only focus on stage t and drop the index t in y_t . We want to bound $G(y + v)$. Throughout this section, let I be the intervals in the support of v . These are the elements the algorithm chooses in the independent set and whose variables get increased. Let O be the intervals in the optimal solution.

Let S be the set of all intervals. Let R be the random set of intervals chosen according to y where every interval is sampled independently. Formally, for each interval i draw a number r_i uniformly at random from $[0, 1]$ and let i be in R if $r_i < y^i$. Let \mathcal{E}_i denote the event $y^i < r_i \leq y^i + \beta_i$. Intuitively, \mathcal{E}_i is the event that i would not be in R if y^i is used for the sampling, but would have if y^i was increased by β_i . For $i \in I$ this is the event i was chosen in the computation of $G(y + v)$, but not $G(y)$.

For any set S' , let $D(S')$ contain the intervals from S' chosen according to the algorithm that is used in G . That is $D(S')$ is constructed from S' by only adding an interval $j \in S'$ to be in $D(S')$ if there is no other interval in S' with earlier start point that also intersects j .

We would like to bound $G(y + v)$ by quantities involving O and $G(y)$. Let $\mathcal{E}(I')$ denote the event that \mathcal{E}_i occurs for all $i \in I'$ and \mathcal{E}_i does not occur for any $i \in I \setminus I'$ and recall that $\Pr[\mathcal{E}_i] = \beta_i = \delta(1 - y^i)e^{y^i}$, the amount the algorithm would increase y^i if $i \in I$. It will

⁵ This was verified using a differential equation solving software from Mathematica and independently verified using numerical evaluation.

be useful to first bound the probability that $R = S'$ for some S' . To do this, the following lemmas bound the probability of either an interval being in R or $R = S'$ depending on the events \mathcal{E}_i . The claim isn't difficult and the proof is deferred to the appendix.

▷ **Claim 9.** For any $i \in I$ it is the case that $\Pr[i \in R \mid \overline{\mathcal{E}}_i] = \frac{\Pr[i \in R]}{1 - \beta_i} \geq \Pr[i \in R]$ and $\Pr[i \notin R \mid \overline{\mathcal{E}}_i] \geq (1 - \beta_i)\Pr[i \notin R]$ when $t \leq \ln 2 - \delta$. Further, for any $i \in I$ and any set $S' \subseteq S$ it is the case that $\Pr[S' = R \mid \mathcal{E}(\{i\})] \geq \Pr[R = S' \mid \mathcal{E}_i] \prod_{j \in I, j \neq i} (1 - \beta_j)$ when $t \leq \ln 2 - \delta$.

Intuitively, the next claim relates the probability R would be the same set if intervals are drawn randomly using y or $y + v$.

▷ **Claim 10.** Fix any set $S' \subseteq S$. It is the case that $\Pr[R = S' \text{ and } \mathcal{E}(\emptyset)] \geq (1 - \sum_{i \in I \setminus S'} \frac{\beta_i}{1 - y^i}) \Pr[R = S']$.

Proof. Notice that for any $i \in I$, it is the case that $\Pr[i \in R \text{ and } \mathcal{E}(\emptyset)] = \Pr[i \in R]$ and $\Pr[i \notin R \text{ and } \mathcal{E}(\emptyset)] = \Pr[i \notin R] - \beta_i = \Pr[i \notin R](1 - \frac{\beta_i}{1 - y^i})$. The last equality follows from $\Pr[i \notin R] = 1 - y^i$ by definition. Knowing that elements are sampled independently, we have the following. The first equality follows since elements are sampled independently. The three terms break up the cases on if an elements is not in I , is in $I \cap S'$ or is in I and not S' .

$$\begin{aligned} & \Pr[R = S' \text{ and } \mathcal{E}(\emptyset)] \\ &= \Pr[R \setminus I = S' \setminus I] \prod_{i \in I \cap S'} \Pr[i \in R \text{ and } \mathcal{E}(\emptyset)] \prod_{i \in I \setminus S'} \Pr[i \notin R \text{ and } \mathcal{E}(\emptyset)] \\ &= \Pr[R = S'] \prod_{i \in I \setminus S'} (1 - \frac{\beta_i}{1 - y^i}) \geq (1 - \sum_{i \in I \setminus S'} \frac{\beta_i}{1 - y^i}) \Pr[R = S']. \end{aligned}$$

The second equality follows from the observation at the beginning of the proof of the lemma. \triangleleft

The next lemma bounds $G(y + v)$ by $G(y)$. Intuitively, the first term says that if \mathcal{E}_i does not occur for any i then $G(y + v)$ is the same as $G(y)$. The second term captures the case for \mathcal{E}_i occurs for exactly one $i \in O$. Finally, the probability that \mathcal{E}_i occurs for more than one i is very small (proportional to δ^2) so this effect is negligible. The proof is deferred to Section 5.

► **Lemma 11.** *It is the case that, $G(y + v) \geq (1 - \sum_{i \in I} \beta_i)G(y) + \sum_{i \in I} \sum_{S' \subseteq S \setminus \{i\}} \beta_i \Pr[R = S' \mid \mathcal{E}_i] f(D(S' \cup \{i\})) - O(n^2 \delta^2 f(O))$.*

Next it is observed that the choice of the set I allows us to swap the terms in the expression in the previous lemma by the optimal solution O .

► **Lemma 12.** *$G(y + v) \geq (1 - \sum_{i \in O} \beta_i)G(y) + \sum_{i \in O} \sum_{S' \subseteq S \setminus \{i\}} \beta_i \Pr[R = S' \mid \mathcal{E}_i] f(D(S' \cup \{i\})) - O(n^2 \delta^2 f(O))$*

Proof. Consider the value of

$$\sum_{i \in I} \beta_i \left(\sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S' \mid \mathcal{E}_i] f(D(S' \cup \{i\})) - G(y) \right).$$

This equals

$$\sum_{i \in I} \beta_i \left(\sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S' \cup \{i\})) - G(y) \right).$$

3:10 Submodular Optimization with Contention Resolution Extensions

This is equal to the following since elements are sampled independently

$$\sum_{i \in I} \beta_i \left(\sum_{S' \subseteq S} \Pr[R = S'] f(D(S' \cup \{i\})) - G(y) \right) = \sum_{i \in I} w_i.$$

By definition, this is only greater than $\sum_{i \in O} w_i$. Reversing the above steps for O and combining with Lemma 11 gives the lemma. \blacktriangleleft

Our remaining goal is to bound part of the expression from the prior lemma,

$$\sum_{S' \subseteq S \setminus \{i\}} \sum_{i \in O} \beta_i \Pr[R = S' \mid \mathcal{E}_i] f(D(S' \cup \{i\})) + \sum_{i \in O} \beta_i G(y).$$

Recall that E_i is the set of intervals starting earlier than i that intersect i and also the interval i itself. The intervals in $E_i \setminus \{i\}$ are the intervals, which if they are sampled to be in R then i will not be in $D(R)$. Let B_i be the set containing intervals that start during interval i and also i . The following fact will be useful for applying submodularity.

► **Lemma 13.** *For any set $S' \subseteq S$ consider $\{S' \setminus B_i\}_{i \in O}$, a collection of subsets of S' . It is the case that every interval in S' appears in exactly $|O| - 1$ sets in this collection. Further, each interval in S appears in exactly one set B_i .*

Proof. To show the lemma, it suffices to show that every interval in S appears in exactly one set B_i for some $i \in O$. Indeed, we may assume that the intervals in O span the entire time horizon (adding dummy intervals as needed). Then, an interval $j \in S$ can only be in B_i if j starts during i . Knowing that O cannot have two intervals that overlap, we have the lemma. \blacktriangleleft

The next lemma is a technical lemma. The purpose is to take an expression $f(D(S') \setminus B_i)$ depending on a set S' and B_i for $i \in O$ and bound it by an expression depending on $f(D(S'))$ without B_i inside the function input. The lemma follows from submodularity and the previous lemma.

► **Lemma 14.** *Fix any set $S' \subseteq S$. It is the case that $\delta f(D(S')) \geq \sum_{i \in O} \beta_i (f(D(S')) - f(D(S') \setminus B_i))$.*

Proof. Consider the term $\sum_{i \in O} \beta_i (f(D(S')) - f(D(S') \setminus B_i))$. We will remove all negative terms as they only makes the expression smaller. Let O' be all i where $f(D(S')) - f(D(S') \setminus B_i) > 0$. The lemma follows if we prove that $f(D(S')) \geq \sum_{i \in O'} (f(D(S')) - f(D(S') \setminus B_i))$ because this implies $\delta f(D(S')) \geq \delta \sum_{i \in O'} (f(D(S')) - f(D(S') \setminus B_i)) \geq \sum_{i \in O'} \beta_i (f(D(S')) - f(D(S') \setminus B_i))$ knowing that $\beta_i \leq \delta$ and all terms are positive.

Now it is established that $f(D(S')) \geq \sum_{i \in O'} (f(D(S')) - f(D(S') \setminus B_i))$, which follows by submodularity. Indeed, let $A_0 = D(S') \setminus \cup_{i \in O'} B_i$. Arbitrarily order the sets $B_1, B_2, \dots, B_{|O'|}$ and let $A_i = A_{i-1} \cup (B_i \cap D(S'))$ for $1 \leq i \leq |O'|$. By submodularity, $\sum_{i \in O'} (f(D(S')) - f(D(S') \setminus B_i)) \leq \sum_{i \in O'} (f(A_i) - f(A_{i-1})) = f(D(S')) - f(A_0) \leq f(D(S'))$. The equality follows from the function being positive and the inequality from submodularity. \blacktriangleleft

Assuming \mathcal{E}_i occurs, the purpose of the following lemma is to separate the cases where at least one interval in E_i is in R and the other where no interval in E_i is in R . Intuitively, if no interval in E_i is in R then i will be in $D(R)$ otherwise i will not. In either case, when \mathcal{E}_i occurs the interval i ensures no interval in B_i is in $D(R)$ and the lemma bounds the cost of removing B_i by applying Lemma 14. The proof is deferred to Section 6.

► **Lemma 15.** *It is the case that,*

$$G(y+v) \geq (1-\delta)G(y) + \sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] \sum_{i \in O, S' \cap E_i = \emptyset} \beta_i(f(D(S') \setminus B_i \cup \{i\}) - f(D(S') \setminus B_i)) - O((n\delta)^2 f(O)).$$

Our goal now is to bound the second term in the previous lemma by showing this following. This shows that the second term is at least $\frac{\delta}{e^t}$ multiplied by the expected value of adding each element of O to R individually.

► **Lemma 16.** $\sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] \sum_{i \in O, S' \cap E_i = \emptyset} \beta_i(f(D(S') \setminus B_i \cup \{i\}) - f(D(S') \setminus B_i)) \geq \frac{\delta}{e^t} \sum_{S' \subseteq S} \Pr[R = S'] \sum_{i \in O} f_{S'}(i)$

Before we prove the lemma, we show how this can be used to complete the proof of Lemma 7.

Proof of Lemma 7. By combining lemmas 15 and 16 we have the following.

$$\begin{aligned} G(y+v) &\geq (1-\delta)G(y) + \frac{\delta}{e^t} \sum_{S' \subseteq S} \Pr[R = S'] \sum_{i \in O} f_{S'}(i) - O((n\delta)^2 f(O)) \\ &\geq (1-\delta)G(y) + \frac{\delta}{e^t} \mathbb{E} \left[\sum_{i \in O} f_R(i) \right] - O((n\delta)^2 f(O)) \end{aligned}$$

This completes the proof. ◀

It only remains to prove Lemma 16.

Proof of Lemma 16. Consider the term $\sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] \sum_{i \in O, S' \cap E_i = \emptyset} \beta_i(f(D(S') \setminus B_i \cup \{i\}) - f(D(S') \setminus B_i))$. Rearranging the summations and using the definition of $f_{S'}(i)$ this is equal to $\sum_{i \in O} \sum_{S' \subseteq S, S' \cap E_i = \emptyset} \Pr[R = S' \mid \mathcal{E}_i] \beta_i f_{D(S') \setminus B_i}(i)$. We know that for any set $S' \subseteq S$ if $S' \cap E_i = \emptyset$ then $S' \subseteq (S \setminus E_i)$. Using this, the term is equal to the following.

$$\begin{aligned} &\sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} \beta_i \Pr[R = S' \mid \mathcal{E}_i] f_{D(S') \setminus B_i}(i) \\ &= \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} \beta_i \Pr[S' = R \setminus E_i \text{ and } R \cap E_i = \emptyset \mid \mathcal{E}_i] f_{D(S') \setminus B_i}(i) \end{aligned}$$

To see why the previous equality holds, notice that $R = S'$ if and only if $S' = R \setminus E_i$ and $R \cap E_i = \emptyset$ for $S' \subseteq (S \setminus E_i)$. Now we continue to lower bound this expression.

$$\begin{aligned} &\sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} \beta_i \Pr[S' = R \setminus E_i \mid \mathcal{E}_i] \Pr[R \cap E_i = \emptyset \mid \mathcal{E}_i] f_{D(S') \setminus B_i}(i) \\ &\quad \text{[Definition of } R \text{ implies independence]} \\ &= \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} \beta_i \Pr[S' = R \setminus E_i] \Pr[R \cap (E_i \setminus \{i\}) = \emptyset] f_{D(S') \setminus B_i}(i) \\ &\quad \text{[Definition of } \mathcal{E}_i \text{]} \\ &\geq \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} \frac{\beta_i}{e^{t-y^i}} \Pr[S' = R \setminus E_i] f_{D(S') \setminus B_i}(i) \quad \text{[Lemma 5]} \\ &= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} (1-y^i) \Pr[R = S' \setminus E_i] f_{D(S') \setminus B_i}(i) \quad \text{[Definition of } \beta_i \text{]} \quad (2) \end{aligned}$$

3:12 Submodular Optimization with Contention Resolution Extensions

Notice that $1 = \sum_{E \subseteq E_i} \Pr[R \cap E_i = E \mid i \notin R]$ because the right hand side captures all the events in a probability distribution. Further, fix an element $i \in O$ and notice that for any set $S' \subseteq (S \setminus E_i)$ and any set $E \subseteq E_i$ it is the case that $\Pr[S' = R \setminus E_i] \cdot \Pr[R \cap E_i = E \mid i \notin R] = \Pr[R = S' \cup E \mid i \notin R]$. This follows for two reasons. One is because elements are sampled independently. The other is because $\Pr[S' = R \setminus E_i] = \Pr[S' = R \setminus E_i \mid i \notin R]$ since $i \in E_i$ and the independence of sampling elements. Using these facts, the following holds.

$$\begin{aligned}
(2) &= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} (1 - y^i) \Pr[S' = R \setminus E_i] f_{D(S') \setminus B_i}(i) \sum_{E \subseteq E_i} \Pr[R \cap E_i = E \mid i \notin R] \\
&= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} (1 - y^i) f_{D(S') \setminus B_i}(i) \sum_{E \subseteq E_i} \Pr[R = S' \cup E \mid i \notin R] \\
&\quad \text{[Independence]} \\
&\geq \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} (1 - y^i) f_{S' \setminus B_i}(i) \sum_{E \subseteq E_i} \Pr[R = S' \cup E \mid i \notin R] \\
&\quad \text{[Submodularity]} \\
&\geq \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus E_i)} (1 - y^i) \sum_{E \subseteq E_i} f_{(S' \cup E) \setminus \{i\}}(i) \Pr[R = S' \cup E \mid i \notin R] \\
&\quad \text{[Submodularity and } i \in B_i\text{]} \\
&= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus \{i\})} (1 - y^i) f_{S' \setminus \{i\}}(i) \Pr[R = S' \mid i \notin R] \\
&= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq (S \setminus \{i\})} f_{S' \setminus \{i\}}(i) \Pr[R = S'] \\
&\quad \text{[}(1 - y^i) = \Pr[i \notin R]\text{ and definition of conditional probability]} \\
&= \frac{\delta}{e^t} \sum_{i \in O} \sum_{S' \subseteq S} f_{S'}(i) \Pr[R = S'] \quad [f_{S'}(i) = 0 \text{ if } i \in S']
\end{aligned}$$

◀

5 Proof of Lemma 11

This section is devoted to proving Lemma 11.

Consider $G(y + v)$. The value of $G(y + v)$ is equal to $\sum_{S' \subseteq S} \sum_{I' \subseteq I} \Pr[R = S' \text{ and } \mathcal{E}(I')] f(D(S' \cup I'))$. This is equal to the following by breaking this into cases. This is a partitioning of the event space by definition of $\mathcal{E}(I')$.

$$\begin{aligned}
&\sum_{S' \subseteq S} \Pr[R = S' \text{ and } \mathcal{E}(\emptyset)] f(D(S')) \\
&+ \sum_{i \in I} \sum_{S' \subseteq S} \Pr[R = S' \text{ and } \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\
&+ \sum_{I' \subseteq I, |I'| \geq 2} \sum_{S' \subseteq S} \Pr[R = S' \text{ and } \mathcal{E}(I')] f(D(S' \cup \{i\}))
\end{aligned}$$

Knowing that f is positive, this is greater than the following.

$$\sum_{S' \subseteq S} \Pr[R = S' \text{ and } \mathcal{E}(\emptyset)] f(D(S')) \tag{3}$$

$$+ \sum_{i \in I} \sum_{S' \subseteq S} \Pr[R = S' \text{ and } \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \tag{4}$$

The proof bounds these two terms separately. First consider (3). Using Claim 10 this is greater than $\sum_{S' \subseteq S} (1 - \sum_{i \in I \setminus S'} \frac{\beta_i}{1-y^i}) \Pr[R = S'] f(D(S')) = G(y) - \sum_{i \in I} \frac{\beta_i}{1-y^i} \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S'))$. The definition of β_i gives that this is equal to $G(y) - \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S')) - \sum_{i \in I} y^i e^{-y^i} \delta \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S'))$. We will establish that this is only greater than $(1 - \sum_{i \in I} \beta_i) G(y)$. Consider the last term.

$$\begin{aligned} & \sum_{i \in I} y^i e^{-y^i} \delta \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S')) \\ = & \sum_{i \in I} y^i e^{-y^i} \delta \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] \Pr[i \notin R] f(D(S')) \\ = & \sum_{i \in I} y^i e^{-y^i} (1 - y^i) \delta \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S')) \\ = & \sum_{i \in I} y^i \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S')) \end{aligned}$$

By definition of the algorithm $\frac{w_i}{\beta_i} = \mathbb{E}[f(D(R \cup \{i\})) - f(D(R))] = \sum_{S' \subseteq S} \Pr[R = S'] (f(D(S' \cup \{i\})) - f(D(S')))$. The last equality follows since a term is 0 if i is in S' . Since elements are sampled independently, this gives that the previous term is only less than the following.

$$\begin{aligned} & \sum_{i \in I} y^i \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S')) \\ \leq & \sum_{i \in I} y^i \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S' \cup \{i\})) \\ = & \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S' \cup \{i\}] f(D(S' \cup \{i\})) \quad [\text{Note that } \Pr[i \in R] = y_i] \end{aligned}$$

Now we use this to bound (3). (3) is greater than or equal to the following.

$$\begin{aligned} & G(y) - \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S')) - \sum_{i \in I} y^i e^{-y^i} \delta \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S')) \\ \geq & G(y) - \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S'] f(D(S')) - \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S' \cup \{i\}] f(D(S' \cup \{i\})) \\ = & (1 - \sum_{i \in I} \beta_i) G(y) \end{aligned}$$

It remains to bound (4). Using conditional probability, this can be bounded as follows.

$$\begin{aligned} & \sum_{i \in I} \Pr[\mathcal{E}(\{i\})] \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\ = & \sum_{i \in I} \Pr[\mathcal{E}_i] \prod_{j \in I, j \neq i} \Pr(\bar{\mathcal{E}}_j) \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\ = & \sum_{i \in I} \beta_i \prod_{j \in I, j \neq i} (1 - \beta_j) \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\ \geq & \prod_{i \in I} (1 - \beta_i) \sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\ \geq & (1 - \sum_{i \in I} \beta_i) \sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \end{aligned}$$

3:14 Submodular Optimization with Contention Resolution Extensions

Knowing that $\beta_i \leq \delta$, this is greater than $\sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) - O(\delta^2 n^2 f(O))$.

Now we know that,

$$\begin{aligned}
& \sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}(\{i\})] f(D(S' \cup \{i\})) \\
&= \sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}_i \text{ and } \bar{\mathcal{E}}_j \text{ for } j \neq i] f(D(S' \cup \{i\})) \quad [\text{Def. of } \mathcal{E}(\{i\})] \\
&\geq \sum_{i \in I} \beta_i \prod_{j \in I, j \neq i} (1 - \beta_j) \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) \quad [\text{Claim 9 and independence}] \\
&\geq \sum_{i \in I} \beta_i \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) - |I| \delta^2 f(O) \\
&\geq \sum_{i \in I} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) - |I| \delta^2 f(O)
\end{aligned}$$

The last line follows since if \mathcal{E}_i occurs then R does not contain i . Putting this all together gives the lemma.

6 Proof of Lemma 15

This section is devoted to proving Lemma 15.

Consider the following expression. Lemma 12 gives the following.

$$G(y + v) \geq \sum_{S' \subseteq S} \sum_{i \in O} \beta_i \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) \quad (5)$$

$$+ (1 - \sum_{i \in O} \beta_i) G(y). \quad (6)$$

We see that (5) equals the following.

$$\begin{aligned}
& \sum_{i \in O} \beta_i \left(\sum_{S' \subseteq S, S' \cap E_i = \emptyset} \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) \right. \\
& \quad \left. + \sum_{S' \subseteq S, S' \cap E_i \neq \emptyset} \Pr[R = S' | \mathcal{E}_i] f(D(S' \cup \{i\})) \right)
\end{aligned}$$

By definition of G , for any set $S' \subseteq S$ it is the case that $D(S' \cup \{i\})$ includes i only if S' includes no interval in $E_i \setminus \{i\}$. We also know that for any $j \in S'$ it is the case that $j \in D(S' \cup \{i\})$ if and only if $j \in D(S')$ and $j \notin B_i$. Using these two facts, the previous term is equal to the following.

$$\begin{aligned}
& \sum_{i \in O} \beta_i \left(\sum_{S' \subseteq S, S' \cap E_i = \emptyset} \Pr[R = S' | \mathcal{E}_i] f(D(S') \setminus B_i \cup \{i\}) \right. \\
& \quad \left. + \sum_{S' \subseteq S, S' \cap E_i \neq \emptyset} \Pr[R = S' | \mathcal{E}_i] f(D(S') \setminus B_i) \right)
\end{aligned}$$

This is equal to the following.

$$\begin{aligned}
& \sum_{i \in O} \beta_i \left(\sum_{S' \subseteq S, S' \cap E_i = \emptyset} \Pr[R = S' | \mathcal{E}_i] \left(f(D(S') \setminus B_i \cup \{i\}) - f(D(S') \setminus B_i) \right) \right. \\
& \quad \left. + \sum_{S' \subseteq S} \Pr[R = S' | \mathcal{E}_i] f(D(S') \setminus B_i) \right)
\end{aligned}$$

We focus on bounding $\sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] f(D(S') \setminus B_i)$ along with (6). The rest of the expression is carried to the end of the proof. First we establish a bound on $\sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] f(D(S') \setminus B_i)$ in the following claim and then it is combined with (6). The purpose of the following claim is to remove the conditioning on \mathcal{E}_i .

▷ **Claim 17.** $\sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] f(D(S') \setminus B_i) = \sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S'] f(D(S') \setminus B_i)$.

Proof. First note that $\Pr[R = S' \mid \mathcal{E}_i] > 0$ if and only if $i \notin S'$. Thus we have that the left hand side is equal to $\sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R = S' \mid \mathcal{E}_i] f(D(S') \setminus B_i)$. Using the definition of conditional probability and the definition of \mathcal{E}_i this is equal to $\sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \frac{\Pr[R \setminus \{i\} = S' \text{ and } \mathcal{E}_i]}{\Pr[\mathcal{E}_i]} f(D(S') \setminus B_i)$. By independence, this equals $\sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S') \setminus B_i) = \sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} \Pr[R \setminus \{i\} = S'] f(D(S') \setminus B_i) (\Pr[i \in R] + \Pr[i \notin R]) = \sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} (\Pr[R = S'] + \Pr[R = S' \cup \{i\}]) f(D(S') \setminus B_i)$.

We know that for any $S' \subseteq S \setminus \{i\}$ it is the case that $f(D(S') \setminus B_i) = f(D(S' \cup \{i\}) \setminus B_i)$ because B_i is the set of intervals that are not in the contention resolution scheme if i is input and also i is in B_i . Using this, we have that the previous expression is equal to $\sum_{i \in O} \beta_i \sum_{S' \subseteq S \setminus \{i\}} (\Pr[R = S'] f(D(S') \setminus B_i) + \Pr[R = S' \cup \{i\}] f(D(S' \cup \{i\}) \setminus B_i)) = \sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S'] f(D(S') \setminus B_i)$. ◁

Going back to $\sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S' \mid \mathcal{E}_i] f(D(S') \setminus B_i)$ with the expansion of (6) using the definition of G and the previous claim, we have the following.

$$\sum_{i \in O} \beta_i \sum_{S' \subseteq S} \Pr[R = S'] f(D(S') \setminus B_i) + (1 - \sum_{i \in O} \beta_i) \sum_{S' \subseteq S} \Pr[R = S'] f(D(S'))$$

We apply Lemma 14 for each term S' to get that this is greater than the following.

$$(1 - \delta) \sum_{S' \subseteq S} \Pr[R = S'] f(D(S')) = (1 - \delta) G(y)$$

The above gives that $G(y + v) \geq (1 - \delta) G(y) + \sum_{i \in O} \beta_i \sum_{S' \subseteq S, S' \cap E_i = \emptyset} \Pr[R = S' \mid \mathcal{E}_i] (f(D(S') \setminus B_i \cup \{i\}) - f(D(S') \setminus B_i))$, giving the lemma.

7 Conclusion

This paper introduces the approach of using contention resolution extensions to optimize a submodular function subject to a set of constraints. This algorithmic approach can be used to improve the best known result when the constraints correspond to independent sets in an interval graph. The next direction is to determine if this approach can be used to improve on the best known approximation for other submodular optimization problems.

A

 Omitted Proofs

Proof of Claim 9. By definition $\Pr[i \in R \mid \bar{\mathcal{E}}_i] = \frac{\Pr[i \in R]}{1 - \beta_i}$. To see the other part of the claim, by definition of \mathcal{E}_i it is the case that $\Pr[i \notin R \mid \bar{\mathcal{E}}_i] = \frac{(1 - y^i - \beta_i)}{1 - \beta_i}$ and $(1 - \beta_i)\Pr[i \notin R] = (1 - \beta_i)(1 - y^i)$. For all $\beta_i \in [0, 1)$ it is the case that $\frac{(1 - y^i - \beta_i)}{1 - \beta_i} \geq (1 - \beta_i)(1 - y^i)$ if $0 \leq y^i \leq \frac{1 - \beta_i}{2}$. Finally, $0 \leq y^i \leq \frac{1 - \delta}{2} \leq \frac{1 - \beta_i}{2}$ when $t \leq \ln 2 - \delta$. This is because $t \leq \ln 2 - \delta$ by assumption and Lemma 4 states that any entry in y is at most $1 - e^{-t} \leq 1 - e^{-(\ln 2 - \delta)} \leq \frac{1 - \delta}{2}$.

Now consider the second part of the lemma. Recall that $\mathcal{E}(\{i\})$ is the event where \mathcal{E}_i occurs as well as $\bar{\mathcal{E}}_j$ for all $j \in I$ where $j \neq i$. We have the following.

$$\Pr[S' = R \mid \mathcal{E}(\{i\})] = \frac{\Pr[S' = R \text{ and } \mathcal{E}(\{i\})]}{\Pr[\mathcal{E}(\{i\})]}$$

By independence this equals the following.

$$\begin{aligned} & \frac{\Pr[S' \setminus I = R \setminus I]}{\Pr[\mathcal{E}(\{i\})]} \Pr[\{i\} \cap S' = \{i\} \cap R \text{ and } \mathcal{E}_i] \prod_{j \in I, j \in S', j \neq i} \Pr[j \in R \text{ and } \bar{\mathcal{E}}_j] \\ & \cdot \prod_{j \in I, j \notin S', j \neq i} \Pr[j \notin R \text{ and } \bar{\mathcal{E}}_j] \end{aligned}$$

By independence we know that $\Pr[\mathcal{E}(\{i\})] = \Pr[\mathcal{E}_i] \prod_{j \in I, j \neq i} \Pr[\bar{\mathcal{E}}_j]$. Using this and conditional probability, the prior term is equal to the following.

$$\begin{aligned} & \frac{\Pr[S' \setminus I = R \setminus I]}{\Pr[\mathcal{E}_i]} \Pr[\{i\} \cap S' = \{i\} \cap R \text{ and } \mathcal{E}_i] \prod_{j \in I, j \in S', j \neq i} \Pr[j \in R \mid \bar{\mathcal{E}}_j] \\ & \cdot \prod_{j \in I, j \notin S', j \neq i} \Pr[j \notin R \mid \bar{\mathcal{E}}_j] \end{aligned}$$

The first argument shown in the lemma gives that this is at least the following. This argument allows us to remove the conditioning on $\bar{\mathcal{E}}_j$.

$$\begin{aligned} & \prod_{j \neq i, j \in I} (1 - \beta_j) \frac{\Pr[S' \setminus I = R \setminus I]}{\Pr[\mathcal{E}_i]} \Pr[\{i\} \cap S' = \{i\} \cap R \text{ and } \mathcal{E}_i] \prod_{j \in I, j \in S', j \neq i} \Pr[j \in R] \\ & \cdot \prod_{j \in I, j \notin S', j \neq i} \Pr[j \notin R] \end{aligned}$$

Using independence, this is equal to the following.

$$\prod_{j \neq i, j \in I} (1 - \beta_j) \frac{\Pr[S' = R \text{ and } \mathcal{E}_i]}{\Pr[\mathcal{E}_i]}$$

Finally, conditional probability gives the following.

$$\prod_{j \neq i, j \in I} (1 - \beta_j) \Pr[S' = R \mid \mathcal{E}_i]$$

Abstract

In this paper we study how to optimally balance cheap inflexible resources with more expensive, reconfigurable resources despite uncertainty in the input problem. Specifically, we introduce the **MinEMax** model to study “build versus rent” problems. In our model different scenarios appear independently. Before knowing which scenarios appear, we may build rigid resources that cannot be changed for different scenarios. Once we know which scenarios appear, we are allowed to rent reconfigurable but expensive resources to use across scenarios. Although computing the objective in our model might seem to require enumerating exponentially-many possibilities, we show it is well estimated by a surrogate objective which is representable by a polynomial-size LP. In this surrogate objective we pay for each scenario only to the extent that it exceeds a certain threshold. Using this objective we design algorithms that approximately-optimally balance inflexible and reconfigurable resources for several NP-hard covering problems. For example, we study variants of minimum spanning and Steiner trees, minimum cuts, and facility location. Up to constants, our approximation guarantees match those of previously-studied algorithms for demand-robust and stochastic two-stage models. Lastly, we demonstrate that our problem is sufficiently general to smoothly interpolate between previous demand-robust and stochastic two-stage problems.

1 Introduction

Optimizing for reconfigurable resources under uncertainty formalizes the challenges of balancing expensive, flexible resources with cheap, inflexible ones. For example, such optimization problems formalize the challenges in “build versus rent” problems. Concretely, consider the algorithmic challenges faced by an Internet service provider (ISP). An ISP must provide content to its customers while balancing between rigid and reconfigurable resources. In particular, it can build out its own network – a rigid resource – or choose to support traffic on a competitor’s network – a flexible resource – at a marked up premium. This latter resource is reconfigurable since an ISP can change which edges in a competitor’s network it uses at any given time. To minimize the additional load on its network, the competitor charges the ISP for the maximum extra bandwidth it must support at any given moment. Furthermore, an ISP only has probabilistic knowledge of where customer demands will occur: Based on where previous demands have occurred an ISP estimates future demands, but it does not exactly know the future demands. If a demand occurs which the ISP’s network cannot service, it must use the competitor’s network to support it. Thus, an ISP balances rigid and flexible resources in the face of uncertainty, and pays for the cost of its own network plus the cost of supporting the *expected maximum* traffic routed on its competitor’s network.

In this paper, we introduce the MinEMax model to study the algorithmic challenges associated with optimizing reconfigurable resources under uncertainty. In our model we are given a set of *scenarios* that might occur. In the preceding example these scenarios were the sets of possible demands. We think of problems in our model as being divided between a first stage where we “build” rigid resources and a second stage where we “rent” flexible resources. In particular, in the first stage we can build non-reconfigurable resources without knowing which scenarios occur. In the second stage, each scenario independently realizes according to its specified Bernoulli probability, and we can rent reconfigurable resources at an increased cost to use among any of our scenarios. For instance, in the preceding example the ISP first built its own network and then, once it learned where demands occurred, it could rent bandwidth to support different demands over time. In fact, this example is exactly our MinEMax Steiner tree problem. Thus, the objective we minimize is the first stage cost plus the *expected maximum* cost of additional reconfigurable resources required for any realized scenario; hence the name of our model.

Since every scenario is an independent Bernoulli, there are exponentially-many ways in which scenarios realize. It is not even clear how to efficiently compute the expected second-stage cost. Nonetheless, we provide techniques to simplify and reason about the MinEMax cost, and therefore solve various MinEMax problems.

The primary contributions of our work are as follows.

1. We introduce the MinEMax model for optimization of reconfigurable resources under uncertainty.
2. We show that, although evaluating the MinEMax objective function may seem difficult, a MinEMax problem can be approximately reduced to a “TruncatedTwoStage” problem whose objective is representable by an LP.
3. Armed with 2, we adapt various rounding techniques to give approximation algorithms for a variety of two-stage MinEMax problems including spanning and Steiner trees, cuts, and facility location problems.
4. Lastly, we show that the MinEMax model captures the commonly studied two-stage models for optimization under uncertainty: the *stochastic* and *demand-robust* models. We even show that it generalizes a “Hybrid” problem that interpolates between these models.

1.1 Related Work

Significant work has been done in two-stage optimization under uncertainty. The two most commonly studied models are the stochastic model [22, 15, 24] and the demand-robust model [9, 4, 14, 13]. In the **stochastic two-stage model** a probability distribution is given over scenarios and our objective is the *expected* total cost. In the **demand-robust** two-stage model we are given scenarios and our objective is the cost of the *worst-case* scenario given our first stage solution.

Another related model is *Distributionally robust optimization* (DRO) [23, 12, 8, 5]. In DRO we are given a distribution along with a ball of “nearby” distributions, and we must pay the *worst-case expectation* over all these distributions. Similarly to our model, DRO generalizes both the stochastic and demand-robust two-stage models. Our model can be seen as a “flip” of the DRO model: while the DRO model takes the worst-case over distributions our model takes a distribution over worst cases. Like DRO, our model is also sufficiently general to capture stochastic and demand-robust optimization. A recent result [20] – which shows that approximation algorithms are possible in DRO – complements our approximation algorithms in MinEMax.

A well studied measure for risk-aversion from stochastic programming is *conditional value at risk* (CVaR) [1]. Roughly, CVaR gives the average cost in the worst-case case α tail of a distribution. A notable recent work in CVaR presents a data-driven approach to two-stage risk aversion [18]. Theorem 1 in their work is reminiscent of our reduction of MinEMax to Hybrid; this theorem shows that their objective can be reformulated as a combination of the CVaR cost and the worst-case distribution. We emphasize that while CVaR might appear similar to the TruncatedTwoStage metric studied in this work, these two metrics are distinct and not readily comparable. Two salient differences are: (1) the threshold in the TruncatedTwoStage objective is the minimizing threshold while in CVaR the threshold is fixed, and (2) the TruncatedTwoStage objective sums up the truncated cost over a set of Bernoulli random variables whereas CVaR takes a truncated average cost with respect to a single distribution. Moreover, to the best of our knowledge, CVaR has not been studied in the context of approximation algorithms.

Several additional models for optimization under uncertainty – some of which even interpolate between stochastic and demand-robust – have also been studied. A series of papers [26, 25, 27] examined various models of two-stage optimization that capture risk-aversion. Notably, the model of [27] interpolates between stochastic and demand-robust while also accommodating *black-box* distributions. Other papers (e.g., [15]) studied algorithms for stochastic optimization given access to black-box distributions. There has also been work on two-stage stochastic models in which – as in our model – independent stochastic outcomes factor prominently. For example, Immorlica et al. [17] study a two-stage stochastic model in which each “client” activates independently and the realized scenario consists of all activated clients. The primary difference between their model and ours is that for us entire scenarios – rather than clients – activate independently. Moreover, reconfigurability of resources is not factored in their model.

Lastly, in our reduction from MinEMax to TruncatedTwoStage, we make use of a bound which has appeared before in other settings [19, 21, 6, 11]. For example, [6] use this bound to tightly estimate the optimum value in an optimization problem where the cost function is random and only marginal distributions for the coefficients of the cost function are known. Unlike our work, these works do not design approximation algorithms for two-stage problems.

1.2 Models

We now formally define our new MinEMax model and the prior models that we generalize. We study two-stage covering problems, defined as follows.

1.2.1 Two-Stage Covering

Let U be the universe of *clients* (or demand requirements), and let X be the set of *elements* that we can purchase. Every scenario S_1, S_2, \dots, S_m is a subset of clients. Let $\text{sol}(S_s)$ for $s \in [m]$ denote the sets in 2^X which are feasible to *cover* scenario S_s . In covering problems if $A \subseteq B$ and $A \in \text{sol}(S_s)$, then $B \in \text{sol}(S_s)$. We are also given a cost function $\text{cost} : 2^X \times 2^X \rightarrow \mathbb{R}$. For a given a specification of cost, scenarios, clients, and feasibility constraints, we must find a set of elements $X_1 \subseteq X$ to be bought in the first stage, and a set of elements $X_2^{(s)} \subseteq X$ to be bought in the second stage s.t. $X_1 \cup X_2^{(s)} \in \text{sol}(S_s)$ for every s . Our goal is to find a solution of minimal cost where the cost of a solution is discussed below.

This paper makes the common assumption that cost is *linear*, i.e., $\text{cost}(X_1, X_2^{(s)})$ equals $\text{cost}(\emptyset, X_2^{(s)}) + \text{cost}(X_1, \emptyset)$ for any $X_1, X_2^{(s)} \subseteq 2^X$. Let $\mathbf{X}_2 := (X_2^{(1)}, \dots, X_2^{(m)})$; throughout the paper a bold variable denotes a vector.

We now describe and discuss how different cost functions yield different two-stage covering models.

1.2.2 Prior Models

In the *demand-robust* two-stage covering model the cost of solution (X_1, \mathbf{X}_2) is the maximum cost over all the scenarios:

$$\text{cost}_{\text{Rob}}(X_1, \mathbf{X}_2) := \max_{s \in [m]} \left\{ \text{cost}(X_1, X_2^{(s)}) \right\}. \quad (1)$$

In the *stochastic* two-stage covering model we are given a probability distribution \mathcal{D} over m scenarios with which exactly one of them realizes; i.e. $\sum_{s \in [m]} \mathcal{D}(s) = 1$. The cost of solution (X_1, \mathbf{X}_2) is the expected cost:

$$\text{cost}_{\text{Stoch}}(X_1, \mathbf{X}_2) := \mathbb{E}_{s \sim \mathcal{D}} [\text{cost}(X_1, X_2^{(s)})]. \quad (2)$$

1.2.3 Our New MinEMax Model

In the MinEMax two-stage covering model we are given probabilities $\mathbf{p} = \{p_1, \dots, p_m\}$ with which each scenario *independently* realizes. The cost of solution (X_1, \mathbf{X}_2) is the expected maximum cost among the realized scenarios:

$$\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2) := \mathbb{E}_{A \sim \mathbf{p}} \left[\max_{s \in A} \left\{ \text{cost}(X_1, X_2^{(s)}) \right\} \right] \quad (3)$$

where A contains each s independently w.p. p_s . To avoid confusion, we reiterate that unlike the stochastic model, in MinEMax multiple scenarios may simultaneously appear in A because each of them independently realizes. We shall assume without loss of generality that $\sum_s p_s \geq 1$ throughout this paper since one can always ensure this without affecting solutions to the problem by adding dummy scenarios of cost 0 and probability 1.

As a concrete example of these models, consider the following star covering problem. We are given a star graph with root r and leaves v_1, \dots, v_m . Each edge $e_i = (r, v_i)$ can be purchased in the first stage at cost c_i and in the second stage at an inflated cost $\sigma \cdot c_i$ for $\sigma > 1$. Our goal is to connect r to an *unknown* vertex v_s with minimum total two-stage cost.

(a) If scenario to be covered is known to be v_1 , problem is trivial. (b) Exactly one scenario realizes according to probability distribution. (c) Given first stage soln., adversary chooses costliest scenario. (d) Given first stage soln., adversary chooses costliest realized scenario.

■ **Figure 1** Star graph MinEMax for $m = 4$. Green edges: edges bought by solution. e_i labeled by its cost in each stage for $\sigma = 2$. Non-opaque second-stage node: realized scenario. Blue square: probability of scenario. Dashed red nodes: nodes chosen by an adversary.

In particular, v_s is only revealed after we purchase our first-stage edges, X_1 , at which point we must purchase e_s in a second stage at cost $\sigma \cdot c_s$ if e_s was not already purchased in the first stage. In all three models we initially buy some set of edges. In the stochastic version of this problem a single v_s then appears according to a distribution and we must pay to connect v_s if we have not already. In the demand-robust version of this problem, v_s is always chosen so as to maximize our second stage cost. However, in our MinEMax version of this problem several v_s appear and we must pay for a budget of reconfigurable edge resources to be reused for every v_s . See Figure 1 for an illustration.

1.3 Technical Results and Intuition

We now discuss our technical results. As earlier noted, capturing the MinEMax objective seems challenging: scenarios may realize in exponentially-many ways and so even computing the objective seems computationally infeasible. We solve this issue by showing that to solve a MinEMax problem, P_{EMax} , it suffices to solve its TruncatedTwoStage version, P_{Trunc} . A TruncatedTwoStage problem is identical to a MinEMax problem but the cost of a solution (X_1, X_2) is its truncated sum:

$$\text{cost}_{Trunc}(X_1, X_2) := \min_B \left[B + \sum_{s \in [m]} p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - B)^+ \right]. \quad (4)$$

We will later see that P_{Trunc} can be represented by an LP and, therefore, can be efficiently approximated by various rounding techniques. The following theorem shows that to approximate a MinEMax problem, it suffices to consider its TruncatedTwoStage version.

► **Theorem 1.** *Let P_{EMax} be a MinEMax problem and let P_{Trunc} be its TruncatedTwoStage version. An α -approximation algorithm for P_{Trunc} is a $\left(\frac{\alpha}{1-1/e}\right)$ -approximation algorithm for P_{EMax} .*

The main observation we use to show this theorem is that a set of expensive scenarios with large total probability mass dominates the cost of a given MinEMax solution. We illustrate this observation with an example. Let (X_1, X_2) be a solution for a MinEMax problem. Now WLOG let $\text{cost}(X_1, X_2^{(s)}) \geq \text{cost}(X_1, X_2^{(s+1)})$ for all s , i.e., the s th scenario is more expensive than the $(s + 1)$ th scenario for our solution. Let $M := [k]$ be the indices of the first k scenarios such that $\sum_{s \leq k} p_s$ is large; say, at least 1. Let the border $B := \text{cost}(X_1, X_2^{(k)})$ be the cost of the least expensive scenario with an index in M . Because there is a great deal of

4:6 Prepare for the Expected Worst

probability mass among scenarios in M we know that with large probability some scenario in M will always appear. Whenever a scenario of cost less than B appears we know that with good probability something in M has also appeared of greater cost. Thus, as far as the expected max is concerned, a scenario that costs less than B can be ignored. Lastly, while it is not immediately clear how to represent $\text{cost}_{\text{Trunc}}$ function in an LP, we show using a simple convexity argument how this can be accomplished.

Next, we design approximation algorithms for two-stage covering problems in the MinEMax model.

► **Theorem 2.** *For two-stage covering problems there exist polynomial-time approximation algorithms with the following guarantees.¹*

MinEMax Problem	Steiner tree	UFL	MST	Min-cut	k -center
Approximation	$\frac{30}{1-1/e}$	$\frac{8}{1-1/e}$	$O(\log n + \log m)$	$\frac{4}{1-1/e}$	$O(1)$

Our earlier Theorem 1 demonstrated that to solve a MinEMax problem, P_{EMax} , we need to only solve its TruncatedTwoStage version, P_{Trunc} . While it is not clear how to represent P_{EMax} with an LP, P_{Trunc} can be represented with an LP. Furthermore, by adapting previous two-stage optimization rounding techniques to the TruncatedTwoStage setting, we are able to approximately solve the TruncatedTwoStage versions of uncapacitated facility location (UFL), Steiner tree, minimum spanning tree (MST), and min-cut. We defer details on min-cut to the full version of our paper.

We use different techniques to give an approximation algorithm for k -center. The intuition for our k -center proof is similar to that of Theorem 1: Truncated costs approximate MinEMax cost. However, for k -center we truncate more aggressively. Rather than truncating costs of scenarios, we truncate distances in the input metric. To do this, we draw on methods of Chakrabarty and Swamy [7].²

It is also worth noting that Anthony et al. [4] proved hardness of approximation for a two-stage k -center problem. In particular, they show stochastic k -center where scenarios consist of *multiple* clients is as hard to approximate as dense k -subgraph. Thus, since our MinEMax model generalizes the stochastic model, we restrict our attention in k -center to scenarios consisting of *single* clients; otherwise our problem would be prohibitively hard to approximate. Since our scenarios consist of single clients the stochastic and demand-robust versions of the k -center problem we solve correspond to k -median and k -center respectively. We defer details on our k -center results to the full version of our paper.

Our last theorem shows that MinEMax generalizes the stochastic and demand-robust models as well as a Hybrid model which smoothly interpolates between stochastic and demand-robust optimization.

► **Theorem 3.** *An α -approximation for a two-stage covering algorithm in the MinEMax model implies an α -approximation for the corresponding two-stage covering problem in the stochastic, demand-robust, and Hybrid models.*

We defer a formal definition and discussion of the Hybrid model as well as the intuition and proof for Theorem 3 to the full version of our paper. As a corollary of Theorems 2 and 3, we immediately recover polynomial-time approximations for Hybrid MST, UFL, Steiner tree and min-cut.³

¹ The $O(1)$ in the k -center approximation is roughly 57.

² We also note here that, unlike the previous problems we study, the cost function in k -center is not linear as described in §1.2.

³ Though not k -center since its cost function is not linear.

■ **Figure 2** $M(X_1, \mathbf{X}_2)$. $B(X_1, \mathbf{X}_2) = \text{cost}(X_1, X_2^{(3)})$. Red circles: scenarios in $M(X_1, \mathbf{X}_2)$. Green circles: all other scenarios. Numbers in circles: probabilities. Scenarios arranged left to right in descending order of $\text{cost}(X_1, X_2^{(s)})$.

2 Reducing MinEMax to TruncatedTwoStage

In this section, we demonstrate a technique to simplify both computing and reasoning about $\text{cost}_{\text{EMax}}$ by reducing a MinEMax problem to a TruncatedTwoStage problem with only a small loss in the approximation factor. Specifically, we show the following theorem.

► **Theorem 1.** *Let P_{EMax} be a MinEMax problem and let P_{Trunc} be its TruncatedTwoStage version. An α -approximation algorithm for P_{Trunc} is a $\left(\frac{\alpha}{1-1/e}\right)$ -approximation algorithm for P_{EMax} .*

As earlier noted, we show this by observing that a set of expensive scenarios with “large” total probability mass dominates the cost of a given MinEMax solution.

We begin by observing that the expected max of a set of independent random variables is approximately bounded by the most expensive of these random variables whose probabilities sum to 1. We remark that this result can be seen to follow from results regarding the “correlation gap” [2, 3] which show a similar bound where instead of max we have any sub-modular function. We give a different proof in §A for completeness that we find simpler in our setting where we consider the max and not any sub-modular function.

► **Lemma 4.** *Let $\mathbf{Y} = \{Y_1, \dots, Y_m\}$ be a set of independent Bernoulli r.v.s, where Y_s is 1 with probability p_s , and 0 otherwise. Let $v_s \in \mathbb{R}_{\geq 0}$ be a value associated with Y_s . WLOG assume $v_s \geq v_{s+1}$ for $s \in [m-1]$. Let $b = \min\{a : \sum_{s=1}^a p_s \geq 1\}$. Then*

$$\left(1 - \frac{1}{e}\right) \left(v_b + \sum_s p_s \cdot (v_s - v_b)^+\right) \leq \mathbb{E}_{\mathbf{Y}} \left[\max_s \{Y_s \cdot v_s\}\right] \leq v_b + \sum_s p_s \cdot (v_s - v_b)^+,$$

where $x^+ := \max\{x, 0\}$.

For a given solution (X_1, \mathbf{X}_2) to MinEMax, Lemma 4 yields a computationally tractable form of $\text{cost}_{\text{EMax}}$. Specifically, let our scenarios be indexed such that $\text{cost}(X_1, X_2^{(s)}) \geq \text{cost}(X_1, X_2^{(s+1)})$ and let b be the smallest positive integer such that $\sum_{s=1}^b p_s \geq 1$. We define the following terms analogous to those in the lemma (see Figure 2 for an illustration):

$$M(X_1, \mathbf{X}_2) := [b] \quad \text{and} \quad B(X_1, \mathbf{X}_2) := \text{cost}(X_1, X_2^{(b)}). \tag{5}$$

Notice that $\sum_{s \in M(X_1, \mathbf{X}_2)} p_s < 2$. Now, by letting $B(X_1, \mathbf{X}_2)$ be v_b in Lemma 4, we can approximate $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2)$. However, we would like to estimate $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2)$ within an LP where (X_1, \mathbf{X}_2) are variables since our algorithms are LP based. Unfortunately, it is not clear how to capture v_b in an LP and so it is not clear how to directly use Lemma 4 to estimate $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2)$ within an LP.

4:8 Prepare for the Expected Worst

For this reason, we derive an even simpler form of the above approximation of the expected max which can be computed using an LP. In particular, we show that the expected max is approximately the $\text{cost}_{\text{Trunc}}$ objective. We remind the reader that, as per Eq.(4), $\text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2) := \min_B [B + \sum_{s \in [m]} p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - B)^+]$. The following lemma shows that the B achieving the minimum in $\text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2)$ is $B(X_1, \mathbf{X}_2)$ and therefore shows that $\text{cost}_{\text{Trunc}}$ is a good approximation of $\text{cost}_{\text{EMax}}$.

► **Lemma 5.** *Let (X_1, \mathbf{X}_2) be a solution to a TruncatedTwoStage or MinEMax problem. We have*

$$B(X_1, \mathbf{X}_2) = \arg \min_B \left[B + \sum_{s \in [m]} p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - B)^+ \right],$$

where the argmin takes the largest B minimizing the relevant quantity.

Proof Sketch. The rough idea of the proof is to show that $B + \sum_s p_s (\text{cost}(X_1, X_2^{(s)}) - B)^+$ is convex in B and that $B(X_1, \mathbf{X}_2)$ is a local minimum. In particular, imagine that B is currently set at $B(X_1, \mathbf{X}_2)$ and consider what happens to $B + \sum_s p_s (\text{cost}(X_1, X_2^{(s)}) - B)^+$ if we shift B to be smaller. Recall that we have at least one probability mass across elements which are larger than B by definition of $B(X_1, \mathbf{X}_2)$. Thus, when we shift B to be smaller, B decreases slower than $\sum_s p_s (\text{cost}(X_1, X_2^{(s)}) - B)^+$ increases and so $B + \sum_s p_s (\text{cost}(X_1, X_2^{(s)}) - B)^+$ becomes larger overall. The case when B is made larger is symmetric. The full proof is available in §A. ◀

Using Lemma 4 and Lemma 5, it is easy to show the following two lemmas. These lemmas – proved in §A – upper and lower bound the MinEMax cost of a solution with respect to its TruncatedTwoStage solution respectively.

► **Lemma 6.** *For feasible solution (X_1, \mathbf{X}_2) of any P_{EMax} we have, $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2) \leq \text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2)$.*

► **Lemma 7.** *Let P_{EMax} be a MinEMax problem and P_{Trunc} be its truncated version. Let (E_1, \mathbf{E}_2) and (T_1, \mathbf{T}_2) be optimal solutions to P_{EMax} and P_{Trunc} respectively. We have that $\text{cost}_{\text{Trunc}}(T_1, \mathbf{T}_2) \leq \left(\frac{1}{1-1/e} \right) \text{cost}_{\text{EMax}}(E_1, \mathbf{E}_2)$.*

The preceding lemmas allow us to conclude that an α -approximation algorithm for a TruncatedTwoStage problem is an $O(\alpha)$ -approximation algorithm for the corresponding MinEMax problem.

Proof of Theorem 1. Let $(\hat{T}_1, \hat{\mathbf{T}}_2)$ be the solution returned by an α -approximation algorithm for P_{Trunc} . Let (E_1, \mathbf{E}_2) and (T_1, \mathbf{T}_2) be the optimal solutions to P_{EMax} and P_{Trunc} respectively. By Lemma 6 we have $\text{cost}_{\text{EMax}}(\hat{T}_1, \hat{\mathbf{T}}_2) \leq \text{cost}_{\text{Trunc}}(\hat{T}_1, \hat{\mathbf{T}}_2)$. Since $(\hat{T}_1, \hat{\mathbf{T}}_2)$ is an α -approximation we have this is at most $\alpha \cdot \text{cost}_{\text{Trunc}}(T_1, \mathbf{T}_2)$. Applying Lemma 7 this is at most $\left(\frac{\alpha}{1-1/e} \right) \text{cost}_{\text{EMax}}(E_1, \mathbf{E}_2)$. Since any solution that is feasible for P_{Trunc} is also feasible for P_{EMax} , we conclude that $(\hat{T}_1, \hat{\mathbf{T}}_2)$ is a feasible solution for P_{EMax} with cost in P_{EMax} at most $\left(\frac{\alpha}{1-1/e} \right) \text{cost}_{\text{EMax}}(E_1, \mathbf{E}_2)$, giving our theorem. ◀

3 Applications to Linear Two-Stage Covering Problems

In this section we give an $O(\log n + \log m)$ -approximation algorithm for MinEMax MST and $O(1)$ approximation algorithms for MinEMax Steiner tree, MinEMax facility location, and MinEMax min-cut. Our algorithms are LP based. To derive our algorithms we use our

reduction from §2 to transform a MinEMax problem into a TruncatedTwoStage problem with only a small constant loss in the approximation factor. This transformation allows us to adapt existing LP rounding techniques in which every scenario has a rounding cost close to its fractional cost [22, 15, 24] to solve our TruncatedTwoStage problems and, therefore, our MinEMax problems.

We first give two general techniques to solve a TruncatedTwoStage problem.

3.1 General Techniques

Our *first technique* is to represent $\text{cost}_{\text{Trunc}}$ as an LP objective. For this technique we need to extend the definition of $\text{cost}_{\text{Trunc}}$ from an integral solution (X_1, \mathbf{X}_2) to a fractional solution (x_1, \mathbf{x}_2) . To do so, in each of our problems we locally define $\text{cost}(x_1, x_2^{(s)})$ for fractional solution $(x_1, x_2^{(s)})$ to scenario s and let $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$ be defined similarly to the integral case, i.e. for fractional (x_1, \mathbf{x}_2) ,

$$\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) := \min_B \left[B + \sum_s p_s (\text{cost}(x_1, x_2(s)) - B)^+ \right]. \quad (6)$$

Given a minimization LP, it is easy to see that by introducing an additional variable to represent B and additional variables to represent $(\text{cost}(x_1, x_2(s)) - B)^+$ for every s , we can represent $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$ in an LP. For cleanliness of exposition, when we write our LPs we omit these additional variables and simply write our objective as “ $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$.” Moreover, even though some of our LPs have an exponential number of constraints, we rely on the existence of efficient separation oracles for these LPs. It is easy to verify that this holds even after one introduces the additional variables needed to represent $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$.

We also extend M and B from the integral case as defined in §2 to the fractional case in the following natural way. Given a fractional solution (x_1, \mathbf{x}_2) and a cost function on fractional solutions, cost , WLOG let our scenarios be indexed such that $\text{cost}(x_1, x_2^{(s)}) \geq \text{cost}(x_1, x_2^{(s+1)})$. Let b be the smallest positive integer such that $\sum_{s=1}^b p_s \geq 1$. For fractional (x_1, \mathbf{x}_2) , we define

$$M(x_1, \mathbf{x}_2) := \lceil b \rceil \quad (7)$$

$$B(x_1, \mathbf{x}_2) := \min_{s \in M(x_1, \mathbf{x}_2)} \text{cost}(x_1, x_2^{(s)}). \quad (8)$$

► **Remark 8.** It is easy to verify that the proof of Lemma 5 also holds for $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$ for fractional (x_1, \mathbf{x}_2) . We will therefore invoke it on fractional (x_1, \mathbf{x}_2) , even though it is stated only for integral (X_1, \mathbf{X}_2) .

Our *second technique* is a generic rounding technique for TruncatedTwoStage problems. Several past works in two-stage optimization show that it is possible to round an LP solution such that the resulting integral solution has cost roughly the same as the fractional solution for *every scenario*. We prove the following lemma to make use of such rounding algorithms.

► **Lemma 9.** *Let P_{Trunc} be a TruncatedTwoStage problem. Let (X_1, \mathbf{X}_2) and (Y_1, \mathbf{Y}_2) be integral or fractional solutions to P_{Trunc} . If for every scenario s we have $\text{cost}(X_1, X_2^{(s)}) \leq c \cdot \text{cost}(Y_1, Y_2^{(s)})$ then*

$$\text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2) \leq c \cdot \text{cost}_{\text{Trunc}}(Y_1, \mathbf{Y}_2).$$

4:10 Prepare for the Expected Worst

Proof. We have

$$\text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2) = \min_B \left[B + \sum_s p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - B)^+ \right] \quad (9)$$

$$\leq c \cdot B(Y_1, \mathbf{Y}_2) + \sum_s p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - c \cdot B(Y_1, \mathbf{Y}_2))^+ \quad (10)$$

$$\leq c \cdot B(Y_1, \mathbf{Y}_2) + \sum_s p_s \cdot (c \cdot \text{cost}(Y_1, Y_2^{(s)}) - c \cdot B(Y_1, \mathbf{Y}_2))^+ \quad (11)$$

$$= c \cdot \left(B(Y_1, \mathbf{Y}_2) + \sum_s p_s \cdot (\text{cost}(Y_1, Y_2^{(s)}) - B(Y_1, \mathbf{Y}_2))^+ \right) \quad (12)$$

$$= c \cdot \text{cost}_{\text{Trunc}}(Y_1, \mathbf{Y}_2) \quad (13)$$

where Eq.(10) is by letting $B = c \cdot B(Y_1, \mathbf{Y}_2)$, Eq.(11) is by $\text{cost}(X_1, X_2^{(s)}) \leq c \cdot \text{cost}(Y_1, Y_2^{(s)})$ and Eq.(13) is by Lemma 5. \blacktriangleleft

3.2 Steiner Tree

In this section we give a $\left(\frac{30}{1-1/e}\right)$ -approximation for MinEMax rooted Steiner tree.

► **Definition 10** (MinEMax Rooted Steiner tree). *We are given a graph $G = (V, E)$, a root $r \in V$, a cost c_e for each edge e . We are also given scenarios $S_1, \dots, S_m \subseteq V$, each with an associated probability p_s and an inflation factor $\sigma_s > 0$. We must find a first stage solution $X_1 \subseteq E$ and a second-stage solution for every scenario, $X_2^{(j)} \subseteq E$. A solution is feasible if for every s we have $X_1 \cup X_2^{(s)}$ connects $\{r\} \cup S_s$. The cost for scenario s in solution (X_1, \mathbf{X}_2) is*

$$\text{cost}(X_1, X_2^{(s)}) := \sum_{e \in X_1} c_e + \sigma_s \cdot \sum_{e \in X_2^{(s)}} c_e. \quad (14)$$

The total cost we pay for (X_1, \mathbf{X}_2) is $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2) := E_{A \sim \mathbf{p}} \left[\max_{s \in A} \{\text{cost}(X_1, X_2^{(s)})\} \right]$.

Our algorithm is based on an LP rounding algorithm of Gupta et al. [16] for two-stage stochastic Steiner tree. Roughly, we use Lemma 9 to argue that the first stage solution for every optimal `TruncatedTwoStage` solution is, up to small constants, a tree rooted at r . This structural property allows us to write an LP that approximately captures `TruncatedTwoStage` Steiner tree. Gupta et al. [16] showed that this LP can be rounded s.t. every scenario has a good cost. We then combine this rounding with Lemma 9 to derive an approximation algorithm for `TruncatedTwoStage` Steiner tree, which is sufficient for approximating MinEMax Steiner tree by Theorem 1.

We begin by arguing that up to small constants, the optimal first stage solution is a tree rooted at r .

► **Lemma 11.** *There exists an integral solution $(\hat{X}_1, \hat{\mathbf{X}}_2)$ to `TruncatedTwoStage` Steiner tree s.t. $G[\hat{X}_1]$ is a tree rooted at r and $\text{cost}_{\text{Trunc}}(\hat{X}_1, \hat{\mathbf{X}}_2) \leq 2 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$, where (O_1, \mathbf{O}_2) is the optimal solution to `TruncatedTwoStage` Steiner tree.*

Proof. Lemma 4.1 of Dhamdhere et al. [9] shows that given (O_1, \mathbf{O}_2) it is possible to modify it to a feasible solution $(\hat{X}_1, \hat{\mathbf{X}}_2)$ such that $G[\hat{X}_1]$ is a tree rooted at r and $\text{cost}(\hat{X}_1, \hat{X}_2^{(s)}) \leq 2 \cdot \text{cost}(O_1, O_2^{(s)})$ for every s . It follows by Lemma 9 that $\text{cost}_{\text{Trunc}}(\hat{X}_1, \hat{\mathbf{X}}_2) \leq 2 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$. \blacktriangleleft

We now describe how to formulate an LP that leverages the structural property in Lemma 11. In particular, this indicates that as one gets closer to r , one must fractionally buy edges to a greater and greater extent. This constraint can be captured in an LP. Specifically, every node in a scenario (a.k.a. terminal) is the source of one unit of flow that is ultimately routed to r ; this flow follows a path whose fractional “first stage-ness” is monotonically increasing.

More formally, we copy each edge $e = \{u, v\}$ into two directed edges (u, v) and (v, u) . Let \vec{e} be either one of these directed edges. Next, for each such directed edge \vec{e} and every terminal in $t \in \bigcup_s S_s$, we define variables $r_1(t, \vec{e})$ and $r_2^{(s)}(t, \vec{e})$ for every s to represent how much t is connected to r by e in the first stage and in scenario s , respectively. Also, for undirected edge e , define variables $x_1(e)$ and $x_2^{(s)}(e)$ to stand for how much we buy e in the first stage and scenario s , respectively. For fractional (x_1, \mathbf{x}_2) , we define

$$\text{cost}_{\text{Trunc}}(x_1, x_2^{(s)}) := \sum_e c_e \cdot x_1(e) + \sigma_s \cdot c_e \cdot x_2(e),$$

which as described by Eq.(6) also defines $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$. Letting $\delta^-(v)$ and $\delta^+(v)$ stand for all directed edges going into and out of v , respectively. The following is our LP.

$$\begin{aligned} \min \quad & \text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) && \text{(ST LP)} \\ \text{s.t.} \quad & \sum_{\vec{e} \in \delta^+(v)} r_1(t, \vec{e}) + r_2^{(s)}(t, \vec{e}) = \sum_{\vec{e} \in \delta^-(v)} r_1(t, \vec{e}) + r_2^{(s)}(t, \vec{e}) && \forall s, t \in S_s, v \notin \{t, r\} \\ & \sum_{\vec{e} \in \delta^+(t)} r_1(t, \vec{e}) + r_2^{(s)}(t, \vec{e}) - \sum_{\vec{e} \in \delta^-(t)} r_1(t, \vec{e}) + r_2^{(s)}(t, \vec{e}) \geq 1 && \forall s, t \in S_s \\ & \sum_{\vec{e} \in \delta^-(v)} r_1(t, \vec{e}) \leq \sum_{\vec{e} \in \delta^+(v)} r_1(t, \vec{e}) && \forall s, t \in S_s, v \notin \{t, r\} \\ & r_1(t, \vec{e}) \leq x_1(e); r_2^{(s)}(t, \vec{e}) \leq x_2^{(s)}(e) && \forall s, t \in S_s, \vec{e} \\ & r, x_1, \mathbf{x}_2 \geq 0 \end{aligned}$$

Notably, the third family of constraints enforces that terminal t is serviced by the first stage more and more as one moves closer to the root. The characteristic vector of (\hat{X}_1, \hat{X}_2) as described in Lemma 11 gives a feasible solution to ST LP. As a result, Lemma 11 demonstrates that ST LP has nearly optimal objective as stated in the following corollary.

► **Corollary 12.** *Let (x_1, \mathbf{x}_2) be the optimal solution of ST LP. We have $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) \leq 2 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$, where (O_1, \mathbf{O}_2) is the optimal solution to TruncatedTwoStage Steiner tree.*

Proof. Let $(\hat{x}_1, \hat{\mathbf{x}}_2)$ be the characteristic vector of (\hat{X}_1, \hat{X}_2) from Lemma 11. Fix an arbitrary terminal t . Let P_2 for terminal t be the shortest path from t to \hat{X}_1 in $G[\hat{X}_2]$. Let u_t be the sink of P_2 and let P_1 be the shortest path from u_t to r in $G[\hat{X}_1]$. Notice that $(\hat{x}_1, \hat{\mathbf{x}}_2)$ along with r_2 which sends one unit of flow from t to u_t along P_2 and r_1 which sends one unit of flow from u_t to r along P_1 for every t is a feasible solution to ST LP. Moreover, notice that cost of this solution is $\text{cost}_{\text{Trunc}}(\hat{x}_1, \hat{\mathbf{x}}_2) = \text{cost}_{\text{Trunc}}(\hat{X}_1, \hat{\mathbf{X}}_2) \leq 2 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$ by Lemma 11. ◀

Previous work of Gupta et al. [16] shows that it is possible to round a fractional solution of ST LP such that every scenario has a good cost.

► **Lemma 13** ([16]). *A fractional solution (x_1, \mathbf{x}_2) to ST LP can be rounded in polynomial time to a feasible integral solution (X_1, \mathbf{X}_2) s.t. $\text{cost}(X_1, \mathbf{X}_2^{(s)}) \leq 15 \cdot \text{cost}(x_1, \mathbf{x}_2^{(s)})$ for every s .*

4:12 Prepare for the Expected Worst

Since Corollary 12 gives ST LP has a good optimal solution, we can round ST LP such that every scenario has a low cost. Now Lemma 9 tells us that such a rounding preserves the cost of a solution for `TruncatedTwoStage` optimization. This gives the following theorem.

► **Theorem 14.** *MinEMax Steiner tree can be $\left(\frac{30}{1-1/e}\right)$ -approximated in polynomial time.*

Proof. Our algorithm first solves ST LP to get fractional solution (x_1, \mathbf{x}_2) . Next, we apply Lemma 13 to round (x_1, \mathbf{x}_2) in polynomial time to give (X_1, \mathbf{X}_2) as our solution. Thus, we have

$$\begin{aligned} \text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2) &\leq 15 \cdot \text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) && \text{(by Lemma 9, Lemma 13)} \\ &\leq 30 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2), && \text{(by Corollary 12)} \end{aligned}$$

where (O_1, \mathbf{O}_2) is the optimal `TruncatedTwoStage` Steiner tree solution. This implies we have a 30-approximation algorithm for `TruncatedTwoStage` Steiner tree. Now by Theorem 1, we have a $\left(\frac{30}{1-1/e}\right)$ -approximation for MinEMax Steiner tree.

Lastly, each of our subroutines has a polynomial runtime by previous lemmas, and so we conclude that our algorithm has a polynomial runtime. ◀

3.3 Uncapacitated Facility Location

In this section we give a polynomial-time $\left(\frac{8}{1-1/e}\right)$ -approximation algorithm for MinEMax uncapacitated facility location (UFL).

► **Definition 15 (MinEMax UFL).** *We are given a set of facilities F and a set of clients \mathcal{D} with a metric c_{ij} specifying the distances between every client j and facility i . We are also given scenarios $S_1, \dots, S_m \subseteq \mathcal{D}$, where in scenario S_s client j has demand $d_j^s \in \{0, 1\}^4$, and a probability p_s for each scenario. Facility i 's opening cost is $f_{1,i}$ in the first stage and $f_{2,i}^{(s)}$ in scenario S_s . These opening costs can be ∞ , which indicates the facility cannot be opened. A feasible solution consists of a set of first and second stage facilities (X_1, \mathbf{X}_2) s.t. $X_1 \cup \bigcup_s X_2^{(s)} \neq \emptyset$. The cost for scenario s in solution (X_1, \mathbf{X}_2) is*

$$\text{cost}(X_1, X_2^{(s)}) := \sum_{i \in X_1} f_{1,i} + \sum_{i \in X_2^{(s)}} f_{2,i}^{(s)} + \sum_{j \in S_s} \min_{i \in X_1 \cup X_2^{(s)}} c_{ij}.$$

The total cost of solution (X_1, \mathbf{X}_2) is $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2) := \mathbb{E}_{A \sim \mathbf{p}} \left[\max_{s \in A} \{\text{cost}(X_1, X_2^{(s)})\} \right]$.

Our algorithm is based on the work of Ravi and Sinha [22] on two-stage stochastic UFL. This work shows how to round an LP such that every scenario has a “good” cost after rounding. Applying Lemma 9 to this rounding gives an algorithm that approximates `TruncatedTwoStage` UFL, which by Theorem 1 is sufficient to approximate MinEMax UFL.

We use the following LP. Variable $z_{ij}^{(s)}$ corresponds to whether client j is served by facility i in scenario s . Variables $x_1(i)$ and $x_2^{(s)}(i)$ corresponds to whether facility i is opened in the first stage or scenario s , respectively. For a fractional solution (x_1, \mathbf{x}_2) , we define

$$\text{cost}(x_1, x_2^{(s)}) := \sum_{i \in F} \left[x_1(i) \cdot f_{1,i} + x_2^{(s)}(i) \cdot f_{2,i}^{(s)} + \sum_{j \in \mathcal{D}} \hat{z}_{ij}^{(s)} \cdot c_{ij} \right],$$

⁴ This easily generalizes to more demand.

where $\hat{z}_{ij}^{(s)}$ is the natural fractional assignment given fractional facilities $(x_1, x_2^{(s)})$; namely, one that sends clients to their nearest fractionally opened facilities. As described by Eq.(6), this definition of $\text{cost}(x_1, x_2^{(s)})$ defines $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$ for fractional (x_1, \mathbf{x}_2) , which allows us to define our LP.

$$\begin{aligned}
 \min \quad & \text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) && \text{(UFL LP)} \\
 \text{s.t.} \quad & \sum_{i \in F} z_{ij}^{(s)} \geq d_j^{(s)} && \forall j \in \mathcal{D}, \forall s \\
 & z_{ij}^{(s)} \leq x_1(i) + x_2^{(s)}(i) && \forall i \in F, \forall j \in \mathcal{D}, \forall s \\
 & 0 \leq x_1, \mathbf{x}_2, \mathbf{z}
 \end{aligned}$$

Note that an integral solution to the above LP is a feasible solution for MinEMax UFL. Ravi and Sinha showed how to round this LP.

► **Lemma 16** (Theorem 2, Lemma 1 in [22]). *Given a fractional solution (x_1, \mathbf{x}_2) to UFL LP, it is possible to round it to integral (X_1, \mathbf{X}_2) in polynomial-time s.t. for every scenario s we have $\text{cost}(X_1, X_2^{(s)}) \leq 8 \cdot \text{cost}(x_1, x_2^{(s)})$.*

We now give our approximation algorithm for MinEMax UFL.

► **Theorem 17.** *MinEMax UFL can be $\left(\frac{8}{1-1/e}\right)$ -approximated in polynomial time.*

Proof. Our algorithm starts by solving UFL LP to get a fractional (x_1, \mathbf{x}_2) . Next, round (x_1, \mathbf{x}_2) using Lemma 16 to integral (X_1, \mathbf{X}_2) . Return (X_1, \mathbf{X}_2) .

Let (O_1, \mathbf{O}_2) be the optimal integral solution to the TruncatedTwoStage instance of our problem and let (o_1, \mathbf{o}_2) be its corresponding characteristic function. By definition, $\text{cost}_{\text{Trunc}}(o_1, \mathbf{o}_2) = \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$. Now using Lemma 9 and Lemma 16 it follows that

$$\text{cost}_{\text{Trunc}}(X_1, X_2) \leq 8 \cdot \text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2).$$

Since (o_1, \mathbf{o}_2) feasible for UFL LP, we get

$$\text{cost}_{\text{Trunc}}(X_1, X_2) \leq 8 \cdot \text{cost}_{\text{Trunc}}(o_1, \mathbf{o}_2) = 8 \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2).$$

Thus, our algorithm is an 8-approximation for TruncatedTwoStage UFL. Applying Theorem 1 gives a $\left(\frac{8}{1-1/e}\right)$ -approximation for MinEMax UFL.

Lastly, notice that our algorithm is trivially polynomial-time. ◀

3.4 MST

In this section we give a randomized polynomial-time algorithm which with high probability has expected cost $O(\log n + \log m)$ times the optimal MinEMax minimum spanning tree (MST) on an n -node graph with m different scenarios.

► **Definition 18** (MinEMax MST). *We are given a graph $G = (V, E)$ where $|V| = n$, a set of m scenarios S_1, \dots, S_m where each scenario S_s has an associated second-stage cost function $\text{cost}_2^{(s)} : E \rightarrow \mathbb{Z}^+$ and a probability p_s . We are also given a first-stage cost function, $\text{cost}_1 : E \rightarrow \mathbb{Z}^+$. We must provide a first stage solution $X_1 \subseteq E$ and a solution $X_2^{(s)} \subseteq E$ for every scenario s , which is feasible if $G[X_1 \cup X_2^{(s)}]$ spans V for every s . The cost for scenario s in solution (X_1, \mathbf{X}_2) is*

$$\text{cost}(X_1, X_2^{(s)}) := \sum_{e \in X_1} \text{cost}_1(e) + \sum_{e \in X_2^{(s)}} \text{cost}_2^{(s)}(e). \quad (15)$$

The total cost for solution (X_1, \mathbf{X}_2) is $\text{cost}_{\text{EMax}}(X_1, \mathbf{X}_2) := \mathbb{E}_{A \sim \mathbf{p}} \left[\max_{s \in A} \{\text{cost}(X_1, X_2^{(s)})\} \right]$.

4:14 Prepare for the Expected Worst

Our algorithm is based on the work of Dhamdhere et al. [10] on two-stage stochastic MST. They give a rounding technique that produces integral solutions where every scenario has a cost close to the fractional cost. Using this rounding, and applying Lemma 9, we get an approximation algorithm for `TruncatedTwoStage` MST, which by Theorem 1 is also sufficient to approximate `MinEMax` MST.

Notice that since `MinEMax` generalizes two-stage robust optimization, our `MinEMax` result gives a $O(\log n + \log m)$ approximation for two-stage robust MST as a corollary. To the best of our knowledge, this is the first non-trivial algorithm for two-stage robust MST.

Our algorithm is based on an LP. We have $m + 1$ variables for each edge e , namely $x_1(e)$ and $x_2^{(s)}(e)$ for $s \in [m]$ indicating if we take e in the first stage and in the second stage for scenario s , respectively. For a fractional solution (x_1, \mathbf{x}_2) , we define

$$\text{cost}(x_1, x_2^{(s)}) := \sum_e x_1(e) \cdot \text{cost}_1(e) + x_2^{(s)}(e) \cdot \text{cost}_2(e), \quad (16)$$

which as described in Eq.(6), defines $\text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2)$ for fractional (x_1, \mathbf{x}_2) . Letting $\delta(S)$ be all edges with exactly one endpoint in $S \subseteq V$. The following is our LP.

$$\begin{aligned} \min \quad & \text{cost}_{\text{Trunc}}(x_1, \mathbf{x}_2) && \text{(MST LP)} \\ \text{s.t.} \quad & \sum_{e \in \delta(S)} (x_1(e) + x_2^{(s)}(e)) \geq 1 && \forall \emptyset \subset S \subset V, s \in [m] \\ & x_1, \mathbf{x}_2 \geq 0 \end{aligned}$$

Note that an integral solution to MST LP is a feasible solution for the `TruncatedTwoStage` MST problem as a set of edges with at least one edge leaving every cut is a spanning tree.⁵ Also, although this LP has super-polynomial constraints, it is easy to obtain an efficient separation by solving min-cut; see Dhamdhere et al. [10].

We need the following result of Dhamdhere et al. [10] to round MST LP such that every scenario has a low cost.

► **Lemma 19** ([10]). *It is possible to randomly round a feasible fractional solution (x_1, \mathbf{x}_2) to MST LP to an integral solution (X_1, \mathbf{X}_2) in polynomial time s.t. with probability at least $1 - \frac{1}{mn^2}$ for every scenario s we have $\mathbb{E}[\text{cost}(X_1, X_2^{(s)})] \leq \text{cost}(x_1, x_2^{(s)}) \cdot (40 \log n + 16 \log m)$. Here the expectation is taken over the randomness of our rounding and m is the number of scenarios.*

We can now design our approximation algorithm for `MinEMax` MST.

► **Theorem 20.** *There exists a randomized polynomial-time algorithm that with probability at least $1 - \frac{1}{mn^2}$ in expectation $O(\log n + \log m)$ -approximates `MinEMax` MST where $n = |V|$ and m is the number of scenarios.*

Proof. Our algorithm starts by following MST LP to get a fractional solution (x_1, \mathbf{x}_2) . Next, apply Lemma 19 to round (x_1, \mathbf{x}_2) to an integral solution (X_1, \mathbf{X}_2) . Return (X_1, \mathbf{X}_2) .

Next consider the cost of (X_1, \mathbf{X}_2) . Let (O_1, \mathbf{O}_2) be the optimal integral solution to our `TruncatedTwoStage` MST problem and let (o_1, \mathbf{o}_2) be the corresponding characteristic vector. Notice that (o_1, \mathbf{o}_2) is a feasible solution to MST LP. Moreover, it is easy to

⁵ If such a solution has any cycles it is not necessarily an MST, though one can always delete an edge from such a cycle and improve the cost of the solution.

verify that $\text{cost}_{\text{Trunc}}(o_1, \mathbf{o}_2) = \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2)$. Taking expectations over the randomness of our algorithm and applying Lemma 9 and Lemma 19, we have with probability at least $1 - \frac{1}{mn^2}$ that

$$\begin{aligned} \mathbb{E}[\text{cost}_{\text{Trunc}}(X_1, \mathbf{X}_2)] &\leq (40 \log n + 16 \log m) \cdot \text{cost}_{\text{Trunc}}(o_1, \mathbf{o}_2) \\ &= (40 \log n + 16 \log m) \cdot \text{cost}_{\text{Trunc}}(O_1, \mathbf{O}_2). \end{aligned}$$

Thus, with probability at least $1 - \frac{1}{mn^2}$ our algorithm's expected `TruncatedTwoStage` cost is within $(40 \log n + 16 \log m)$ of the cost of the optimal `TruncatedTwoStage` MST solution. We conclude by Theorem 1 that with high probability in expectation our algorithm $O(\log n + \log m)$ -approximates `MinEMax` MST.⁶

Our algorithm is trivially polynomial-time by the separability of our LP and Lemma 19. ◀

A

 Deferred Proofs of §2

► **Lemma 4.** Let $\mathbf{Y} = \{Y_1, \dots, Y_m\}$ be a set of independent Bernoulli r.v.s, where Y_s is 1 with probability p_s , and 0 otherwise. Let $v_s \in \mathbb{R}_{\geq 0}$ be a value associated with Y_s . WLOG assume $v_s \geq v_{s+1}$ for $s \in [m-1]$. Let $b = \min\{a : \sum_{s=1}^a p_s \geq 1\}$. Then

$$\left(1 - \frac{1}{e}\right) \left(v_b + \sum_s p_s \cdot (v_s - v_b)^+\right) \leq \mathbb{E}_{\mathbf{Y}} \left[\max_s \{Y_s \cdot v_s\} \right] \leq v_b + \sum_s p_s \cdot (v_s - v_b)^+,$$

where $x^+ := \max\{x, 0\}$.

Proof. We begin by showing the lower bound on $\mathbb{E}_{A \sim \mathbf{Y}} [\max_{s \in A} v_s]$. Let $M := [b]$. Consider the new set of probabilities

$$p'_s = \begin{cases} 1 - \sum_{s < b} p_s & \text{if } s = b \\ p_s & \text{otherwise} \end{cases} \quad (17)$$

and let \mathbf{Y}' be the corresponding Bernoulli r.v.s. Notice that $\sum_{s \in M} p'_s = 1$.

Since $p'_s \leq p_s$, clearly we have that $\mathbb{E}_{A \sim \mathbf{Y}} [\max_{s \in A} v_s] \geq \mathbb{E}_{A \sim \mathbf{Y}'} [\max_{s \in A} v_s]$. Thus, we will focus on lower bounding $\mathbb{E}_{A \sim \mathbf{Y}'} [\max_{s \in A} v_s]$. The probability that no element of M is in A when drawn from \mathbf{Y}' is

$$\prod_{s \in M} (1 - p'_s) \leq e^{-\sum_{s \in M} p'_s} = \frac{1}{e}$$

because $1 - x \leq e^{-x}$ and $\sum_{s \in M} p'_s = 1$. It follows that

$$\begin{aligned} \mathbb{E}_{A \sim \mathbf{Y}} \left[\max_{s \in A} v_s \right] &\geq \mathbb{E}_{A \sim \mathbf{Y}'} \left[\max_{s \in A} v_s \right] \\ &\geq \left(1 - \frac{1}{e}\right) \mathbb{E}_{A \sim \mathbf{Y}'} \left[\max_{s \in A} v_s \mid \text{at least 1 element from } M \text{ in } A \right] \\ &\geq \left(1 - \frac{1}{e}\right) \mathbb{E}_{A \sim \mathbf{Y}'} \left[\max_{s \in A} v_s \mid \text{exactly 1 element from } M \text{ in } A \right] \\ &= \left(1 - \frac{1}{e}\right) \sum_{s \in M} v_s \frac{p'_s}{\sum_{i \in M} p'_i} = \left(\frac{1 - 1/e}{1}\right) \sum_{s \in M} p'_s v_s \end{aligned}$$

where the last line follows since $\sum_{s \in M} p'_s = 1$.

Thus, we have that

$$\begin{aligned} \mathbb{E}_{A \sim \mathbf{Y}} \left[\max_{s \in A} v_s \right] &\geq \left(1 - \frac{1}{e}\right) \sum_{s \in M} p'_s v_s \\ &= \left(1 - \frac{1}{e}\right) \sum_{s \in M} p'_s \left((v_s - v_b)^+ + v_b \right) \quad (\text{by } v_s \geq v_b \text{ for } s \in M) \\ &\geq \left(1 - \frac{1}{e}\right) \left(v_b + \sum_{s \in M} p'_s \left((v_s - v_b)^+ \right) \right) \quad \left(\text{by } 1 = \sum_{s \in M} p'_s \right) \\ &\geq \left(1 - \frac{1}{e}\right) \left(v_b + \sum_{s \in M} p_s \left((v_s - v_b)^+ \right) \right) \quad (\text{by } (v_b - v_b)^+ = 0) \\ &= \left(1 - \frac{1}{e}\right) \left(v_b + \sum_s p_s \left((v_s - v_b)^+ \right) \right) \quad (\text{by } v_s > v_b \text{ iff } s \in M) \end{aligned}$$

which gives our lower bound.

We now show the upper bound. Recall $x^+ := \max(x, 0)$. Notice that we have for any t ,

$$\max(x, y) \leq t + (x - t)^+ + (y - t)^+. \quad (18)$$

In particular, Eq. (18) follows because the RHS in each of the following cases is always $\geq \max\{x, y\}$.

- if $t \geq \max\{x, y\}$ we get t for the RHS.
- if $t \geq x$ and $t < y$ we get $t + y - t = y = \max\{x, y\}$ for the RHS; the symmetric case also holds.
- if $t < x$ and $t < y$ we get $t + x - t + y - t = x + y - t \geq \max\{x, y\}$ for the RHS.

4:18 Prepare for the Expected Worst

It is easy to verify that this holds for a max of more than two inputs; i.e. for a set S of reals we have $\max(S) \leq t + \sum_{s \in S} (s - t)^+$. Thus, we have

$$\mathbb{E}_{A \sim \mathbf{Y}} \left[\max_{s \in A} v_s \right] \leq \mathbb{E}_{A \sim \mathbf{Y}} \left[v_b + \sum_{s \in A} (v_s - v_b)^+ \right] = v_b + \mathbb{E}_{A \sim \mathbf{Y}} \left[\sum_{s \in A} (v_s - v_b)^+ \right] \quad (19)$$

$$= v_b + \mathbb{E}_{A \sim \mathbf{Y}} \left[\sum_{s \in A \cap M} (v_s - v_b)^+ + \sum_{s \in A \setminus M} (v_s - v_b)^+ \right] \quad (20)$$

$$= v_b + \mathbb{E}_{A \sim \mathbf{Y}} \left[\sum_{s \in A \cap M} (v_s - v_b)^+ \right] \quad (21)$$

$$= v_b + \mathbb{E}_{A \sim \mathbf{Y}} \left[\sum_{s \in A \cap M} (v_s - v_b) \right] \quad (22)$$

$$= v_b + \sum_{s \in M} p_s \cdot (v_s - v_b) \quad (23)$$

$$= v_b + \sum_s p_s \cdot (v_s - v_b)^+, \quad (24)$$

where Eq.(19) is by Eq.(18), Eq.(21) is by $v_s > v_b$ iff $s \leq b$, Eq.(22) is by $v_s \geq v_b$ for $s \in M$ and Eq.(24) is by $v_s > v_b$ iff $s \in M$. This is exactly the desired upper bound. ◀

► **Lemma 5.** *Let (X_1, \mathbf{X}_2) be a solution to a TruncatedTwoStage or MinEMax problem. We have*

$$B(X_1, \mathbf{X}_2) = \arg \min_B \left[B + \sum_{s \in [m]} p_s \cdot (\text{cost}(X_1, X_2^{(s)}) - B)^+ \right],$$

where the arg min takes the largest B minimizing the relevant quantity.

Proof. To clear our notation we let $\bar{B} := B(X_1, \mathbf{X}_2)$, $c_s := \text{cost}(X_1, X_2^{(s)})$ and $\bar{M} := M(X_1, \mathbf{X}_2)$. Let $f(B) := B + \sum_{s \in [m]} p_s \cdot (c_s - B)^+$. We argue that \bar{B} is the largest global minimum of f by showing that for any $\epsilon > 0$ we know that $f(\bar{B}) < f(\bar{B} + \epsilon)$ and $f(\bar{B}) \leq f(\bar{B} - \epsilon)$.

We begin by noting that for any reals $a \leq b$ we have

$$a^+ - b^+ \geq a - b \quad (25)$$

by casing on which of a and b are larger than 0.

Let $\hat{M} := \{s \in \bar{M} : c_s > \bar{B}\}$. Notice that $\sum_{s \in \hat{M}} p_s < 1$. For fixed and arbitrary $\epsilon > 0$ consider the relative values of $f(\bar{B})$ and $f(\bar{B} + \epsilon)$. We have

$$\begin{aligned} f(\bar{B} + \epsilon) - f(\bar{B}) &= \epsilon + \sum_{s \in [m]} p_s \cdot ((c_s - \bar{B} - \epsilon)^+ - (c_s - \bar{B})^+) \\ &= \epsilon + \sum_{s \in \hat{M}} p_s \cdot ((c_s - \bar{B} - \epsilon)^+ - (c_s - \bar{B})^+), \end{aligned} \quad (26)$$

where Eq.(26) follows since for $s \notin \hat{M}$ we have $c_s \leq \bar{B}$ and so $((c_s - \bar{B} - \epsilon)^+ - (c_s - \bar{B})^+) = 0$ for $s \notin \hat{M}$. Now noticing that for every s we have $(c_s - \bar{B} - \epsilon) \leq (c_s - \bar{B})$, applying (25) to (26) gives

$$f(\bar{B} + \epsilon) - f(\bar{B}) \geq \epsilon + \sum_{s \in \hat{M}} p_s \cdot (-\epsilon) = \epsilon \left(1 - \sum_{s \in \hat{M}} p_s \right) > 0,$$

where the last inequality uses $\sum_{s \in \hat{M}} p_s < 1$. Thus, we have $f(\bar{B} + \epsilon) > f(\bar{B})$.

Now consider the relative values of $f(\bar{B})$ and $f(\bar{B} - \epsilon)$. We have

$$\begin{aligned} f(\bar{B} - \epsilon) - f(\bar{B}) &= -\epsilon + \sum_s p_s \cdot ((c_s - \bar{B} + \epsilon)^+ - (c_s - \bar{B})^+) \\ &\geq -\epsilon + \sum_{s \in \bar{M}} p_s \cdot ((c_s - \bar{B} + \epsilon)^+ - (c_s - \bar{B})^+) \end{aligned} \quad (27)$$

$$\geq -\epsilon + \sum_{s \in \bar{M}} p_s \cdot ((c_s - \bar{B} + \epsilon) - (c_s - \bar{B})) \quad (28)$$

$$\geq \epsilon \left(1 - \sum_{s \in \bar{M}} p_s\right) \geq 0 \quad (29)$$

where Eq.(27) is by $(c_s - \bar{B} + \epsilon)^+ \geq (c_s - \bar{B})^+$, Eq.(28) is by $c_s \geq \bar{B}$ for $s \in \bar{M}$ and Eq.(29) is by $\sum_{s \in \bar{M}} p_s \geq 1$. Thus, for any $\epsilon > 0$ we know that $f(\bar{B}) < f(\bar{B} + \epsilon)$ and $f(\bar{B}) \leq f(\bar{B} - \epsilon)$. It follows that, not only is \bar{B} a global minimum of f but it is the largest global minimum. The lemma follows immediately. \blacktriangleleft

► **Lemma 6.** *For feasible solution (X_1, \mathbf{X}_2) of any P_{EMax} we have, $\text{cost}_{EMax}(X_1, \mathbf{X}_2) \leq \text{cost}_{Trunc}(X_1, \mathbf{X}_2)$.*

Proof. We have

$$\text{cost}_{EMax}(X_1, \mathbf{X}_2) = \mathbb{E}_A[\max_{s \in A} \{\text{cost}(X_1, X_2^{(s)})\}] \quad (30)$$

$$\leq B(X_1, \mathbf{X}_2) + \sum_s p_s \cdot \left(\text{cost}(X_1, X_2^{(s)}) - B(X_1, \mathbf{X}_2)\right)^+ \quad (31)$$

$$= \text{cost}_{Trunc}(X_1, \mathbf{X}_2) \quad (32)$$

where Equation (31) is by Lemma 4 and Equation (32) is by Lemma 5. \blacktriangleleft

► **Lemma 7.** *Let P_{EMax} be a MinEMax problem and P_{Trunc} be its truncated version. Let (E_1, \mathbf{E}_2) and (T_1, \mathbf{T}_2) be optimal solutions to P_{EMax} and P_{Trunc} respectively. We have that $\text{cost}_{Trunc}(T_1, \mathbf{T}_2) \leq \left(\frac{1}{1-1/e}\right) \text{cost}_{EMax}(E_1, \mathbf{E}_2)$.*

Proof. We have that

$$\begin{aligned} &\text{cost}_{Trunc}(T_1, \mathbf{T}_2) \\ &\leq \text{cost}_{Trunc}(E_1, \mathbf{E}_2) \quad (\text{by } (T_1, \mathbf{T}_2) \text{ minimizes } \text{cost}_{Trunc}) \\ &= \min_B \left[B + \sum_s p_s \cdot (\text{cost}(E_1, E_2^{(s)}) - B)^+ \right] \\ &\leq B(E_1, \mathbf{E}_2) + \sum_s p_s \cdot (\text{cost}(E_1, E_2^{(s)}) - B(E_1, \mathbf{E}_2))^+ \\ &\leq \left(\frac{1}{1-1/e}\right) \mathbb{E}_A[\max_{s \in A} \{\text{cost}(E_1, E_2^{(s)})\}] \quad (\text{by Lemma 4}) \\ &= \left(\frac{1}{1-1/e}\right) \text{cost}_{EMax}(E_1, \mathbf{E}_2). \quad \blacktriangleleft \end{aligned}$$

Streaming Hardness of Unique Games

Abstract

We study the problem of approximating the value of a Unique Game instance in the streaming model. A simple count of the number of constraints divided by p , the alphabet size of the Unique Game, gives a trivial p -approximation that can be computed in $O(\log n)$ space. Meanwhile, with high probability, a sample of $\tilde{O}(n)$ constraints suffices to estimate the optimal value to $(1 + \epsilon)$ accuracy. We prove that any single-pass streaming algorithm that achieves a $(p - \epsilon)$ -approximation requires $\Omega_\epsilon(\sqrt{n})$ space. Our proof is via a reduction from lower bounds for a communication problem that is a p -ary variant of the Boolean Hidden Matching problem studied in the literature. Given the utility of Unique Games as a starting point for reduction to other optimization problems, our strong hardness for approximating Unique Games could lead to *downstream* hardness results for streaming approximability for other CSP-like problems.

1 Introduction

The Unique Games (UG) problem is a type of constraint satisfaction problem on a graph. Given an alphabet $[p] = \{0, 1, \dots, p - 1\}$ and a graph $G = (V, E)$, we need to find a label assignment $x : V \rightarrow [p]$. The constraint on an edge $(u, v) \in E$ is specified described by a permutation $\pi_{uv} : [p] \rightarrow [p]$ and we want to find the assignment to maximize the number of equations $\pi_{uv}(x_u) = x_v$ that are satisfied. This maximum possible value over all possible assignments is called the optimal value of the UG instance. Simply picking a random assignments satisfies a fraction $1/p$ of the constraints in expectation, giving a trivial factor p approximation algorithm to the optimal value of any instance. More sophisticated algorithms based on semidefinite programming give better approximation guarantees [1], but even on almost-satisfiable instances where the optimal value is a $(1 - \epsilon)$ fraction of the total number of constraints, the algorithm satisfies only a fraction $\approx p^{-\epsilon/2}$ of the constraints. Under Khot's celebrated Unique Games conjecture [11], this guarantee cannot be improved [12],

¹ Now affiliated with Columbia University, New York, USA.

and the conjecture further implies optimal hardness results for a host of problems. In terms of proven hardness results (under say the standard assumption that $P \neq NP$), we know that Unique Games does not admit any constant factor approximations [3], and in an exciting recent line of work this was also established on instances that have optimum value close to a fraction $1/2$ [2, 15].

To shed further light on the (difficulty of the) Unique Games problem from a different angle, in this work, we consider the Unique Games problem in the streaming model of computation. The constraints are assumed to arrive one-by-one in a single pass. The algorithm is only given a limited amount of memory, so cannot store the entire instance as it passes by. The goal of the algorithm is to estimate the optimal value of the Unique Games instance. That is, it must output a value T which is a lower bound on the optimum number of constraints that can be satisfied, and which is at most an approximation factor f from the optimum. In recent years, numerous algorithms and hardness for problems in the streaming model have been developed, and this work address the important Unique Games problem from the streaming perspective.

The simple-minded algorithm which simply counts the number of constraints and outputs a $1/p$ fraction of it as a valid estimate for every instance (by virtue of the random assignment algorithm), and delivers a factor p approximation. This algorithm can obviously be implemented in the streaming model using $O(\log n)$ space. Meanwhile, if we are given $\tilde{O}(n)$ space, we can sample a random $\tilde{O}(n)$ -size subset of constraints and the answer of sampled unique game gives us an arbitrarily close approximation for the original stream.² A natural question which arises, and which motivates this work, is thus: *can we do better than the trivial factor p approximation in polylogarithmic space?*

In a beautiful work, Kapralov, Khanna, and Sudan [9] showed that the problem of Max-CUT, which is a special case of the Unique Games problem with alphabet size 2, does not admit an approximation better than the trivial factor 2 in $o(\sqrt{n})$ space in the streaming model where the edges arrive one-by-one. On the other hand, a recent work [7] showed that for the Max 2CSP problem (arbitrary Boolean arity two constraints) and Max-DICUT (the analog of Max-CUT on directed graphs), one can in fact beat the trivial factor 4 algorithm (that outputs $1/4$ 'th the number of constraints, which is the expected value of a random assignment), and achieve a $\approx 5/2$ -approximation using $O(\log n)$ space. The status of the streaming approximability of Unique Games over larger alphabet sizes was not addressed and remained open until our work.

1.1 Our Result

We show that for Unique Games with alphabet size p , a single-pass streaming algorithm requires at least $\tilde{\Omega}(\sqrt{n})$ space to have any chance of delivering a better estimate than the trivial factor p approximation. In particular, we cannot beat the trivial constraint-counting algorithm in the worst-case in polylogarithmic space.

► **Theorem 1.** *Let $p \geq 2$ be an integer and $\epsilon > 0$ be a small constant. Any streaming algorithm giving $(p - \epsilon)$ -approximation for Unique Games with alphabet size p with success probability at least $9/10$ over its internal randomness must use $c_{p,\epsilon}\sqrt{n}$ space, for some positive constant $c_{p,\epsilon}$ that depends only on p, ϵ .*

² Note that We do not place any computational restriction on the algorithm, only on the amount of space it may use. Also, since we are talking about sub-linear space, we do not focus on finding an approximate solution, but only outputting an estimate of the optimal value. Since our focus is on lower bounds, this only makes our technical result stronger.

Furthermore, the hardness holds for distinguishing between satisfiable instances and those for which at most a fraction $(1/p+\epsilon)$ of the constraints can be satisfied by any assignment, and when the Unique Games constraints are linear (of the form $x_u+x_v = \alpha_{uv}$ over integers mod p).

1.2 Proof Structure

In our proof, we first introduce in Section 3, a communication problem called the p -ary Hidden Matching problem, which is a p -ary variant of the (Boolean) Hidden Matching problem proposed by Gavinsky et al.[4] and first used for streaming lower bounds by Verbin and Yu in [16]. The (distributional) p -ary Hidden Matching problem is a two-party one-way communication problem where Alice holds a random p -ary vector $x \in \mathbb{Z}_p^n$ and Bob holds a random matching of size $r = \alpha n$ (for some suitable $\alpha \in (0, 1)$) and a vector $w \in \mathbb{Z}_p^r$. Alice must send one message to Bob, based on which he must distinguish between two distributions on the inputs. In both distributions x is uniformly random, and M is a random matching of the prescribed size. In the YES distribution, we set $w_e = x_u + x_v$ for each $e = (u, v)$ in the matching (i.e., $w = Mx$ where $M \in \{0, 1\}^{\alpha n \times n}$ is the incidence matrix of the matching); in the NO distribution, w is uniformly random. We prove a communication lower bound of this problem using Fourier-analytic methods, which is similar to [8].

The vector w and the matching in the p -ary Hidden Matching problem can be seen as a description of some Unique Game constraints $x_u + x_v = w_e$. Of course each such instance individually is trivially always satisfiable. We can construct hard instances of Unique Game by combining together $O(1/\epsilon^2)$ independent copies of the random matching and corresponding w . In the YES case, we let w be according to the *same* (random) x , so that the constraints can be satisfied by x . In the NO case, the various choices of w are random and independent. This implies that every assignment $x \in \mathbb{Z}_p^n$ is close in performance to a random assignment, and thus satisfies only $\approx 1/p$ of the constraints, by concentration bounds.

We prove that a low-space streaming algorithm cannot distinguish between these distributions, which then implies Theorem 1. To prove this indistinguishability result, we give a reduction from the p -ary Hidden Matching problem. The proof is a classical hybrid argument since the streaming instance can be seen as a “multi-stage” version of the communication problem.

1.3 Differences from [9]

Our approach heavily borrows from the Max-CUT streaming lower bound from of Kapralov, Khanna, and Sudan [9]. Compared to their work, we only prove Theorem 1 for a *worst-case* arrival order of constraints, whereas the Max-CUT hardness result is shown even for a *random* arrival order for the edges. At each stage, instead a matching, Kapralov et. al. used a sub-critical random Erdős-Rényi graph with edge probability $\approx \alpha/n$. If the parameter α is sufficiently small, the graph obtained by putting together edges from all the stages is close in distribution to a random graph. As a result the arrival of edges in a random order does not help the streaming algorithm. For the analysis of each stage, they use a communication problem called the Boolean Hidden Partition problem that is variant of the Boolean Hidden Matching problem, since they have to work with Erdős-Rényi graphs rather than random matchings. This requires changes to some components in the proof outline of [4, 16].

Our communication problem still concerns matchings (rather than sub-critical Erdős-Rényi graphs), though we allow for (components of) x, w to take values from \mathbb{Z}_p instead of Boolean values. By using Fourier analysis over the group \mathbb{Z}_p instead of \mathbb{Z}_2 , we are able to adapt the communication lower bound of [4].

5:4 Streaming Hardness of Unique Games

It remains an interesting question to prove a streaming hardness for Unique Games similar to Theorem 1 for the case of random arrival order of constraints.

2 Preliminaries

Let $\mathbb{Z}_p = \{0, 1, \dots, p-1\}$ be the ring with addition and multiplication modulo p . (We do not assume that p is a prime.) Fourier analysis over \mathbb{Z}_p^n plays a key role in our proof. Consider the space of functions $\mathbb{Z}_p^n \rightarrow \mathbb{C}$. We define the inner product and 2-norm in it by

$$\langle f, g \rangle = \frac{1}{p^n} \sum_{x \in \mathbb{Z}_p^n} f(x) \overline{g(x)} \quad \|f\|_2^2 = \langle f, f \rangle = \frac{1}{p^n} \sum_{x \in \mathbb{Z}_p^n} |f(x)|^2$$

The Fourier transform of f is a function $\hat{f} : \mathbb{Z}_p^n \rightarrow \mathbb{C}$ defined by

$$\hat{f}(z) = \langle f, \chi_z \rangle = \frac{1}{p^n} \sum_{x \in \mathbb{Z}_p^n} f(x) \overline{\omega^{z \cdot x}}$$

where $\chi_z : \mathbb{Z}_p^n \rightarrow \mathbb{C}$ is the character $\chi_z(x) = \omega^{z \cdot x}$ with “ \cdot ” being the scalar product and $\omega = e^{2\pi i/p}$ being the primitive p 'th root of unity. For $z \in \mathbb{Z}_p^n$, we denote by $|z|$ the number of nonzero entries in z .

In our later proof, we use the following two lemmas concerning Parseval's identity and hypercontractivity.

► **Lemma 2** (Parseval). *For every function $f : \mathbb{Z}_p^n \rightarrow \mathbb{C}$, we have*

$$\|f\|_2^2 = \sum_{z \in \mathbb{Z}_p^n} |\hat{f}(z)|^2.$$

► **Lemma 3** (Hypercontractivity Theorem, [13]). *For function $f \in L_2(\mathbb{Z}_p^n)$, if $1 < q < 2$ and $0 \leq \rho \leq \sqrt{q-1}(1/p)^{1/q-1/2}$, we have*

$$\|T_\rho f\|_2 \leq \|f\|_q$$

where T_ρ is the operator defined by $T_\rho f(x) = \sum_{z \in \mathbb{Z}_p^n} \hat{f}(z) \rho^{|z|} \chi_z(x)$.

Using the above theorem, we can derive an estimate on the sum of Fourier coefficients weighted by its support size.

► **Lemma 4**. *For a set $A \subseteq \mathbb{Z}_p^n$ and let f be its indicator function and let $|z|$ denote the number of non-zero coordinates of $z \in \mathbb{Z}_p^n$. Then for every $\delta \in [0, 1/p]$, we have*

$$\sum_{z \in \mathbb{Z}_p^n} \delta^{|z|} |\hat{f}(z)|^2 \leq \left(\frac{|A|}{p^n} \right)^{2/(1+p\delta)}.$$

Proof. Let $\rho = \sqrt{q-1}(1/p)^{1/2} \leq \sqrt{q-1}(1/p)^{1/q-1/2}$, then $q = 1 + p\rho^2$. By the hypercontractivity theorem, we know that

$$\|T_\rho f\|_2 \leq \|f\|_{1+p\rho^2}$$

Meanwhile, we have $\|T_\rho f\|_2^2 = \sum_{z \in \mathbb{Z}_p^n} \rho^{2|z|} |\hat{f}(z)|^2$. Taking the square of the equation above and setting $\delta = \rho^2$ will get our desired result. ◀

3 p -ary Hidden Matching

In this section, we analyze a two-party (distributional) one-way communication problem, defined as follows.

p -ary Hidden Matching problem. Alice gets a random vector $x \in \mathbb{Z}_p^n$. Bob gets a random α -partial matching G (i.e., a matching of size αn on $\{1, 2, \dots, n\}$) and a vector $w \in \mathbb{Z}_p^{\alpha n}$. Let $M \in \{0, 1\}^{\alpha n \times n}$ be the incidence matrix of G , i.e., $M_{ev} = 1$ if v is an endpoint of e and 0 otherwise. There are two choices for the distribution of w , distinguishing which is the communication problem.

- In the **YES** distribution w is correlated with x as $w = Mx$ (arithmetic done in \mathbb{Z}_p);
- in the **NO** distribution, w is uniformly random in $\mathbb{Z}_p^{\alpha n}$ (and thus independent of x).

Alice must send a message to Bob, based on which Bob needs to distinguish distribution w belongs to. Formally, Bob must output Yes or No (based on Alice's message and his input w), and we say a protocol achieves advantage ϵ if the difference in probability of Bob outputting Yes differs under the Yes and No distributions by at least ϵ . The following shows that Alice needs to send at least $\Omega(\sqrt{n})$ bits for Bob to achieve constant advantage.

► **Theorem 5.** *For $\alpha \in (0, 1/4]$, any protocol that achieves advantage $\epsilon > 0$ for the p -ary Hidden Matching problem requires at least $\Omega(\epsilon\sqrt{n})$ bits of communication from Alice to Bob.*

The proof of the above lemma is the main result of this section. Our proof closely follows the structure of [4], from which the main difference is that our proof has to work for the p -ary case.

Before we embark on the proof, we need some more lemmas. We begin with an application of hypercontractivity to bound the Fourier mass at any level.

► **Lemma 6.** *For a set $A \subseteq \mathbb{Z}_p^n$ with size at least $p^n/2^c$ and let f be its indicator function and let $|z|$ denote the number of non-zero coordinates of $z \in \mathbb{Z}_p^n$. Then for every $k \leq 4c$ we have*

$$\frac{p^{2n}}{|A|^2} \sum_{|z|=k} |\hat{f}(z)|^2 \leq \left(\frac{4\sqrt{2}pc}{k} \right)^k.$$

Proof. By Lemma 4, given some constant $0 \leq \delta \leq 1/p$, we have

$$\begin{aligned} \frac{p^{2n}}{|A|^2} \sum_{|z|=k} |\hat{f}(z)|^2 &\leq \frac{p^{2n}}{|A|^2} \frac{1}{\delta^k} \sum_{z \in \mathbb{Z}_p^n} \delta^{|z|} |\hat{f}(z)|^2 \\ &\leq \frac{p^{2n}}{|A|^2} \frac{1}{\delta^k} \left(\frac{|A|}{p^n} \right)^{2/(1+p\delta)} \\ &= \frac{1}{\delta^k} \left(\frac{p^n}{|A|} \right)^{2p\delta/(1+p\delta)} \\ &\leq \frac{1}{\delta^k} \left(\frac{p^n}{|A|} \right)^{2p\delta}. \end{aligned}$$

Choosing $\delta = k/4cp$ will give our desired result. ◀

We also need a combinatorial lemma about counting of some matchings.

5:6 Streaming Hardness of Unique Games

► **Lemma 7.** *Let G be a uniformly random α -partial matching and M be its incidence matrix. If $x \in \mathbb{Z}_p^n$ has $|x| = k$ for some even³ k , then*

$$\Pr_G[\exists z \in \mathbb{Z}_p^{\alpha n} \text{ s.t. } M^T z = x] \leq \binom{\alpha n}{k/2} / \binom{n}{k}.$$

Proof. We know that the total number of all α -partial matchings of n vertices is $n!/(2^{\alpha n}(\alpha n)!(n - 2\alpha n)!)$. And if there exists some z such that $M^T z = x$, then G must have exactly $k/2$ edges between those vertices v with $x_v \neq 0$. There are $k!/(2^{k/2}(k/2)!)$ number of ways to choose those edges. Also, we need to choose $\alpha n - k/2$ edges amongst those v whose $x_v = 0$, which we have $(n - k)!/(2^{n-k}(\alpha n - k/2)!(n - 2\alpha n)!)$ ways to do. Combining them together leads to the lemma. ◀

From the lemmas above, we can derive an important result in our proof.

► **Lemma 8.** *Let $A \subseteq \mathbb{Z}_p^n$ be of size at least $p^n/2^c$ for some $c \geq 1$, G be a uniformly random α -partial matching for some $0 < \alpha \leq 1/4$ and M be its incidence matrix. There exists a constant γ independent of n, c and α , such that for all $\epsilon > 0$, if $c \leq \gamma \epsilon \sqrt{n/\alpha}$ then*

$$E_M[\|p_M - U\|_{tvd}] \leq \epsilon,$$

where $p_M(w) = |\{x \in A \mid Mx = w\}|/|A|$ is the distribution of w in the **YES** case when x is uniformly random in A .

Proof. To show that $E_M[\|p_M - U\|_{tvd}] \leq \epsilon$, we can start by bounding the Fourier coefficients of p_M . In fact they are closely related to \hat{f} (where recall that f is the indicator function for membership in the set A):

$$\begin{aligned} \widehat{p_M}(z) &= \frac{1}{p^{\alpha n}} \sum_{w \in \mathbb{Z}_p^{\alpha n}} p_M(w) \omega^{-w \cdot z} \\ &= \frac{1}{|A|p^{\alpha n}} \sum_{k=0}^{p-1} \omega^{-k} |\{x \in A \mid (Mx) \cdot z = k\}| \\ &= \frac{1}{|A|p^{\alpha n}} \sum_{k=0}^{p-1} \omega^{-k} |\{x \in A \mid x \cdot (M^T z) = k\}| \\ &= \frac{1}{|A|p^{\alpha n}} \sum_{x \in A} \omega^{-x \cdot (M^T z)} \\ &= \frac{p^n}{|A|p^{\alpha n}} \widehat{f}(M^T z) \end{aligned}$$

From the bound of Fourier coefficients, we can give a bound on squared total variation distance

$$\begin{aligned} E_M[\|p_M - U\|_{tvd}^2] &\leq p^{2\alpha n} E_M[\|p_M - U\|_2^2] \\ &= p^{2\alpha n} E_M \left[\sum_{z \in \mathbb{Z}_p^{\alpha n} \setminus \{0^{\alpha n}\}} |\widehat{p_M}(z)|^2 \right] \\ &= \frac{p^{2n}}{|A|^2} E_M \left[\sum_{z \in \mathbb{Z}_p^{\alpha n} \setminus \{0^{\alpha n}\}} |\widehat{f}(M^T z)|^2 \right] \end{aligned}$$

³ We note that if $|x|$ is odd, then there can be no z such that $M^T z = x$.

by Cauchy-Schwarz inequality, Parseval equality and the bound above. Since there is at most one $z \in \mathbb{Z}_p^{\alpha n}$ such that $x = M^T z$ for given x , we have

$$\begin{aligned} &= \frac{p^{2n}}{|A|^2} E_M \left[\sum_{x \in \mathbb{Z}_p^n \setminus \{0^n\}} |\hat{f}(x)|^2 |\{z \in \mathbb{Z}_p^{\alpha n} | x = M^T z\}| \right] \\ &= \frac{p^{2n}}{|A|^2} \sum_{x \in \mathbb{Z}_p^n \setminus \{0^n\}} \Pr_M[\exists z \in \mathbb{Z}_p^{\alpha n} \text{ s.t. } M^T z = x] |\hat{f}(x)|^2 \\ &\leq \frac{p^{2n}}{|A|^2} \sum_{k=2, \text{keven}}^{2\alpha n} \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}} \sum_{|x|=k} |\hat{f}(x)|^2. \end{aligned}$$

We then split the sum into two parts $k < 4c$ and $k \geq 4c$. For $k < 4c$, using $(n/k)^k \leq \binom{n}{k} \leq (en/k)^k$, we have

$$\begin{aligned} \frac{p^{2n}}{|A|^2} \sum_{k=2, \text{keven}}^{4c-2} \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}} \sum_{|x|=k} |\hat{f}(x)|^2 &\leq \sum_{k=2, \text{keven}}^{4c-2} \frac{(2e\alpha n/k)^{k/2}}{(n/k)^k} \left(\frac{4\sqrt{2}pc}{k} \right)^k \quad (\text{using Lemma 6}) \\ &\leq \sum_{k=2, \text{keven}}^{4c-2} \left(\frac{64e\gamma^2 \epsilon^2 p^2}{k} \right)^{k/2}, \end{aligned}$$

which is at most $\epsilon^2/2$ when γ is sufficiently small. For $k \geq 4c$ note that $\sum_x |\hat{f}(x)|^2 = |A|/p^n$ by Parseval and $\binom{\alpha n}{k/2}/\binom{n}{k}$ is decreasing for even $k \leq 2\alpha n$, we have

$$\begin{aligned} \frac{p^{2n}}{|A|^2} \sum_{k=4c, \text{keven}}^{2\alpha n} \frac{\binom{\alpha n}{k/2}}{\binom{n}{k}} \sum_{|x|=k} |\hat{f}(x)|^2 &\leq 2^c \frac{\binom{\alpha n}{2c}}{\binom{n}{4c}} \\ &\leq 2^c \left(\frac{8c\alpha e}{n} \right)^{2c} \\ &\leq \left(8\sqrt{2}e\gamma\epsilon\sqrt{\alpha/n} \right)^{2c} \leq \epsilon^2/2. \end{aligned}$$

The last inequality holds because $n \geq 1$ and $c \geq 1$, and we let γ be a sufficiently small constant. Thus, in total we have $E_M \|p_M - U\|_{\text{tvd}}^2 \leq \epsilon^2$, which means by Jensen $E_M \|p_M - U\|_{\text{tvd}} \leq \epsilon$. \blacktriangleleft

From the lemma above, we can prove the communication lower bound of p -ary Hidden Matching problem.

Proof of Theorem 5. By fixing the randomness of the protocol, we can assume without loss of generality that the protocol is deterministic. Fix $\epsilon > 0$ to a small constant and let $c = \gamma\epsilon\sqrt{n/\alpha}$. Consider any protocol that communicates at most $C = c - \log(1/\epsilon)$ bits. In the protocol, Alice's message gives an partition of \mathbb{Z}_p^n into 2^C subsets. We call the sets with size $\epsilon p^n/2^C = p^n/2^c$ be "large sets", then for a uniformly random $x \in \mathbb{Z}_p^n$, with probability $1 - \epsilon$, x belongs to a large set. When x is in a large set, by Lemma 8, Bob can get an advantage of at most ϵ . Together with the advantage from small sets, the overall advantage Bob can get is at most $O(\epsilon)$, which completes the proof. \blacktriangleleft

4 Reduction to Streaming Algorithm for Unique Games

In this section, we will prove Theorem 1. Towards this end, we will describe a pair of distributions, \mathbf{Y} and \mathbf{N} , where \mathbf{Y} is supported on satisfiable instances of Unique Games, and \mathbf{N} is supported with high probability on instances where at most $\approx 1/p$ fraction of constraints can be satisfied. We will then establish, via reduction from the p -ary Hidden Matching communication problem, that any low-space streaming algorithm cannot distinguish between these distributions, thus establishing Theorem 1.

4.1 Input distributions

We construct the above-mentioned distributions in a “multi-stage” way (using k stages) based on the **YES** and **NO** distributions (defined at the beginning of Section 3) for p -ary Hidden Matching. First we independently sample k α -partial matchings on n vertices. The Unique Games instance graph G will be the union of these matchings. It will thus have n vertices and $k\alpha n$ edges (we allow multiple edges should they be sampled). We next specify the Unique Games constraints, which will be two-variable linear equations, one for each edge.

- In the \mathbf{Y} distribution, we sample a random $z \in \mathbb{Z}_p^n$ uniformly. We let the constraint on edge (u, v) of G be $x_u + x_v = z_u + z_v$.
- In the \mathbf{N} distribution, for each edge (u, v) of G , we let the constraint be $x_u + x_v = q$ for a random $q \in \mathbb{Z}_p$, independently chosen for each edge.

For instances sampled in the \mathbf{Y} distribution, the best solution is obviously $x_u = z_u$ for all $u \in [n]$, which satisfies all the constraints. For the \mathbf{N} distribution, we can use Chernoff bounds to upper bound the value of the optimal solution.

► **Lemma 9.** *Let $0 < \epsilon < 1$. If $k = Cp \log p / (\alpha \epsilon^2)$ for some large constant $C > 0$, then for a Unique Games instance sampled from the \mathbf{N} distribution, the optimal fraction of satisfiable constraints is at most $(1 + \epsilon)/p$ with high probability.*

Before we proceed to the proof, we first state the Chernoff bound for negatively correlated random variables.

► **Lemma 10** ([14]). *Let X_1, \dots, X_n be negatively correlated Bernoulli random variables and $X = X_1 + \dots + X_n$. Then we have*

$$\Pr[X \geq (1 + \epsilon)E[X]] \leq \exp(-E[X]\epsilon^2/3).$$

Proof of Lemma 9. Fix an assignment $x \in \mathbb{Z}_p^n$. For $1 \leq \ell \leq k$, let $X_{ij}^{(\ell)}$ be the indicator of the following event: “in the ℓ -th stage, the edge (i, j) is included in the α -partial matching and is satisfied by the assignment x .” Then, $S = \sum_{\ell, i, j} X_{ij}^{(\ell)}$, summed over $1 \leq \ell \leq k$, and $1 \leq i < j \leq n$, is the random variable counting the number of constraints satisfied by the assignment x . Note that $\mathbb{E}[S] = k\alpha n/p$ is the expected number of constraints by the assignment x . And we know that each $X_{ij}^{(\ell)}$ is a Bernoulli random variable with probability of equaling 1 being $2\alpha n/(pn(n-1))$.

We first claim that these random variables are negatively correlated. In fact, edges in different stages are independent. For edges in the same stage ℓ , consider that we know that random variables $X_{i_1 j_1}^{(\ell)}, X_{i_2 j_2}^{(\ell)}, \dots, X_{i_t j_t}^{(\ell)}$ have value 1, and a vertex pair (i_0, j_0) . If i_0 or j_0 is occurred in some i_s or j_s , then $X_{i_0 j_0}^{(\ell)}$ must be 0. Otherwise the conditional expectation of $X_{i_0 j_0}^{(\ell)}$ is $2(\alpha n - t)/(p(n - t)(n - 1 - t))$, which is less than the unconditional expectation of $2\alpha n/(pn(n - 1))$. In all cases we have $E[X_{i_0 j_0}^{(\ell)} \mid X_{i_1 j_1}^{(\ell)} = X_{i_2 j_2}^{(\ell)} = \dots = X_{i_t j_t}^{(\ell)} = 1] \leq E[X_{i_0 j_0}^{(\ell)}]$, which in turn means negative correlation.

Thus, by Chernoff bound for negatively random variables, we know that

$$\Pr[S \geq (1 + \epsilon)k\alpha n/p] \leq \exp(-\epsilon^2 k\alpha n/3p) = p^{-Cn/3} \leq p^{-2n}.$$

The proof is now complete by a union bound over all p^n candidate assignments. \blacktriangleleft

4.2 Reduction from p -ary Hidden Matching

Note that each stage of constraints in the Unique Games instance corresponds to the p -ary Hidden Matching problem, with the \mathbf{Y} distribution (resp. \mathbf{N} distribution) coinciding with the YES distribution (NO distribution) of the Hidden Matching problem. Using this, we can link the hardness of the two problems via a hybrid argument. Recall that we say that a decision algorithm distinguishes between two distributions D_1 and D_2 with advantage η if it accepts samples from one distribution with probability at least η more than those from the other distribution.

► **Lemma 11.** *Suppose there exists a streaming algorithm \mathbf{ALG} using c bits of memory that can achieve advantage $1/4$ in distinguishing between instances from the \mathbf{Y} and \mathbf{N} distributions of Unique Games instances. Then there exists a protocol with c bits of communication for the p -ary Hidden matching problem with advantage $\Omega(1/k)$ in distinguishing between \mathbf{YES} and \mathbf{NO} distributions.*

We now prepare for the proof of Lemma 11. Our proof follows along the lines of a similar argument in [9]. In the execution of \mathbf{ALG} on instances from the \mathbf{Y} and \mathbf{N} distributions, let the memory after receiving the i -th stage constraints be $S_i^{\mathbf{Y}}$ and $S_i^{\mathbf{N}}$ respectively. Thus $S_i^{\mathbf{Y}}, S_i^{\mathbf{N}}$ are random variables in $\{0, 1\}^c$. Without loss of generality, we assume that $S_0^{\mathbf{Y}} = S_0^{\mathbf{N}} = 0$.

We now define the notion of an informative index, as in [9].

► **Definition 12** (Informative index). *An index $j \in \{0, \dots, k-1\}$ is said to be δ -informative for $\delta > 0$ if*

$$\left\| S_{j+1}^{\mathbf{Y}} - S_{j+1}^{\mathbf{N}} \right\|_{\text{tvd}} \geq \left\| S_j^{\mathbf{Y}} - S_j^{\mathbf{N}} \right\|_{\text{tvd}} + \delta$$

We now show the existence of a $\Omega(1/k)$ -informative index for any streaming algorithm that distinguishes between \mathbf{Y} and \mathbf{N} distributions.

► **Lemma 13.** *Suppose a streaming algorithm \mathbf{ALG} uses c bits of memory and distinguishes the \mathbf{Y} and \mathbf{N} distributions with advantage $1/4$. Then the algorithm has a $\Omega(1/k)$ -informative index.*

Proof. At first, $\|S_0^{\mathbf{Y}} - S_0^{\mathbf{N}}\|_{\text{tvd}} = 0$; at the end of the algorithm, since advantage is at least $1/4$, $\|S_k^{\mathbf{Y}} - S_k^{\mathbf{N}}\|_{\text{tvd}}$ must be at least some constant C . Let j be the first index such that $\|S_{j+1}^{\mathbf{Y}} - S_{j+1}^{\mathbf{N}}\|_{\text{tvd}} \geq C(j+1)/k$, then j is a C/k -informative index. \blacktriangleleft

Let j^* be a $\Omega(1/k)$ -informative index of a streaming algorithm \mathbf{ALG} . Using \mathbf{ALG} , we can devise a communication protocol for the p -ary Hidden Matching problem as follows.

1. Suppose Alice holds as input a random string $x \in \mathbb{Z}_p^n$. She samples j^* random α -partial matchings and feeds the streaming algorithm UG constraints for the first j^* stages that follow the \mathbf{Y} distribution with the setting $z = x$.
2. Alice sends the memory contents of \mathbf{ALG} after j^* stages to Bob.

5:10 Streaming Hardness of Unique Games

3. Bob samples an α -partial matching and gives constraints $x_u + x_v = w_e$ for $e = (u, v)$ according to his w . He then continues running **ALG** on these constraints as the $(j^* + 1)$ 'th stage.

Let the memory Bob gets be s .

4. Let the resulting memory distribution under the two cases (depending on w 's distribution) be \tilde{S}^{YES} and \tilde{S}^{NO} . (Note that these distribution can be computed by Bob since **ALG** is known.)

Bob outputs 1 if $\Pr[\tilde{S}^{\text{YES}} = s] \geq \Pr[\tilde{S}^{\text{NO}} = s]$, and otherwise 0.

The above completes the description of the reduction. Before we analyze it and proceed to the proof of Lemma 11, we need the following fact about the statistical (total variation) distance between random variables.

► **Lemma 14** (Claim 6.5, [9]). *Let X, Y be two random variables and W be independent of (X, Y) . Then for any function f , we have*

$$\|f(X, W) - f(Y, W)\|_{\text{tvd}} \leq \|X - Y\|_{\text{tvd}} .$$

Proof of Lemma 11. We argue that the above protocol for p -ary Hidden Matching achieves the claimed advantage of $\Omega(1/k)$ in distinguishing between **YES** and **NO** distributions.

Let f be the function that maps the memory after stage j^* and constraints of stage $(j^* + 1)$ to the memory after stage $(j^* + 1)$. Thus we have $\tilde{S}^{\text{YES}} = S_{j^*+1}^Y = f(S_{j^*}^Y, C^Y)$ and $\tilde{S}^{\text{NO}} = f(S_{j^*}^Y, C^N)$, where C^Y, C^N be the constraints Bob generated in both cases. We also know that $S_{j^*+1}^N = f(S_{j^*}^N, C^N)$.

By Lemma 14, we know that

$$\|\tilde{S}^{\text{NO}} - S_{j^*+1}^N\|_{\text{tvd}} = \|f(S_{j^*}^Y, C^N) - f(S_{j^*}^N, C^N)\|_{\text{tvd}} \leq \|S_{j^*}^Y - S_{j^*}^N\|_{\text{tvd}} .$$

Hence, we have

$$\begin{aligned} \|\tilde{S}^{\text{YES}} - \tilde{S}^{\text{NO}}\|_{\text{tvd}} &\geq \|S_{j^*+1}^Y - S_{j^*+1}^N\|_{\text{tvd}} - \|\tilde{S}^{\text{NO}} - S_{j^*+1}^N\|_{\text{tvd}} \\ &\geq \|S_{j^*+1}^Y - S_{j^*+1}^N\|_{\text{tvd}} - \|S_{j^*}^Y - S_{j^*}^N\|_{\text{tvd}} \\ &\geq \Omega(1/k). \end{aligned}$$

The strategy in Step 4 that Bob uses distinguishes between \tilde{S}^{YES} and \tilde{S}^{NO} with advantage exactly $\|\tilde{S}^{\text{YES}} - \tilde{S}^{\text{NO}}\|_{\text{tvd}}$, which is at least $\Omega(1/k)$. This concludes the proof of Lemma 11. ◀

Our main result, Theorem 1, now follows by choosing $\alpha = 1/8$ and $k = \lceil Cp \log p / \epsilon^2 \rceil$ for a large enough absolute constant C , and combining together Theorem 5, Lemma 11, and Lemma 9.

5 Conclusion

We proved that Unique Games is hard for single-pass streaming algorithms in a strong sense: even if the instance is perfectly satisfiable, the algorithm cannot certify that it is even $(1/p + \epsilon)$ -satisfiable, where p is the alphabet size, and $\epsilon > 0$ is an arbitrary constant. Some natural directions to extend our lower bound would be to multi-pass algorithms, and for random arrival order of the constraints.

An interesting direction for future work would be to establish limitations of streaming algorithms for other approximation problems which are only known to be “Unique Games-hard.” An example, which partly motivated this work initially, is the Maximum Acyclic Subgraph (MAS) problem. The MAS problem is another one of those notorious problems for which there is a trivial algorithm that achieves approximation ratio of 2 (the algorithm is simply to order the vertices arbitrarily, and take either all the forward-going or backward-going edges as an acyclic subgraph with at least $1/2$ the edges), and no efficient algorithm achieving a factor $(2 - \epsilon)$ -approximation is known for any fixed $\epsilon > 0$. On the other hand, known NP-hardness results are rather weak, but under the Unique Games conjecture, it is known that there is no efficient $(2 - \epsilon)$ -approximation for MAS [6, 5].

One can try to explain the difficulty of MAS in the streaming model, by proving a result similar in spirit to the result we established for Unique Games. Specifically, given as input a directed graph whose edges arrive one-by-one, can a low-space single-pass streaming algorithm distinguish between the cases when the directed graph is acyclic and when it has no acyclic subgraph with even $1/2 + \epsilon$ of the edges? (The $1/2$ threshold being trivial, since any directed graph has an acyclic subgraph with $1/2$ the edges.) A result of this flavor was shown with $1/2$ replaced by $7/8$ in [7].

The reduction from Unique Games to $(2 - \epsilon)$ -approximating MAS [6] and our inapproximability result for UG in the streaming model gives hope to prove the desired streaming hardness for MAS as well, by implementing the reduction in a streaming manner. Since reductions involving CSPs are usually local, the arrival of one constraint of problem \mathbb{A} can be mimicked by the arrival of the constraints of problem \mathbb{B} that implement it. The reduction from UG to MAS (and indeed many other CSPs), however, introduces constraints between all pairs of variables that share a constraint with a UG vertex u . So to implement it one would need the UG streaming hardness under a “vertex arrival” model, where the graph is bipartite, and all constraints involving a left hand side vertex arrive in sequence. We *can* adapt the reduction in [6] to something local, based only on a single constraint, thereby making it more friendly to the edge arrival model. However, this only yields a weaker hardness result that distinguishing DAGs from graphs whose MAS has at most $\approx 3/4$ edges requires $\Omega(\sqrt{n})$ space.

Obtaining a tight streaming hardness result for MAS, and more broadly leveraging our tight streaming hardness result for Unique Games toward streaming inapproximability results for other optimization problems for which we have optimal reductions from Unique Games, are interesting directions for future work. Further, given the hardness results in this work and [9], one can ask which CSPs and related problems admit non-trivial approximate estimation algorithms in the streaming model. Even though one might suspect that strong hardness results should be pervasive, it seems that it is rather non-trivial to establish strong limitations of streaming algorithms, and the algorithms for Max 2CSP in [7] suggest that there might be more interesting cases where streaming algorithms can provide non-trivial guarantees.

In recent work [10], Kapralov and Krachun give an $\tilde{\Omega}(n)$ space lower bound on beating a 2-approximation for MAX-CUT by a single-pass streaming algorithm. A generalization of their techniques to the p -ary case may lead to a near-tight streaming space lower bound for Unique Games.

On Strong Diameter Padded Decompositions

Arnold Filtser

arnold273@gmail.com

Abstract

Given a weighted graph $G = (V, E, w)$, a partition of V is Δ -bounded if the diameter of each cluster is bounded by Δ . A distribution over Δ -bounded partitions is a β -padded decomposition if every ball of radius $\gamma\Delta$ is contained in a single cluster with probability at least $e^{-\beta\gamma}$. The weak diameter of a cluster C is measured w.r.t. distances in G , while the strong diameter is measured w.r.t. distances in the induced graph $G[C]$. The decomposition is weak/strong according to the diameter guarantee.

Formerly, it was proven that K_r free graphs admit weak decompositions with padding parameter $O(r)$, while for strong decompositions only $O(r^2)$ padding parameter was known. Furthermore, for the case of a graph G , for which the induced shortest path metric d_G has doubling dimension ddim , a weak $O(\text{ddim})$ -padded decomposition was constructed, which is also known to be tight. For the case of strong diameter, nothing was known.

We construct strong $O(r)$ -padded decompositions for K_r free graphs, matching the state of the art for weak decompositions. Similarly, for graphs with doubling dimension ddim we construct a strong $O(\text{ddim})$ -padded decomposition, which is also tight. We use this decomposition to construct $(O(\text{ddim}), \tilde{O}(\text{ddim}))$ -sparse cover scheme for such graphs. Our new decompositions and cover have implications to approximating unique games, the construction of light and sparse spanners, and for path reporting distance oracles.

1 Introduction

Divide and conquer is a widely used algorithmic approach. In many distance related graph problems, it is often useful to randomly partition the vertices into clusters, such that small neighborhoods have high probability to be clustered together. Given a weighed graph $G = (V, E, w)$, a partitions is Δ -bounded if the diameter of every cluster is at most Δ . A distribution \mathcal{D} over partitions is called a (β, δ, Δ) -padded decomposition, if every partition is Δ -bounded, and for every vertex $v \in V$ and $\gamma \in [0, \delta]$, the probability that the entire ball $B_G(v, \gamma\Delta)$ of radius $\gamma\Delta$ around v is clustered together, is at least $e^{-\beta\gamma}$. If G admits a (β, δ, Δ) -padded decomposition for every $\Delta > 0$, we say that G is (β, δ) -decomposable. If in addition $\delta = \Omega(1)$ is a universal constant, we say that G is β -decomposable. Among other

applications, padded decompositions have been used for multi-commodity flow [33], metric embeddings [41, 40, 34], edge and vertex cut problems [37, 24], routing [4], near linear SDD solvers [12], approximation algorithms [16], and many more.

The *weak* diameter of a cluster $C \subseteq V$ is the maximal distance between a pair of vertices in the cluster w.r.t. the shortest path metric in the entire graph G , i.e. $\max_{u,v \in C} d_G(u,v)$. The *strong* diameter is the maximal distance w.r.t. the shortest path metric in the induced graph $G[C]$, i.e. $\max_{u,v \in C} d_{G[C]}(u,v)$. Padded decomposition can be weak/strong according to the provided guarantee on the diameter of each cluster. It is considerably harder to construct padded decompositions with strong diameter. Nevertheless, strong diameter is more convenient to use, and some applications indeed require that (e.g. for routing, spanners etc.).

Previous results on padded decompositions are presented in Table 1. General n -vertex graphs are strongly $O(\log n)$ -decomposable [10], which is also tight. In a seminal work, given a K_r free graph G , Klein, Plotkin and Rao [33] showed that G is weakly $O(r^3)$ -decomposable. Fakcharoenphol and Talwar [23] improved the decomposability of K_r free graph to $O(r^2)$ (weak diameter). Finally, Abraham et al. [5] improved the decomposition parameter to $O(r)$, still with weak diameter. The first result on strong diameter for K_r free graphs is by Abraham et al. [6], who constructed decompositions with padding parameter exponential in r . In fact, they study a somewhat weaker notion of decomposition called separating decompositions (see Definition 16). Afterwards, in the same paper providing the state of the art for weak diameter, Abraham et al. [5] proved that K_r free graphs are strongly $(O(r^2), \Omega(\frac{1}{r^2}))$ -decomposable. It was conjectured [5] that K_r free graphs are $O(\log r)$ -decomposable. However, even improving strong diameter decompositions to match the state of the art of weak diameter remained elusive.

Another family of interest are graph with bounded doubling dimension¹. Abraham, Bartal and Neiman [2] showed that a graph with doubling dimension ddim is weakly $O(\text{ddim})$ -decomposable, generalizing a result from [29]. No prior strong diameter decomposition for this family is known.

A related notion to padded decompositions is *sparse cover*. A collection \mathcal{C} of clusters is a (β, s, Δ) -sparse cover if it is strongly Δ -bounded, each ball of radius $\frac{\Delta}{\beta}$ is contained in some cluster, and each vertex belongs to at most s different clusters. A graph admits (β, s) -sparse cover scheme if it admits (β, s, Δ) -sparse cover for every $\Delta > 0$. Awerbuch and Peleg [9] showed that for $k \in \mathbb{N}$, general n -vertex graphs admit a strong $(2k - 1, 2k \cdot n^{\frac{1}{k}})$ -sparse cover scheme. For K_r free graphs, Abraham et al. [6] constructed $(O(r^2), 2^r(r+1)!)$ -sparse cover scheme. Busch, LaFortune and Tirthapura [15] constructed $(4, f(r) \cdot \log n)$ -sparse cover scheme for K_r free graphs².

For the case of graphs with doubling dimension ddim , Abraham et al. [4] constructed a $(2, 4^{\text{ddim}})$ -sparse cover scheme. No other tradeoff are known. In particular, if ddim is larger than $\log \log n$, the only way to get a sparse cover where each vertex belongs to $O(\log n)$ clusters is through [9], with only $O(\log n)$ padding.

1.1 Results and Organization

In our first result (Theorem 15 in Section 5), we prove that K_r free graphs are strongly $(O(r), \Omega(\frac{1}{r}))$ -decomposable. Providing quadratic improvement compared to [5].

¹ A metric space (X, d) has doubling dimension ddim if every ball of radius $2r$ can be covered by 2^{ddim} balls of radius r . The doubling dimension of a graph is the doubling dimension of its induced shortest path metric.

² $f(r)$ is a function coming from the Robertson and Seymour structure theorem [42].

■ **Table 1** Summary of all known and new padding decompositions for various graph families.

Family	Partition type	Padding	δ	Reference

K_r minor free	Strong	$O(r^2)$	$\Omega(\frac{1}{r^2})$	[5]
Our results				
Doubling	Strong	$O(\text{ddim})$	$\Omega(1)$	Corollary 9
K_r minor free	Strong	$O(r)$	$\Omega(\frac{1}{r})$	Theorem 15

Our second result (Corollary 9 in Section 4) is the first strong diameter padded decompositions for doubling graphs, which is also asymptotically tight. Specifically, we prove that graphs with doubling dimension ddim are strongly $O(\text{ddim})$ -decomposable.

Both of these padded decomposition constructions are based on a technical theorem (Theorem 4 in Section 3). Given a set of centers N , such that each vertex has a center at distance at most Δ and at most τ centers at distance at most 3Δ ($\forall v, |B_G(v, 3\Delta) \cap N| \leq \tau$), we construct a strong $(O(\log \tau), \Omega(1), 4\Delta)$ -padded decomposition. We also provide an alternative construction for the decomposition of Theorem 4 in Appendix B. All of our decompositions can be efficiently constructed in polynomial time. See Table 1 for a summary of results on padded decompositions.

Our third result (Theorem 10 in Section 4) is a sparse cover for doubling graphs. For every parameter $t \geq 1$, we construct an $(O(t), O(2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log t))$ -sparse cover scheme. Note that for $t = 1$ we (asymptotically) obtain the result of [6]. However, we also get the entire spectrum of padding parameters. In particular, for $t = \text{ddim}$ we get an $(O(\text{ddim}), O(\text{ddim} \cdot \log \text{ddim}))$ -sparse cover scheme.

Next, we overview some of the previously known applications of strong diameter padded decomposition, and analyze the various improvements achieved using our results. Specifically:

1. Given an instance of the unique games problem where the input graph is K_r free, Alev and Lau [7] showed that if there exist an assignment that satisfies all but an ϵ -fraction of the edges, then there is an efficient algorithm that finds an assignment that satisfies all but an $O(r \cdot \sqrt{\epsilon})$ -fraction. Using our padded decompositions for minor-free graphs, we can find an assignment that satisfies all but an $O(\sqrt{r \cdot \epsilon})$ -fraction of the edges. See Section 6.1.
2. Using the framework of Filtser and Neiman [26], given an n vertex graph, with doubling dimension ddim , for every parameter $t > 1$ we construct a graph-spanner with stretch $O(t)$, lightness $O(2^{\frac{\text{ddim}}{t}} \cdot t \cdot \log^2 n)$ and $O(n \cdot 2^{\frac{\text{ddim}}{t}} \cdot \log n \cdot \log \Lambda)$ edges⁴. The only previous spanner of this type appeared in [26], was based on weak diameter decompositions, had the same stretch and lightness, while having no bound whatsoever on the number of edges. See Section 6.2.

³ In fact [6] studied separating decompositions instead of padded (see Definition 16).

⁴ Lightness is the ratio between the weight of the spanner to the weight of the MST. $\Lambda = \max_{u,v \in V} d_G(u,v) / \min_{u,v \in V} d_G(u,v)$ is the aspect ratio.

3. Elkin, Neiman and Wulff-Nilsen [19] constructed a path reporting distance oracle for K_r free graphs with stretch $O(r^2)$, space $O(n \cdot \log \Lambda \cdot \log n)$ and query time $O(\log \log \Lambda)$. That is, on a query $\{u, v\}$ the distance oracle returns a $u - v$ path P of weight at most $O(r^2) \cdot d_G(u, v)$ in $O(|P| + \log \log \Lambda)$ time. Using our strong diameter padded decompositions we improve the stretch to $O(r)$, while keeping the other parameters intact. See Appendix A.
4. We further use the framework of [19] to create a path reporting distance oracle for graphs having doubling dimension ddim with stretch $O(\text{ddim})$, space $O(n \cdot \text{ddim} \log \Lambda)$ and query time $O(\log \log \Lambda)$. This is the first path reporting distance oracle for doubling graphs. The construction uses our sparse covers. See Appendix A.

1.2 Related Work

Other than padded decompositions, separating decompositions have been studied. Here, instead of analyzing the probability to cut a ball, we analyze the probability to cut an edge [8, 36, 16, 22]. Separating decompositions been used to minimize the number of inter-cluster edges in a partition. In particular, strong diameter version of such partitions were used for SDD solvers [12].

Miller et al. [38] constructed strong diameter partitions for general graphs, which they later used to construct spanners and hop-sets in parallel and distributed regimes (see also [18]). Hierarchical partitions with strong diameter had been studied and used for constructing distributions over spanning trees with small expected distortion [17, 1], Ramsey spanning trees [3] and for universal Steiner trees [14]. Another type of partitions studied is when we require only weak diameter, and in addition for each cluster to be connected [21, 25].

Padded decompositions were studied for additional graph families. Kamma and Krauthgamer [31] showed that treewidth r graphs are weakly $O(\log r + \log \log n)$ -decomposable. Abraham et al. [5] showed that treewidth r graphs are strongly $O(\log r + \log \log n)$ -decomposable and strongly $(O(r), \Omega(\frac{1}{r}))$ -decomposable. [5] also showed that pathwidth r graphs are strongly $O(\log r)$ -decomposable. Finally [5] proved that genus g graphs are strongly $O(\log g)$ -decomposable, improving a previous weak diameter version of Lee and Sidiropoulos [35].

1.3 Technical Ideas

The basic approach for creating padded decompositions is by ball carving [10, 2]. That is, iteratively create clusters by taking a ball centered around some vertex, with radius drawn according to exponential distribution. The process halts when all the vertices are clustered. Intuitively, if every vertex might join the cluster associated with at most τ centers, the padding parameter is $O(\log \tau)$. We think of these centers as *threateners*. This approach worked very well for general graphs as the number of vertices is n . Similarly it also been used for doubling graphs, where the number of threateners is bounded by $2^{O(\text{ddim})}$. However, in doubling graphs ball carving produces only weak diameter clustering.

Our main technical contribution is a proof that the intuition above holds for strong diameter as well. Specifically, we show that if there is a set N of centers such that each vertex has a center at distance at most Δ , and at most τ centers at distance 3Δ (these are the threateners), then the graph is strongly $(O(\log \tau), \Omega(1), 4\Delta)$ -decomposable. We use the clustering approach of Miller et al. [38] with exponentially distributed starting times. In short, in [38] clustering each center x samples a starting time δ_x . Vertex v joins the cluster of the center x_i maximizing $\delta_x - d_G(x, v)$. This approach guaranteed to creates strong

diameter clusters. The key observation is that if for every center $y \neq x_i$, $(\delta_{x_i} - d_G(x_i, v)) - (\delta_y - d_G(y, v)) \geq 2\gamma\Delta$, then the ball $B_G(v, \gamma\Delta)$ is fully contained in the cluster of x_i . Using truncated exponential distribution, we lower bound the probability of this event by $e^{-\gamma \cdot O(\log \tau)}$. It is the first time [38]-like algorithm is used to create padded decompositions.

In addition to the [38]-based algorithm, we also show a simpler algorithm, based on cone carving ([17]). The cone approach, although less involved, is inherently sequential and implies dependencies of each vertex on the entire center set. [38] algorithm can be efficiently implemented in distributed and parallel setting. Moreover, as each vertex depends only on centers in its local area, we are able to use the Lovász Local Lemma to create a sparse cover from padded decompositions.

Decompositions of K_r free graphs did not use ball carving directly. Rather, they tend to use the topological structure of the graph. We say that a cluster of G has an r -core with radius Δ if it contains at most r shortest paths (w.r.t. d_G) such that each vertex is at distance at most Δ from one of these paths. [5]'s strong decomposition for K_r free graphs is based on a partition into 1-core clusters, such that a ball with radius $\gamma\Delta$ is cut with probability at most $1 - e^{-O(\gamma r^2)}$. This partition is the reason for their $O(r^2)$ padding parameter. Although not stated explicitly, [5] also constructed a partition into r -core clusters, such that a ball with radius $\gamma\Delta$ is cut with probability at most $1 - e^{-O(\gamma r)}$. Apparently, [5] lacked an algorithm for partitioning r -clusters. Taking a union of Δ -nets from each shortest path to the center set N , it will follow that each vertex has at most $O(r)$ centers in its $O(\Delta)$ neighborhood. In particular, our theorem above implies a clustering of each r -core cluster into bounded diameter clusters. Our strong decomposition with parameter $O(r)$ follows.

2 Preliminaries

Graphs. We consider connected undirected graphs $G = (V, E)$ with edge weights $w : E \rightarrow \mathbb{R}_{\geq 0}$. We say that vertices v, u are neighbors if $\{v, u\} \in E$. Let d_G denote the shortest path metric in G . $B_G(v, r) = \{u \in V \mid d_G(v, u) \leq r\}$ is the ball of radius r around v . For a vertex $v \in V$ and a subset $A \subseteq V$, let $d_G(x, A) := \min_{a \in A} d_G(x, a)$, where $d_G(x, \emptyset) = \infty$. For a subset of vertices $A \subseteq V$, let $G[A]$ denote the induced graph on A , and let $G \setminus A := G[V \setminus A]$. The *diameter* of a graph G is $\text{diam}(G) = \max_{v, u \in V} d_G(v, u)$, i.e. the maximal distance between a pair of vertices. Given a subset $A \subseteq V$, the *weak-diameter* of A is $\text{diam}_G(A) = \max_{v, u \in A} d_G(v, u)$, i.e. the maximal distance between a pair of vertices in A , w.r.t. to d_G . The *strong-diameter* of A is $\text{diam}(G[A])$, the diameter of the graph induced by A .

A graph H is a *minor* of a graph G if we can obtain H from G by edge deletions/contractions, and isolated vertex deletions. A graph family \mathcal{G} is *H -minor-free* if no graph $G \in \mathcal{G}$ has H as a minor. Some examples of minor free graphs are planar graphs (K_5 and $K_{3,3}$ free), outer-planar graphs (K_4 and $K_{3,2}$ free), series-parallel graphs (K_4 free) and trees (K_3 free).

Doubling dimension. The doubling dimension of a metric space is a measure of its local “growth rate”. A metric space (X, d) has doubling constant λ if for every $x \in X$ and radius $r > 0$, the ball $B(x, 2r)$ can be covered by λ balls of radius r . The doubling dimension is defined as $\text{ddim} = \log_2 \lambda$. A d -dimensional ℓ_p space has $\text{ddim} = \Theta(d)$, and every n point metric has $\text{ddim} = O(\log n)$. We say that a weighted graph $G = (V, E, w)$ has doubling dimension ddim , if the corresponding shortest path metric (V, d_G) has doubling dimension ddim . The following lemma gives the standard packing property of doubling metrics (see, e.g., [29]).

► **Lemma 1** (Packing Property). *Let (X, d) be a metric space with doubling dimension ddim . If $S \subseteq X$ is a subset of points with minimum interpoint distance r that is contained in a ball of radius R , then $|S| \leq \left(\frac{2R}{r}\right)^{O(\text{ddim})}$.*

6:6 On Strong Diameter Padded Decompositions

Nets. A set $N \subseteq V$ is called a Δ -net, if for every vertex $v \in V$ there is a net point $x \in N$ at distance at most $d_G(v, x) \leq \Delta$, while every pair of net points $x, y \in N$, is farther than $d_G(x, y) > \Delta$. A Δ -net can be constructed efficiently in a greedy manner. In particular, by Lemma 1, given a Δ -net N in a graph of doubling dimension ddim , a ball of radius $R \geq \Delta$, will contain at most $\left(\frac{2R}{\Delta}\right)^{O(\text{ddim})}$ net points.

Padded Decompositions and Sparse Covers. Consider a *partition* \mathcal{P} of V into disjoint clusters. For $v \in V$, we denote by $P(v)$ the cluster $P \in \mathcal{P}$ that contains v . A partition \mathcal{P} is strongly Δ -bounded (resp. weakly Δ -bounded) if the strong-diameter (resp. weak-diameter) of every $P \in \mathcal{P}$ is bounded by Δ . If the ball $B_G(v, \gamma\Delta)$ of radius $\gamma\Delta$ around a vertex v is fully contained in $P(v)$, we say that v is γ -padded by \mathcal{P} . Otherwise, if $B_G(v, \gamma\Delta) \not\subseteq P(v)$, we say that the ball is *cut* by the partition.

► **Definition 2 (Padded Decomposition).** Consider a weighted graph $G = (V, E, w)$. A distribution \mathcal{D} over partitions of G is strongly (resp. weakly) (β, δ, Δ) -padded decomposition if every $\mathcal{P} \in \text{supp}(\mathcal{D})$ is strongly (resp. weakly) Δ -bounded and for any $0 \leq \gamma \leq \delta$, and $z \in V$,

$$\Pr[B_G(z, \gamma\Delta) \subseteq P(z)] \geq e^{-\beta\gamma}.$$

We say that a graph G admits a strong (resp. weak) (β, δ) -padded decomposition scheme, if for every parameter $\Delta > 0$ it admits a strongly (resp. weakly) (β, δ, Δ) -padded decomposition that can be sampled in polynomial time.

A related notion to padded decompositions is sparse covers.

► **Definition 3 (Sparse Cover).** A collection of clusters $\mathcal{C} = \{C_1, \dots, C_t\}$ is called a (β, s, Δ) -sparse cover if the following conditions hold.

1. *Bounded diameter:* The strong diameter of every $C_i \in \mathcal{C}$ is bounded by Δ .
2. *Padding:* For each $v \in V$, there exists a cluster $C_i \in \mathcal{C}$ such that $B_G(v, \frac{\Delta}{\beta}) \subseteq C_i$.
3. *Overlap:* For each $v \in V$, there are at most s clusters in \mathcal{C} containing v .

We say that a graph G admits a (β, s) -sparse cover scheme, if for every parameter $\Delta > 0$ it admits a (β, s, Δ) -sparse cover that can be constructed in expected polynomial time.

Truncated Exponential Distributions. To create padded decompositions, similarly to previous works, we will use truncated exponential distribution. That is, exponential distribution conditioned on the event that the outcome lays in a certain interval. The $[\theta_1, \theta_2]$ -truncated exponential distribution with parameter λ is denoted by $\text{Texp}_{[\theta_1, \theta_2]}(\lambda)$, and the density function is: $f(y) = \frac{\lambda e^{-\lambda \cdot y}}{e^{-\lambda \cdot \theta_1} - e^{-\lambda \cdot \theta_2}}$, for $y \in [\theta_1, \theta_2]$. For the $[0, 1]$ -truncated exponential distribution we drop the subscripts and denote it by $\text{Texp}(\lambda)$; the density function is $f(y) = \frac{\lambda e^{-\lambda \cdot y}}{1 - e^{-\lambda}}$.

3 Strongly Padded Decomposition

In this section we prove the main technical theorem of this paper.

► **Theorem 4.** Let $G = (V, E, w)$ be a weighted graph and $\Delta > 0, \tau = \Omega(1)$ parameters. Suppose that we are given a set $N \subseteq V$ of center vertices such that for every $v \in V$:

- **COVERING.** There is $x \in N$ such that $d_G(v, x) \leq \Delta$.
 - **PACKING.** There are at most τ vertices in N at distance 3Δ , i.e. $|B_G(v, 3\Delta) \cap N| \leq \tau$.
- Then G admits a strongly $(O(\ln \tau), \frac{1}{16}, 4\Delta)$ -padded decomposition that can be efficiently sampled.

We start with description of the [38] algorithm (with some adaptations), and its properties. Later, in Section 3.2 we will prove Theorem 4. An alternative construction is given in Appendix B.

3.1 Clustering Algorithm Based on Starting Times

As we make some small adaptations, and the role of the clustering algorithm is essential, we provide full details. Let $\Delta > 0$ be some parameter and let $N \subseteq V$ be some set of centers such that for every $v \in V$, $d_G(v, N) \leq \Delta$. For each center $x \in N$, let $\delta_x \in [0, \Delta]$ be some parameter. The choice of $\{\delta_x\}_{x \in N}$ differs among different implementations of the algorithm. In our case we will sample δ_x using truncated exponential distribution. Each vertex v will join the cluster C_x of the center $x \in N$ for which the value $\delta_x - d_G(x, v)$ is maximized. Ties are broken in a consistent manner⁵. Note that it is possible that a center $x \in N$ will join the cluster of a different center $x' \in N$. An intuitive way to think about the clustering process is as follows: each center x wakes up at time $-\delta_x$ and begins to “spread” in a continuous manner. The spread of all centers done in the same unit tempo. A vertex v joins the cluster of the first center that reaches it.

▷ **Claim 5.** Every non-empty cluster C_x created by the algorithm has strong diameter at most 4Δ .

Proof. Consider a vertex $v \in C_x$. First we argue that $d_G(v, x) \leq 2\Delta$. This will already imply that C_x has weak diameter 4Δ . Let x_v be the closest center to v , then $d_G(v, x_v) \leq \Delta$. As v joined the cluster of x , it holds that $\delta_x - d_G(v, x) \geq \delta_{x_v} - d_G(v, x_v)$. In particular $d_G(v, x) \leq \delta_x + d_G(v, x_v) \leq 2\Delta$.

Let \mathcal{I} be the shortest path in G from v to x . For every vertex $u \in \mathcal{I}$ and center $x' \in N$, it holds that

$$\begin{aligned} \delta(x) - d_G(u, x) &= \delta(x) - (d_G(v, x) - d_G(v, u)) \geq \delta(x') - d_G(v, x') + d_G(v, u) \\ &\geq \delta(x') - d_G(u, x') . \end{aligned}$$

We conclude that $\mathcal{I} \subseteq C_x$, in particular $d_{G[C_x]}(v, x) \leq 2\Delta$. The claim now follows. ◁

▷ **Claim 6.** Consider a vertex v , and let x_1, x_2, \dots be an ordering of the centers w.r.t. $\delta(x_i) - d_G(v, x_i)$. That is $\delta(x_1) - d_G(v, x_1) \geq \delta(x_2) - d_G(v, x_2) \geq \dots$. Set $\Upsilon = (\delta(x_1) - d_G(v, x_1)) - (\delta(x_2) - d_G(v, x_2))$. Then for every vertex u such that $d_G(v, u) < \frac{\Upsilon}{2}$ it holds that $u \in C_{x_1}$.

Proof. For every center $x_i \neq x_1$ it holds that,

$$\delta(x_1) - d_G(u, x_1) > \delta(x_1) - d_G(v, x_1) - \frac{\Upsilon}{2} \geq \delta(x_i) - d_G(v, x_i) + \frac{\Upsilon}{2} > \delta(x_i) - d_G(u, x_i) .$$

In particular, $u \in C_{x_1}$. ◁

3.2 Proof of Theorem 4

For every center $x \in N$, we sample $\delta'_x \in [0, 1]$ according to $\text{Texp}(\lambda)$ truncated exponential distribution with parameter $\lambda = 2 + 2 \ln \tau$. Set $\delta_x = \delta'_x \cdot \Delta \in [0, \Delta]$. We execute the clustering algorithm from Section 3.1 with parameters $\{\delta_x\}_{x \in N}$ to get a partition \mathcal{P} .

⁵ That is we have some order x_1, x_2, \dots . Among the centers x_i that minimize $\delta_{x_i} - d_G(x_i, v)$, v joins the cluster of the center with minimal index.

6:8 On Strong Diameter Padded Decompositions

According to Claim 5, we created a distribution over strongly 4Δ -bounded partitions. Consider some vertex $v \in V$ and parameter $\gamma \leq \frac{1}{4}$. We will argue that the ball $B = B_G(v, \gamma\Delta)$ is fully contained in $P(v)$ with probability at least $e^{-O(\gamma \log \tau)}$. Let N_v be the set of centers x for which there is non zero probability that C_x intersects B . Following the calculation in Claim 5, each vertex joins the cluster of a center at distance at most 2Δ . By triangle inequality, all the centers in N_v are at distance at most $(2 + \gamma)\Delta \leq 3\Delta$ from v . In particular $|N_v| \leq \tau$.

Set $N_v = \{x_1, x_2, \dots\}$ ordered arbitrarily. Denote by \mathcal{F}_i the event that v joins the cluster of x_i , i.e. $v \in C_{x_i}$. Denote by \mathcal{C}_i the event that v joins the cluster of x_i , but not all of the vertices in B joined that cluster, that is $v \in C_{x_i} \cap B \neq B$. To prove the theorem, it is enough to show that $\Pr[\cup_i \mathcal{C}_i] \leq 1 - e^{-O(\gamma \cdot \lambda)}$. Set $\alpha = e^{-2\gamma \cdot \lambda}$.

▷ **Claim 7.** For every i , $\Pr[\mathcal{C}_i] \leq (1 - \alpha) \left(\Pr[\mathcal{F}_i] + \frac{1}{e^{\lambda} - 1} \right)$.

Proof. As the order in N_v is arbitrary, assume w.l.o.g. that $i = |N_v|$ and denote $x = x_{|N_v|}$, $\mathcal{C} = \mathcal{C}_i$, $\mathcal{F} = \mathcal{F}_i$, $\delta = \delta_{x_i}$ and $\delta' = \delta'_{x_i}$. Let $X \in [0, 1]^{|N_v|-1}$ be the vector where the j 'th coordinate equals δ'_{x_j} . Set $\rho_X = \frac{1}{\Delta} \cdot (d_G(x, v) + \max_{j < |N_v|} \{\delta_{x_j} - d_G(x_j, v)\})$. Note that ρ_X is the minimal value of δ' such that if $\delta' > \rho_X$, that x has the maximal value $\delta_x - d_G(x, v)$, and therefor v will join the cluster of x . Note that it is possible that $\rho_X > 1$. Conditioning on the samples having values X , and assuming that $\rho_X \leq 1$ it holds that

$$\Pr[\mathcal{F} \mid X] = \Pr[\delta' > \rho_X] = \int_{\rho_X}^1 \frac{\lambda \cdot e^{-\lambda y}}{1 - e^{-\lambda}} dy = \frac{e^{-\rho_X \cdot \lambda} - e^{-\lambda}}{1 - e^{-\lambda}}.$$

If $\delta' > \rho_X + 2\gamma$ then $\delta - d_G(x, v) > \max_{j \neq i} \{\delta_{x_j} - d_G(x_j, v)\} + 2\gamma\Delta$. In particular, by Claim 6 the ball B will be contained in C_x . We conclude

$$\begin{aligned} \Pr[\mathcal{C} \mid X] &\leq \Pr[\rho_X \leq \delta' \leq \rho_X + 2\gamma] \\ &= \int_{\rho_X}^{\max\{1, \rho_X + 2\gamma\}} \frac{\lambda \cdot e^{-\lambda y}}{1 - e^{-\lambda}} dy \\ &\leq \frac{e^{-\rho_X \cdot \lambda} - e^{-(\rho_X + 2\gamma) \cdot \lambda}}{1 - e^{-\lambda}} \\ &= (1 - e^{-2\gamma \cdot \lambda}) \cdot \frac{e^{-\rho_X \cdot \lambda}}{1 - e^{-\lambda}} \\ &= (1 - \alpha) \cdot \left(\Pr[\mathcal{F} \mid X] + \frac{1}{e^{\lambda} - 1} \right). \end{aligned}$$

Note that if $\rho_X > 1$ then $\Pr[\mathcal{C} \mid X] = 0 \leq (1 - \alpha) \cdot \left(\Pr[\mathcal{F} \mid X] + \frac{1}{e^{\lambda} - 1} \right)$ as well. Denote by f the density function of the distribution over all possible values of X . Using the law of total probability, we can bound the probability that the cluster of x cuts B

$$\begin{aligned} \Pr[\mathcal{C}] &= \int_X \Pr[\mathcal{C} \mid X] \cdot f(X) dX \\ &\leq (1 - \alpha) \cdot \int_X \left(\Pr[\mathcal{F} \mid X] + \frac{1}{e^{\lambda} - 1} \right) \cdot f(X) dX \\ &= (1 - \alpha) \cdot \left(\Pr[\mathcal{F}] + \frac{1}{e^{\lambda} - 1} \right) \end{aligned} \quad \triangleleft$$

We bound the probability that the ball B is cut.

$$\begin{aligned} \Pr [\cup_i \mathcal{C}_i] &= \sum_{i=1}^{|N_v|} \Pr [\mathcal{C}_i] \leq (1 - \alpha) \cdot \sum_{i=1}^{|N_v|} \left(\Pr [\mathcal{F}_i] + \frac{1}{e^\lambda - 1} \right) \\ &\leq (1 - e^{-2\gamma \cdot \lambda}) \cdot \left(1 + \frac{\tau}{e^\lambda - 1} \right) \\ &\leq (1 - e^{-2\gamma \cdot \lambda}) \cdot (1 + e^{-2\gamma \cdot \lambda}) = 1 - e^{-4\gamma \cdot \lambda} , \end{aligned}$$

where the last inequality follows as $e^{-2\gamma\lambda} = \frac{e^{-2\gamma\lambda}(e^\lambda - 1)}{e^\lambda - 1} \geq \frac{e^{-2\gamma\lambda} \cdot e^{\lambda-1}}{e^\lambda - 1} \geq \frac{e^{\frac{\lambda}{2}-1}}{e^\lambda - 1} = \frac{\tau}{e^\lambda - 1}$.

► **Remark 8.** Actually we can prove a generalized version of Theorem 4. Suppose that there is a set N of centers such that each vertex $v \in V$ has at least one center at distance at most Δ and at most τ_v centers at distance 3Δ . Then for every parameter $\lambda = \Omega(1)$, there is a distribution over partitions with strong diameter 4Δ such that for every parameter $\gamma \in (0, \frac{1}{4})$, the ball around every vertex v of radius $\gamma\Delta$ is cut with probability at most $(1 - e^{-2\gamma\lambda})(1 + \frac{\tau_v}{e^\lambda - 1})$.

4 Doubling Dimension

Our strongly padded decompositions for doubling graphs are a simple corollary of Theorem 4.

► **Corollary 9.** *Let $G = (V, E, w)$ be a weighted graph with doubling dimension ddim . Then G admits a strong $(O(\text{ddim}), \Omega(1))$ -padded decomposition scheme.*

Proof. Fix some $\Delta > 0$. Let N be a Δ -net of X . According to Lemma 1, for every vertex v , the number of net points at distance 3Δ is bounded by $2^{O(\text{ddim})}$. The corollary follows by Theorem 4. ◀

Next, we construct a sparse cover scheme.

► **Theorem 10.** *Let $G = (V, E, w)$ be a weighted graph with doubling dimension ddim and parameter $t = \Omega(1)$. Then G admits an $(O(t), O(2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log t))$ -sparse cover scheme. In particular, there is an $(O(\text{ddim}), O(\text{ddim} \cdot \log \text{ddim}))$ -sparse cover scheme.*

Proof. Let $\Delta > 0$ be the diameter parameter. Let $\alpha = \theta(1)$ be a constant to be determined later, set $\beta = \alpha \cdot t$. We will construct a $(\beta, O(2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log t), 4\Delta)$ -sparse cover. As Δ is arbitrary, this will imply $(4\beta, O(2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log t))$ -sparse cover scheme.

The sparse cover is constructed by sampling $O(2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log t)$ independent partitions using Corollary 9 with diameter parameter Δ , and taking all the clusters from all the partitions to the cover. The sparsity and strong diameter properties are straightforward. To argue that each vertex is padded in some cluster we will use the constructive version of the Lovász Local Lemma by Moser and Tardos [39].

► **Lemma 11 (Constructive Lovász Local Lemma).** *Let \mathcal{P} be a finite set of mutually independent random variables in a probability space. Let \mathcal{A} be a set of events determined by these variables. For $A \in \mathcal{A}$ let $\Gamma(A)$ be a subset of \mathcal{A} satisfying that A is independent from the collection of events $\mathcal{A} \setminus (\{A\} \cup \Gamma(A))$. If there exist an assignment of reals $x : \mathcal{A} \rightarrow (0, 1)$ such that*

$$\forall A \in \mathcal{A} : \Pr[A] \leq x(A) \prod_{B \in \Gamma(A)} (1 - x(B)) ,$$

then there exists an assignment to the variables \mathcal{P} not violating any of the events in \mathcal{A} . Moreover, there is an algorithm that finds such an assignment in expected time $\sum_{A \in \mathcal{A}} \frac{x(A)}{1 - x(A)}$. poly $(|\mathcal{A}| + |\mathcal{P}|)$.

6:10 On Strong Diameter Padded Decompositions

Formally, recall the construction of Theorem 4 used in Corollary 9. Let N be a Δ -net, that we will use as centers. Consider a vertex $v \in V$, and fix some sample of the starting times $\{\delta_x\}_{x \in N}$. Let x_v be the vertex maximizing $\delta_x - d_G(x, v)$ and y_v the second largest. In other words, $\delta_{x_v} - d_G(x_v, v) \geq \delta_{y_v} - d_G(y_v, v) \geq \max_{x \in N \setminus \{x_v, y_v\}} \{\delta_x - d_G(x, v)\}$. Let Ψ_v be the event that $(\delta_{x_v} - d_G(x_v, v)) - (\delta_{y_v} - d_G(y_v, v)) < 4\frac{\Delta}{\beta}$. Recall that the event that the ball of radius $2\frac{\Delta}{\beta}$ around v is cut contained in Ψ_v . Following the analysis of Theorem 4, $\Pr[\Psi_v] \leq 1 - e^{-O(\text{ddim} \cdot \frac{\Delta}{\beta} / \Delta)} = 1 - 2^{-\text{ddim}/t}$, where the equality follows by an appropriate choice of α .

Let \hat{x} be the closest center to v . It holds that $\delta_{\hat{x}} - d_G(\hat{x}, v) \geq -\Delta$, while for every center x at distance larger than 3Δ it holds that $\delta_x - d_G(x, v) \leq -2\Delta$. Therefore Ψ_v depends only on centers at distance at most 3Δ . In particular, by triangle inequality, if v and u are farther away than 6Δ , Ψ_v and Ψ_u are independent.

We take $m = \alpha_m \cdot 2^{\frac{\text{ddim}}{t}} \cdot \text{ddim} \cdot \log t$ independent partitions of X using Corollary 9, for $\alpha_m = \Theta(1)$ to be determined later. Denote by Ψ_v^i the event representing Ψ_v in the i 'th partition. Let $\Phi_v = \bigwedge_{i=1}^m \Psi_v^i$ be the event that v "failed" in all the partitions. It holds that

$$\Pr[\Phi_v] \leq \left(1 - 2^{-\text{ddim}/t}\right)^m \leq e^{-2^{-\text{ddim}/t} \cdot m} = e^{-\alpha_m \cdot \text{ddim} \cdot \log t}.$$

Note that if Ψ_v did not occurred, then the ball of radius $2\frac{\Delta}{\beta}$ around v was contained in a single cluster in at least one partition.

Let Y be an $\frac{\Delta}{\beta}$ -net of X . Set $\mathcal{A} = \{\Phi_v\}_{v \in Y}$, to be a set of events determined by $\{\delta_x^i\}_{x \in N, 1 \leq i \leq m}$ (δ_x^i denotes δ_x in the i 'th partition). Each event Φ_v might depend only on events Φ_u corresponding to vertices u at distance at most 6Δ from v . By Lemma 1, Φ_v is independent of all, but $\Gamma(\Phi_v) \leq \left(\frac{12\Delta}{\Delta/\beta}\right)^{O(\text{ddim})} = 2^{O(\text{ddim} \cdot \log t)}$ events. For every $\Phi_v \in \mathcal{A}$, set $x(\Phi_v) = p = 2^{-O(\text{ddim} \cdot \log t)}$, such that $\max_{v \in Y} |\Gamma(v)| \leq \frac{1}{2p}$. Then, for every $\Phi_v \in \mathcal{A}$ it holds that,

$$x(\Phi_v) \cdot \prod_{B \in \Gamma(\Phi_v)} (1 - x(B)) = p \cdot (1 - p)^{|\Gamma(\Phi_v)|} \geq p \cdot (1 - p)^{\frac{1}{2p}} \geq \frac{p}{e} \geq \Pr(\Phi_v),$$

where the last inequality holds for large enough α_m . By Lemma 11 we can efficiently find an assignment to $\{\delta_x^i\}_{x \in N, 1 \leq i \leq m}$ such that none of the events $\{\Phi_v\}_{v \in Y}$ occurred. Under this assumption, we argue that our sparse cover has the padding property. Consider some vertex $v \in V$. There is a net point $u \in Y$ at distance at most $\frac{\Delta}{\beta}$ from v . As the event Φ_u did not occur, there is some cluster C in the cover in which u is padded. In particular $B_G(v, \gamma\Delta) \subseteq B_G(u, 2\gamma\Delta) \subseteq C$ as required.

Suppose that $|V| = n$, then the running time is $|Y| \cdot \frac{p}{1-p} \cdot \text{poly}(|Y| + |Y|) = \text{poly}(n)$. ◀

5 Minor Free Graphs

Our clustering algorithm is based on the clustering algorithm of [5], with a small modification. The clustering of [5] has two steps. In the first step the graph is partitioned into r -Core clusters (see Definition 12 bellow). While r -core clusters do not have bounded diameter, they do have a simple geometric structure. Moreover, this clustering also has the padding property for small balls. In the second step, each r -core cluster is partitioned into bounded diameter sub-clusters using Theorem 4.

► **Definition 12** (*r*-Core). *Given a weighted graph $G = (V, E, w)$, we say that G has an r -core with radius Δ , if there is a set of at most r shortest paths $\mathcal{I}_1, \dots, \mathcal{I}_r$ such that for every $v \in V$, $d_G(v, \cup_i \mathcal{I}_i) \leq \Delta$.*

Given a cluster $C \subseteq G$, we say that C is an r -core cluster with radius Δ , if $G[C]$ has an r -core with radius Δ . Given a partition \mathcal{P} of G , we say that it is an r -core partition with radius Δ if each cluster $C \in \mathcal{P}$, is an r -core cluster with radius Δ .

The following theorem was proved implicitly in [5].

► **Lemma 13** (Core Clustering [5]). *Given a weighted graph $G = (V, E, w)$ that excludes K_r as a minor and a parameter $\Delta > 0$, there is a distribution \mathcal{D} over r -core partitions with radius Δ , such that for every vertex $v \in V$ and $\gamma \in (0, \Omega(\frac{1}{r}))$ it holds that*

$$\Pr [B_G(v, \gamma\Delta) \subseteq P(v)] \geq e^{-O(r \cdot \gamma)} .$$

Even though we will not provide full details of the proof of Lemma 13, we will describe the algorithm itself and provide some intuition for the core clustering in Section 5.2. Our clustering algorithm will be executed in two steps: first we partition the graph into core clustering (Lemma 13) and then we partition each r -core cluster using Theorem 4.

Some historical notes: [5] presented two different algorithms for strong and weak padded decompositions. Each of these algorithms consisted of two steps. For weak decompositions, essentially they first partitioning the graph using r -core clustering. Secondly, instead of partition further each cluster, they pick a net from the r -cores in all the clusters, and iteratively grow balls around net points, ending with weak diameter guarantee. For strong decompositions, they partition the graph into 1-core clusters (instead of r -core), ending with a probability of only $e^{-O(r^2 \cdot \gamma)}$ for a vertex x to be γ -padded.

5.1 Strong Padded Partitions for K_r Minor Free Graphs

► **Lemma 14.** *Let $G = (V, E, w)$ be a weighted graph that has an r -core with radius Δ . Then G admits a strong $(O(\log r), \Omega(1), \Delta)$ -padded decomposition.*

Proof. Let $\mathcal{I}_1, \mathcal{I}_2, \dots, \mathcal{I}_r$ be the r -core of G . For each i , let N_i be a $\frac{\Delta}{8}$ -net of \mathcal{I}_i . Set $N = \cup_i N_i$. Every vertex $v \in V$ has some vertex in N at distance at most $\frac{\Delta}{4}$. Indeed, by definition of r -core, there is $x \in \mathcal{I}_i$ such that $d_G(v, x) \leq \frac{\Delta}{8}$. Furthermore, there is a net point $y \in N_i$ at distance at most $\frac{\Delta}{8}$ from x . By triangle inequality $d_G(v, y) \leq \frac{\Delta}{4}$. As \mathcal{I}_i is a shortest path and N_i is a $\frac{\Delta}{8}$ -net, there are at most $O(1)$ net points at distance $\frac{3}{4}\Delta$ from v in N_i . We conclude that in N there are at most $O(r)$ net points at distance $\frac{3}{4}\Delta$ from v . The lemma now follows by Theorem 4. ◀

► **Theorem 15.** *Let $G = (V, E, w)$ be a weighted graph that excludes K_r as a minor. Then G admits a strong $(O(r), \Omega(\frac{1}{r}))$ -padded decomposition scheme.*

Proof. Let $\Delta > 0$ be some parameter. We construct the decomposition in two steps. First we sample an r -core partition \mathcal{P} with radius parameter Δ using Lemma 13. Next, for every cluster $C \in \mathcal{P}$, we create a partition \mathcal{P}_C using Lemma 14. The final partition is simply $\cup_{C \in \mathcal{P}} \mathcal{P}_C$, the union of all the clusters in all the created partitions. It is straightforward that the created partition has strong diameter Δ . To analyze the padding, consider a vertex $v \in V$ and parameter $0 < \gamma \leq \Omega(\frac{1}{r})$. Denote by C_v the cluster containing v in \mathcal{P} , and by $P(v)$ the cluster of v in the final partition. Then,

$$\begin{aligned} \Pr [B_G(v, \gamma\Delta) \subseteq P(v)] &= \Pr [B_G(v, \gamma\Delta) \subseteq P(v) \mid B_G(v, \gamma\Delta) \subseteq C_v] \cdot \Pr [B_G(v, \gamma\Delta) \subseteq C_v] \\ &\geq e^{-O(\gamma \cdot r)} \cdot e^{-O(\gamma \cdot \log r)} = e^{-O(\gamma \cdot r)} , \end{aligned}$$

where we used the fact that conditioning on $B_G(v, \gamma\Delta) \subseteq C_v$, it holds that $B_G(v, \gamma\Delta) = B_{G[C_v]}(v, \gamma\Delta)$. ◀

5.2 The Core Clustering Algorithm

In this section we describe the construction of the partition from Lemma 13. Afterwards, we will provide some intuition regarding the proof. For full details, we refer to [5]. Given two disjoint subsets $A, B \subseteq V$, we write $A \sim B$ if there exists an edge from a vertex in A to some vertex in B .

We denote the partition created by the algorithm by \mathcal{S} , and the clusters by $\{S_1, S_2, \dots\}$. The clusters are constructed iteratively. Initially $G_1 = G$. At step i , $G_i = G \setminus \cup_{j=1}^{i-1} S_j$. For a connected component $C \in G_i$, let $\mathcal{K}_{|C} = \{S_j \mid j < i \wedge C \sim S_j\}$ be the set of previously created clusters with a neighbor in C_i . To create S_i , pick arbitrary connected component C_i in G_i , and a vertex $x_i \in C_i$. For every neighboring cluster $S_j \in \mathcal{K}_{|C_i}$, pick arbitrary vertex $u_j \in C_i$ such that u_j has a neighbor in S_j . For each such u_j , let \mathcal{I}_j be the shortest path in G_i from x_i to u_j . Let T_i be the tree created by the union of $\{\mathcal{I}_j\}_{S_j \in \mathcal{K}_{|C_i}}$ ⁶. Sample a radius parameter R_i using truncated exponential distribution $\text{Texp}_{[0,1]}(2r)$. The cluster S_i defined as $B_{G_i}(T_i, R_i\Delta)$, the set of all vertices at distance at most $R_i\Delta$ from T_i w.r.t. d_{G_i} . This finishes the construction of S_i . The algorithm halts when all the vertices are clustered. See pseudo-code in Algorithm 1. See also Figure 1 for illustration of the algorithm.

■ **Algorithm 1** Core-Partition(G, Δ, r).

- 1: Let $G_1 \leftarrow G$, $i \leftarrow 1$.
 - 2: Let $\mathcal{S} \leftarrow \emptyset$.
 - 3: **while** G_i is non-empty **do**
 - 4: Let C_i be a connected component of G_i .
 - 5: Pick arbitrary $x_i \in C_i$. For each $S_j \in \mathcal{K}_{|C_i}$, let $u_j \in C_i$ be some vertex with a neighbor in S_j .
 - 6: Let T_i be a tree rooted at x_i , consisting of shortest paths towards $\{u_j \mid S_j \in \mathcal{K}_{|C_i}\}$.
 - 7: Let R_i be a random variable drawn independently from the distribution $\text{Texp}_{[0,1]}(2r)$.
 - 8: Let $S_i \leftarrow B_{G_i}(T_i, R_i\Delta)$.
 - 9: Add S_i to \mathcal{S} .
 - 10: $G_{i+1} \leftarrow G_i \setminus S_i$.
 - 11: $i \leftarrow i + 1$.
 - 12: **end while**
 - 13: **return** \mathcal{S} .
-

Provided that the graph G excludes K_r as a minor, for every C_i it holds that $|\mathcal{K}_{|C_i}| \leq r-2$. Indeed, by induction for every $S_j, S_{j'} \in \mathcal{K}_{|C_i}$, there is an edge between S_j to $S_{j'}$ ⁷. Assume for contradiction that $|\mathcal{K}_{|C_i}| \geq r-1$. By contracting all the internal edges in C_i and in the clusters in $\mathcal{K}_{|C_i}$ we will obtain K_r as a minor, a contradiction. It follows that for every i , T_i is an r -core of S_i . In particular, Algorithm 1 indeed produces an r -core partitions with radius Δ .

Abraham et al. [5] called the core T_i of each cluster a *skeleton*. Their algorithm induce an iterative process that creates “skeletons” and removes their R_i neighborhoods (a buffer) from the graph. R_i was sampled according to truncated exponential distribution. They called such an algorithm a *threatening* skeleton-process. In general, they consider such a process where each R_i is drawn according to $\text{Texp}_{[l,u]}(\frac{b}{u-l})$, for $0 = l < u \leq 1$.

⁶ Note that there is always a way to pick $\{\mathcal{I}_j\}_{S_j \in \mathcal{K}_{|C_i}}$ such that T_i will indeed be a tree.

⁷ To see this note that there is a path between u_j to $u_{j'}$ in C_i . Therefore, when creating $S_{j'}$ (assuming $j < j'$), it was the case that $S_j \in \mathcal{K}_{|C_{j'}}$. In particular $T_{j'}$ contains a vertex with neighbor in S_j .

■ **Figure 1** The figure illustrates the 6 first steps in Algorithm 1. Here G is the (weighted) grid graph. Note that G excludes K_5 as a minor. In step (4), G_4 is the graph induced by all the vertices not colored in blue, orange or red. G_4 has a single connected component C_4 . The green vertex defined as x_4 . $\mathcal{K}_{|C_i|}$ consist of 3 clusters S_1, S_2, S_3 colored respectively by blue, orange and red. T_4 is a tree rooted in x_4 colored in bold green, that consist of 3 shortest paths. Each of S_1, S_2, S_3 has a leaf of T_4 as a neighbor. R_4 is chosen according to $\text{Texp}_{[0,1]}(10)$. The new cluster S_4 , colored in green, consist of all vertices in C_4 at distance at most $R_4\Delta$ from T_4 w.r.t. d_{G_4} .

Let $\gamma > 0$ be a padding parameter, fix some vertex $z \in V$ and set $B_z = B_G(z, \gamma\Delta)$. We say that a skeleton T_i threatens z if $d_{G_i}(z, T_i) \leq (u + \gamma)\Delta$, in other words, if there is a positive probability that some vertex of B_z joins C_i . Let $\mathcal{J}_z = \{T_i \mid d_{G_i}(z, T_i) \leq (u + \gamma)\Delta\}$ be the set of threatening skeletons. To bound the probability that B_z is cut, [5] first bound the expected number of threatening skeletons. A key lemma in [5] is that if we guaranteed that for every i , $|\mathcal{K}_{|C_i|}| \leq s$, and sample each radius R_i from $\text{Texp}_{[l,u]}(\frac{b}{u-l})$ for $b = 2s$, it holds that

$$\mathbb{E}[|\mathcal{J}_z|] \leq 3e^{(2s+1) \cdot (1+\gamma/u)}.$$

In a second key lemma, [5] argued that the probability that B_z is cut by a threatening skeleton-process, provided that $\tau = \mathbb{E}[|\mathcal{J}_z|]$, is at most

$$(1 - e^{-2b\gamma/(u-l)}) \left(1 + \frac{\tau}{e^b - 1}\right).$$

In our case, as G is K_r free, thus we can pick $s = r - 2$. In Algorithm 1 we used the parameters $l = 0$, $u = 1$ and $b = 2r$. Therefore $\mathbb{E}[|\mathcal{J}_z|] \leq 3e^{(2r+1) \cdot (1+\gamma)}$. Assuming that $\gamma = O(\frac{1}{r})$, we conclude that the probability that B_z is cut is at most

$$(1 - e^{-4r\gamma}) \left(1 + \frac{3e^{(2r+1) \cdot (1+\gamma)}}{e^{2r} - 1}\right) = O(r\gamma).$$

In particular, the probability that B_z is padded is at least $1 - O(r\gamma) = e^{-O(r\gamma)}$.

6 Applications

In this section we present some applications of stochastic decompositions. Some applications are using a weaker type of decomposition called *separating* decompositions. The difference being that padding decompositions bound the probability for a ball to be cut, while separating decompositions bound the probability of an edge to be cut.

► **Definition 16** (Separating Decomposition). *A distribution \mathcal{D} over partitions of a graph G is strongly (resp. weakly) (β, Δ) -separating decomposition if every $\mathcal{P} \in \text{supp}(\mathcal{D})$ is strongly (resp. weakly) Δ -bounded and for every pair $u, v \in V$, $\Pr[P(v) \neq P(u)] \leq \beta \cdot \frac{d_G(u,v)}{\Delta}$.*

Note that in contrast to padding decomposition, there is no upper bound δ on the distance between u to v . Nevertheless, we argue that padded decompositions imply separating ones.

► **Lemma 17.** *Let $G = (V, E, w)$ be a weighted graph with a strongly (β, δ, Δ) -padded decomposition \mathcal{D} such that $\delta \geq \frac{1}{\beta}$. Then \mathcal{D} is also a strongly (β, Δ) -separating decomposition.*

Proof. Let $v, u \in V$ be a pair of vertices. If $d_G(u, v) \geq \frac{\Delta}{\beta}$, then obviously $\Pr[P(v) \neq P(u)] \leq 1 \leq \beta \cdot \frac{d_G(u,v)}{\Delta}$. Thus we can assume $d_G(u, v) \leq \frac{\Delta}{\beta} \leq \delta\Delta$. Set $\gamma = \frac{d_G(u,v)}{\Delta}$. It holds that

$$\Pr[P(v) = P(u)] \geq \Pr[B_G(v, \gamma\Delta) \subseteq P(v)] \geq e^{-\beta\gamma} \geq 1 - \beta\gamma.$$

In particular, $\Pr[P(v) \neq P(u)] \leq \beta\gamma = \beta \cdot \frac{d_G(u,v)}{\Delta}$ as required. ◀

Applying Lemma 17 on Corollary 9 and Theorem 15 we conclude,

- **Corollary 18.** *Let G be a weighted graph and $\Delta > 0$ some parameter.*
 - *If G excludes K_r as a minor, it admits an efficient strongly $(O(r), \Delta)$ -separating decomposition.*
 - *If G has doubling dimension ddim , it admits an efficient strongly $(O(\text{ddim}), \Delta)$ -separating decomposition.*

6.1 Approximation for Unique Games on Minor Free Graphs

In the *Unique Games* problem we are given a graph $G = (V, E)$, an integer $k \geq 1$ and a set of permutations $\Pi = \{\pi_{uv}\}_{uv \in E}$ on $[k]$ satisfying $\pi_{uv} = \pi_{vu}^{-1}$. Given an assignment $x : V \rightarrow [k]$, the edge $uv \in E$ is satisfied if $\pi_{uv}(x(u)) = x(v)$. The problem is to find an assignment that maximizes the number of satisfied edges. The Unique Games Conjecture of Khot [32] postulates that it is NP-hard to distinguish whether a given instance of unique games is almost satisfiable or almost unsatisfiable. The unique games conjecture was thoroughly studied. The conjecture has numerous implications.

Alev and Lau [7] studied a special case of the unique games problem, where the graph G is K_r free. Given an instance (G, Π) where the optimal assignment violates ϵ -fraction of the edge constraints, Alev and Lau used an LP-based approach to efficiently find an assignment that violates at most $O(\sqrt{\epsilon} \cdot r)$ -fraction. Specifically, in the rounding step of their LP, they used strong diameter separating decompositions with parameter $O(r^2)$. Using instead our decompositions from Corollary 18 with parameter $O(r)$ we obtain a quadratic improvement in the dependence on r .

► **Theorem 19.** *Consider an instance (G, Π) of the unique games problem, where the graph G is K_r free. Suppose that the optimal assignment violates at most an ϵ -fraction of the edge constraints. There is an efficient algorithm that find an assignment that violates at most an $O(\sqrt{\epsilon} \cdot r)$ -fraction.*

6.2 Spanner for Graphs with Moderate Doubling Dimension

Given a weighted graph $G = (V, E, w)$, a weighted graph $H = (V, E_H, w_H)$ is a t -spanner of G , if for every pair of vertices $v, u \in V$, $d_G(v, u) \leq d_H(v, u) \leq t \cdot d_G(v, u)$. If in addition H is a subgraph of G (that is $E_H \subseteq E$ and w_H agrees with w on E_H) then H is a *graph spanner*. The factor t is called the *stretch* of the spanner. The number of edges $|E_H|$ is the *sparsity* of the spanner. The weight of H is $w_H(H) = \sum_{e \in E_H} w_H(e)$ the sum of its edge weights. The *lightness* of H is $\frac{w_H(H)}{w(\text{MST}(G))}$ the ratio between the weight of the spanner to the weight of the MST of G . The tradeoff between stretch and sparsity/lightness of spanners had been the focus of an intensive research effort, and low stretch graph spanners were used in a plethora of applications.

There is an extensive study of spanners for doubling metrics. Recently, for an n -vertex graph with doubling dimension ddim , Borradaile, Le and Wulff-Nilsen [13] contrasted a graph spanner with $1 + \epsilon$ stretch, $\epsilon^{-O(\text{ddim})}$ lightness and $n \cdot \epsilon^{-O(\text{ddim})}$ sparsity (improving [43, 28, 27]). This result is also asymptotically tight. Note that the dependency on ddim is exponential, which is unavoidable for small, $1 + \epsilon$ stretch. In cases where ddim is moderately large (say $\sqrt{\log n}$), it might be preferable to accept larger stretch in order to obtain reasonable lightness.

In a recent work, Filtser and Neiman [26], for every stretch parameter $t \geq 1$, constructed a spanner with stretch $O(t)$, lightness $O(2^{\frac{\text{ddim}}{t}} \cdot t \cdot \log^2 n)$ and $O(n \cdot 2^{\frac{\text{ddim}}{t}} \cdot \log n \cdot \log t)$ edges. However, this spanner was not a subgraph. Most applications require a graphic spanner. It is possible to transform [26] into a graphic spanner, but the number of edges becomes unbounded. The spanner construction of [26] is based on a variant of separating decompositions, where they used a weak-diameter version. If we replaced this with our strongly padded decompositions Corollary 9, and plug this into Theorem 3 from [26], we obtain a spanner with the same stretch to lightness ratio, but also with an additional sparsity guarantee.

► **Corollary 20.** *Let $G = (V, E, w)$ be an n vertex graph, with doubling dimension ddim and aspect ratio $\Lambda = \frac{\max_{e \in E} w(e)}{\min_{e \in E} w(e)}$. Then for every parameter $t > 1$ there is an graph-spanner of G with stretch $O(t)$, lightness $O(2^{\frac{\text{ddim}}{t}} \cdot t \cdot \log^2 n)$ and $O(n \cdot 2^{\frac{\text{ddim}}{t}} \cdot \log n \cdot \log \Lambda)$ edges.*

7 Conclusion and Open Problems

In this paper we closed the gap left in [5] between the padding parameters of strong and weak padded decompositions for minor free graphs. Our second contribution is tight strong padded decomposition scheme for graphs with doubling dimension ddim , which we also use to create sparse cover schemes. Some open questions remain:

1. Prove/disprove that K_r free graphs admit strong/weak decompositions with padding parameter $O(\log r)$, as conjectured by [5].
2. The question above is already open for the more restricted family of treewidth r graphs.
3. The δ parameter: [5] constructed weak $(O(r), \Omega(1))$ -padded decomposition scheme, while we constructed strong $(O(r), \Omega(\frac{1}{r}))$ -padded decomposition scheme. It will be nice to construct strong $(O(r), \Omega(1))$ -padded decomposition scheme. Such a decomposition will imply a richer spectrum of sparse covers (with $o(r)$ stretch).
4. Sparse covers for K_r free graphs: [6] constructed $(O(r^2), 2^r(r+1)!)$ -sparse cover scheme, while [15] constructed $(4, f(r) \cdot \log n)$ -sparse cover scheme. An interesting open question is to create additional sparse cover schemes. Specifically, our padded decompositions suggest that an $(O(r), g(r))$ -sparse cover scheme for some function g independent of n , should be possible. Currently it is unclear how to construct such a cover. Optimally, we would like to construct $(O(1), g(r))$ -sparse cover scheme.

A Path Reporting Distance Oracles

Given a weighted graph $G = (V, E, w)$, a *distance oracle* is a data structure that supports distance queries between pairs $u, v \in V$. The distance oracle has stretch t , if for every query $\{u, v\}$, the estimated distance $\text{est}(u, v)$ is within $d_G(u, v)$ and $t \cdot d_G(u, v)$. The studied objects are stretch, size the query time. An additional requirement that been recently studied [20] is *path reporting*: in addition to distance estimation, the distance oracle should also return a path of the promised length. In this case, we say that distance oracle has query time q , if answering a query when the reported path has m edges, takes $q + O(m)$ time.

Path reporting distance oracles were studied for general graphs [20, 19]. For the special case of graphs excluding K_r as a minor, Elkin, Neiman and Wulff-Nilsen [19] constructed a path reporting distance oracles with stretch $O(r^2)$, space $O(n \cdot \log \Lambda \cdot \log n)$ and query time $O(\log \log \Lambda)$, where $\Lambda = \frac{\max_{u,v} d_G(u,v)}{\min_{u,v} d_G(u,v)}$ is the aspect ratio. For this construction they used the strongly padded decomposition of [5] (in fact strong-diameter sparse covers). Implicitly, given

a graph G that admits a strong (β, s) -sparse cover scheme, [19] constructs a path reporting distance oracle with stretch β , size $O(n \cdot s \cdot \log_\beta \Lambda)$ and query time $O(\log \log \Lambda)$. Following similar arguments to [19]⁸, our padded decompositions from Theorem 15 implies that every K_r free graph admits a strong $(O(r), O(\log n))$ -sparse cover scheme. We conclude:

► **Corollary 21.** *Given an n -vertex weighted graph $G = (V, E, w)$ which excludes K_r as a minor, with aspect ratio Λ , there is a path reporting distance oracle with stretch $O(r)$, space $O(n \cdot \log_r \Lambda \cdot \log n)$ and query time $O(\log \log \Lambda)$.*

It is interesting to mention that Busch et al. [15] constructed a $(4, O(f(r) \log n))$ sparse cover scheme for K_r free graphs, where $f(r)$ is an extremely large function of r . Using the framework of [19], it will imply a path reporting distance oracle with stretch 4, space $O(n \cdot \log \Lambda \cdot f(r))$ and query time $O(\log \log \Lambda)$. The value of $f(r)$ is larger than a square of the constant from the Robertson and Seymour structure theorem [42]. In particular, an estimation by Johnson [30] implies that $f(r)$ is larger than $2 \uparrow (2 \uparrow (2 \uparrow (r/2) + 3))$ ⁹. This value is so big, that the [15]-based oracle is completely impractical already for quite small values of r .

For the case of graphs with doubling dimension ddim , we constructed the first strong-diameter sparse covers. Plugging our Theorem 10 into the framework of [19], we obtain the first path reporting distance oracle for doubling graphs. The only relevant previous distance oracle for doubling metrics is by Bartal et al. [11]. However, they focused on the $1 + \epsilon$ -stretch regime, where inherently the oracle size has exponential dependency on ddim .

► **Corollary 22.** *Given an n -vertex weighted graph $G = (V, E, w)$ with doubling dimension ddim and aspect ratio Λ , for every parameter $t \geq \Omega(1)$, there is a path reporting distance oracle with stretch $O(t)$, space $O(n \cdot 2^{\text{ddim}/t} \cdot \text{ddim} \cdot \log \Lambda)$ ¹⁰ and query time $O(\log \log \Lambda)$.*

In particular, there is a path reporting distance oracle with stretch $O(\text{ddim})$, space $O(n \cdot \text{ddim} \cdot \log \Lambda)$ and query time $O(\log \log \Lambda)$.

B Proof of Theorem 4 using Cones

We will prove a Theorem 4 with slightly weaker parameters. Specifically we will construct a strongly $(O(\ln \tau), \frac{1}{32}, 4\Delta)$ -padded decomposition.

Order the vertices in $N = \{x_1, x_2, \dots\}$ arbitrarily. For every center $x_i \in N$, sample $\delta_i \in [0, 1]$ according to $\text{Texp}(\lambda)$ truncated exponential distribution with parameter $\lambda = 2 + 2 \ln \tau$. Set $R_i = \delta_i \cdot \Delta \in [0, \Delta]$. The clustering algorithm is executed in an iterative manner. We denote by S the set of unclustered vertices, which are also called *active* vertex. Initially $S = V$. As long as there is an active center $S \cap N \neq \emptyset$, pick active center $x_i \in N$ with minimal index and create the cluster

$$C_i = \{v \in S \mid d_{G[S]}(v, x_i) - d_{G[S]}(v, N \cap S) \leq R_i\} .$$

This procedure halts when all the centers are clustered. See Algorithm 2 for pseudo code.

▷ **Claim 23.** For a vertex $v \in G$ let $x_v \in N$ be the closest center, and let \mathcal{I}_v be the shortest path from v to x_v . Then if some vertex of \mathcal{I}_v is clustered, so do v .

⁸ Taking $O(\log n)$ independent copies and using union bound,

⁹ $2 \uparrow t$ denotes an exponential tower of t 2's. That is $2 \uparrow 0 = 1$ and $2 \uparrow t = 2^{2 \uparrow (t-1)}$.

¹⁰ This is assuming $\Lambda > \log t$, otherwise simply using an arbitrary shortest path tree will provide a distance oracle with stretch $O(\log t)$.

6:20 On Strong Diameter Padded Decompositions

■ **Algorithm 2** Partition-To-Cones($G = (V, E, w), N, \Delta, \tau$).

```

1: Let  $S \leftarrow V$ ,  $\mathcal{S} \leftarrow \emptyset$ .
2: Order the vertices in  $N = x_1, x_2, \dots$  arbitrarily.
3: for  $i = 1$  to  $|N|$  do
4:   if  $x_i \in S$  then
5:     Sample  $R_i$  independently from the distribution  $\text{Exp}(2 + 2 \ln \tau)$ .
6:      $C_i \leftarrow \emptyset$ 
7:     for all  $v \in S$  do
8:       if  $d_{G[S]}(v, x_i) - d_{G[S]}(v, N \cap S) \leq R_i$  then
9:         Add  $v$  to  $C_i$ .
10:      end if
11:    end for
12:     $S \leftarrow S \setminus C_i$ 
13:    Add  $C_i$  to  $\mathcal{S}$ .
14:  end if
15: end for
16: return  $\mathcal{S}$ .
```

Proof. Suppose that $u \in \mathcal{I}_v$ joined the cluster of x_j while the set of active vertices were S (in particular $\mathcal{I}_v \subseteq S$). Then

$$\begin{aligned} d_{G[S]}(v, x_j) &\leq d_{G[S]}(v, u) + d_{G[S]}(u, x_j) \\ &\leq d_{G[S]}(v, u) + d_{G[S]}(u, x_v) + R_j = d_{G[S]}(v, x_v) + R_j. \end{aligned} \quad \triangleleft$$

► **Corollary 24.** *All vertices are clustered.*

Proof. The vertex v will be clustered at the first time some vertex from \mathcal{I}_v is clustered. As x_v itself necessarily clustered, the corollary follows. ◀

▷ **Claim 25.** Every cluster has strong diameter 4Δ .

Proof. Suppose that at the time we constructed C_i the set of active vertices was S . Let $v \in C_i$, and $x_v \in N$ the closest center to v . As v joined C_i and was active, all the vertices in \mathcal{I}_v the shortest path from v to x_v were active as well. Therefore,

$$d_{G[S]}(v, x_i) \leq d_{G[S]}(v, x_v) + R_i \leq 2\Delta.$$

Let \mathcal{I} be the shortest path from v to x_i in $G[S]$. We argue that all the vertices on \mathcal{I} also joined C_i . Indeed, consider $u \in \mathcal{I}$. Then

$$\begin{aligned} d_{G[S]}(u, x_i) &= d_{G[S]}(v, x_i) - d_{G[S]}(v, u) \\ &\leq d_{G[S]}(v, N \cap S) + R_i - d_{G[S]}(v, u) \leq d_{G[S]}(u, N \cap S) + R_i. \end{aligned}$$

It follows that $d_{G[C_i]}(v, x_i) \leq 2\Delta$. In particular C_i has strong diameter bounded by 4Δ . ◀

Consider some vertex $v \in V$ and parameter $\gamma \leq \frac{1}{8}$. We will argue that the ball $B = B_G(v, \gamma\Delta)$ is fully contained in $P(v)$ with probability at least $2^{-O(\gamma \log \tau)}$, in other words that v is $\frac{\gamma}{4}$ -padded. Let N_v be the set of centers x_i for which there is a non zero probability that C_i intersects B . Following the calculation in Claim 25, each vertex joins the cluster of a center at distance at most 2Δ . By triangle inequality, all the centers in N_v are at distance at most $(2 + \gamma)\Delta \leq 3\Delta$ from v . In particular $|N_v| \leq \tau$.

For x_i , denote by \mathcal{F}_i the event that some vertex of B joins the cluster C_i for the first time. I.e. $B \cap C_i \neq \emptyset$ and for all $j < i$, $B \cap C_j = \emptyset$. Denote by \mathcal{C}_i the event that \mathcal{F}_i occurred and B is cut by C_i . Note that for every $x_i \notin N_v$, $\mathcal{F}_i = \mathcal{C}_i = \emptyset$. To prove the theorem, it is enough to show that $\Pr[\cup_i \mathcal{C}_i] \leq 1 - e^{-O(\gamma \cdot \lambda)}$. Set $\alpha = e^{-4\gamma \cdot \lambda}$.

▷ **Claim 26.** For every i , $\Pr[\mathcal{C}_i] \leq (1 - \alpha) \left(\Pr[\mathcal{F}_i] + \frac{1}{e^\lambda - 1} \right)$.

Proof. Let $S \subset V$ be the set of active vertices at the beginning of round i . If $B \cup \{x_i\} \not\subseteq S$ then $\Pr[\mathcal{C}_i] = 0$ and we are done. Let ρ_S be the minimal value of δ_i such that if $\delta_i \geq \rho_S$, some vertex of B joins C_i . Formally $\rho_S = \frac{1}{\Delta} \cdot \min_{u \in B} \{d_{G[S]}(u, x_i) - d_{G[S]}(u, N \cap S)\}$. If $\rho_S > 1$, then $\Pr[\mathcal{C}_i] = 0$ and we are done, thus we assume $\rho_S \leq 1$. Conditioning on S , it holds that

$$\Pr[\mathcal{F}_i \mid S] = \Pr[\delta_i \geq \rho_S] = \int_{\rho_S}^1 \frac{\lambda \cdot e^{-\lambda y}}{1 - e^{-\lambda}} dy = \frac{e^{-\rho_S \cdot \lambda} - e^{-\lambda}}{1 - e^{-\lambda}}$$

Let $v' \in B$ some vertex that joins C_i if $\delta_i = \rho_S$. Then for every $u \in B$ it holds that

$$\begin{aligned} d_{G[S]}(u, x_i) &\leq d_{G[S]}(v', x_i) + 2\gamma\Delta \leq d_{G[S]}(v', N \cap S) + \rho_S \cdot \Delta + 2\gamma\Delta \\ &\leq d_{G[S]}(u, N \cap S) + (\rho_S + 4\gamma) \cdot \Delta. \end{aligned}$$

Therefore, if $\delta_i \geq \rho_S + 4\gamma$, the entire ball B will be contained in C_i . We conclude,

$$\begin{aligned} \Pr[\mathcal{C}_i \mid S] &\leq \Pr[\rho_S \leq \delta_i < \rho_S + 4\gamma] \\ &= \int_{\rho_S}^{\max\{1, \rho_S + 4\gamma\}} \frac{\lambda \cdot e^{-\lambda y}}{1 - e^{-\lambda}} dy \\ &\leq \frac{e^{-\rho_S \cdot \lambda} - e^{-(\rho_S + 4\gamma) \cdot \lambda}}{1 - e^{-\lambda}} \\ &= (1 - e^{-4\gamma \cdot \lambda}) \cdot \frac{e^{-\rho_S \cdot \lambda}}{1 - e^{-\lambda}} \\ &= (1 - \alpha) \cdot \left(\Pr[\mathcal{F}_i \mid S] + \frac{1}{e^\lambda - 1} \right). \end{aligned}$$

By the law of total probability, we can remove the conditioning on S . Denote by f the density function of the distribution over all possible choices of S . It holds that,

$$\begin{aligned} \Pr[\mathcal{C}_i] &= \int_S \Pr[\mathcal{C}_i \mid S] \cdot f(S) dS \\ &\leq (1 - \alpha) \cdot \int_S \left(\Pr[\mathcal{F}_i \mid S] + \frac{1}{e^\lambda - 1} \right) \cdot f(S) dS \\ &= (1 - \alpha) \cdot \left(\Pr[\mathcal{F}_i] + \frac{1}{e^\lambda - 1} \right). \quad \triangleleft \end{aligned}$$

We bound the probability that the ball B is cut,

$$\begin{aligned} \Pr[\cup_i \mathcal{C}_i] &= \sum_{x_i \in N_v} \Pr[\mathcal{C}_i] \leq (1 - \alpha) \cdot \sum_{x_i \in N_v} \left(\Pr[\mathcal{F}_i] + \frac{1}{e^\lambda - 1} \right) \\ &\leq (1 - e^{-4\gamma \cdot \lambda}) \cdot \left(1 + \frac{\tau}{e^\lambda - 1} \right) \\ &\leq (1 - e^{-4\gamma \cdot \lambda}) \cdot (1 + e^{-4\gamma \cdot \lambda}) = 1 - e^{-8\gamma \cdot \lambda}, \end{aligned}$$

where the last inequality follows as $e^{-4\gamma \cdot \lambda} = \frac{e^{-4\gamma \cdot \lambda}(e^\lambda - 1)}{e^\lambda - 1} \geq \frac{e^{-4\gamma \cdot \lambda} \cdot e^{\lambda - 1}}{e^\lambda - 1} \geq \frac{e^{\frac{\lambda}{2} - 1}}{e^\lambda - 1} = \frac{\tau}{e^\lambda - 1}$.

Max-Min Greedy Matching

Abstract

A bipartite graph $G(U, V; E)$ that admits a perfect matching is given. One player imposes a permutation π over V , the other player imposes a permutation σ over U . In the greedy matching algorithm, vertices of U arrive in order σ and each vertex is matched to the highest (under π) yet unmatched neighbor in V (or left unmatched, if all its neighbors are already matched). The obtained matching is maximal, thus matches at least a half of the vertices. The max-min greedy matching problem asks: suppose the first (max) player reveals π , and the second (min) player responds with the worst possible σ for π , does there exist a permutation π ensuring to match strictly more than a half of the vertices? Can such a permutation be computed in polynomial time?

The main result of this paper is an affirmative answer for these questions: we show that there exists a polytime algorithm to compute π for which for every σ at least $\rho > 0.51$ fraction of the vertices of V are matched. We provide additional lower and upper bounds for special families of graphs, including regular and Hamiltonian graphs. Our solution solves an open problem regarding the welfare guarantees attainable by pricing in sequential markets with binary unit-demand valuations.

1 Introduction

Given a bipartite graph $G(U, V; E)$, where U and V are the sets of vertices and $E \subseteq U \times V$ is the set of edges, a matching $M \subseteq E$ is a set of edges such that every vertex is incident with at most one edge of M . For simplicity of notation, for every n we shall only consider the following class of bipartite graphs, that we shall refer to as G_n . For every $G(U, V; E) \in G_n$ it holds that $|U| = |V| = n$ and that E contains a matching of size n (and hence G has a perfect matching). All results that we will state for G_n hold without change for all bipartite graphs that have a matching of size n (and arbitrarily many vertices).

Karp, Vazirani and Vazirani [12] introduced the *online bipartite matching* problem. This setting can be viewed as a game between two players: a maximizing player who wishes the resulting matching to be as large as possible, and a minimizing player who wishes the matching to be as small as possible. First, the minimizing player chooses $G(U, V; E)$ in private (without the maximizing player seeing E), subject to $G \in G_n$. Thereafter, the structure of G is revealed to the maximizing player in n steps, where at step j (for $1 \leq j \leq n$) the set $N(u_j) \subseteq V$ of vertices adjacent to u_j is revealed. At every step j , upon seeing $N(u_j)$ (and based on all edges previously seen and all previous matching decisions made), the maximizing player needs to irrevocably either match u_j to a currently unmatched vertex in $N(u_j)$, or leave u_j unmatched.

There is much recent interest in the online bipartite matching problem and variations and generalizations of it, as such models have applications for allocation problems in certain economic settings, in which buyers (vertices of U) arrive online and are interested in purchasing various items (vertices of V). A prominent example of such an application is online advertising; for more details, see for example the survey by Mehta [17]. The new problems are both theoretically elegant and practically relevant.

Max-Min Greedy Matching

We study a setting related to online bipartite matching, that we call *Max-Min Greedy matching*. Our setting is also a game between a maximizing player and a minimizing player. The bipartite graph $G(U, V; E) \in G_n$ is given upfront. Upon seeing G the maximizing player chooses a permutation π over V . Upon seeing G and π , the minimizing player chooses a permutation σ over U . The combination of G , π and σ define a unique matching $M_G[\sigma, \pi]$ that we refer to as the greedy matching. It is the matching produced by the greedy matching algorithm in which vertices of U arrive in order σ and each vertex $u \in U$ is matched to the highest (under π) yet unmatched $v \in N(u)$ (or left unmatched, if all $N(u)$ is already matched).

The matching $M_G[\sigma, \pi]$ has several additional equivalent definitions. For example, $M_G[\sigma, \pi]$ is the matching produced by the greedy matching algorithm in which vertices of V arrive in order π and each vertex $v \in V$ is matched to the highest (earliest in arrival order under σ) yet unmatched $u \in N(v)$ (or left unmatched, if all $N(v)$ is already matched). Also, $M_G[\sigma, \pi]$ is the unique stable matching in G (in the sense of [9]), if the preference order of every vertex $u \in U$ over its neighbors is consistent with π , and the preference order of every vertex $v \in V$ over its neighbors is consistent with σ .

Let $\rho[G] = \frac{1}{n} \max_{\pi} \min_{\sigma} [|M_G[\sigma, \pi]|]$, and let $\rho = \min_{G \in G_n} [\rho[G]]$. It is easy to see that $\rho \geq \frac{1}{2}$. In fact, to ensure a matching of size $n/2$, the max player need not work hard. Since every greedy matching is a *maximal* matching, for *every* permutation π the obtained matching is of size at least $n/2$. The question we study in this work is whether the max player can ensure a matching of size strictly greater than $n/2$; that is, whether ρ is strictly greater than $\frac{1}{2}$.

For an upper bound on ρ , it was observed by Cohen Addad et al. [4] that $\rho \leq 2/3$. To show this, they observe that in the 6-cycle graph, depicted in Figure 1, no permutation π can guarantee to match more than two vertices in the worst case. Indeed, suppose (without loss of generality) that $\pi = (v_3, v_2, v_1)$. For $\sigma = (u_1, u_3, u_2)$, u_1 is matched to v_2 , u_3 is matched to v_3 , and u_2 is left unmatched, resulting in a matching of size 2.

■ **Figure 1** For every permutation π there exists a permutation σ that matches only 2 of the 3 vertices. Thick edges are in the matching; gray vertices are unmatched.

1.1 Our Results

Our main result resolves the open problem in the affirmative:

► **Theorem (main theorem).** *It holds that $\rho \geq \frac{1}{2} + \frac{1}{86} > 0.51$. Moreover, there is a polynomial time algorithm that given $G(U, V; E)$ produces a permutation π over V satisfying the above bound.*

The significance of this result is that $1/2$ is not the optimal answer. We believe that further improvements are possible. In fact, for Hamiltonian graphs we show that $\rho \geq \frac{5}{9}$ (see Section 6).

The proof method is quite involved; it is natural to ask whether simpler approaches may work. In what follows we specify three natural attempts that all fail.

Failed attempt 1: random permutation

A first attempt would be to check whether a random permutation π obtains the desired result (in expectation). The performance of a random permutation is interesting for an additional reason: it is the performance in scenarios where the graph structure is unknown to the designer. Unfortunately, there exists a bipartite graph G , even one where all vertices have high degree, for which a random permutation matches no more than a fraction $1/2 + o(1)$ of the vertices (see Section 4).

In contrast, we show that in the case of Hamiltonian graphs a random permutation guarantees a competitive ratio strictly greater than $1/2$ (Section 4). A similar proof approach applies to regular graphs as well.

► **Theorem (random permutation).** *There is some $\rho_0 > \frac{1}{2}$ such that for every Hamiltonian graph $G \in G_n$, regardless of n , a random permutation π results in $\rho \geq \rho_0$. Similarly, there is some constant $\rho_0 > \frac{1}{2}$ such that for every d -regular graph G , regardless of d, n , a random permutation π results in $\rho \geq \rho_0$.*

Failed attempt 2: iterative upgrading

A second attempt would be to iteratively “upgrade” unmatched vertices, with the hope that the iterative process will reach a state where many vertices will be matched. That is, in every iteration consider the worst order σ for the current permutation π and move all unmatched vertices (in the matching induced by (π, σ)) to be ranked higher in π . This algorithm is similar to the *k-pass Category Advice* algorithm of [1], but with the difference that in [1] σ remains unchanged throughout the k iterations. In [1] it was shown that in their setting, the fraction of matched vertices approaches $\frac{2}{1+\sqrt{5}} \simeq 0.619$ as k grows. In contrast, in Appendix B we show that in our setting this process can go on for $\log n$ iterations before reaching a permutation that matches more than a half of the vertices. This fact gives some indication that establishing a proof using this operator might be difficult.

Failed attempt 3: degree-based ranking

A third attempt would be to give preference to vertices with lower degrees, as they would have fewer opportunities to be matched to incoming vertices of U . Consider a graph with multiple copies of the subgraph $(u_1, v_1), (u_2, v_2), (u_1, v_2)$ along with two additional vertices u_a, u_b (and their partners v_a, v_b). If we connect all vertices of type v_1 to u_a and u_b , we get that their degree is 3, while the degree of vertices of type v_2 is 2. If π is chosen according to the degree, vertices of type v_2 will be ranked higher than vertices of type v_1 . In this case, if σ orders the vertices of type u_1 first, they will be matched to vertices of type v_2 , leaving the vertices of type v_1 unmatched. The resulting matching will therefore be of size $(1/2 + o(1))n$.

Why is this model interesting mathematically?

The setting of max-min greedy matching is easy to state. The problem of getting a ratio better than half turns out to be deceptively difficult. As discussed above, several natural approaches fail to achieve this. The problem remained open for quite some time, despite attempts to solve it. Indeed, the solution that we find is not simple; it involves taking the best of four algorithms. However, these algorithms are not unrelated. They all share a unifying theme that involves a clean combinatorial property, referred to as a maximal path cover (see Section 2). This theme enabled us to break the barrier of half, but interesting problems remain open, such as whether the bound of $2/3$ can be achieved. We hope that the progress made in this work will motivate and enable further improvement in this interesting problem.

1.2 Additional Results

We further establish lower and upper bounds for regular graphs.

► **Theorem (regular graphs).** *For d -regulars bipartite graphs, $\rho \geq \frac{5}{9} - O(\frac{1}{\sqrt{d}})$. On the other hand, for every integer $d \geq 1$, there is a regular graph G_d of even degree $2d$ such that $\rho(G_d) \leq \frac{8}{9}$.*

An additional natural problem is to find the best permutation π , given a graph G . We suspect that this is a difficult computational problem. However, the special case of determining whether there is a *perfect* π (a permutation on V that for every permutation σ leads to a perfect matching) does have a polynomial time algorithm (proof appears in Section 5).

► **Proposition 1.** *There is a polynomial time algorithm that given a graph $G \in G_n$ determines whether G has a perfect π , and if so, outputs a perfect π .*

1.3 Application to Resource Allocation and Pricing

Various problems related to online bipartite matching are closely related to problems that attract attention in the algorithms community. Gaining better understanding of the max-min greedy matching problem sheds light on more general problems, some of which are still open. In what follows we elaborate on an application to a pricing problem.

Feldman et al. [8] study the design of pricing mechanisms for allocation of items in markets. The basic setting is a matching market, where v_{ij} is the value of agent i for item j , and every agent can receive at most a single item. The seller assigns prices to items, and agents arrive in an adversarial order (after observing the prices), each purchasing an (arbitrary) item that maximizes their utility (defined as value minus price). It is shown that, given a weighted bipartite graph (with agents on one side, items of the other side, and weight v_{ij} for the edge between agent i and item j), one can set item prices that guarantee at least half of the optimal welfare for any arrival order. The last result holds in much more general settings, namely settings where buyers have submodular valuations over bundles of items ¹, and even in a Bayesian settings, where the seller knows only the (product) distribution from which agent valuations are drawn, but not their realizations.

In the Bayesian setting no item prices can guarantee better than half of the optimal welfare in the worst case. A natural question is whether this ratio can be improved in scenarios where the designer knows the realized values of the buyers from the outset ². Concretely, do there exist item prices that guarantee strictly more than half the optimal welfare, for any arrival order σ ? Not only has this question been open for general combinatorial auctions with submodular valuations, it has been open even for unit-demand buyers, and even if all individual values are in $\{0, 1\}$ (henceforth referred to as binary unit demand valuations). In the latter setting, pricing is equivalent to imposing a permutation over the items, hence the max-min greedy matching is a precise formulation for the pricing problem in binary unit-demand settings.

An equivalent scenario is one where in each step the “items player” offers an item, and the “buyers player”, upon seeing the item, allocates the item to one of the buyers who wants the item (if there is any), and that buyer leaves. The items player is non-adaptive (plays blindfolded, without seeing which buyers remain³). The size of the matching that can be guaranteed by the items player is equivalent to the max-min greedy matching problem.

Yet an additional equivalent formulation of the problem is one where the permutation π is imposed over the buyers rather than over the items. The buyers then arrive in the order of π , each taking an arbitrary item she wants. One can verify that the size of the matching that can be guaranteed by an ordering over the buyers is equivalent to the max-min greedy matching problem.

¹ A valuation is said to be submodular if for every two sets S, T , $v(S) + v(T) \geq v(S \cup T) + v(S \cap T)$.

² The full information assumption is sensible in repeated markets or in markets where the stakes are high and the designer may invest in learning the demand in the market before setting prices.

³ We note that when the items player is adaptive (chooses the next item based on what happened in the past), the items player can ensure a perfect matching. This is done as follows: in each step, find a minimal tight set of items, and offer an arbitrary item from that set. Here, a set of items is tight if the number of buyers that want items in the set is equal to the size of the set.

1.4 Relation to Previous Work

Relation to online bipartite matching

The Max-Min Greedy Matching problem is a nonstandard version of online problems. In the standard online matching problem [12], the algorithm designer has control over the matching algorithm, but has no control over the arrival order of clients (vertices). Our setting can model a situation in which the designer (the maximizing player) has full control over the arrival order of clients (it knows which “items” in U each “client” in V wants, and it chooses π based on this knowledge), but no control over the matching algorithm (the minimizing player can choose the worst possible match in every step, effectively resulting in a permutation σ).

Karp et al. [12] introduced the *Ranking* algorithm which has a $1 - 1/e$ competitive ratio in the online bipartite matching setting. Translating this algorithm to our Max-Min Greedy setting, it amounts to simply selecting π at random, and then the minimizing player selects σ after seeing π . We show that there are bipartite graphs $G \in G_n$ for which with high probability over the random choice of π , there is a choice of σ resulting in $M_G[\sigma, \pi] \leq 1/2 + o(1)$. Karp et al. [12] also showed that no algorithm for online bipartite matching has a competitive ratio better than $1 - 1/e + o(1)$. This was shown by exhibiting a distribution over “difficult” graphs. Each graph in the support of this distribution has a unique perfect matching, and consequently (see Proposition 3), there is a permutation π in the Max-Min Greedy setting that ensures that all vertices are matched (regardless of σ). Hence neither the lower bounds nor the upper bounds known for the online matching model give useful bounds in the Max-Min Greedy model.

There are additional known results for online bipartite matching. For d -regular graphs, Cohen and Wajc [3] present a random algorithm that obtains $1 - O(\sqrt{\log d}/\sqrt{d})$ in expectation, and a lower bound of $1 - O(1/\sqrt{d})$. This is in contrast to our Theorem 12 that shows that ρ is bounded away from 1 even when d is arbitrarily large. For general bipartite graphs, under random (rather than adversarial) arrival order, the deterministic greedy algorithm gives $1 - 1/e$, and no deterministic algorithm can obtain more than $3/4$ [10]. *Ranking* (which is a randomized algorithm) obtains at least 0.696 of the optimal matching [15] and at most 0.727 [11]. No random algorithm can obtain more than 0.823 [16].

Relation to pricing mechanisms

Our work is also related to the recent body of literature on pricing mechanisms. Motivated by the fact that in real-life situations one is often willing to trade optimality for simplicity, the study of simple mechanisms has gained a lot of interest in the literature on algorithmic mechanism design. One of the simplest forms of mechanisms is that of posted price mechanisms, where prices are associated with items and agents buy their most preferred bundles as they arrive. Pricing mechanisms have many advantages: they are simple, straightforward, and allow for asynchronous arrival and departure of buyers. Various forms of posted price mechanisms for welfare maximization have been proposed for various combinatorial settings [8, 5, 14, 6]. These mechanisms are divided along several axes, such as item vs. bundle pricing, static vs. dynamic pricing, and anonymous vs. personalized pricing. For any market with submodular valuations, one can obtain $1/2$ of the optimal welfare by static, anonymous item prices [8]. Until the present paper, no better results than $1/2$ were known even for markets with unit-demand valuations with $\{0, 1\}$ individual values. For a market with m identical items, there exists a pricing scheme that obtains at least $5/7 - 1/m$ of the optimal welfare for submodular valuations [6].

2 Proof of Main Result

The graph $G(U, V; E)$ with $|U| = |V| = n$ has a perfect matching M in which $u_i \in U$ is matched with $v_i \in V$ for every $1 \leq i \leq n$. For a given i , we refer to u_i and v_i as *partners* of each other. Given a set $S \subset V$, the set of neighbors of S is denoted as $N(S)$ (where necessarily $N(S) \subset U$). In this section we prove our main result.

► **Theorem 2.** *Given a bipartite graph $G(U, V; E)$ with a perfect matching $\{(u_i, v_i)\}$, there exists a permutation π that guarantees that the greedy matching will be of size at least $\frac{22}{43}n$, regardless of σ . Moreover, there is a polynomial time algorithm that chooses π with such a guarantee.*

Our proof approach is as follows. We shall first associate with G an auxiliary directed graph that we refer to as the spoiling graph $H(V, D)$. This notion by itself is not new – similar notions appeared also in previous related work. The new aspect related to the spoiling graph and the key to our approach is a notion of a *maximal path cover*. Given a maximal path cover of the spoiling graph (which as we show in Proposition 4, can be found in polynomial time), we partition the set V of vertices into four classes, depending on their roles in the maximal path cover. The classes are V_1 (singleton vertices), S (start vertices of paths), T (end vertices of paths), and I (intermediate vertices of paths). By considering several carefully chosen orders among the classes of vertices, and also of vertices within the classes, we obtain four possible candidate permutations for π , denoted $\pi_1, \pi_2, \pi_3, \pi_4$. We show that for every bipartite graph with a perfect matching, at least one of these permutations, if used as π , guarantees that the greedy matching will be of size at least $\frac{22}{43}n$, for every σ . Put in other words, if for each of $\{\pi_1, \pi_2, \pi_3, \pi_4\}$ there is a permutation over U for which the greedy matching is smaller than $\frac{22}{43}n$, this would imply (using properties listed in Lemma 5) that the path cover giving rise to these permutations was not maximal.

We now proceed to define the spoiling graph. Given $G(U, V; E)$, consider a directed graph $H(V, D)$ whose vertices are the set V , and whose set D of directed edges (arcs) is defined as follows: $(v_i, v_j) \in D$ iff $(u_j, v_i) \in E$. We refer to $H(V, D)$ as the *spoiling graph* for G , because arc $(v_i, v_j) \in D$ allows for the possibility that edge $(u_j, v_i) \in E$ is chosen into a matching M' in G , spoiling for v_j the possibility (offered by M) of being matched to u_j . Note that this spoiling effect may materialize in a (σ, π) matching only if v_i is ranked higher than v_j in π . Hence the spoiling graph conveys information that may be relevant to the choice of π .

As an example of the information that can be derived from the spoiling graph, consider the following proposition (whose proof can be also obtained as a special case of a result given in [4] and [13] for the more general case of Gross Substitutes valuations).

► **Proposition 3.** *If G has a unique perfect matching, then $\rho(G) = 1$.*

Proof. Let $u_i \in U$ and $v_i \in V$ be partners in the unique perfect matching M of G . We claim that the spoiling graph H of G is a *directed acyclic graph* (DAG). Suppose toward contradiction that H contains a simple directed cycle $v_{i_1}, v_{i_2}, \dots, v_{i_\ell}, v_{i_1}$. This directed cycle corresponds to the cycle $u_{i_1}, v_{i_1}, u_{i_2}, v_{i_2}, \dots, u_{i_\ell}, v_{i_\ell}, u_{i_1}$ in G . But removing the edges (u_{i_j}, v_{i_j}) , $1 \leq j \leq \ell$ from M and adding the edges $(u_{i_j}, v_{i_{j+1}})$ to M (where $i_{\ell+1} = i_1$) yields a different perfect matching, contradicting the uniqueness of M .

Since H is a DAG, we can topologically sort its vertices and choose a permutation π such that earlier vertices in the topological order have a lower rank in π . This ensures that for every directed edge (v, w) in H , v 's partner will never prefer w over v . Thus, every vertex chooses its partner in M upon arrival. ◀

7:8 Max-Min Greedy Matching

We now proceed to define the notion of a maximal path cover. A *directed path* P (whose length is denoted by $|P|$) in H is a sequence of $|P|$ vertices (say, $v_1, \dots, v_{|P|}$) such that $(v_i, v_{i+1}) \in D$ for all $1 \leq i \leq |P| - 1$. A single vertex is a path of length 1. A *path cover* of H is a collection of vertex disjoint directed paths that covers all vertices in V . We consider the following operations that can transform a given path cover to a different one:

1. *Path merging*: Two paths can be merged into one longer path if $H(V, D)$ has an arc from the end of one path to the start of the other path.
2. *Path unbalancing*: Consider any two paths P and P' with $1 < |P| \leq |P'|$, let v_s and v_t denote the first and last vertices of P , and let v'_s and v'_t denote the first and last vertices of P' . If $(v_s, v'_s) \in D$ we may remove v_s from P and append it at the beginning of P' . Likewise, if $(v'_t, v_t) \in D$ we may remove v_t from P and append it at the end of P' .
3. *Rotation*: if there is a path P (say, v_s, \dots, v_t) such that $(v_t, v_s) \in D$, we may add the arc (v_t, v_s) to P (obtaining a cycle), and then remove any other single arc from the resulting cycle to get a path P' . Observe that P' and P have the same vertex set, but they differ in their starting vertex along the cycle v_s, \dots, v_t, v_s .

A path cover is *maximal* if no path merging operation and no path unbalancing can be applied to it, and furthermore, this continues to hold even after performing any single rotation operation.

► **Proposition 4.** *Given a bipartite graph $G(U, V; E)$ with a perfect matching $\{(u_i, v_i)\}$, a maximal path cover in the associated spoiling graph $H(V, D)$ can be found in $O(n^2)$ time.*

Proof. Start with the trivial path cover in which each vertex of V forms a path of length 1, and perform arbitrary path merging and path unbalancing operations (some of which are preceded by a single rotation operation) until no longer possible. The process must end within $O(n^2)$ operations, because each path merging and each path unbalancing operation increases the sum of squares of the lengths of the paths, and the sum of squares of the lengths is at most n^2 . ◀

Given a maximal path cover of H (where p denotes the number of paths in the path cover), sort the paths in order of increasing lengths, breaking ties arbitrarily. Hence $1 \leq |P_1| \leq |P_2| \leq \dots \leq |P_p|$. We consider the following classes of vertices of V :

1. *Singleton vertices* V_1 . These are the vertices that belong to paths of length 1 in the given maximal path cover. Let $k = |V_1|$ denote the number of singleton vertices. Observe that $|P_k| = 1$ and $|P_{k+1}| > 1$.
2. *Other vertices* $V_2 = V \setminus V_1$. We partition V_2 into three subclasses of vertices:
 - a. *Start vertices* S . These are the starting vertices of those paths that have length larger than 1. The start vertex of path j , for $k < j \leq p$, is denoted by s_j .
 - b. *End vertices* T . These are the end vertices of those paths that have length larger than 1. The end vertex of path j , for $k < j \leq p$, is denoted by t_j .
 - c. *Intermediate vertices* $I = V_2 \setminus (S \cup T)$.

► **Lemma 5.** *The classes of vertices listed above have the following properties:*

1. *There are no arcs in H between vertices of V_1 . Hence no vertex of V_1 can be a spoiler vertex for another vertex in V_1 .*
2. *There are no arcs in H from vertices of V_1 to vertices in S . Hence no vertex of V_1 can be a spoiler vertex for a vertex in S .*

3. There are no arcs in H from vertices of T to vertices in V_1 . Hence no vertex of T can be a spoiler vertex for a vertex in V_1 .
4. For $i \neq j$, there are no arcs in H from any vertex $t_i \in T$ to any vertex $s_j \in S$. Hence no vertex of T can be a spoiler vertex for a vertex in S , unless they both belong to the same path in the given maximal path cover.
5. $(s_i, s_j) \notin D$ for any $s_i, s_j \in S$ with $i < j$. Hence s_i cannot be a spoiler vertex for s_j if $i < j$.
6. $(t_j, t_i) \notin D$ for any $t_i, t_j \in S$ with $i < j$. Hence t_j cannot be a spoiler vertex for t_i if $i < j$.
7. If for some $s_j \in S$ and $t_j \in T$ (where s_j and t_j are start and end vertices of the same path P_j) it holds that $(t_j, s_j) \in D$, then there are no arcs from $(T \setminus \{t_j\}) \cup V_1$ to any of the vertices of P_j , and likewise, no arcs from s_{k+1}, \dots, s_{j-1} to any of the vertices of P_j .

Proof. All properties follow from the maximality of the path cover. Properties 1,2,3 and 4 hold because otherwise one could perform a path merging operation. Properties 5 and 6 hold because otherwise one could perform a path unbalancing operation. Property 7 holds because otherwise one could perform a rotation operation for path P_j , followed either by a path merging operation (if there is an arc from $(T \setminus \{t_j\}) \cup V_1$ to any of the vertices of P_j) or a path unbalancing operation (if there is an arc from s_{k+1}, \dots, s_{j-1} to any of the vertices of P_j). ◀

We now introduce additional notation. Considering only the arcs in D leading from V_2 to V_1 , we let M_{21} denote the maximum matching among these arcs. In our analysis we shall consider three parameters:

1. ϵ_1 : its value is such that $k = (\frac{1}{2} - \epsilon_1) n$ (recall that $k = |V_1|$ is the number of singleton paths in the maximal path cover). Observe that ϵ_1 might be negative.
2. ϵ_2 : its value is such that $p = k + \epsilon_2 n = (\frac{1}{2} - \epsilon_1 + \epsilon_2) n$ (recall that p is the total number of paths in the maximal path cover). Necessarily, $\epsilon_2 \geq 0$.
3. ϵ_3 : its value is such that $|M_{21}| = (\frac{1}{2} - \epsilon_3) n$. Necessarily, $\epsilon_3 \geq 0$.

Given the above classes of vertices, we consider four possible candidate permutations for π (denoted $\pi_1, \pi_2, \pi_3, \pi_4$, see below for details). Given some permutation π , we shall use the notation $\rho(\pi)$ to denote the fraction of vertices guaranteed to be matched under π . This fraction will be expressed as a function of the parameters ϵ_1, ϵ_2 and ϵ_3 , and we will show that regardless of the value of these parameters, there must be some π with $\rho(\pi) \geq \frac{22}{43}$.

The following four lemmas present the four candidate permutations for π along with their corresponding guarantees. Whenever unspecified, the order within a set of vertices can be arbitrary; e.g., for two sets of vertices X, Y , $\pi = X, Y$ means that the set X precedes Y and the order within X , as well as the order within Y , is arbitrary.

► **Lemma 6.** For G and $\pi_1 = V_2, V_1$,

$$\rho(\pi_1) \geq \frac{1}{n} \left(|V_1| + \frac{|V_2|}{2} - \frac{|M_{21}|}{2} \right) = \frac{1}{2} - \frac{\epsilon_1}{2} + \frac{\epsilon_3}{2}.$$

Proof. Let σ be an arbitrary permutation over U . Let m denote the number of vertices in V_2 that are matched to vertices in U_1 , where U_1 is the set of partners of V_1 . Then $m \leq |M_{21}|$. Of the $|V_2| - m$ vertices of V_2 not matched to vertices in U_1 , at least half are matched (because for every unmatched vertex from this set, its partner must be matched to a different vertex from this set). In addition, all those vertices of V_1 whose partner is not matched to V_2 are matched, because of property 1 of Lemma 5. Hence the total number of vertices matched is at least $m + \frac{|V_2| - m}{2} + |V_1| - m \geq |V_1| + \frac{|V_2|}{2} - \frac{|M_{21}|}{2}$, as desired. ◀

7:10 Max-Min Greedy Matching

► **Lemma 7.** For G and $\pi_2 = V_1, V_2$,

$$\rho(\pi_2) \geq \frac{2}{3} - \frac{1}{3}(\epsilon_1 + \epsilon_3).$$

Proof. Let σ be an arbitrary permutation over U . All vertices in V_1 are matched because of property 1 of Lemma 5. As to the vertices in V_2 , observe that $|N(V_2)| \geq |V_2| + |M_{21}|$, as the set $N(V_2)$ includes the $|V_2|$ partners of V_2 , plus at least $|M_{21}|$ additional neighbors in U_1 (due to the matching M_{21}). Moreover, if x vertices are removed from V_2 , the number of remaining neighbors is at least $|V_2| + |M_{21}| - 2x$, because each vertex of V_2 contributed at most two neighbors to the lower bound that we provided on the number of neighbors.

Let x denote the number of vertices in V_2 matched under (π, σ) . Then the size of the matching is $|V_1| + x$, the number of unmatched vertices in V_2 is $|V_2| - x$, and they have at least $|V_2| + |M_{21}| - 2x$ neighbors which have to be matched. Since the number of matched vertices at each side is the same, we have that $|V_1| + x \geq |V_2| + |M_{21}| - 2x$.

We get that

$$\begin{aligned} 3x \geq |V_2| + |M_{21}| - |V_1| &= n \left(\frac{1}{2} + \epsilon_1 \right) + n \left(\frac{1}{2} - \epsilon_3 \right) - n \left(\frac{1}{2} - \epsilon_1 \right) \\ &= \left(\frac{1}{2} + 2\epsilon_1 - \epsilon_3 \right) n. \end{aligned}$$

Therefore, the size of the matching is at least

$$|V_1| + x \geq \left(\frac{1}{2} - \epsilon_1 \right) n + \left(\frac{1}{6} + \frac{2\epsilon_1}{3} - \frac{\epsilon_3}{3} \right) n = \left(\frac{2}{3} - \frac{1}{3}(\epsilon_1 + \epsilon_3) \right) n. \quad \blacktriangleleft$$

► **Lemma 8.** For G and $\pi_3 = t_p, \dots, t_{k+1}, V_1, s_{k+1}, \dots, s_p, I$,

$$\rho(\pi_3) \geq \frac{2p - k}{n} = \frac{1}{2} - \epsilon_1 + 2\epsilon_2.$$

Proof. In π_3 , we refer to the vertices of $T \cup V_1 \cup S$ as the *prefix* of π_3 , and to the vertices of I as the *suffix*. Lemma 5 implies that within the prefix, the only arcs of H that go from an earlier vertex to a later vertex are of the form (t_j, s_j) (for a path P_j that can undergo a rotation). We claim that regardless of σ , all the prefix will be matched. As the length of this prefix is $2p - k$, this will prove the lemma.

It remains to prove the claim. Suppose first that in the above prefix there are no arcs of H that go from an earlier vertex to a later vertex. Then earlier vertices in this prefix cannot be spoiling vertices for later vertices. Hence indeed, regardless of σ , all the prefix will be matched.

Suppose now that in the prefix of π_3 there are arcs of H that go from an earlier vertex to a later vertex. As noted above, such an arc would be of the form (t_j, s_j) . We need to show that even if t_j acts as a spoiling vertex for s_j under π_3 and σ , the vertex s_j will still be matched. Consider the path P_j , and let us rename its vertices as x_1, \dots, x_ℓ (where previously we used $s_j = x_1$ and $t_j = x_\ell$). We wish to show the x_1 would be matched even if x_ℓ is matched to the partner of x_1 . The path P_j implies that the partner of x_2 is a neighbor of x_1 in G . Hence x_1 will be matched if no vertex preceding $x_1 = s_j$ in π_3 is matched to the partner of x_2 . By property 7 of Lemma 5, there is no arc in H from any of the vertices $T \cup V_1 \cap \{s_{k+1}, \dots, s_{j-1}\} \setminus \{t_j\}$ to x_2 , and consequently none of them can be matched to the partner of x_2 . As to $t_j = x_\ell$, it might be a neighbor of the partner of x_2 (in fact, it could be that $\ell = 2$), but we already assumed that t_j is matched to the partner of x_1 , and hence it is not matched to the partner of x_2 . Hence no vertex preceding $x_1 = s_j$ in π_3 is matched to the partner of x_2 , and hence s_j will be matched. \blacktriangleleft

Let V_e (V_o , respectively) denote those vertices of $S \cup I$ that are at even (odd, respectively) distance from the beginning of their respective path. Observe that $S \subset V_e$.

► **Lemma 9.** For G and $\pi_4 = t_p, \dots, t_{k+1}, V_1, V_o, V_e$,

$$\rho(\pi_4) \geq \frac{5}{9} - \frac{p}{9n} = \frac{1}{2} + \frac{\epsilon_1}{9} - \frac{\epsilon_2}{9}.$$

Proof. Observe that $|V_e| \geq |V_o|$, because in every path (of length above 1) the vertices alternate in entering V_e and V_o , and start with V_e . Observe also that every vertex $v \in V_e$ contributes two distinct neighbors to $N(V_e)$: the partner of v , and the partner of the vertex that follows v on its path (note that the vertex that follows v is not in V_e). Likewise, every vertex $v \in V_o$ contributes two distinct neighbors to $N(V_o)$.

Regardless of σ , all p vertices of T and V_1 are matched, as in Lemma 8. For a given σ , let n_o be the number of vertices matched in V_o and let n_e be the number of vertices matched in V_e . Then, $|V_o| - n_o$, the number of unmatched vertices in V_o , satisfies $2(|V_o| - n_o) \leq p + n_o$, because the neighbors of the unmatched vertices in V_o need to be matched to earlier vertices in $T \cup V_1 \cup V_o$. Likewise, $|V_e| - n_e$, the number of unmatched vertices in V_e , satisfies $2(|V_e| - n_e) \leq p + n_o + n_e$. Adding two times the first inequality and three times the second we get that $4|V_o| + 6|V_e| - 4n_o - 6n_e \leq 5p + 5n_o + 3n_e$. Using $|V_o| + |V_e| = n - p$ and $|V_e| \geq |V_o|$, we can replace $4|V_o| + 6|V_e|$ by $5(n - p)$, implying that $9(p + n_o + n_e) \geq 5n - p$, as desired. ◀

We can now prove Theorem 2.

Proof. Observe that $\rho(G) \geq \max_{i \in [1,4]} [\rho(\pi_i)]$.

By Lemma 6 we have: $\rho(\pi_1) \geq \frac{1}{2} - \frac{\epsilon_1}{2} + \frac{\epsilon_3}{2}$.

By Lemma 7 we have: $\rho(\pi_2) \geq \frac{2}{3} - \frac{1}{3}(\epsilon_1 + \epsilon_3)$.

By Lemma 8 we have: $\rho(\pi_3) \geq \frac{1}{2} - \epsilon_1 + 2\epsilon_2$.

By Lemma 9 we have: $\rho(\pi_4) \geq \frac{1}{2} + \frac{\epsilon_1}{9} - \frac{\epsilon_2}{9}$.

Taking a weighted average of the lower bounds provided by the four lemmas, with weights $\frac{2}{43}, \frac{3}{43}, \frac{2}{43}, \frac{36}{43}$, respectively, results in a weighted average of $\frac{22}{43}$. Hence regardless, of the values of ϵ_1, ϵ_2 and ϵ_3 , at least one of the lemmas gives $\rho(G) \geq \frac{22}{43}$. For $\epsilon_1 = \frac{19}{86}, \epsilon_2 = \frac{10}{86}$ and $\epsilon_3 = \frac{21}{86}$, none of the lemmas implies a bound better than $\frac{1}{2} + \frac{1}{86} = \frac{22}{43}$.

The above analysis leads to a polynomial time algorithm for finding π that ensures $\rho(G) \geq \frac{22}{43}$. A maximal path cover of $H(V, D)$ can be found in polynomial time by Proposition 4. Thereafter, the sets V_1, S, T, V_e and V_o can easily be determined, and likewise, the values of ϵ_1 and ϵ_2 can be easily computed. A maximum matching M_{21} (from V_2 to V_1 in H) can be computed in polynomial time using any standard algorithm for maximum bipartite matching. Thereafter, ϵ_3 can be easily computed. Given the values ϵ_1, ϵ_2 and ϵ_3 , one can determine which of π_1, π_2, π_3 or π_4 provides a higher lower bound on ρ , and use that permutation as π . ◀

3 Regular Graphs

In this section we consider the case where $G(U, V; E)$ is a d -regular bipartite graph with $2n$ vertices. Given that such graphs have d edge disjoint perfect matchings, one can hope to achieve higher values for ρ for these graphs.

3.1 Positive Result

The following known proposition (see for example [18]) establishes a lower bound on ρ , as a function of d . A proof is provided for completeness.

► **Proposition 10.** *For every d -regular graph $G \in G_n$, it holds that $\rho[G] \geq \frac{d}{2d-1}$.*

Proof. Since the greedy algorithm produces a maximal matching, it suffices to show that every maximal matching in a d -regular graph has size at least $\frac{d}{2d-1}n$. To see this, let $S \subset U$ and $T \subset V$ be the sets of unmatched nodes in an arbitrary maximal matching, and suppose $|S| = |T| = (1 - \alpha)n$. The nodes in S, T must form an independent set. Consider the size of the edge set connecting S and $V \setminus T$. On the one hand, this size equals $(1 - \alpha)nd$ (since all edges from S go to $V \setminus T$); on the other hand, this size is at most $\alpha n(d - 1)$ (since at least one edge from each node in $V \setminus T$ goes to $U \setminus S$). Thus, $(1 - \alpha)nd \leq \alpha n(d - 1)$, implying that $\alpha \geq d/(2d - 1)$. Hence we have that $|M_G[\sigma, \pi]| \geq \frac{d}{2d-1}n$, for every π . ◀

Remark: For every d there exists a d -regular graph with a perfect matching that admits a maximal matching of size $\frac{d}{2d-1}n$. Suppose that $n = 2d - 1$, and consider a d -regular graph where $|S| = |T| = d - 1$ for some $S \subset U, T \subset V$, every node in $U \setminus S$ is connected to a single, different node in $V \setminus T$, and to all $d - 1$ nodes in T , and every node in $V \setminus T$ is connected to a single, different node in $U \setminus S$, and to all $d - 1$ nodes in S . The perfect matching between $U \setminus S$ and $V \setminus T$ is a maximal matching of size $\frac{d}{2d-1}n$.

The lower bound of Proposition 10 approaches $\frac{1}{2}$ from above as d grows. The following theorem shows that there exists some permutation π that ensures that the fraction of matched vertices approaches $5/9$. This is a direct corollary from Lemma 9 and a theorem in [7].

► **Corollary 11.** *For d -regulars bipartite graphs, $\rho \geq \frac{5}{9} - O(\frac{1}{\sqrt{d}})$.*

Proof. Theorem 3 in [7] shows that every n -vertex d -regular graph has a path cover (referred to as a *linear forest*) with $p = O(\frac{n}{\sqrt{d}})$ paths. By Lemma 9, $\rho(G) \geq \frac{5}{9} - O(\frac{1}{\sqrt{d}})$. ◀

Remarks.

1. For small d , the bound of $\rho \geq \frac{d}{2d-1}$ which holds for every maximal matching is stronger than the bound in Corollary 11.
2. The proof of Corollary 11 extends to graphs that are nearly d -regular, by using Theorem 5 from [7].
3. For d -regular graphs, conjectures mentioned in [7] combined with our proof approach suggest that $\rho \geq \frac{5}{9} - O(\frac{1}{\sqrt{d}})$.

3.2 Negative Result

The following example shows that even in a regular graph with arbitrarily high degree, there may be no permutation π that ensures to match more than a fraction $8/9$ of the vertices.

► **Theorem 12.** *For every integers $d, t \geq 1$, there is a regular bipartite graph $G_{d,t}$ of even degree $2d$ and $n = 3dt$ vertices on each side such that $\rho(G_{d,t}) \leq \frac{8}{9}$.*

Proof. Consider a regular bipartite graph $G(U, V; E)$ with even degree $2d$, and $3d$ vertices on each side. To define the edge set, let $U = U_1 \cup U_2 \cup U_3$ with each U_i of cardinality d , and similarly $V = V_1 \cup V_2 \cup V_3$ with each V_i of cardinality d . For every $i \neq j$, we have a complete bipartite graph between U_i and V_j , and for every i , there are no edges between U_i and V_i .

Let π be an arbitrary permutation over V , let S be the first $2d$ vertices in π , and let T be the last d vertices. Let i be such that $|V_i \cap T|$ is largest (breaking ties arbitrarily). Without loss of generality we may assume that $i = 3$, and then $|V_3 \cap T| \geq d/3$. Hall's condition implies that there is a perfect matching between $U_1 \cup U_2$ and S (and more generally, between $U_1 \cup U_2$ and any $2d$ vertices from V). Hence one can choose a permutation σ over U whose first $2d$ vertices are $U_1 \cup U_2$ that will match the vertices of S one by one. Thereafter, the vertices of $T \cap V_3$ will remain unmatched.

To get the graph $G_{d,t}$ claimed in the theorem, take t disjoint copies of $G(U, V; E)$ above. \blacktriangleleft

4 Random Permutation

In this section we consider scenarios in which the maximizing player is unaware of the graph structure. In such scenarios, the best she can do is impose a random permutation over the vertices in V .

We first show that there exists a graph $G \in G_n$ for which a random permutation does not match significantly more than a half of the vertices, even if every vertex has a high degree.

► **Proposition 13.** *There exists a bipartite graph $G(U, V; E) \in G_n$ such that a random permutation gets $\rho(G) = \frac{1}{2} + o(1)$ almost surely.*

Proof. Consider the graph $G(U, V; E)$, where $U = (U_1, U_2)$, $V = (V_1, V_2)$, and each of U_1, U_2, V_1, V_2 is of size $n/2$. The set of edges constitutes of a perfect matching between U_1 and V_1 , a perfect matching between U_2 and V_2 , and a bi-clique between U_1 and V_2 . Let π be a random permutation. With high probability, for each vertex $v_1 \in V_1$, except for $\sim \sqrt{n}$ such vertices, we can associate a unique vertex $v_2 \in V_2$ that precedes v_1 in π . Let $S \subseteq V_1$ denote this set. Consider an arrival order σ in which agents in U_1 arrive first, with a vertex u_{1j} preceding a vertex $u_{1j'}$ if $\pi(v_{2j}) < \pi(v_{2j'})$. Every vertex in U_1 such that its neighbor in V_1 (according to the perfect matching) belongs to S will be matched to the corresponding vertex in V_2 . Therefore, all but $\sim \sqrt{n}$ vertices of V_1 remain unmatched, and the size of the matching is $n(1/2 + o(1))$, whereas $OPT = n$. \blacktriangleleft

In the above example, if the vertices of V with degree 1 are placed in the prefix of π , then the obtained matching is optimal. This might suggest that prioritizing low degree vertices in π (and randomizing within sets of vertices of comparable degrees) leads to good performance. However, the example above can be transformed into one where all vertices in V have the same degree. To see this, consider a graph where vertices are partitioned into sets of perfect matchings of size \sqrt{n} , $\{(U_{11}, V_{11}), \dots, (U_{1\sqrt{n}}, V_{1\sqrt{n}}), (U_{21}, V_{21}), \dots, (U_{2\sqrt{n}}, V_{2\sqrt{n}})\}$. Each V_{1i} is also connected in a bi-clique to U_{2i} , and in addition, there are sets U', V' of size \sqrt{n} each connected to the vertices of the other side to balance out the degrees. A similar argument shows that in this graph, a random permutation performs badly as well.

In contrast to the last examples, in some classes of graphs, a random permutation guarantees to match a fraction of the vertices that is bounded away from a half. This is the case, for example, in Hamiltonian graphs. The formal statement and proof are deferred to Section 6.

5 Finding a perfect π

A permutation π over V is said to be *perfect* if for every permutation σ over U , $|M_G[\sigma, \pi]| = n$. A vertex $v \in V$ is *good* with respect to a set of vertices $S \subset V$ if there is no matching between $N(v)$ and S . Given permutation π over V , let $\bar{\pi}(v)$ be the set of vertices preceding v in π .

► **Observation 14.** π is perfect if and only if every vertex $v \in V$ is good with respect to $\bar{\pi}(v)$.

Proof. Suppose there exists a vertex $v \in V$ that is not good. Then, consider a permutation σ where the vertices in $N(v)$ are placed first, in an order corresponding to the rank (according to π) of their partners in the perfect matching between $N(v)$ and $\bar{\pi}(v)$. In such a σ , v will not be matched. Now suppose that all vertices in V are good. Then, for every σ , for every $v \in V$, there exists a vertex $u \in U$ that is not matched to a vertex in $\bar{\pi}(v)$; therefore v will surely be matched. ◀

We present an algorithm that finds a perfect π if one exists, and claims that no such π exists otherwise.

Checking whether v_i is good can be done in polynomial time by running a maximum matching algorithm on $N(v_i)$ and S_i .

An algorithm for finding a perfect π .

1. Let $S_1 = V$.
2. In iteration $i = 1, \dots, n$:
 - a. Find an arbitrary good vertex $v_i \in S_i$ with respect to $S_i \setminus \{v_i\}$, and place it in rank $n - i + 1$ in π .
 - b. Set $S_{i+1} = S_i \setminus \{v_i\}$.

► **Lemma 15.** *If there exists a perfect π , then the algorithm is guaranteed to find a good v_i in every iteration i .*

Proof. Consider some perfect permutation π (not necessarily the one produced by our algorithm), and the suffix $V_{i-1} = v_{i-1}, v_{i-2}, \dots, v_1$ of vertices chosen in the first $i - 1$ iterations of the algorithm (of course, there must be a good v_1 at the first iteration, otherwise there is no perfect π). Let π' be the permutation that places $v_{i-1}, v_{i-2}, \dots, v_1$ as the lowest ranked vertices in the same order as the algorithm picked them, and places all other vertices of $V \setminus V_{i-1}$ in a higher rank than V_{i-1} according to their internal order in π .

Since every v_j , $1 \leq j \leq i - 1$, is good with respect to $V \setminus \{v_1, \dots, v_j\}$, then clearly v_j is good with respect to $\bar{\pi}'(v_j)$ (since $\bar{\pi}'(v_j) = V \setminus \{v_1, \dots, v_j\}$). Now consider a vertex $v \in V \setminus V_{i-1}$. This vertex is good with respect to $\bar{\pi}(v)$, and since $\bar{\pi}'(v) \subseteq \bar{\pi}(v)$, it is clear that v is good with respect to $\bar{\pi}'(v)$. It follows that π' is perfect as well.

Let v'_i be the vertex ranked in position $n - i + 1$ in π' . Since π' is perfect, this vertex is good with respect to $\bar{\pi}'(v'_i)$. But since $\bar{\pi}'(v'_i) \cup \{v'_i\}$ is exactly the set S_i in iteration i , it is guaranteed that the algorithm can find a good v_i in this iteration. ◀

Let π be the permutation computed by the algorithm. Since every vertex v is good with respect to $\bar{\pi}(v)$, it follows from Observation 14 that π is perfect, and Proposition 1 follows.

6 Hamiltonian Bipartite Graphs

In this section we establish two results about Hamiltonian graphs. First, we show that $\rho \geq \frac{5}{9}$. Note that, since for the case of a Hamiltonian graph there exists a path cover using only a single path (*i.e.*, $p = 1$), Lemma 9 directly implies that $\rho \geq \frac{5}{9} - \frac{1}{9n}$. Theorem 16 improves this bound to $5/9$. Second, we show that for Hamiltonian graphs, even a random permutation π ensures a ratio that is bounded away from $\frac{1}{2}$ (this is in contrast to general graphs, see Section 4).

► **Theorem 16.** *For every Hamiltonian graph G , it holds that $\rho \geq \frac{5}{9}$.*

Proof. Consider a Hamiltonian graph G and a Hamiltonian cycle $u_1, v_1, u_2, v_2, \dots, u_n, v_n, u_1$ that traverses through its vertices. Let $V_o = \{v_i : i = 2\ell + 1, \ell \in \mathbb{N}, i \leq n\}$ be the set of odd labeled vertices of the cycle, and $V_e = V \setminus V_o$.

We first claim that if the number of vertices is even ($|V_o| = |V_e| = \frac{n}{2}$), then $\pi = V_e, V_o$ (and in fact, also $\pi = V_o, V_e$) ensures that $\rho \geq 5/9$. Let n_e (respectively, n_o) be the number of vertices of V_e (respectively, V_o) matched in $M_G[\sigma, \pi]$ defined using $\pi = (V_e, V_o)$ and an arbitrary σ . Similar to the proof of Lemma 9, it is easy to see that each vertex in V_e contributes two distinct neighbors to $N(V_e)$, and each vertex in V_o contributes two distinct neighbors to $N(V_o)$ (the difference from the proof of Lemma 9 is that this property also holds for $v_1 \in V_o$ and $v_n \in V_e$, and this follows because v_1 and v_n contribute u_1 to $N(V_o)$ and $N(V_e)$, respectively). The number of unmatched vertices in V_o , namely $|V_o| - n_o$, satisfies

$$2(|V_o| - n_o) \leq n_o,$$

because the neighbors of the unmatched vertices in V_o must be matched to vertices in V_o , as they precede the vertices in V_e in π . Likewise, the number of unmatched vertices in N_e , namely $|V_e| - n_e$, satisfies

$$2(|V_e| - n_e) \leq n_e + n_o.$$

Adding two times the first inequality and three times the second, we get

$$4|V_o| + 6|V_e| \leq 9(n_o + n_e) \Rightarrow \frac{5}{9} \cdot n \leq n_o + n_e.$$

As $|V| = n$ and $|M_G[\sigma, \pi]| = n_o + n_e$, this implies that $\rho \geq \frac{5}{9}$.

We now handle the case where n is odd. Lemma 9 ensures that $\frac{5}{9} \cdot n - \frac{1}{9}$ of the vertices are matched by π_4 when the path cover is of a single path. If $\frac{5}{9} \cdot n - \frac{1}{9}$ is not integral, then $\lceil \frac{5}{9} \cdot n - \frac{1}{9} \rceil$ is at least $\frac{5}{9} \cdot n$, thus $\rho \geq \frac{5}{9}$. Therefore, it only remains to handle the case where $\frac{5}{9} \cdot n - \frac{1}{9}$ is integral; namely where $n = 18\ell + 11$ for some integer ℓ . In this case, we show that $\pi = V_e, V_o$ ensures that $|M[\sigma, \pi]| > \frac{5}{9} \cdot n$ for every σ . Since $n = 18\ell + 11$, it holds that $|V_o| = 9\ell + 6$ and $|V_e| = 9\ell + 5$. As in the case where n is even, every vertex in V_e contributes two distinct neighbors to $N(V_e)$. As for V_o , every vertex in $V_o \setminus \{v_1, v_n\}$ also contributes two distinct neighbors to $N(V_o)$, and v_1 and v_n contribute (together) to $N(V_o)$ three additional distinct vertices (since they share a vertex along the Hamiltonian cycles). Using the same reasoning as before, it follows that

$$2(|V_e| - n_e) \leq n_e \Rightarrow 18\ell + 10 \leq 3 \cdot n_e \Rightarrow n_e \geq 6\ell + 3\frac{1}{3}.$$

Since n_e is integral, this implies that

$$n_e \geq 6\ell + 4. \tag{1}$$

Again, for $|V_o| - n_o$ we have $2(|V_o| - n_o) - 1 \leq n_o + n_e$. Rearranging gives us

$$n_e + 3n_o \geq 18\ell + 11.$$

Adding twice Inequality (1) to the last inequality yields

$$n_e + n_o \geq 10\ell + 6\frac{1}{3} > 10\ell + 6\frac{1}{9} = \frac{5}{9} \cdot |V|,$$

which implies $\rho > \frac{5}{9}$. This concludes the proof. ◀

7:16 Max-Min Greedy Matching

Next, we show that for the case of a Hamiltonian graph, a random permutation yields a $\rho > 1/2$.

► **Theorem 17.** *Consider choosing a permutation π uniformly at random. For every Hamiltonian graph G , it holds that $E_\pi[\min_\sigma [|M_G[\sigma, \pi]|]] > 0.5012$.*

We explain the proof approach here, and present the full details in Appendix A.

Proof Approach

We first provide a high level overview of our proof approach.

A permutation π (over V) is said to be *safe* for a set $S \subset V$ if for every permutation σ (over U) the greedy process matches at least one vertex in S (i.e., no σ leaves all vertices in S unmatched). Fix some constant ϵ . In order to establish that $\rho \geq (1/2 + \epsilon)$, we need to show that there exists a permutation π that is safe for every set S of size $(1/2 - \epsilon)n$. Our proof approach is the following: we show that for a permutation π chosen uniformly at random, the expected number (expectation taken over choice of π) of sets of size $(1/2 - \epsilon)n$ for which π is unsafe is smaller than 1. This implies that there exists a permutation π that is safe for all sets of size $(1/2 - \epsilon)n$, as desired.

First, we define a collection of sets that can potentially remain unmatched (“bad” sets). Let B_ϵ denote the set of all sets $S \subset U$ of size $(1/2 - \epsilon)n$ such that there exists a permutation π that is unsafe for S .

Second, for a given set S and permutation π we identify a sufficient condition for π to be safe for S . Let $S' \subset S$ be the lowest αn vertices in S (according to π), let v' be the last vertex in S' (i.e., the vertex with rank αn in S'), and let P be the set of vertices in $V - S'$ that precede v' in π . We claim that if the size of P is smaller than the size of $N(S')$ (the neighbors of S'), then π is safe for S . To see this, assume by way of contradiction that π is unsafe for S' . This implies that every vertex in $N(S')$ is matched to a vertex in $V - S'$. Since there are strictly less than $|N(S')|$ vertices in $V - S'$ that precede v' , at least one of the vertices in $N(S')$ must be matched to a vertex higher than v' . But, this vertex has a neighbor in S' with lower rank, contradicting the greedy process.

We now proceed by establishing the following three lemmas:

- **Few bad sets lemma:** the size of B_ϵ is at most $n_B = n_B(\epsilon)$.
- **Expansion lemma:** given a set $S \subset V$ and parameters α, β , the probability (over a random choice of π) that the lowest αn vertices in S have less than βn neighbors is at most $p = p(\alpha, \beta)$.
- **Good order lemma:** given a set $S \subset V$ and parameters α, β , the probability (over a random choice of π) that the $(\alpha n)^{th}$ lowest vertex in S is higher than βn vertices in $V \setminus S$ is at most $q = q(\alpha, \beta)$.

The three lemmas are combined as follows. For a given set S , due to the sufficient condition identified above, it follows from the union bound that the probability that a uniformly random permutation π is unsafe for S is at most $p + q$. Applying the union bound once more over all bad sets (at most n_B sets, as implied by the few bad sets lemma), implies that the probability that a uniformly random permutation π is unsafe for some set of size $(1/2 - \epsilon)n$ is at most $n_B(p + q)$. Thus, to conclude the proof, it remains to find parameters such that $n_B(p + q) < 1$.

The good order lemma is independent of the graph structure. In contrast, the expansion lemma and the few bad sets lemma rely heavily on the structure of the graph. As it turns out, Hamiltonian graphs have properties that enable us to establish the two lemmas with good parameters.

A Full Proof of Theorem 17

Throughout this section we use $H(\cdot)$ to denote the binary entropy function; i.e., given a constant $p \in (0, 1)$, $H(p) = -p \log_2 p - (1 - p) \log_2(1 - p)$.

► **Fact 18** (Stirling's Approximation). *As $n \rightarrow \infty$,*

$$n! = (1 + o(1))\sqrt{2\pi n} \left(\frac{n}{e}\right)^n.$$

Using Stirling's Approximation, one can derive the following bound.

► **Fact 19.** *For n and $k = pn$ for some constant $p \in (0, 1)$,*

$$\binom{n}{k} = 2^{(H(p)+o(1))n}, \tag{2}$$

where $H(p) = -p \log_2 p - (1 - p) \log_2(1 - p)$ is the binary entropy function.

We first establish the good order lemma, which is independent of the graph structure.

► **Lemma 20** (Good order lemma). *Let $\alpha < \beta < 1$, $\rho = \frac{1}{2} + \epsilon$ for some $\epsilon > 0$ and $\bar{\rho} = 1 - \rho$ such that $\frac{\beta}{\alpha} > \frac{\rho}{\bar{\rho}}$. Let $S \subset V$ be a set of size $\bar{\rho}n$. The probability that in a random permutation π there are at least βn vertices of $V \setminus S$ before αn vertices from S is at most $2^{-(H(\alpha+\beta)-H(\frac{\alpha}{\bar{\rho}})\bar{\rho}-H(\frac{\beta}{\rho})\rho-o(1))n}$.*

Proof. We first analyze the case that in the first $(\alpha + \beta)n$ vertices in π there are exactly αn vertices from S . The number of possibilities for this case is $\binom{\bar{\rho}n}{\alpha n} \binom{\rho n}{\beta n}$.

Let $\beta' = \beta + x$ and $\alpha' = \alpha - x$. By the conditions on α, β and ϵ , we have that $\frac{\beta'}{\alpha'} \geq \frac{\beta}{\alpha} \geq \frac{\rho}{\bar{\rho}}$. Therefore,

$$\begin{aligned} \beta' \bar{\rho} \geq \alpha' \rho &\Rightarrow \beta' \bar{\rho} - \alpha' \beta' \geq \alpha' \rho - \alpha' \beta' \Rightarrow \frac{(\bar{\rho} - \alpha')}{\alpha'} \cdot \frac{\beta'}{(\rho - \beta')} \geq 1 \\ &\Rightarrow \frac{(\bar{\rho}n - \alpha'n + 1)}{\alpha'n} \cdot \frac{\beta'n + 1}{(\rho n - \beta'n)} \geq 1 \iff \frac{\binom{\bar{\rho}n}{\alpha'n} \binom{\rho n}{\beta'n}}{\binom{\bar{\rho}n}{\alpha'n-1} \binom{\rho n}{\beta'n+1}} > 1. \end{aligned}$$

It follows that $\binom{\bar{\rho}n}{\alpha n} \binom{\rho n}{\beta n} > \binom{\bar{\rho}n}{\alpha'n} \binom{\rho n}{\beta'n}$ for every $\alpha' < \alpha$ and $\beta' > \beta$ such that $\alpha + \beta = \alpha' + \beta'$. Therefore, the probability to have at most αn vertices from S in the first $(\alpha + \beta)n$ vertices in π is at most

$$\begin{aligned} \frac{\alpha n \cdot \binom{\bar{\rho}n}{\alpha n} \binom{\rho n}{\beta n}}{\binom{n}{(\alpha+\beta)n}} &= \frac{2^{(H(\frac{\alpha}{\bar{\rho}})\bar{\rho}+H(\frac{\beta}{\rho})\rho+o(1))n}}{2^{(H(\alpha+\beta)+o(1))n}} \\ &= 2^{-(H(\alpha+\beta)-H(\frac{\alpha}{\bar{\rho}})\bar{\rho}-H(\frac{\beta}{\rho})\rho-o(1))n}, \end{aligned}$$

where the first equality follows Fact 19. ◀

Let $\rho = \frac{1}{2} + \epsilon$ for some constant $\epsilon > 0$, $\bar{\rho} = 1 - \rho = \frac{1}{2} - \epsilon$. The next lemma will be used in order to prove the few bad sets lemma and the expansion lemma. It uses the existence a Hamiltonian cycle in the graph in order to claim that most sets will have a large number of neighbors. Therefore, a random set will have a large expansion. In addition, there will be few sets of size $(\frac{1}{2} - \epsilon)n$ with less than $(\frac{1}{2} + \epsilon)n$ neighbors (i.e., a few bad sets).

► **Lemma 21.** *Let $\alpha \in (0, 1/2)$ and $\beta \in (\alpha, 1)$ be two constants such that $\delta = \beta - \alpha < \alpha/2$. The number of sets S of size αn where $|N(S)| \leq \beta n$ is at most $2^{(\alpha H(\frac{\delta}{\alpha}) + (1-\alpha)H(\frac{\delta}{1-\alpha}) + o(1))n}$.*

Proof. Consider a Hamiltonian cycle that traverses through the graph's vertices $H = (v_1, u_1, v_2, u_2, \dots, v_n, u_n, v_1)$, where $\{v_i\}_{i \in [n]} = V$ and $\{u_i\}_{i \in [n]} = U$. Let S be some set of vertices from V of cardinality ρn . Note that in the cycle H , each vertex v of S has two neighbors, where one of these neighbors is joined with an adjacent vertex from V in the cycle. Therefore, the number of neighbors of a sequence of k consecutive vertices of V in H is $k + 1$. Thus, the set $N(S)$ is of size αn plus the number of consecutive blocks of vertices from V chosen.

We bound the number of ways to pick at most δn consecutive blocks of vertices from V . We first bound the number of ways to pick *exactly* δn such blocks. In this case, the αn chosen elements have to be within δn blocks. The number of ways to partition αn elements to δn non empty blocks is $\binom{\alpha n - 1}{\delta n - 1}$. After deciding the number of elements in each block, we need to figure out their location along the Hamiltonian cycle. $(1 - \alpha)n$ elements reside outside of the blocks of chosen αn elements. We need to chose the location of the first block in H (for which there are n possibilities), and then the number of element between each block, where two blocks are separated by at least one element. The latter is equivalent to splitting $(1 - \alpha)n$ elements into δn non empty bins, for which there are $\binom{(1-\alpha)n - 1}{\delta n - 1}$ possibilities. Overall, there are $n \binom{\alpha n - 1}{\delta n - 1} \binom{(1-\alpha)n - 1}{\delta n - 1}$ such possibilities⁴.

For $\delta' < \delta$, one can similarly devise the bound of $n \binom{\alpha n - 1}{\delta' n - 1} \binom{(1-\alpha)n - 1}{\delta' n - 1}$ which is smaller than $n \binom{\alpha n - 1}{\delta n - 1} \binom{(1-\alpha)n - 1}{\delta n - 1}$ by our conditions on α and δ . Overall, we can bound the number of ways to pick at most δn consecutive blocks of vertices from V by

$$\begin{aligned} \delta n^2 \binom{\alpha n - 1}{\delta n - 1} \binom{(1 - \alpha)n - 1}{\delta n - 1} &< \delta n^2 \binom{\alpha n}{\delta n} \binom{(1 - \alpha)n}{\delta n} \\ &= 2^{o(1)n} \cdot 2^{(H(\frac{\delta}{\alpha}) + o(1))\alpha n} \cdot 2^{(H(\frac{\delta}{1-\alpha}) + o(1))(1-\alpha)n} \\ &= 2^{(\alpha H(\frac{\delta}{\alpha}) + (1-\alpha)H(\frac{\delta}{1-\alpha}) + o(1))n}, \end{aligned}$$

where the first equality follows Fact 19. ◀

The expansion and few bad sets lemmas are obtained as direct corollaries of Lemma 21.

► **Lemma 22 (Few bad sets Lemma for Hamiltonian graphs).** *Let ϵ be a constant such that $\epsilon < 0.1$. The number of bad sets in any Hamiltonian graph is at most*

$$|B_\epsilon| \leq 2^{(\bar{\rho}H(\frac{2\epsilon}{\bar{\rho}}) + \rho H(\frac{2\epsilon}{\rho}) + o(1))n}.$$

⁴ Notice there's some over-counting in this argument, but this bound suffices for our purpose.

7:20 Max-Min Greedy Matching

Proof. Notice that if a set S of size $\bar{\rho}n = (\frac{1}{2} - \epsilon)n$ has more than ρn neighbors, it cannot be left unmatched, since at least one of its neighbors will not be matched to $V \setminus S$. A direct application of Lemma 21 yields that the number of such sets is at most $2^{(\bar{\rho}H(\frac{2\epsilon}{\bar{\rho}}) + \rho H(\frac{2\epsilon}{\bar{\rho}}) + o(1))n}$. ◀

We note that this lemma is not true for general graphs. An example of a graph that admits $2^{n/4}$ bad sets is given in the full version.

► **Lemma 23** (Expansion Lemma for Hamiltonian graphs). *Consider a set $S \subset V$ of size $\bar{\rho}n$ and parameters α, β . The probability that the lowest αn vertices in S have less than βn neighbors is at most*

$$2^{(-H(\frac{\alpha}{\bar{\rho}}) + \alpha H(\frac{\beta}{\alpha}) + (1-\alpha)H(\frac{\beta}{1-\alpha}) + o(1))\bar{\rho}n}.$$

Proof. Consider a set S of size $\bar{\rho}n$, and the first αn vertices in S in a random permutation. This set is just a random subset of S of size αn . The number of choices of such subset is

$$\binom{\bar{\rho}n}{\alpha n} = 2^{(H(\frac{\alpha}{\bar{\rho}}) + o(1))\bar{\rho}n}.$$

Notice that we can apply Lemma 21 for with set S , even though S is just a subset of V , because the same proof applies only with respect to a subset of vertices in one side of a Hamiltonian graph. Therefore, the number of subsets of size αn of S with at most βn neighbors is at most

$$2^{(\alpha H(\frac{\beta}{\alpha}) + (1-\alpha)H(\frac{\beta}{1-\alpha}) + o(1))\bar{\rho}n}.$$

Combining the above, we get that the probability that a random set of αn vertices of S have at most βn neighbors is at most

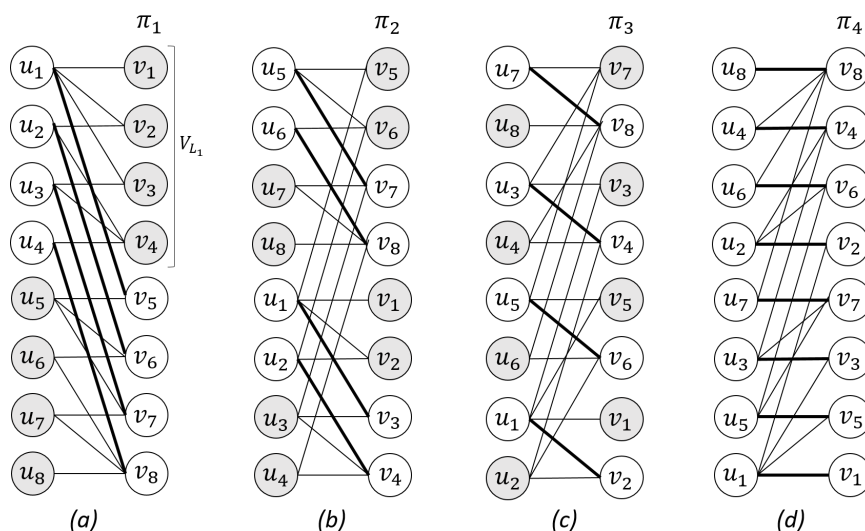

$$2^{(-H(\frac{\alpha}{\bar{\rho}}) + \alpha H(\frac{\beta}{\alpha}) + (1-\alpha)H(\frac{\beta}{1-\alpha}) + o(1))\bar{\rho}n}. \quad \blacktriangleleft$$

Now that we have established the three lemmas we are ready to prove Theorem 17.

Proof of Theorem 17. Setting $\epsilon = 0.0012$, $\alpha = 0.245$ and $\beta = 0.3675$ (and $\rho = \frac{1}{2} + \epsilon$, $\bar{\rho} = 1 - \rho$), we get that these parameters satisfy the conditions for Lemmas 20, 23 and 22.

Applying Lemma 22, we get that the size of B_ϵ is at most $n_B \leq 2^{0.044n}$. Applying Lemma 23, we get that the probability that the lowest αn vertices of a set of size $\bar{\rho}n$ have less than βn neighbors is at most $p \leq 2^{-0.86n}$. Applying Lemma 20, we get that the probability that for a set S of size $\bar{\rho}n$ the αn th vertex in a random π comes after βn vertices of $V - S$ is at most $q \leq 2^{-0.45n}$. Combining these three, we get that the probability there exists a set of size $\bar{\rho}n$ unmatched by a random π is at most $n_B(p + q) < 1$, therefore, there must be a π that matches at least one vertex in each set of size $\bar{\rho}n$, and the proof follows. ◀

This proof approach can be also used to show that a random permutation guarantees to match more than a half of the vertices in every regular graph. On the other hand, Theorem 24 in Section C shows that one cannot hope to get $\rho > 3/4$ with a random permutation in regular graphs.

■ **Figure 2** An iterative process where unmatched vertices are given priority. In every iteration thick edges are in the matching; gray vertices are unmatched.

B Iterative Process

A natural approach for establishing the existence of a good permutation π is the following iterative process of “upgrading” unmatched vertices. Given a permutation $\pi : V \rightarrow [n]$ and a permutation $\sigma : U \rightarrow [n]$, let $M[\pi, \sigma]$ be the result of the greedy matching where vertices in U arrive in order σ (from low to high) and each vertex $u \in U$ is matched to its lowest (under π) neighbor (or left unmatched if all its neighbors are already matched).

Fix an arbitrary permutation π_1 on V , and let σ_1 be a permutation on U minimizing the greedy matching⁵. Let $M_1 = M[\pi_1, \sigma_1]$ be the result of the greedy matching under permutations σ_1 and π_1 . If $|M_1|/n$ is some constant greater than $1/2$, then terminate with permutation π_1 . Otherwise, partition V into the set V_{L_1} of unmatched vertices (L for *low*, as they will be placed low in the next iteration, and also for *losers*, or *leftovers*) and the set V_{H_1} of matched vertices (H for *high*, as they will be placed high in the next iteration, and also for *hitters*, or *happy*).

Consider now a permutation π_2 in which V_{L_1} precedes V_{H_1} (preserving the internal order between vertices in V_{L_1} and similarly between vertices in V_{H_1}), and let σ_2 be a permutation on U minimizing the resulting greedy matching. Let $M_2 = M[\pi_2, \sigma_2]$. If $|M_2|/n$ is some constant greater than $1/2$, then terminate with permutation π_2 . Else, partition V into the set V_{L_2} of unmatched vertices and the set V_{H_2} of matched vertices, and consider a permutation π_3 in which V_{L_2} precedes V_{H_2} (preserving internal orders). Continue this iterative process until the obtained permutation π_k ensures a matching greater than a half.

The intuition behind this approach is that the unmatched vertices need some “help” in order to be matched, and we provide this help in the form of prioritizing them over their mates. One might hope that this process will reach a good permutation within a constant number of iterations. Unfortunately, we show an example where the process goes through $\log n$ iterations before it first obtains a permutation ensuring a matching that exceeds $n/2$.

⁵ It is unclear whether σ_1 can be computed in polynomial time. The related problem of computing a minimum maximal matching in bipartite graphs is known to be NP-hard [2]. However, here we consider the existential problem.

The construction of the graph is inductive. The base is $G_0(U_0, V_0; E_0)$, with two vertices u, v and a single edge between them. For every $i = 1, 2, \dots$, $G_i(U_i, V_i; E_i)$ is such that $|U_i| = |V_i| = 2^i$; it is obtained by taking two (disjoint) copies of G_{i-1} , with additional edges of the form (u_j, v_j) for every u_j from one copy of G_{i-1} to v_j in the second copy of G_{i-1} . An example of G_3 is presented in Figure 2(a). The iterative process is depicted in Figure 2(a)-(d). In all iterations preceding the last one, exactly $n/2$ vertices are matched in the worst σ .

C Additional Results

The following theorem shows that one cannot hope to get $\rho > 3/4$ with a random permutation in regular graphs.

► **Theorem 24.** *For every $\epsilon > 0$ and sufficiently large d , there are d -regular graphs G for which a random permutation π results in $\rho \leq \frac{3}{4} + \epsilon$.*

Proof. Consider a d -regular bipartite graph $G(U, V; E)$, where d is very large, there is a balanced bipartite independent set (S, T) of size $\frac{1-\epsilon}{2}n$, and conditioned on that, G is random. Let Q (a random variable) be the set of first $\frac{1+\epsilon}{2}n$ vertices under the random permutation π . Then, $E[|T \cap (V \setminus Q)|] = (\frac{1-\epsilon}{2})^2 n \simeq \frac{1}{4}n$. W.h.p. there will be a perfect matching between Q and $U \setminus S$. Hence one can choose a permutation σ over U that matches all of $U \setminus S$ to Q . But then the vertices $T \cap (V \setminus Q)$ will remain unmatched. ◀

We also establish a few impossibility results for regular graphs of low degree.

► **Theorem 25.** *The following hold:*

- *There exists a 3-regular bipartite graph G for which $\rho(G) = \frac{5}{7}$.*
- *There exists a 4-regular bipartite graph G for which $\rho(G) = \frac{10}{13}$.*

The proof relies on graphs induced by projective planes. A projective plane consists of a set of lines and a set of points, where (among other properties) every two lines intersect in a single point and every two points are incident to a single line. A projective plane induces a bipartite graph $G(U, V; E)$, where every vertex $u \in U$ corresponds to a point in the plane, every vertex $v \in V$ corresponds to a line, and there exists an edge between u and v if the point corresponding to u is incident to the line corresponding to v .

Proof. For the first result, we show that $\rho = \frac{5}{7}$ for the bipartite graph induced by the Fano plane. The Fano plane is a projective plane consisting of 7 points and 7 lines, with 3 points on every line and 3 lines through every point. Consider the 3-regular bipartite graph $G(U, V; E)$ induced by the Fano plane. Let $N(V')$ denote the neighbors of a set $V' \in V$. For every set $V' \in V$ such that $|V'| = 2$, it holds that $|N(V')| = 5$. We show below that for every such V' there exists a perfect matching between $N(V')$ and $V \setminus V'$. Hence one can choose a permutation σ over U whose first 5 vertices are $N(V')$ that will match the vertices of $V \setminus V'$ one by one. Thereafter, the vertices of V' will remain unmatched. By Hall's condition, it suffices to show that for every set $U' \subset N(V')$ such that $|U'| \leq 5$ it holds that $|N(U')| \geq |U'| + 2$ (so that Hall's condition applies with respect to the set $V \setminus V'$). Indeed, for every set U' of size 1, $|N(U')| = 3$, for every set U' of size ≥ 2 , $|N(U')| \geq 6$, and for every set U' of size 5, $|N(U')| = 7$. It follows that $\rho(G) = 5/7$.

The second result follows a similar argument. It is known that there exists a projective plane consisting of 13 points and 13 lines, with 4 points on every line and 4 lines through every point. We claim that $\rho = \frac{10}{13}$ for the bipartite graph $G(U, V; E)$ induced by this projective plane. By the properties of a projective plane, for every set $V' \in V$ such that $|V'| = 3$, it

holds that $|N(V')| \in \{9, 10\}$. We show below that for every such V' there exists a perfect matching between $N(V')$ (and possibly an additional vertex u in case $|N(V')| = 9$) and $V \setminus V'$. Hence one can choose a permutation σ over U whose first 10 vertices are $N(V')$ (possibly with the additional vertex) that will match the vertices of $V \setminus V'$ one by one. Thereafter, the vertices of V' will remain unmatched. By Hall's condition, it suffices to show that for every set $U' \subset N(V')$ such that $|U'| \leq 10$ it holds that $|N(U')| \geq |U'| + 3$ (so that Hall's condition applies with respect to the set $V \setminus V'$). Indeed, for every set U' of size 1, $|N(U')| = 4$, for every set U' of size ≥ 2 , $|N(U')| \geq 7$, for every set U' of size ≥ 5 , $|N(U')| \geq 11$, and for every set U' of size ≥ 9 , $|N(U')| = 13$. It follows that $\rho(G) = 10/13$. ◀

Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues

Abstract

We present two graph quantities $\Psi(G, S)$ and $\Psi_2(G)$ which give constant factor estimates to the Dirichlet and Neumann eigenvalues, $\lambda(G, S)$ and $\lambda_2(G)$, respectively. Our techniques make use of a discrete Hardy-type inequality due to Muckenhoupt.

1 Introduction

Possibly one of the most important constants of a graph is λ_2 , the fundamental eigenvalue of its graph Laplacian. In computer science, this quantity is used to analyze the mixing time of random walks [14], Markov chains [16], the convergence of Laplacian solvers [11, 18, 20], the performance of spectral clustering [22] and more. The quantity λ_2 is also important in other domains: in quantum mechanics it is related to the uncertainty principles [13], and in numerical analysis arises in the analysis of partial differential equations [2]. As such, it is often necessary to give analytic estimates of this quantity.

In this paper we reexamine an inequality originating with the work of Hardy [9] and show its connection to the eigenvalues of the graph Laplacian. Using this tool, we provide an alternative to Cheeger's inequality and give a 4-approximation of λ_2 in a general setting.

Let $G = (V, E)$ be a connected graph and let $\mu \in \mathbb{R}_{>0}^V$ and $\kappa \in \mathbb{R}_{>0}^E$ be functions on the vertices and edges respectively. We will think of our graphs as spring mass systems where vertex v has mass μ_v and edge e has spring constant κ_e . The Laplacian matrix is defined as $L = D - A$ where D is the weighted diagonal degree matrix and A is the weighted

8:2 Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues

adjacency matrix. Let M be the diagonal mass matrix. Then, the generalized eigenvalues of L with respect to M have a nice interpretation. Specifically, solutions of the generalized eigenvalue problem

$$Lx = \lambda Mx$$

correspond to modes of vibration of the associated spring mass system. When the spring mass system is connected, λ_2 is the fundamental mode of vibration¹. In this paper we will refer to λ_2 as the Neumann eigenvalue to emphasize the implicit boundary assumptions. For an introduction to spring mass systems and the Laplacian, see chapter 5 of [21].

Another interpretation of the weighted graph comes from electrical systems. In this interpretation, we will treat κ_e as the conductance of edge e and $\frac{1}{\kappa_e}$ as its resistances. In this paper we will go back and forth between these two interpretations and will refer to κ_e as either a conductance or a spring constant.

The following result, known as Cheeger's inequality, can be traced back to [1, 4, 5]. Define the isoperimetric constant² of G to be

$$\Phi(G) = \min_A \left\{ \frac{\sum_{e \in E(A, \bar{A})} \kappa_e}{\min(\mu(A), \mu(\bar{A}))} \mid A, \bar{A} \neq \emptyset \right\}.$$

Here, and in the rest of the paper, \bar{A} denotes the complement of A

Then in the case of the normalized Laplacian (i.e, when $\mu_v = d_v$, the degree of v), we can bound λ_2 by

$$\frac{\lambda_2}{2} \leq \Phi \leq \sqrt{2\lambda_2}, \quad \text{or equivalently,} \quad \frac{\Phi^2}{2} \leq \lambda_2 \leq 2\Phi.$$

It is well known that both sides of the bound are tight up to constants (see [6] for simple examples). Thus we see that Φ fails to give good control over λ_2 when both quantities are small.

In this paper, we introduce the Neumann content, $\Psi_2(G)$, of a graph G (see Section 6 for a formal definition).

$$\Psi_2(G) \approx \min_{A, B} \left\{ \frac{\kappa(A, B)}{\min(\mu(A), \mu(B))} \mid A, B \neq \emptyset, A \cap B = \emptyset \right\}$$

where $\kappa(A, B)$ is the effective resistance between the sets A and B . When $B = \bar{A}$, it can be shown that $\kappa(A, \bar{A}) = \sum_{e \in E(A, \bar{A})} \kappa_e$, thus the Neumann content can be thought of as a relaxation of the isoperimetric constant. We will show that $\Psi_2(G)$ gives a constant factor estimate of λ_2 even in a much more general setting.

Along the way, we will consider another eigenvalue problem, which we refer to as the Dirichlet problem (see Section 2). This is a variant of the Laplacian eigenvalue problem where we hold a particular boundary set of vertices, S , to zero. In this setting, we will define the Dirichlet content, $\Psi(G, S)$, which allows us to estimate the Dirichlet eigenvalue.

Specifically, we will prove the following theorems.

¹ The quantity λ_2 is referred to in the literature under various names: the algebraic connectivity, the Fiedler value, the fundamental eigenvalue, etc.

² The quantity Φ is often referred to as the conductance of the graph or the Cheeger constant. In this paper we will refer to Φ as the isoperimetric constant and reserve the term conductance for the conductance of an edge.

► **Theorem 1.** *Let (G, S) be a nondegenerate weighted graph with boundary. Let $\lambda(G, S)$ be the Dirichlet eigenvalue and let $\Psi(G, S)$ be the Dirichlet content of (G, S) . Then*

$$\frac{\Psi}{4} \leq \lambda \leq \Psi.$$

► **Theorem 2.** *Let G be a nondegenerate weighted graph. Let $\lambda_2(G)$ be the Neumann eigenvalue and let $\Psi_2(G)$ be the Neumann content of G . Then,*

$$\frac{\Psi_2}{4} \leq \lambda_2 \leq \Psi_2.$$

It can be shown that the constants in both of these theorems are optimal. In particular, there exist nondegenerate weighted graphs (with and without boundary) for which $\lambda(G, S) = \Psi(G, S)$ and $\lambda_2(G) = \Psi_2(G)$. This shows that the constant 1 in the upper bound is optimal. There also exist sequences of nondegenerate weighted graphs (with and without boundary) for which $\frac{\lambda(G, S)}{\Psi(G, S)} \rightarrow \frac{1}{4}$ and $\frac{\lambda_2(G)}{\Psi_2(G)} \rightarrow \frac{1}{4}$. This shows that the constant $\frac{1}{4}$ in the lower bound is optimal. See Appendix A for these constructions.

► **Remark 3.** The proof strategy we apply is general and the theorems can be extended to the p -Laplacian³ for $1 < p < \infty$. The proofs for the case of a general p are almost identical to the proofs for the case of $p = 2$, which we present in this paper, and thus will be omitted. More specifically, with the appropriate definitions for the Dirichlet and Neumann p -contents, both theorem statements above will hold after replacing the 4 in the denominator of the lower bound with $pq^{p/q}$, where q is the Hölder dual of p . The constants in this setting are also optimal.

1.1 Related work

A very recent independent paper [19] introduced a quantity $\rho(G)$ specifically in the case of the normalized Laplacian, i.e., when $\mu_v = d_v$. In this setting, the Neumann content $\Psi_2(G)$ is equivalent to the definition of $\rho(G)$ up to constant factors: $\frac{\Psi_2}{2} \leq \rho \leq \Psi_2$. In [19], it is proved that

$$\frac{\rho}{25600} \leq \lambda_2 \leq 2\rho.$$

This is a special subcase of our Theorem 35 with weaker constants.

The application of the Hardy-Muckenhoupt inequality to estimating the Dirichlet eigenvalue was noted in [15]. In that paper, the authors showed how to bound the Dirichlet eigenvalue on an infinite path graph by the (infinite path analogue of) Ψ . Specifically,

$$\frac{\Psi}{4} \leq \lambda \leq 2\Psi.$$

This is a special subcase of our Theorem 28 with weaker constants.

In contrast with the above related work, we can show that our constants are optimal (see Appendix A).

Other methods for estimating λ_2 have been proposed. A method for lower bounding λ_2 based on path embeddings is presented in [7, 8, 10]. In this method, a graph with known eigenstructure is embedded into a host graph. Then the fundamental eigenvalue of the host graph can be estimated in terms of the eigenstructure of the embedded graph and the “distortion” of the embedding. For a review of path embedding methods, see the introduction in [8].

³ We refer the curious reader to [3] for basic background on this topic.

1.2 Roadmap

In section 2, we set notation and discuss background related to weighted graphs, Laplacians, the eigenvalue problems, interpreting graphs as electrical networks, and minimum energy extensions. In section 3, we introduce Muckenhoupt's weighted Hardy inequality. In section 4, we introduce the Hardy quantity and the Dirichlet content and show how Muckenhoupt's result can be used to bound the Dirichlet eigenvalue on a path graph. In section 5, we extend the bounds on the Dirichlet eigenvalue from path graphs to arbitrary graphs. Finally in section 6, we introduce the two-sided Hardy quantity and the Neumann content and extend the bounds on the Dirichlet eigenvalue on a graph to the Neumann eigenvalue on a graph.

2 Preliminaries

2.1 Miscellaneous notation

For $A \subseteq V$, we denote by \bar{A} the complement of A in V .

2.2 Vertex and edge weighted graphs

We collect some definitions and notation we will use related to weighted graphs.

► **Definition 4.** A weighted graph is $G = (V, E, \mu, \kappa)$ where (V, E) forms an undirected graph, $\mu \in \mathbb{R}_{\geq 0}^V$ and $\kappa \in \mathbb{R}_{> 0}^E$. We call μ_v the mass of vertex v and κ_e the conductance⁴ of edge e .

► **Definition 5.** A weighted graph with boundary is a pair (G, S) where G is a weighted graph and $S \subseteq V$ is a proper nonempty subset of the vertices.

We will make the following assumptions on our graphs. This will ensure that the appropriate eigenvalue quantities exist and are nonzero.

► **Definition 6.** A nondegenerate weighted graph is a weighted graph $G = (V, E, \mu, \kappa)$ where (V, E) forms a connected graph, $|V| \geq 2$, and $\mu \in \mathbb{R}_{> 0}^V$.

► **Definition 7.** A nondegenerate weighted graph with boundary is a weighted graph with boundary (G, S) where every connected component of G contains some $s \in S$, $|\bar{S}| \geq 1$, and $\mu_v > 0$ for all $v \in \bar{S}$.

For notational simplicity, we extend μ to subsets of vertices, $\mu(A) = \sum_{v \in A} \mu_v$.

2.3 Laplacians

► **Definition 8.** Let G be a weighted graph. Define $d_v = \sum_{(u,v) \in E} \kappa_{(u,v)}$ to be the degree of vertex v . Let D be the diagonal degree matrix $D_{v,v} = d_v$. Let $A \in \mathbb{R}^{V \times V}$ be the adjacency matrix of G , i.e. $A_{u,v} = \kappa_{(u,v)}$ if $(u,v) \in E$ and 0 otherwise. Then the Laplacian matrix corresponding to G is

$$L = D - A.$$

⁴ As we are dealing with spring mass systems, perhaps it would be better to refer to these quantities as spring constants and compliances. Nonetheless, we have chosen to refer to these quantities as conductances and resistances as this is the terminology most commonly found in the spectral graph theory literature.

Note that the quadratic form associated with L is

$$x^\top Lx = \sum_{(u,v) \in E} \kappa_{(u,v)} (x_u - x_v)^2.$$

► **Definition 9.** Let G be a weighted graph. The mass matrix corresponding to G is the diagonal matrix $M(G)$ where $M_{v,v} = \mu_v$.

2.4 The generalized Laplacian eigenvalue problem

► **Definition 10.** Let G be a nondegenerate weighted graph. Let $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_{|V|}$ be the generalized eigenvalues of L with respect to M . We refer to λ_2 as the Neumann eigenvalue of G , denoted $\lambda_2(G)$ and we refer to an associated eigenvector as a Neumann eigenvector.

Nondegeneracy ensures that $\lambda_2(G)$ exists as $|V| \geq 2$ and $\lambda_2(G) > 0$ by connectivity.

We state a version of the Courant-Fischer min-max theorem. This will allow us to give variational characterizations of eigenvalues.

► **Theorem 11 (Courant-Fischer).** Let $A, B \in \mathbb{R}^{n \times n}$ be symmetric matrices and suppose $B \succ 0$. Let $\lambda_1 \leq \dots \leq \lambda_n$ be the ordered generalized eigenvalues of A with respect to B . Let $k \in [n]$ and let S denote a subspace of \mathbb{R}^n . Then,

$$\lambda_k = \min_S \max_x \left\{ \frac{x^\top Ax}{x^\top Bx} \mid \dim(S) = k, x \in S, x \neq 0 \right\}.$$

Furthermore, suppose v_1, \dots, v_{k-1} are orthogonal eigenvectors corresponding to $\lambda_1, \dots, \lambda_{k-1}$ then

$$\lambda_k = \min_x \left\{ \frac{x^\top Ax}{x^\top Bx} \mid \begin{array}{l} x^\top Bv_i = 0, \forall i \in [k-1] \\ x \neq 0 \end{array} \right\}$$

and x is a generalized eigenvector with eigenvalue λ_k if and only if x is a minimizer of this second expression.

Noting that $\mathbf{1}$, the all ones vector, is a generalized eigenvector of L with respect to M with eigenvalue 0, we may apply the Courant-Fischer theorem to get a variational characterization of the Neumann eigenvalue and its eigenvectors.

► **Lemma 12.** Let G be a nondegenerate weighted graph. Then

$$\lambda_2(G) = \min_{x \in \mathbb{R}^V} \left\{ \frac{x^\top Lx}{x^\top Mx} \mid x^\top M\mathbf{1} = 0, x \neq 0 \right\}.$$

Furthermore, x is a Neumann eigenvector of G if and only if x is a minimizer in this optimization problem.

The expression $\frac{x^\top Lx}{x^\top Mx}$ plays a large role in our analysis. This quantity is known as the Rayleigh quotient.

We will also consider the Laplacian eigenvalue problem on weighted graphs with boundaries. This corresponds to fixing the value of x at the boundary to zero.

► **Definition 13.** Let (G, S) be a nondegenerate weighted graph with boundary. Let $L_{\bar{S}}$ be the submatrix of L associated with the complement of S and let $M_{\bar{S}}$ be the corresponding submatrix of M . Let $\lambda_1 \leq \lambda_2 \leq \dots \leq \lambda_{|\bar{S}|}$ be the generalized eigenvalues of

$$L_{\bar{S}}x = \lambda M_{\bar{S}}x.$$

8:6 Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues

We refer to λ_1 as the Dirichlet eigenvalue of (G, S) , denoted $\lambda(G, S)$. Let $x \in \mathbb{R}^{\bar{S}}$ be an associated eigenvector and extend it to \mathbb{R}^V by zeros. We will refer to $x \in \mathbb{R}^V$ as a Dirichlet eigenvector.

Nondegeneracy ensures that $\lambda(G, S)$ exists as $|\bar{S}| \geq 1$ and $\lambda(G, S) > 0$ by connectivity.

Again by Courant-Fischer, we can give a variational characterization of the Dirichlet eigenvalue.

► **Lemma 14.** *Let (G, S) be a nondegenerate weighted graph with boundary. Then,*

$$\lambda(G, S) = \min_{x \in \mathbb{R}^V} \left\{ \frac{x^\top Lx}{x^\top Mx} \mid x|_S = 0, x \neq 0 \right\}.$$

Furthermore, λ is a Dirichlet eigenvalue if and only if x is a minimizer in this optimization problem.

Note that the masses of vertices $s \in S$ play no role in either characterization. We will often neglect to assign masses to vertices in the boundary when convenient.

2.5 Graphs as electrical networks

Given a weighted graph G , we can think of its edges as electrical conductors where edge e has conductance κ_e . Thinking of $x \in \mathbb{R}^V$ as an assignment of voltages to the vertices of our electrical network, we have that

$$x^\top Lx = \sum_{(u,v) \in E} \kappa_{(u,v)} (x_u - x_v)^2$$

is the power dissipated in our system. Drawing inspiration from physics, we define the effective resistance between two sets of vertices in terms of the minimum power required to maintain a unit voltage drop.

► **Definition 15.** *Let G be a weighted graph and let $A, B \subseteq V$ be disjoint nonempty sets such that there exists a path between a and b for some $a \in A$ and $b \in B$. The effective resistance between A and B , denoted $R(A, B)$, and the effective conductance between A and B , denoted $\kappa(A, B)$, are the quantities such that*

$$\frac{1}{R(A, B)} = \kappa(A, B) = \min_{x \in \mathbb{R}^V} \{x^\top Lx \mid x|_A = 0, x|_B = 1\}.$$

The quantity on the right is well-defined as $x^\top Lx$ is continuous and without loss of generality, we may optimize over $x \in [0, 1]^V$, a compact set. Then, by the connectivity assumption, $\kappa(A, B) \in (0, \infty)$. Thus, $R(A, B)$ is also well-defined.

If $A = \{a\}$ is a single element, we will opt to write $R(a, B)$ instead of the more cumbersome $R(\{a\}, B)$. Similarly we will write $R(A, b)$ or $R(a, b)$ where appropriate.

► **Remark 16.** When $A = \{a\}$ and $B = \{b\}$ are singleton sets, this definition agrees with the standard definition $R(a, b) = \chi_{a,b} L^+ \chi_{a,b}$. In general, we can define $R(A, B)$ in a different way. Consider contracting all vertices in A to a single vertex v_A and all vertices to a single vertex v_B . Then $R(A, B)$ is the effective resistance between v_A and v_B in the new graph. This is the definition given in [19].

2.6 Splitting edges and minimum energy extensions

Let G be a weighted graph. At times, we will split edges using vertices with zero mass. This can be done without affecting the variational quantities⁵.

► **Lemma 17.** *Let $\alpha_i > 0$ such that $\sum_{i=1}^k \alpha_i = 1$. Let $\kappa > 0$ and let $\kappa_i = \kappa/\alpha_i$. Let $y_0, y_k \in \mathbb{R}$ be fixed. Then*

$$\min_{y_1, \dots, y_{k-1}} \sum_{i=1}^k \kappa_i (y_i - y_{i-1})^2 = \kappa (y_k - y_0)^2.$$

Furthermore, the unique optimum is achieved by $y_i^* = y_0 + \left(\sum_{j=1}^i \alpha_j\right) (y_k - y_0)$.

Proof. Note that $\sum_{i=1}^k \kappa_i (y_i - y_{i-1})^2$ is a strictly convex function as y_0 and y_k are fixed. Thus it suffices to show that y^* is a local optimum. Differentiating with respect to y_j and evaluating at y^* ,

$$\begin{aligned} \frac{\partial}{\partial y_j} \left(\sum_{i=1}^k \kappa_i (y_i - y_{i-1})^2 \right)_{y=y^*} &= 2 (\kappa_j (y_j^* - y_{j-1}^*) - \kappa_{j+1} (y_{j+1}^* - y_j^*)) \\ &= 2 \left(\frac{\kappa}{\alpha_j} \alpha_j - \frac{\kappa}{\alpha_{j+1}} \alpha_{j+1} \right) (y_k - y_0) = 0. \end{aligned}$$

Then y^* is the unique minimizer achieving objective value

$$\sum_{i=1}^k \kappa_i (y_i^* - y_{i-1}^*)^2 = \kappa (y_k - y_0)^2 \sum_{i=1}^k \alpha_i = \kappa (y_k - y_0)^2. \quad \blacktriangleleft$$

Let G be a weighted graph and consider an edge (a, b) of conductance κ in G . Given $\alpha_i > 0$ summing to 1, we can split the edge (a, b) into k edges by inserting $k - 1$ new vertices, removing the edge (a, b) , and inserting edges $(a, c_1), (c_1, c_2), \dots, (c_{k-1}, b)$ with conductances according to the lemma. We will assign $\mu'(v) = 0$ for all newly added vertices. Let this new weighted graph be $G' = (V', E', \mu', \kappa')$.

► **Definition 18.** *Let G be a weighted graph and let G' be a weighted graph constructed from G by splitting edges using the procedure described above. Let $x \in \mathbb{R}^V$. The minimum energy extension of x to V' is the vector y given by*

$$y = \arg \min_{y \in \mathbb{R}^{V'}} \{y^\top L' y \mid y|_V = x\}.$$

Then by the above lemma it is immediate that $\min_{y \in \mathbb{R}^{V'}} \{y^\top L' y \mid y|_V = x\} = x^\top L x$. Thus, as $\mu'(v) = 0$ for all $v \in V' \setminus V$, we have,

$$\begin{aligned} &\min_{y \in \mathbb{R}^{V'}} \left\{ \frac{y^\top L' y}{y^\top M' y} \mid y^\top M 1 = 0, y \neq 0 \right\} \\ &= \min_{x \in \mathbb{R}^V} \left\{ \frac{\min_{y \in \mathbb{R}^{V'}} \{y^\top L' y \mid y|_V = x\}}{x^\top M x} \mid x^\top M 1 = 0, x \neq 0 \right\} \\ &= \min_{x \in \mathbb{R}^V} \left\{ \frac{x^\top L x}{x^\top M x} \mid x^\top M 1 = 0, x \neq 0 \right\}. \end{aligned}$$

⁵ In fact, this can be done without affecting the eigenvalue quantities provided they exist. However, proving this requires more set up than is given in this paper.

8:8 Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues

Similarly, if S is a proper nonempty subset of V , then

$$\begin{aligned} & \min_{y \in \mathbb{R}^{V'}} \left\{ \frac{y^\top L' y}{y^\top M' y} \mid y \upharpoonright_S = 0, y \neq 0 \right\} \\ &= \min_{x \in \mathbb{R}^V} \left\{ \frac{\min_{y \in \mathbb{R}^{V'}} \{y^\top L' y \mid y \upharpoonright_V = x\}}{x^\top M x} \mid x \upharpoonright_S = 0, x \neq 0 \right\} \\ &= \min_{x \in \mathbb{R}^V} \left\{ \frac{x^\top L x}{x^\top M x} \mid x \upharpoonright_S = 0, x \neq 0 \right\}. \end{aligned}$$

► **Definition 19.** Let G be a nondegenerate weighted graph and let G' be a weighted graph constructed from G using the procedure described above. The Neumann eigenvalue of G' is

$$\lambda_2(G') = \min_{y \in \mathbb{R}^{V'}} \left\{ \frac{y^\top L' y}{y^\top M' y} \mid y^\top M 1 = 0, y \neq 0 \right\}.$$

A vector y is a Neumann eigenvector of G' if y is a minimizer of this optimization problem.

► **Definition 20.** Let (G, S) be a nondegenerate weighted graph with boundary and let G' be a weighted graph constructed from G using the procedure described above. The Dirichlet eigenvalue of (G', S) is

$$\lambda(G', S) = \min_{y \in \mathbb{R}^{V'}} \left\{ \frac{y^\top L' y}{y^\top M' y} \mid y \upharpoonright_S = 0, y \neq 0 \right\}$$

A vector y is a Dirichlet eigenvector of (G', S) if y is a minimizer of this optimization problem.

3 Muckenhoupt's weighted Hardy inequality

The following theorem, due⁶ to Muckenhoupt [17], relates the $L^2(\mathbb{R}_{\geq 0}, \kappa)$ norm of a function and the $L^2(\mathbb{R}_{\geq 0}, \mu)$ norm of the “running integral” of the function.⁷ In other words, this theorem characterizes the boundedness of the Hardy operator. In this paper we will refer to this inequality as Muckenhoupt's weighted Hardy inequality (see [12] for a more thorough account of the development and history of the Hardy inequality).

► **Theorem 21** (Muckenhoupt 1972). Let μ, κ be measurable functions from $\mathbb{R}_{\geq 0}$ to $\mathbb{R}_{> 0}$. Let C be the smallest (possibly infinite) constant such that for all $f \in L^1_{loc}(\mathbb{R}_{\geq 0})$,

$$\int_0^\infty \mu(x) \left(\int_0^x f(t) dt \right)^2 dx \leq C \int_0^\infty \kappa(x) f(x)^2 dx.$$

Let

$$B = \sup_{r > 0} \left(\int_r^\infty \mu(x) dx \right) \left(\int_0^r \frac{1}{\kappa(x)} dx \right).$$

Then $B \leq C \leq 4B$. In particular, C is finite if and only if B is finite.

⁶ A similar theorem may have been known previous to Muckenhoupt. Indeed [17] cites the work of Tomaselli and Artola, however we were unable to obtain copies of these papers.

⁷ The original theorem deals more generally with L_p norms and Borel measures – see [17].

We will state and prove a finite, discrete version of the above inequality in the following section. Our proof will be stated in the language of graph Laplacians but closely follows the structure of [15, 17] and is only included for completeness.

We first sketch, non-rigorously, why this theorem may be useful. Suppose we have a differentiable function g satisfying $g(0) = 0$. Then taking $f = \frac{d}{dx}g$, and rearranging the above theorem, we have that

$$\frac{1}{C} \leq \frac{\int_0^\infty \kappa(x)g'(x)^2 dx}{\int_0^\infty \mu(x)g(x)^2 dx} \approx \frac{\sum_{i=1}^\infty \kappa_i(g_i - g_{i-1})^2}{\sum_{i=1}^\infty \mu_i g_i^2}.$$

Note that the right hand side is the Rayleigh quotient of the Laplacian of a weighted infinite path graph (cf. Lemma 14 above). Then minimizing over g , we have that $1/C$ corresponds to a Dirichlet eigenvalue and the bound $B \leq C \leq 4B$ allows us to estimate this eigenvalue.

4 The Dirichlet problem on path graphs

Throughout this section, let $P = (V, E, \mu, \kappa)$ be a weighted path graph. Let the vertices be numbered $\{v_0, v_1, \dots, v_N\}$ for some $N \geq 1$ and let the boundary set be $S = \{v_0\}$. Let the edges be $E = \{(v_i, v_{i-1}) \mid i \in [N]\}$ and let edge (v_i, v_{i-1}) have conductance $\kappa_i > 0$. Let vertex v_i have mass $\mu_i > 0$.

It is immediate that (G, S) is a nondegenerate weighted graph with boundary.

4.1 The Hardy quantity and the Dirichlet content

Let $A \subseteq V \setminus S$ be a set of vertices disjoint from the boundary. Consider the graph consisting of two vertices v_S, v_A . Let v_A have mass $\mu(A)$ and let the edge (v_S, v_A) has conductance $\kappa(S, A)$. Then the Dirichlet eigenvalue of this two node system with boundary set $\{v_S\}$ is given by $\frac{\kappa(S, A)}{\mu(A)}$. We will define the Dirichlet content of G , $\Psi(G)$, to be the minimum such quantity over choices of A and, for historical reasons, we will define the Hardy quantity to be $H = \Psi^{-1}$.

► **Definition 22.** Let (G, S) be a nondegenerate weighted graph with boundary. The Dirichlet content of (G, S) , denoted $\Psi(G, S)$, is

$$\Psi(G, S) = \min_{A \subseteq V} \left\{ \frac{\kappa(S, A)}{\mu(A)} \mid A \neq \emptyset, A \cap S = \emptyset \right\}.$$

► **Definition 23.** Let (G, S) be a nondegenerate weighted graph with boundary. The Hardy quantity of (G, S) , denoted $H(G, S)$, is $H(G, S) = \Psi(G, S)^{-1}$, i.e.

$$H(G, S) = \max_{A \subseteq V} \{R(S, A)\mu(A) \mid A \neq \emptyset, A \cap S = \emptyset\}.$$

In a path graph, it suffices to optimize over tail sets. This gives us a second characterization of H (and thus Ψ) on path graphs.

► **Lemma 24.** Let (P, v_0) be a nondegenerate weighted path graph with boundary. Let $A_k = \{v_i \mid i \geq k\}$ be the tail set beginning at v_k . Then

$$H(P, v_0) = \max_{1 \leq k \leq N} R(v_0, A_k)\mu(A_k).$$

Proof. Let $A \subseteq V \setminus S$. Let $k = \min\{i \mid v_i \in A\}$ be the minimum element in A . Then $R(S, A) = R(S, A_k)$ and $\mu(A_k) \geq \mu(A)$ thus $R(S, A_k)\mu(A_k) \geq R(S, A)\mu(A)$. ◀

8:10 Hardy-Muckenhoupt Bounds for Laplacian Eigenvalues

For a path graph, we have the following closed form expression for the resistance between v_0 and A_k . This is a consequence of Lemma 17.

► **Lemma 25.** *In a weighted path graph, $R(v_0, A_k) = \sum_{i=1}^k \frac{1}{\kappa_i}$.*

4.2 Bounding the Dirichlet eigenvalue

► **Theorem 26.** *Let (P, v_0) be a nondegenerate weighted path graph with boundary. Let $\lambda(P, v_0)$ be the Dirichlet eigenvalue and let $H(P, v_0)$ be the Hardy quantity of (P, v_0) . Then,*

$$\frac{1}{4H} \leq \lambda \leq \frac{1}{H}.$$

We reiterate that the below proof has been known since [17] and is included only for completeness.

Proof. We begin by proving the upper bound. Note that if $x \upharpoonright_A = 1$, then $x^\top Mx \geq \mu(A)$ for any $A \subseteq V \setminus S$. Applying this bound to λ , we note that the numerator of the Rayleigh quotient becomes an effective conductance term.

$$\begin{aligned} \lambda &= \min_x \left\{ \frac{x^\top Lx}{x^\top Mx} \mid x_0 = 0, x \neq 0 \right\} \\ &\leq \min_{1 \leq k \leq N} \min_x \left\{ \frac{x^\top Lx}{x^\top Mx} \mid x_0 = 0, x \upharpoonright_{A_k} = 1 \right\} \\ &\leq \min_{1 \leq k \leq N} \frac{1}{\mu(A_k)} \min_x \{x^\top Lx \mid x_0 = 0, x \upharpoonright_{A_k} = 1\} \\ &= \min_{1 \leq k \leq N} \frac{\kappa(S, A_k)}{\mu(A_k)} \\ &= H^{-1}. \end{aligned}$$

We turn to the lower bound. Begin by rewriting x_i as a sum of differences in the denominator. Let $\alpha_j > 0$ to be fixed later. We apply Cauchy-Schwarz,

$$\begin{aligned} \sum_{i=1}^n \mu_i x_i^2 &= \sum_{i=1}^n \mu_i \left(\sum_{j=1}^i (x_j - x_{j-1}) \left(\frac{\kappa_j}{\alpha_j} \right)^{1/2} \left(\frac{\alpha_j}{\kappa_j} \right)^{1/2} \right)^2 \\ &\leq \sum_{i=1}^n \mu_i \left(\sum_{j=1}^i (x_j - x_{j-1})^2 \frac{\kappa_j}{\alpha_j} \right) \left(\sum_{j=1}^i \frac{\alpha_j}{\kappa_j} \right). \end{aligned}$$

Let $y_j = \left(\sum_{i=1}^j \frac{1}{\kappa_i} \right)^{1/2}$ and $y_0 = 0$. We will pick⁸ $\alpha_j = \kappa_j(y_j - y_{j-1})$. Thus, plugging in this choice of α_j , noticing the telescoping sum and reversing the order of summation,

⁸ This choice ensures that Cauchy-Schwarz is tight when $x = y$ and corresponds to the intuition that the true eigenvector is “close to” y .

$$\begin{aligned} \dots &\leq \sum_{i=1}^n \mu_i \left(\sum_{j=1}^i (x_j - x_{j-1})^2 \frac{\kappa_j}{\alpha_j} \right) y_i \\ &= \sum_{j=1}^n \kappa_j (x_j - x_{j-1})^2 \frac{1}{\alpha_j} \sum_{i=j}^n \mu_i y_i \\ &\leq \left(\sum_{j=1}^n \kappa_j (x_j - x_{j-1})^2 \right) \left(\max_{1 \leq j \leq n} \frac{1}{\alpha_j} \sum_{i=j}^n \mu_i y_i \right). \end{aligned}$$

It remains to bound the final term. Note that $y_j = R(v_0, A_j)^{1/2} \leq H^{1/2} \mu(A_k)^{-1/2}$. Then,

$$\sum_{i=j}^n \mu_i y_i \leq H^{1/2} \sum_{i=j}^n \mu_i \left(\sum_{k=i}^n \mu_k \right)^{-1/2}.$$

Note that if $A, a \geq 0$, then $a(A+a)^{-1/2} \leq 2((A+a)^{1/2} - A^{1/2})$. Indeed, this holds by noting that $(A+ta)^{1/2}$ is concave: $a(A+a)^{-1/2} = \frac{d}{dt} (2(A+ta)^{1/2})_{t=1} \leq 2((A+a)^{1/2} - A^{1/2})$.

Then, taking $A = \sum_{k=i+1}^n \mu_k$ and $a = \mu_i$ in this inequality, we get

$$\begin{aligned} \sum_{i=j}^n \mu_i y_i &\leq 2H^{1/2} \left(\sum_{i=j}^{n-1} \left(\mu(A_i)^{1/2} - \mu(A_{i+1})^{1/2} \right) + \mu(A_n)^{1/2} \right) \\ &= 2H^{1/2} \mu(A_j)^{1/2}. \end{aligned}$$

We will use the inequality once more. This time, take $A = \sum_{k=1}^{j-1} \frac{1}{\kappa_k}$ and $a = \frac{1}{\kappa_j}$. Then,

$$\begin{aligned} \alpha_j &= \kappa_j (y_j - y_{j-1}) \\ &= \kappa_j \left((A+a)^{1/2} - A^{1/2} \right) \\ &\geq \kappa_j \left(\frac{a}{2} (A+a)^{-1/2} \right) \\ &= \frac{1}{2} R(v_0, A_j)^{-1/2}. \end{aligned}$$

Finally,

$$\begin{aligned} \max_{1 \leq j \leq n} \frac{1}{\alpha_j} \sum_{i=j}^n \mu_i y_i &\leq 4H^{1/2} \max_{1 \leq j \leq n} (\mu(A_j) R(v_0, A_j))^{1/2} \\ &\leq 4H. \end{aligned}$$

Rearranging completes the proof. ◀

The following theorem follows as a corollary.

► **Theorem 27.** *Let (P, v_0) be a nondegenerate weighted path graph with boundary. Let $\lambda(P, v_0)$ be the Dirichlet eigenvalue and let $\Psi(P, v_0)$ be the Dirichlet content of (P, v_0) . Then,*

$$\frac{\Psi}{4} \leq \lambda \leq \Psi.$$

5 The Dirichlet problem on general graphs

5.1 Bounding the Dirichlet eigenvalue

► **Theorem 28.** *Let (G, S) be a nondegenerate weighted graph with boundary. Let $\lambda(G, S)$ be the Dirichlet eigenvalue and let $H(G, S)$ be the Hardy quantity of G . Then*

$$\frac{1}{4H} \leq \lambda \leq \frac{1}{H}.$$

The proof of the upper bound in the graph case is the same as the proof of the upper bound in the path case. To prove the lower bound, we split edges by inserting zero mass vertices. We then treat the new graph as a path graph.

Proof. The upper bound follows immediately.

$$\begin{aligned} \lambda &= \min_x \left\{ \frac{x^\top Lx}{x^\top Mx} \mid x|_S = 0, x \neq 0 \right\} \\ &\leq \min_{A \subseteq V, x} \left\{ \frac{x^\top Lx}{x^\top Mx} \mid A \neq \emptyset, A \cap S = \emptyset, x|_S = 0, x|_{A^c} = 1 \right\} \\ &\leq \min_{A \subseteq V} \left\{ \frac{\kappa(S, A)}{\mu(A)} \mid A \neq \emptyset, A \cap S = \emptyset \right\} \\ &= H^{-1}. \end{aligned}$$

We turn to the lower bound. We construct a new weighted graph $G' = (V', E', \mu', \kappa')$ from G as follows. Let x be a Dirichlet eigenvector corresponding to $\lambda(G, S)$. Without loss of generality x is nonnegative. Let $0 = l_0 < \dots < l_N$ be the distinct values of x . For each edge $(a, b) \in E$ such that $x_a = l_i < l_{i+1} < l_j = x_b$, split e into $j - i$ segments such that in the minimum energy extension of x , the new vertices on e take on all intermediate values l_{i+1}, \dots, l_{j-1} . This is possible by Lemma 17 and the discussion following it. Let y be the minimum energy extension of x .

Let $\tilde{v}_i = \{v \in V' \mid y_v = l_i\}$, let $\tilde{A}_k = \{v \in V' \mid y_v \geq l_k\}$. Let $\tilde{\kappa}_i = \sum_{u \in \tilde{v}_i, v \in \tilde{v}_{i-1}} \kappa'_{(u,v)}$ be the conductance between \tilde{v}_i and \tilde{v}_{i-1} . Let $\tilde{\mu}_i = \mu'(\tilde{v}_i)$. Note that $S \subseteq \tilde{v}_0$. Then,

$$\begin{aligned} \lambda(G, S) &= \lambda(G', S) \\ &= \min_{y \in \mathbb{R}^{V'}} \left\{ \frac{y^\top L'y}{y^\top M'y} \mid y|_S = 0, y \neq 0 \right\} \\ &= \min_{z \in \mathbb{R}^N} \left\{ \frac{\sum_{i=1}^N \tilde{\kappa}_i (z_i - z_{i-1})^2}{\sum_{i=1}^N \tilde{\mu}_i z_i^2} \mid z_0 = 0, z \neq 0 \right\}. \end{aligned}$$

Equality in the last line follows by taking $z_i = l_i$. Then note that the objective function in the final optimization problem is the Rayleigh quotient of a nondegenerate weighted path graph with boundary with vertices \tilde{v}_i , conductances $\tilde{\kappa}_i$, and boundary set \tilde{v}_0 . Then applying the lower bound of Theorem 26.

$$\begin{aligned}
\lambda(G, S) &\geq \frac{1}{4} \min_{1 \leq k \leq N} \frac{\min_{z \in \mathbb{R}^N} \left\{ \sum_{i=1}^n \tilde{\kappa}_i (z_i - z_{i-1})^2 \mid z_0 = 0, z_{\{k, \dots, N\}} = 1 \right\}}{\sum_{i=k}^N \tilde{\mu}_i} \\
&\geq \frac{1}{4} \min_{1 \leq k \leq N} \frac{\min_{y \in \mathbb{R}^{V'}} \left\{ y^\top L' y \mid y \upharpoonright_S = 0, y \upharpoonright_{\tilde{A}_k} = 1 \right\}}{\mu'(\tilde{A}_k)} \\
&= \frac{1}{4} \min_{1 \leq k \leq N} \frac{\kappa'(S, \tilde{A}_k)}{\mu'(\tilde{A}_k)} \\
&\geq \frac{1}{4} \min_{A' \subseteq V'} \left\{ \frac{\kappa'(S, A')}{\mu'(A')} \mid A' \neq \emptyset, A' \cap S = \emptyset \right\}.
\end{aligned}$$

Note that for any $A' \subseteq V'$, we can take $A = A' \cap V$. For this choice of A , we have $\mu(A) = \mu'(A')$ and $\kappa'(S, A') \geq \kappa(S, A)$. Thus,

$$\begin{aligned}
\lambda(G, S) &\geq \frac{1}{4} \min_{A \subseteq V} \left\{ \frac{\kappa(S, A)}{\mu(A)} \mid A \neq \emptyset, A \cap S = \emptyset \right\} \\
&= \frac{1}{4H}. \quad \blacktriangleleft
\end{aligned}$$

The following theorem follows as a corollary.

► **Theorem 29.** *Let (G, S) be a nondegenerate weighted graph with boundary. Let $\lambda(G, S)$ be the Dirichlet eigenvalue and let $\Psi(G, S)$ be the Dirichlet content of G . Then*

$$\frac{\Psi}{4} \leq \lambda \leq \Psi.$$

6 The Neumann problem on general graphs

Throughout this section, let $G = (V, E, \mu, \kappa)$ be a nondegenerate weighted graph.

6.1 The two-sided Hardy quantity and the Neumann content

Let $A, B \subseteq V$ be disjoint nonempty sets. Consider the graph consisting of two vertices v_A, v_B where vertex v_A has mass $\mu(A)$, vertex v_B has mass $\mu(B)$ and the edge (v_A, v_B) has conductance $\kappa(A, B) > 0$. Then the Neumann eigenvalue of this two node system is given by $\frac{\kappa(A, B)}{(\mu(A)^{-1} + \mu(B)^{-1})^{-1}}$. We will define the Neumann content of G , $\Psi_2(G)$, to be the minimum such quantity over choices of A and B . For historical reasons, we will define the two-sided Hardy quantity to be $H_2 = \Psi_2^{-1}$.

► **Definition 30.** *Let G be a nondegenerate weighted graph. The Neumann content of G , denoted $\Psi_2(G)$, is*

$$\Psi_2(G) = \min_{A, B \subseteq V} \left\{ \frac{\kappa(A, B)}{(\mu(A)^{-1} + \mu(B)^{-1})^{-1}} \mid A, B \neq \emptyset, A \cap B = \emptyset \right\}.$$

► **Definition 31.** *Let G be a nondegenerate weighted graph. The two-sided Hardy quantity of G , denoted $H_2(G)$, is $H_2(G) = \Psi_2(G)^{-1}$, i.e.,*

$$H_2 = \max_{A, B \subseteq V} \left\{ \frac{R(A, B)}{\mu(A)^{-1} + \mu(B)^{-1}} \mid A, B \neq \emptyset, A \cap B = \emptyset \right\}.$$

6.2 Bounding the Neumann eigenvalue

In this section we show how to extend the bounds on the Dirichlet eigenvalue to the Neumann eigenvalue.

We will bound the Neumann eigenvalue by applying Courant-Fischer to a carefully chosen two-dimensional subspace. In particular, we will split our graph into two parts sharing a common boundary. We will then take our two-dimensional subspace to be the linear span of solutions to the Dirichlet problem on either side of this boundary.

Let $f \in \mathbb{R}^V$ such that f takes both positive and negative values. We will write this concisely as $\pm f \notin \mathbb{R}_{\geq 0}^V$. We will “pinch” the graph at the zero level set of f to create a new weighted graph $G' = (V', E', \mu', \kappa')$: for every edge $(u, v) \in E$ such that $f_u < 0 < f_v$, insert a new vertex s such that the minimum energy extension of f assigns $f(s) = 0$. Let $\mu'(s) = 0$.

Abusing notation we will also let $f \in \mathbb{R}^{V'}$ be the minimum energy extension of f to V' . Let $F_0 = \{v \in V' \mid f_v = 0\}$, let $F_{\geq 0} = \{v \in V' \mid f_v \geq 0\}$ and $F_{\leq 0} = \{v \in V' \mid f_v \leq 0\}$. Similarly define $F_{> 0}, F_{< 0}$ and note that G' has no edges between $F_{> 0}$ and $F_{< 0}$. For $A, B \subseteq V$, let $A <_f B$ if $f_a < f_b$ for all $a \in A, b \in B$.

We have the following lemma regarding the optimal “pinch.”

► **Lemma 32.** *Let G be a nondegenerate weighted graph. Let $f \in \mathbb{R}^V$ take both positive and negative values. Then $(G', F_{\geq 0})$ and $(G', F_{\leq 0})$ are both nondegenerate weighted graphs with boundary and*

$$\lambda_2(G) = \min_f \{ \max(\lambda(G', F_{\geq 0}), \lambda(G', F_{\leq 0})) \mid \pm f \notin \mathbb{R}_{\geq 0}^V \}.$$

Proof. Let \mathcal{R} denote the quantity on the right hand side.

We begin by showing that $\lambda_2(G) \leq \mathcal{R}$. Let $f \in \mathbb{R}^V$ take both positive and negative values. Note that $\lambda_2(G) = \lambda_2(G')$. It is easy to see that $(G', F_{\geq 0})$ and $(G', F_{\leq 0})$ are both nondegenerate weighted graphs with boundaries. Let $y, z \in \mathbb{R}^{V'}$ be Dirichlet eigenvectors with Dirichlet eigenvalues $\lambda(G', F_{\geq 0})$ and $\lambda(G', F_{\leq 0})$ respectively. Note that $\text{supp}(L'y) \subseteq F_{\leq 0}$ and that $z \upharpoonright_{F_{\leq 0}} = 0$, thus $z^\top L'y = 0$. Noting that there exists some nonzero $x \in \text{span}(y, z)$ such that $x^\top M'1 = 0$,

$$\begin{aligned} \lambda_2(G) &= \lambda_2(G') \\ &= \min_{x \in \mathbb{R}^{V'}} \left\{ \frac{x^\top L'x}{x^\top M'x} \mid x^\top M'1 = 0, x \neq 0 \right\} \\ &\leq \max_{x \in \text{span}(y, z)} \frac{x^\top L'x}{x^\top M'x} \\ &= \max_{(\alpha, \beta) \neq 0} \frac{\alpha^2 y^\top L'y + \beta^2 z^\top L'z}{\alpha^2 y^\top M'y + \beta^2 z^\top M'z} \\ &= \max(\lambda(G', F_{\geq 0}), \lambda(G', F_{\leq 0})). \end{aligned}$$

Next we show that $\mathcal{R} \leq \lambda_2(G)$. We will exhibit a choice of f taking both positive and negative values such that $\lambda(G', F_{\geq 0}), \lambda(G', F_{\leq 0}) \leq \lambda_2(G)$. This will additionally imply that the minimum is achieved.

Let x be a Neumann eigenvector of G . As $x \neq 0$ and $x^\top M1 = 0$, it is clear that x takes both positive and negative values. We will pick $f = x$. Abusing notation, also let $x \in \mathbb{R}^{V'}$ be the minimum energy extension of x to V' . Note that $x \upharpoonright_{F_0} = 0$. Let $y = \min(x, 0)$ and $z = \max(x, 0)$ where \min and \max are taken element wise. Note that $L'y$ agrees with $L'x = \lambda_2(G)M'x$ on the support of y and that y agrees with x on the support of y . Thus

$y^\top L'y = \lambda_2(G)y^\top M'x = \lambda_2(G)y^\top M'y$. Then,

$$\begin{aligned}\lambda(G', F_{\geq 0}) &\leq \frac{y^\top L'y}{y^\top M'y} \\ &= \lambda_2(G).\end{aligned}$$

Similarly, $\lambda(G', F_{\leq 0}) \leq \lambda_2(G)$. ◀

We will need the two following technical lemmas regarding summing resistances.

► **Lemma 33.** *Let G be a nondegenerate weighted graph. Let $A, B \subseteq V$ be disjoint nonempty subsets. Let $f \in \mathbb{R}^{V'}$ such that $A \subseteq F_{<0}$ and $B \subseteq F_{>0}$. Then*

$$R'(A, F_{\geq 0}) + R'(F_{\leq 0}, B) \leq R'(A, B).$$

Proof. Let

$$\kappa_A = \kappa'(A, F_{\geq 0}) = \min_y \left\{ y^\top L'y \mid y|_A = 1, y|_{F_{\geq 0}} = 0 \right\}$$

and let y be the minimizer. Similarly define κ_B and let z be its minimizer. Note that $\text{supp}(L'y) \subseteq F_{\leq 0}$ and $z|_{F_{\leq 0}} = 0$, i.e., $z^\top L'y = 0$.

Let $\alpha = \frac{\kappa_A}{\kappa_A + \kappa_B}$. Note that $(1 - \alpha)y - \alpha z$ assigns $1 - \alpha$ to vertices in A and $-\alpha$ to vertices in B . Thus

$$\begin{aligned}\frac{1}{R'(A, B)} &\leq ((1 - \alpha)y - \alpha z)^\top L'((1 - \alpha)y - \alpha z) \\ &= (1 - \alpha)^2 \kappa_A + \alpha^2 \kappa_B \\ &= \frac{\kappa_A \kappa_B}{\kappa_A + \kappa_B} \\ &= \frac{1}{R'(A, F_{\geq 0}) + R'(F_{\leq 0}, B)}.\end{aligned}$$

Rearranging terms completes the proof. ◀

► **Lemma 34.** *Let G be a nondegenerate weighted graph. Let $A, B \subseteq V$ be disjoint nonempty subsets. For any $\alpha \in (0, 1)$, there exists some $f \in \mathbb{R}^V$ with $A \subseteq F_{<0}$ and $B \subseteq F_{>0}$ such that*

$$\kappa'(A, F_{\geq 0}) = \frac{\kappa(A, B)}{\alpha} \quad \text{and} \quad \kappa'(B, F_{\leq 0}) = \frac{\kappa(A, B)}{1 - \alpha}.$$

Proof. Let

$$\kappa(A, B) = \min_x \left\{ x^\top Lx \mid x|_A = 0, x|_B = 1 \right\}$$

and let x be the minimizer. Define $f = x - \alpha 1$ and take $y = \min(f, 0)$, where the minimum and maximum is element-wise. Note that $L'y$ agrees with Lx on the support of y . By optimality of x , for $v \in A \setminus (A \cup B)$, we have $0 = \frac{\partial}{\partial x_v}(x^\top Lx) = 2(Lx)_v$. Then,

$$\begin{aligned}
 \kappa'(A, F_{\geq 0}) &\leq \frac{y^\top L' y}{\alpha^2} \\
 &= \frac{\sum_{v \in \text{supp}(y)} y_v (Lx)_v}{\alpha^2} \\
 &= \frac{\sum_{v \in A} (-Lx)_v}{\alpha} \\
 &= \frac{x^\top Lx}{\alpha} \\
 &= \frac{\kappa(A, B)}{\alpha}.
 \end{aligned}$$

Similarly, $\kappa'(B, F_{\leq 0}) \leq \frac{\kappa(A, B)}{(1-\alpha)}$. Then both inequalities must hold with equality by Lemma 33. \blacktriangleleft

We are now ready to prove the following theorem.

► Theorem 35. *Let G be a nondegenerate weighted graph. Let $\lambda_2(G)$ be the Neumann eigenvalue and let $H_2(G)$ be the two-sided Hardy quantity of G . Then*

$$\frac{1}{4H_2} \leq \lambda_2 \leq \frac{1}{H_2}.$$

Proof. Both the upper and lower bound will follow the same template: we will apply the pinch point characterization, apply Theorem 28 to each Dirichlet problem, and reorder the minima.

The upper bound is,

$$\begin{aligned}
 \lambda_2(G) &= \min_f \left\{ \max(\lambda(G', F_{\geq 0}), \lambda(G', F_{\leq 0})) \mid \pm f \notin \mathbb{R}_{\geq 0}^V \right\} \\
 &\leq \min_f \min_{A, B} \left\{ \max \left(\frac{\kappa'(A, F_{\geq 0})}{\mu(A)}, \frac{\kappa'(B, F_{\leq 0})}{\mu(B)} \right) \mid A <_f 0 <_f B, A, B \neq \emptyset \right\} \\
 &= \min_{A, B} \min_f \left\{ \max \left(\frac{\kappa'(A, F_{\geq 0})}{\mu(A)}, \frac{\kappa'(B, F_{\leq 0})}{\mu(B)} \right) \mid A, B \neq \emptyset, A <_f 0 <_f B \right\}.
 \end{aligned}$$

The lower bound is,

$$\begin{aligned}
 \lambda_2(G) &= \min_f \left\{ \max(\lambda(G', F_{\geq 0}), \lambda(G', F_{\leq 0})) \mid \pm f \notin \mathbb{R}_{\geq 0}^V \right\} \\
 &\geq \frac{1}{4} \min_f \min_{A, B} \left\{ \max \left(\frac{\kappa'(A, F_{\geq 0})}{\mu(A)}, \frac{\kappa'(B, F_{\leq 0})}{\mu(B)} \right) \mid A <_f 0 <_f B, A, B \neq \emptyset \right\} \\
 &= \frac{1}{4} \min_{A, B} \min_f \left\{ \max \left(\frac{\kappa'(A, F_{\geq 0})}{\mu(A)}, \frac{\kappa'(B, F_{\leq 0})}{\mu(B)} \right) \mid A, B \neq \emptyset, A <_f 0 <_f B \right\}.
 \end{aligned}$$

It remains to understand the following quantity for disjoint nonempty $A, B \subseteq V$.

$$\min_f \left\{ \max \left(\frac{\kappa'(A, F_0)}{\mu(A)}, \frac{\kappa'(B, F_0)}{\mu(B)} \right) \mid \pm f \notin \mathbb{R}_{\geq 0}^V, A <_f 0 <_f B, A, B \neq \emptyset \right\} \quad (1)$$

Let $\alpha = \frac{\kappa'(A, B)}{\kappa(A, F_{\geq 0})}$. Then by lemma 33, for all f , we have $\kappa'(B, F_{\leq 0}) \geq \kappa(A, B)/(1-\alpha)$. On the other hand, by lemma 34, there exists some f for which we get equality. Thus,

$$\begin{aligned}
 (1) &= \kappa(A, B) \min_{\alpha \in (0,1)} \max \left(\frac{1}{\mu(A)\alpha}, \frac{1}{\mu(B)(1-\alpha)} \right) \\
 &= \frac{\kappa(A, B)}{(\mu(A)^{-1} + \mu(B)^{-1})^{-1}}.
 \end{aligned}$$

Taking the minimum over A, B completes the proof. \blacktriangleleft

The following theorem follows as a corollary.

► **Theorem 36.** *Let G be a nondegenerate weighted graph. Let $\lambda_2(G)$ be the Neumann eigenvalue and let $\Psi_2(G)$ be the Neumann content of G . Then,*

$$\frac{\Psi_2}{4} \leq \lambda_2 \leq \Psi_2.$$

7 Conclusion and future work

In this paper we introduced the Dirichlet and Neumann contents for nondegenerate weighted graphs (with and without boundary) and showed that these quantities can be related to the Dirichlet and Neumann eigenvalues (Theorems 28 and 35). We believe that these quantities are natural as evidenced by the simplicity of the corresponding proofs. An open question is whether it is possible to develop approximation algorithms based on these new inequalities as opposed to Cheeger's inequality. Such algorithms would be able to exploit the tighter bounds provided by our theorems under a more general setting of weights. We are hopeful that this open question will be answered affirmatively.

A Constants in Theorems 28 and 35 are sharp

In this appendix we give constructions of nondegenerate weighted graphs (with and without boundary) that show that the constants in our Theorems 28 and 35 are optimal.

We begin with the Dirichlet case. It is clear that the upper bound is achieved by any nondegenerate weighted graph with boundary (G, S) such that $|\bar{S}| = 1$. In this case

$$\Psi(G, S) = \frac{\kappa(\bar{S}, S)}{\mu(\bar{S})} = \lambda(G, S).$$

We turn to the lower bound. Let $n \in \mathbb{N}$ and let $N = ne^n$. Consider the path graph P with vertices $V = \{v_0, v_1, \dots, v_N\}$ where v_i has mass

$$\mu_i = \begin{cases} \frac{1}{i(i+1)} & 1 \leq i \leq N - 1 \\ \frac{1}{N} & i = N \end{cases}$$

and the usual path edges. Let $\kappa = 1$ for every edge and let v_0 be the boundary set. We compute the Dirichlet content of (P, v_0) .

$$\begin{aligned} \Psi(P, v_0) &= \min_{1 \leq k \leq N} \frac{\kappa(v_0, v_k)}{\sum_{i=k}^N \mu_i} \\ &= \min_{1 \leq k \leq N} \frac{1/k}{1/k} \\ &= 1. \end{aligned}$$

We next show that $\lambda(P, v_0) \leq \frac{1}{4} + o(1)$. Consider the assignment

$$x_i = \begin{cases} 0 & 0 \leq i \leq n - 1, \\ \sqrt{i} - \sqrt{n - 1} & n - 1 \leq i. \end{cases}$$

Then

$$\lambda(P, v_0) \leq \frac{x^\top Lx}{x^\top Mx}.$$

We can bound the numerator above by

$$\begin{aligned} x^\top Lx &= \sum_{i=1}^N (x_i - x_{i-1})^2 \\ &= \sum_{i=n}^N (\sqrt{i} - \sqrt{i-1})^2 \\ &\leq \sum_{i=n}^N \left(\frac{1}{2\sqrt{i-1}} \right)^2 \\ &= \frac{1}{4} \sum_{i=n}^N \frac{1}{i-1} \\ &= \frac{1}{4} \left(\sum_{i=n}^N \frac{1}{i} \right) + O(1). \end{aligned}$$

We can bound the denominator below by

$$\begin{aligned} x^\top Mx &= \sum_{i=1}^N \mu_i x_i^2 \\ &= \sum_{i=n}^N \mu_i (\sqrt{i} - \sqrt{n-1})^2 \\ &= \sum_{i=n}^{N-1} \frac{1}{i(i+1)} (i + (n-1) - 2\sqrt{i(n-1)}) + \frac{1}{N} (\sqrt{N} - \sqrt{n-1})^2 \\ &= \sum_{i=n}^{N-1} \frac{1}{i(i+1)} (i + (n-1) - 2\sqrt{i(n-1)}) + O(1) \\ &= \left(\sum_{i=n}^N \frac{1}{i} \right) + \left(\sum_{i=n}^{N-1} \frac{(n-1)}{i(i+1)} \right) - 2 \left(\sum_{i=n}^{N-1} \frac{\sqrt{n-1}}{\sqrt{i(i+1)}} \right) + O(1) \\ &= \left(\sum_{i=n}^N \frac{1}{i} \right) + O(1). \end{aligned}$$

Finally, noting that $\sum_{i=n}^N 1/i \geq \int_n^N t^{-1} dt = \ln(ne^n/n) = n$ diverges to infinity with n , we have that $\lambda(P, v_0) = \frac{1}{4} + o(1)$. We conclude that the constants in Theorem 28 are optimal.

The same construction and a simple symmetry argument shows that the constants in Theorem 35 are optimal.

Improved 3LIN Hardness via Linear Label Cover

Abstract

We prove that for every constant c and $\varepsilon = (\log n)^{-c}$, there is no polynomial time algorithm that when given an instance of 3-LIN with n variables where an $(1 - \varepsilon)$ -fraction of the clauses are satisfiable, finds an assignment that satisfies at least $(\frac{1}{2} + \varepsilon)$ -fraction of clauses unless $\mathbf{NP} \subseteq \mathbf{BPP}$. The previous best hardness using a *polynomial time* reduction achieves $\varepsilon = (\log \log n)^{-c}$, which is obtained by the LABEL COVER hardness of Moshkovitz and Raz [*J. ACM*, 57(5), 2010] followed by the reduction from LABEL COVER to 3-LIN of Håstad [*J. ACM*, 48(4):798–859, 2001].

Our main idea is to prove a hardness result for LABEL COVER similar to Moshkovitz and Raz where each projection has a *linear* structure. This linear structure of LABEL COVER allows us to use Hadamard codes instead of long codes, making the reduction more efficient. For the hardness of LINEAR LABEL COVER, we follow the work of Dinur and Harsha [*SIAM J. Comput.*, 42(6):2452–2486, 2013] that simplified the construction of Moshkovitz and Raz, and observe that running their reduction from a hardness of the problem LIN (of unbounded arity) instead of the more standard problem of solving quadratic equations ensures the linearity of the resultant LABEL COVER.

1 Introduction

In this paper, we study the 3-LIN problem. An instance of 3-LIN consists of a set of n variables over \mathbb{F}_2 and a set of m equations that contain at most three variables each, and the goal is to find an assignment to the n variables that satisfies the most number of equations.¹ If the given set of linear equations admits an assignment that satisfies every equation, then one such assignment can be found in polynomial time by Gaussian elimination. However, the general problem of finding the most of number of equations is **NP**-hard when the instance does not admit a satisfying assignment, and a large amount of research has been done on the limit of polynomial time approximation algorithms.

Assigning random values to variables satisfies exactly half the equations in expectation, giving a $1/2$ -approximation algorithm. Håstad and Venkatesh [7] achieved an approximation factor of $1/2 + 1/O(\sqrt{m})$, which was improved by Khot and Naor [10] to $1/2 + O(\sqrt{\log n/n})$.

From the hardness side, there are strong hardness results even when the instance is *almost-satisfiable*. For $1 \geq c > s > 0$, let $\text{GAP 3-LIN}(c, s)$ denote the problem of distinguishing whether the given instance of 3-LIN is at least c -satisfiable or at most s -satisfiable. Håstad's classic hardness results [6] show the following.

► **Theorem 1.1** ([6]). *The following hardness results for GAP 3-LIN hold.*

1. *For any constant $\varepsilon > 0$, $\text{GAP 3-LIN}(1 - \varepsilon, 1/2 + \varepsilon)$ is **NP**-hard.*
2. *There exists a constant $c > 0$ such that for $\varepsilon = 1/(\log n)^c$, there is no polynomial time algorithm that solves $\text{GAP 3-LIN}(1 - \varepsilon, 1/2 + \varepsilon)$ unless $\mathbf{NP} \subseteq \mathbf{DTIME}[n^{O(\log \log n)}]$.*

Håstad's results are proved by giving the reduction from LABEL COVER to 3-LIN. LABEL COVER is a common starting point for hardness results, and we define the optimization problem below.

► **Definition 1.2** (LABEL COVER). *An instance of LABEL COVER contains a regular bipartite multi-graph $G = (A, B, E)$ and two finite sets Σ_A and Σ_B , where $|\Sigma_A| \geq |\Sigma_B|$. Every vertex in A is supposed to get a label in Σ_A , and every vertex in B is supposed to get a label in Σ_B . For each edge $e \in E$ there is a projection $\pi_e : \Sigma_A \rightarrow \Sigma_B$. Given a labeling to the vertices of the graph, i.e., functions $\phi_A : A \rightarrow \Sigma_A$ and $\phi_B : B \rightarrow \Sigma_B$, an edge $e = (a, b) \in E$ is said to be “satisfied” if $\pi_e(\phi_A(a)) = \phi_B(b)$. For $1 \geq c > s > 0$, $\text{GAP LABEL COVER}(c, s)$ is the problem of distinguishing whether the given instance of LABEL COVER is at least c -satisfiable or at most s -satisfiable.*

Håstad's theorem can be stated in terms of reduction from $\text{GAP LABEL COVER}(1, \delta)$ as follows.

► **Theorem 1.3** ([6]). *For every $\varepsilon \in (0, 1)$ and positive integer ℓ , there exists a $\delta = \text{poly}(\varepsilon)$ and a $\text{poly}(n, 2^\ell, 2^{1/\varepsilon})$ -time reduction from n -sized instances of $\text{GAP LABEL COVER}(1, \delta)$ with label size ℓ to $\text{GAP 3-LIN}(1 - \varepsilon, 1/2 + \varepsilon)$.*

When [6] was published, the hardness of LABEL COVER was achieved by the PCP theorem [2, 1] and parallel repetition [13]. More precisely, $\text{GAP LABEL COVER}(1, \varepsilon)$ with label size $\text{poly}(1/\delta)$ was **NP**-hard under $\text{poly}(n^{\log 1/\delta})$ -time reductions. The two results of Håstad stated in Theorem 1.1 follow from this hardness of GAP LABEL COVER and Theorem 1.3 by setting δ to be an arbitrarily small constant and $1/\log n$ respectively. Since

¹ This maximization version is also known as MAX 3-LIN in the literature.

achieving a subconstant soundness for LABEL COVER by parallel repetition requires a superpolynomial blowup in the instance size, $\varepsilon > 0$ could not be taken to subconstant under *polynomial time* reductions. Later in a celebrated paper, Moshkovitz and Raz [12] gave an improved hardness of LABEL COVER that achieves sub-constant error under polynomial time reductions. Their main result can be stated as follows.

► **Theorem 1.4** ([12, Theorem 11]). *For every n , and every $\delta > 0$ (that can be any function of n), 3-SAT on inputs of size n can be reduced to GAP LABEL COVER($1, \delta$) when LABEL COVER instance has $n^{1+o(1)} \cdot \text{poly}(1/\delta)$ vertices and $|\Sigma_A| \leq \exp(\text{poly}(1/\delta))$, $|\Sigma_B| \leq \text{poly}(\log 1/\delta)$.*

A corollary of the above result, obtained by combining it with Håstad's reduction from Theorem 1.3, is that given a system of linear equations, it is **NP**-hard to distinguish between cases where $1 - o(1)$ fraction of equations are satisfied vs at most $1/2 + o(1)$ fraction are satisfied, where the $o(1)$ term is $1/(\log \log n)^{-\Omega(1)}$.

► **Theorem 1.5** ([12]). *There exists some constant $c > 0$ such that for $\varepsilon = 1/(\log \log n)^c$, GAP 3-LIN($1 - \varepsilon, 1/2 + \varepsilon$) is **NP**-hard.*

Later, an improved parallel repetition by Dinur and Steurer [4] allowed c to be an arbitrary constant.

The above route prove hardness of 3-LIN is restricted by the large size of the alphabet in the resulting LABEL COVER instance in Theorem 1.4. Quantitatively, the alphabet size is exponential in $\text{poly}(1/\varepsilon)$. The fact that the long code in Håstad's reduction has size exponential in the alphabet size restricts $\varepsilon = 1/(\log \log n)^{O(1)}$.

Our main contribution for 3-LIN is to bring ε in the above result down to $1/(\log n)^c$ for any constant c , while keeping the size of the reduced instance polynomial (albeit the reduction becomes randomized).

► **Theorem 1.6 (Main)**. *For any constant $c > 0$ and $\varepsilon = 1/(\log n)^c$, there is no polynomial time algorithm for GAP 3-LIN($1 - \varepsilon, 1/2 + \varepsilon$) unless **NP** \subseteq **BPP**.*

We get around the above alphabet barrier by starting with a reduction that would make the resulting LABEL COVER *linear*, and use Hadamard codes instead of long codes. Since the Hadamard code keeps the reduction size polynomial in the alphabet size, we can take $\varepsilon = 1/(\log n)^{\Omega(1)}$. A similar idea was previously used by Khot [8]. We define LINEAR LABEL COVER as follows.

► **Definition 1.7 (LINEAR LABEL COVER)**. *A LINEAR LABEL COVER is a special case of LABEL COVER where the alphabets are of the form $\Sigma_A = \mathbb{F}_2^a, \Sigma_B = \mathbb{F}_2^b$ where a, b are natural numbers. Each projection $\pi : \mathbb{F}_2^a \rightarrow \mathbb{F}_2^b$ is affine in the sense that $\pi(x) = \alpha x + \beta$ for some $\alpha \in \mathbb{F}_2^{b \times a}, \beta \in \mathbb{F}_2^b$. For $1 \geq c > s > 0$, the GAP LINEAR LABEL COVER(c, s) is defined similarly to GAP LABEL COVER(c, s).*

We prove the following hardness result for LINEAR LABEL COVER, which may be of independent interest.

► **Theorem 1.8 (Hardness of Linear Label Cover)**. *For any constant $c > 0$, for $\delta = 1/(\log n)^c$, there is no polynomial time algorithm for GAP LINEAR LABEL COVER($1 - \delta, \delta$) unless **NP** \subseteq **BPP**, when LABEL COVER instance has $\text{poly}(n)$ vertices and $|\Sigma_A| = \text{poly}(n), |\Sigma_B| = \text{polylog}(n)$.*

We remark that if the above theorem can be further strengthened to obtain $\delta = 1/n^c$ (i.e., a linear version of the Sliding Scale conjecture), then this leads to near-optimal hardness of 3-LIN (i.e., GAP 3-LIN($1 - \varepsilon, 1/2 + \varepsilon$) is hard for $\varepsilon = 1/\text{poly}(n)$) [11].

1.1 Proof Ideas

Our main technical contribution is Theorem 1.8 for LINEAR LABEL COVER, essentially proving a linear analogue of the Moshkovitz-Raz PCP [12] followed by the Dinur-Steurer parallel repetition [4]. The proof is given through a long sequence of reductions. We split them in 3 major steps.

1. Interestingly, the starting point of our reduction is again the hardness of (not necessarily linear) LABEL COVER proved by Moshkovitz and Raz [12] augmented by Dinur and Steurer [4], proving **NP**-hardness of GAP LABEL COVER($1, 1/\log^c n$) for any $c > 0$, while keeping the reduction size and the alphabet size polynomial. In Section 2, we give a *randomized* reduction from this LABEL COVER to GAP LIN($1 - 1/\log^c n, 0.9$). This style of reduction appeared previous from LABEL COVER to CLOSEST VECTOR PROBLEM [9]. Note that the standard proof of the PCP theorem encodes 3-SAT (or CIRCUIT SAT) by solving quadratic equations over \mathbb{F}_2 , and this is essentially the only place that needs where nonlinearity occurs. Our hardness result for solving linear equations with completeness very close to (but not exactly) 1 allows us to follow previous PCP constructions that will ensure linearity of the LABEL COVER instance in the subsequent steps.
2. To prove the hardness of LINEAR LABEL COVER given the above hardness of LIN, we closely follow the steps of Dinur and Harsha [3], who gave a simpler and modular proof of [12]. The two basic building blocks in their proof are robust PCPs and decodable PCPs. Robust PCPs are PCPs where in the soundness case, for any proof and most random choices of the verifier, not only are the local views non-accepting, but they are also very far from any accepting string. It is indeed equivalent to LABEL COVER. Using our previous hardness for LIN as the starting point and following the standard robust PCP construction (e.g., low-degree extension and sum-check protocol), we can prove a polynomial time reduction to LINEAR LABEL COVER($1 - 1/\log^c n, 1/\log^c n$) for any $c > 1$, but the alphabet size will be always $\exp(\log^{c_0} n)$ for some $c_0 > 1$, which is superpolynomial.
3. The second building block, decodable PCP, is similar to robust PCP with the additional requirement that the prover is given a position i in the original string and supposed to output the value of the i th position if the given proof is a honest encoding of a valid original string. The main idea of Dinur and Harsha [3] is to iteratively compose a robust PCP with a suitable decodable PCP, where the composed PCP is another robust PCP that consists of a decodable PCP for each constraint of the original robust PCP. This iteratively reduces the query complexity and the alphabet size of the robust PCP, which is related to the alphabet size of the equivalent LABEL COVER instance. This iterative composition is interleaved and preprocessed by technical operations that reduce the alphabet size of the robust PCP and make it regular.

Once these two building blocks are linear, the operations of [3] can be used verbatim in our construction. Our main observation is that every step of this construction preserves (1) the robust completeness $1 - \delta$ for some $\delta = 1/\text{polylog}(n)$, and (2) the linearity, which were not issues in [3]. In Section 3, we introduce the basic building blocks and these operations, and show how they preserve robust completeness and linearity. These iterative operations will eventually reduce the alphabet size of the LINEAR LABEL COVER polynomial, proving Theorem 1.8.

After the hardness of LINEAR LABEL COVER is proved, we give a reduction from LINEAR LABEL COVER with the above parameters to 3-LIN with the required parameters. We do this by composing with the Hadamard Code to get a $(1 - \varepsilon)$ vs $(1/2 + \varepsilon)$ **NP**-hardness result for 3LIN. Similar PCP constructions based on Hadamard codes were presented in [8]. Details of this step can be found in Section 4.

2 Reduction to System of Linear Equations

In this section, we first prove the hardness of approximate solving linear equations over large fields, where each equation can involve as many variables as possible. It will serve as the starting point towards proving hardness of LABEL COVER.

► **Theorem 2.1.** *For any constant $c > 0$, $\varepsilon = 1/(\log n)^c$, GAP LIN($1 - 1/(\log n)^c, 0.9$) is NP-hard under polynomial time randomized reductions.*

Proof. The proof starts from the following hardness of LABEL COVER, which is obtained by combining the main result of Moshkovitz and Raz [12] with the parallel repetition of Dinur and Steurer [4].

► **Theorem 2.2** ([12, 4]). *For any constant $c > 0$, for $\delta = 1/(\log n)^c$, GAP LABEL COVER($1, \delta$) is NP-hard when the LABEL COVER instance satisfies $|\Sigma_A|, |\Sigma_B| \leq |A| + |B|$.*

Let $G = (A, B, E)$, Σ_A, Σ_B , and $\{\pi_e\}_{e \in E}$ be an instance of LABEL COVER. We show a reduction to LIN over \mathbb{F}_2 where

- If all LABEL COVER edges are satisfiable, at least $(1 - \frac{1}{|\Sigma_A|})$ fraction of equations are satisfiable.
- If at most δ fraction of LABEL COVER edges are satisfiable, at most $(1 - \frac{1}{(\delta|\Sigma_A|)})$ fraction of equations are satisfiable.

For each vertex $v \in \Sigma_A \cup \Sigma_B$ and possible label ℓ on the Label Cover instance, we have a variable $x_{v,\ell}$ in the LIN instance. Let $n = |A||\Sigma_A| + |B||\Sigma_B| = \text{poly}(|A| + |B|)$ be the number of variables. Consider the following four kinds of equations. Recall that every arithmetic is performed over \mathbb{F}_2 .

$$\begin{aligned}
 (1) \quad & \sum_{\ell \in \Sigma_A} x_{v,\ell} = 1 && \forall v \in A \\
 (2) \quad & \sum_{\ell \in \Sigma_B} x_{v,\ell} = 1 && \forall v \in B \\
 (3) \quad & \sum_{r: \pi_{uv}(r)=\ell} x_{v,r} = x_{u,\ell} && \forall (u,v) \in E, \forall \ell \in \Sigma_B \\
 (4) \quad & x_{v,\ell} = 0 && \forall (v,\ell) \in A \times \Sigma_A
 \end{aligned}$$

In our final LIN instance, we treat (1), (2), and (3) as *hard constraints* that need to be always satisfied, and find x that always satisfies all hard constraints and as many constraints in (4) as possible. Also note that in (4), we only consider vertices in A .

This is equivalent to the usual LIN problem with hard constraints by *folding*. Formally, let V be the set of assignments that satisfy (1), (2), and (3). If V is empty, we can conclude that the LABEL COVER instance is unsatisfiable. Otherwise, there exist $c \in \mathbb{N}$ and linearly independent vectors $y_0, \dots, y_c \in \mathbb{F}_2^{(A \times \Sigma_A) \cup (B \times \Sigma_B)}$ such that $V = \{y_0 + \sum_{i=1}^c y_i z_i : z_1, \dots, z_c \in \mathbb{F}_2^c\}$. This gives an one-to-one correspondence between \mathbb{F}_2^c and V , so we can treat z_1, \dots, z_c as the variables of LIN and write the fourth constraints $x_{v,\ell} = 0$ in terms of z , which gives an instance of LIN without hard constraints.

Completeness

If the LABEL COVER instance is satisfiable, $x_{v,\ell} = 1$ if and only if v is assigned with ℓ gives an assignment that satisfies (1), (2), and (3), and violates one equation in (4) for each $v \in A$.

Soundness

Let x be an assignment that satisfies (1), (2), and (3). For $v \in A \cup B$, let $L_v := \{\ell : x_{v,\ell} = 1\}$. Since (1) and (2) require $\sum_{\ell} x_{v,\ell} = 1$ for every $v \in A \cup B$, L_v is not empty for every v .

Consider the randomized strategy for LABEL COVER where each $v \in A \cup B$ is assigned with a uniform random label from L_v independently. For $(u, v) \in E$ with $u \in A, v \in B$, by (3), $x_{v,\ell} = 1$ for some $\ell \in \Sigma_B$ implies that there exists $r \in \Sigma_A$ with $\pi_{uv}(r) = \ell$ such that $x_{u,r} = 1$. This implies (u, v) is satisfied with probability at least $\frac{1}{|L_u|}$ by the randomized strategy. Then the expected fraction of the LABEL COVER constraints satisfied by the strategy is at least

$$\mathbf{E}_{u \in A} \left[\frac{1}{|L_u|} \right] \geq \frac{1}{\mathbf{E}_{u \in A}[|L_u|]}.$$

Therefore, if at most δ fraction of LABEL COVER constraints are simultaneously satisfiable, we can conclude that

$$\delta \geq \frac{1}{\mathbf{E}_{u \in A}[|L_u|]} \Leftrightarrow \mathbf{E}_{u \in A}[|L_u|] \geq \frac{1}{\delta}.$$

So in total, at least $\frac{1}{(\delta|\Sigma_A|)}$ fraction of equations are violated.

Gap Amplification

We have a hardness of LIN over \mathbb{F}_2 where the completeness value is at least $1 - \frac{1}{|\Sigma_A|}$ and the soundness value is at most $1 - \frac{1}{(\delta|\Sigma_A|)}$. Consider a new system of linear equations where we sample m linear equations independently, where each new equation randomly chooses $\delta \cdot |\Sigma_A|$ old equations and takes a random linear combination of them. In the completeness case, at least an $(1 - O(\delta))$ fraction of new equations can be satisfied by a good assignment to old equations.

In the soundness case, fix an assignment to n possible variables. (There are 2^n of them.) It satisfies at most an $1 - \frac{1}{(\delta|\Sigma_A|)}$ fraction of old equations. Note that if a new equation chooses an old equation not satisfied by the assignment, it is satisfied with probability exactly $1/2$. Therefore, the expected number of new equations satisfied by this fixed assignment is at most

$$m \cdot \left(\left(1 - \frac{1}{(\delta|\Sigma_A|)}\right)^{\delta \cdot |\Sigma_A|} + \frac{1}{2} \right) \leq m \cdot \left(\frac{1}{e} + \frac{1}{2} \right) \leq 0.87m.$$

For a given $c \in \mathbb{N}$, let $\delta = 1/\log^c n$. By taking sufficiently large $m = O(n)$, we can apply the Chernoff and union bound to conclude that no assignment satisfies more than a 0.9 fraction of new equations. So we reduce from LABEL COVER to GAP LIN($1 - O(\delta), 0.9$), which finishes the proof. ◀

We remark that the sampling performed above is the only step in our reduction involving randomization.

3 Reduction to Linear Label Cover

In this section, we show for any $c > 0$, unless $\mathbf{NP} \subseteq \mathbf{BPP}$, there is no polynomial time algorithm for GAP LINEAR LABEL COVER($1 - \varepsilon, \varepsilon$) with $\varepsilon = 1/(\log n)^c$, proving Theorem 1.8.

The construction we employ is almost identical to that of Dinur and Harsha [3], except that the basic building blocks (robust PCP and decodable PCP) try to prove (almost) satisfiability of linear equations instead of standard quadratic equations. They are introduced in Sections 3.1 and 3.2.

After constructing the building blocks, the result of [3] is proved by iterative composition of them followed by technical steps including alphabet and degree reduction. Our main observation in this part is that each of the steps in the construction preserves *linearity* so that the final LABEL COVER instance produced also has a linear structure. We present them in Section 3.3 and Section 3.4. Finally, Section 3.5 shows how to combine all these steps to prove Theorem 1.8.

3.1 Robust PCPs

In this subsection, we define robust PCPs. For two strings x, y of the same length n , let $\text{agr}(x, y)$ denote the relative agreement of the strings x, y , defined as

$$\text{agr}(x, y) := \Pr_{i \in [n]} [x_i = y_i]$$

If S is a set of strings, $\text{agr}(x, S)$ is defined as $\max_{y \in S} \{\text{agr}(x, y)\}$.

► **Definition 3.1** (Robust PCPs). *For functions $r, q, m, a, s : \mathbb{N} \rightarrow \mathbb{N}$ and $c, \delta : \mathbb{N} \rightarrow [0, 1]$, a verifier V is a robust probabilistically checkable proof (robust PCP) system for a promise problem $L = (L_{\text{YES}}, L_{\text{NO}})$ with randomness complexity r , query complexity q , proof length m , alphabet size a , robust completeness c , and robust soundness error δ if V is a probabilistic polynomial-time algorithm that behaves as follows: On input x of length n and oracle access to a proof string $\pi \in \Sigma^{m(n)}$ over the (proof) alphabet Σ where $|\Sigma| = a(n)$, V reads the input x , tosses at most $r = r(n)$ random coins, and generates a sequence of locations $I = (i_1, \dots, i_q) \in [m]^{q(n)}$ and a predicate $f : \Sigma^q \rightarrow \{0, 1\}$, which satisfy the following properties.*

Robust Completeness. *If $x \in L_{\text{YES}}$ then there exists π such that*

$$\mathbf{E}_{(I, f)} [\text{agr}(\pi_I, f^{-1}(1))] \geq c. \quad (1)$$

Robust Soundness. *If $x \in L_{\text{NO}}$ then for every π ,*

$$\mathbf{E}_{(I, f)} [\text{agr}(\pi_I, f^{-1}(1))] \leq \delta, \quad (2)$$

where the distribution over (I, f) is determined by x and the random coins of V .

We say that V is *linear* if $\Sigma = \mathbb{F}_2^b$ for some b and for every f , the accepting sets of the predicate f , i.e., $f^{-1}(1)$, forms an affine subspace of $\Sigma^q = \mathbb{F}_2^{bq}$ over the field \mathbb{F}_2 .

Robust completeness and soundness must be contrasted with (regular) completeness and soundness of standard PCP verifiers in which the expression for completeness and soundness given in (1) and (2) respectively are replaced as follows:

$$\text{Completeness: } \Pr_{I, f} [f(\pi_I) = 1] \geq c,$$

$$\text{Soundness: } \Pr_{I, f} [f(\pi_I) = 1] \leq \delta.$$

In fact, this is the only difference between the above definition and the standard definition of a PCP system. The robust soundness states that not only does the local view violate the local predicate f , but in fact has very little agreement with any of the satisfying assignments of f (and thus is a strengthening of standard robustness). Robust completeness on the other hand is a weakening of standard completeness.

Another crucial aspect of robust PCP is its equivalence to LABEL COVER. Namely, existence of robust PCP for L with parameters r, q, m, a, s, c, δ is equivalent to existence of a reduction from L to GAP LABEL COVER(c, δ) where $|A| = 2^r, |B| = m, |\Sigma_A| \leq a^q, |\Sigma_B| = a$ and each $v \in A$ has degree q . See Lemma 2.5 of [3]. Also note that the definition of linearity is equivalent in robust PCP and LABEL COVER.

► **Theorem 3.2** (Robust PCP, Analog of [3, Theorem 6.4]). *There exist constants $b_1, b_2 > 0, c_0 > 1$ such that for any $c > c_0$ and $\varepsilon = 1/\log^c n$, GAP LIN($1 - \varepsilon, 0.9$) with n variables has a linear robust verifier with robust completeness $1 - \varepsilon$, robust soundness error ε , query complexity $1/\varepsilon^{b_1}$, proof length $\text{poly}(n)$, randomness complexity $O(\log n)$, and proof alphabet size at most $1/\varepsilon^{b_2}$.*

Equivalently, there is a (deterministic) polynomial time reduction from GAP LIN($1 - \varepsilon, 0.9$) to GAP LINEAR LABEL COVER($1 - \varepsilon, \varepsilon$), where the LABEL COVER instance has $\text{poly}(n)$ vertices, $|\Sigma_A| \leq \exp(1/\varepsilon^{b_1} \log(1/\varepsilon^{b_2}))$, $|\Sigma_B| \leq 1/\varepsilon^{b_2}$, and each $v \in A$ has degree $1/\varepsilon^{b_1}$.

The proof of this theorem is identical to that of [3, Theorem 6.4] and omitted here. The only difference is GAP LIN($1 - \varepsilon, 0.9$) with $1/\varepsilon = \log^{O(c)} n$ instead of standard quadratic equations when performing the low degree-extension and the sum-check protocol. The theorem follows by observing that all the operations are linear and hence the final predicate is also linear. The completeness of the robust PCP is dictated by the completeness value in Theorem 2.1.

Combining this reduction with the randomized reduction from Theorem 2.1, we obtain the following theorem (which is a more formal version of Theorem 1.8).

► **Theorem 3.3** (Hardness of Linear Label Cover). *There exist constants $b_1, b_2 > 0, c_0 > 1$ such that for any $c > c_0$ and $\varepsilon = 1/\log^c n$, unless $\mathbf{NP} \subseteq \mathbf{BPP}$, there is no polynomial time algorithm for GAP LINEAR LABEL COVER($1 - \varepsilon, \varepsilon$) where the LABEL COVER instance has $\text{poly}(n)$ vertices, $|\Sigma_A| \leq \exp(1/\varepsilon^{b_1} \log(1/\varepsilon^{b_2}))$, $|\Sigma_B| \leq 1/\varepsilon^{b_2}$, and each $v \in A$ has degree $1/\varepsilon^{b_1}$.*

3.2 Decodable PCPs

We now discuss the decodable PCP (dPCP), which differs from a PCP in that it has a decoder as opposed to a verifier. A *decoder* is similar to a verifier in that it checks whether a string is in the given language or not by probabilistically checking a small number of positions in the proof, but it is additionally supposed to return the i th position of the original string for given i .

For $\Sigma = \mathbb{F}_2^a$ for some $a \in \mathbb{N}$, let LIN_Σ denote the problem of solving linear equations where an instance consists of k variables that can have a value from Σ , and a system of linear equations C on $k \cdot a$ variables over \mathbb{F}_2 canonically represented by the k variables over Σ . It is equivalent to LIN over \mathbb{F}_2 on $k \cdot a$ variables, except that we consider each block of a variables as one variable that can take a value from Σ . We define a decoder for LIN_Σ below.

► **Definition 3.4** (Decoder for LIN_Σ). *Let $\Sigma = \mathbb{F}_2^a$ and $\sigma = \mathbb{F}_2^b$ for some a and b . A decoder for LIN_Σ over a proof alphabet σ with parameters $m, q, r : \mathbb{N} \rightarrow \mathbb{N}$ is a probabilistic polynomial-time algorithm \mathcal{D} . It is given a system of linear equations C on n variables over Σ , and an index $j \in [n]$ as input, and oracle access to a proof π of length $m(n)$ over proof alphabet σ . It tosses $r = r(n)$ random coins and generates (1) a sequence of $q = q(n)$ locations $I = (i_1, \dots, i_q)$ and (2) a (local decoding) function $f : \sigma^q \rightarrow \Sigma \cup \{\perp\}$. \mathcal{D} is called linear if for every $f, P := f^{-1}(\Sigma)$ is an affine space of $\sigma^q = (\mathbb{F}_2^{qb})$ and $f : P \rightarrow \Sigma$ is an affine function over the base field \mathbb{F}_2 .*

Now we define a dPCP for LIN_Σ . The dPCP in [3] is defined for CIRCUIT SAT , whereas ours is for LIN_Σ . Note that unlike in [3], the dPCP we will construct does not imply any computational hardness, because it only proves whether the given system of linear equations is perfectly satisfiable or not, which is a computationally easy problem. The key point is it proves the system is satisfiable using a proof which is in some sense “locally decodable”. The dPCP will then be composed with the previous linear robust PCP, which is a system of linear equations with *imperfect completeness*, to reduce the query complexity.

► **Definition 3.5** (Decodable PCPs for LIN_Σ). *For functions $\delta : \mathbb{N} \rightarrow [0, 1]$ and $L : \mathbb{N} \rightarrow \mathbb{N}$, we say that a PCP decoder \mathcal{D} is a decodable probabilistically checkable proof (dPCP) system for LIN_Σ with perfect completeness, soundness δ and list size L if the following completeness and soundness properties hold for every system of linear equations C on n variables over Σ .*

Completeness. *For any $y \in \Sigma^n$ that satisfies every equation in C , there exists a proof $\pi \in \sigma^m$, also called a decodable PCP, such that*

$$\Pr_{j,I,f} [f(\pi_I) = y_j] = 1,$$

where $j \in [n]$ is chosen uniformly at random and I, f are distributed according to C, j , and the verifier’s random coins.

Soundness. *For any $\pi \in \sigma^m$, there is a list of $0 \leq \ell \leq L$ strings y^1, \dots, y^ℓ , where each y^i satisfies all equations in C , such that*

$$\Pr_{j,I,f} [f(\pi_I) \notin \{\perp, y_j^1, \dots, y_j^\ell\}] \leq \delta.$$

Robust soundness. *We say that \mathcal{D} is a robust dPCP system for LIN_Σ with robust soundness error δ , if the soundness criterion above can be strengthened to the following robust soundness criterion,*

$$\mathbf{E}_{j,I,f} [\text{agr}(\pi_I, \text{BAD}(f))] \leq \delta,$$

where

$$\text{BAD}(f) := \{w \in \sigma^q : f(w) \notin \{\perp, y_j^1, \dots, y_j^\ell\}\}.$$

The dPCP result we use is the following.

► **Theorem 3.6** (dPCP, Analog of [3, Theorem 6.5]). *There exist constants $\alpha, \gamma > 0$ such that for every $\delta \geq n^{-\alpha}$ and input alphabet size Σ of size at most n^γ , LIN_Σ has a linear robust decodable PCP system with perfect completeness, robust soundness error $\delta > 0$ and list size $L \leq 2/\delta$, query complexity $n^{1/8}$, proof alphabet σ of size n^γ , proof length $\text{poly}(n)$, and randomness complexity $O(\log n)$.*

The proof of this theorem is identical to that of [3, Theorem 6.5], except that the initial starting point is LIN_Σ instead of $\text{CIRCUIT SAT}_\Sigma$. Since the starting point is linear and all transformations are linear, the final object is also linear. The perfect completeness is also maintained. As mentioned before, the dPCP constructed here does not imply any computational hardness unlike in [3].

3.3 Composition

After having building blocks, Dinur and Harsha [3] show how to compose those blocks iteratively to reduce the query complexity and the alphabet size. Each composition involves several other operations including alphabet and degree reductions. While the soundness analyses for them are already proved in [3], we show that all of their operations preserve linearity and robust completeness.

Efficient Composition ([3, Theorem 4.2])

In the composition, given a regular robust linear PCP verifier V and a robust linear PCP decoder \mathcal{D} , the composed verifier V' expects a decodable PCP for each constraint of V . Recall that the linearity of V is equivalent to the fact that each constraint of V is a system of linear equations over \mathbb{F}_2 , which is exactly what \mathcal{D} expects. An informal description of the composed verifier is as follows:

1. Randomly choose a location i of the proof for V . Let C_1, \dots, C_D be the constraints of V containing the location.
2. Using a $(\varepsilon, \varepsilon^2)$ -sampler $([D], [D], E)$ and a random $s \in [D]$, choose a subset $S \subseteq \{1, \dots, D\}$ and run the inner PCP decoder \mathcal{D} for each C_j with $j \in S$ to decode the i th symbol in the original proof.
3. Accept if all the values returned by the PCP decoders are the same.

For the second step above, we use $(\varepsilon, \varepsilon^2)$ -samplers given in [5]. Theorem 4.2 of [3] shows the soundness of the composed verifier V' , yielding Table 1 below (Table 4.2 in [3]).

■ **Table 1** Parameters for Composition.

	V	\mathcal{D}	V'
proof alphabet	Σ	σ	σ
randomness complexity	R	r	$\log M + r + \log D$
query complexity	Q	q	$4/\varepsilon^4 \cdot q$
proof degree	D	d	d
proof length	M	m	$2^R \cdot m$
robust soundness error	Δ	δ	$\Delta L + 4L\varepsilon + \delta$
list size	-	L	-

We check this composition preserves robust completeness and linearity.

- **Linearity:** Linearity (over \mathbb{F}_2) is preserved if both V and \mathcal{D} are linear, since the only additional check we perform is to check whether the returned values are equal.
- **Robust completeness:** Suppose that there exists a proof Π for V that achieves the robust completeness of at least $1 - \xi$. Recall that the composed verifier expects, for each constraint of the outer PCP, a satisfying assignment encoded by the inner dPCP. The proof for the composed verifier is the concatenation of all these encodings. Consider the proof to the composed verifier constructed by the honest encoding of the assignment that achieves the robust completeness for the outer PCP verifier. We will show that this proof achieves robust completeness $1 - \xi$.

Let i be a proof location in the outer PCP and C_1, \dots, C_D be the constraints involving i . Furthermore, let ξ_i be the fraction of these constraints violated by the proof. Since Π is at least $(1 - \xi)$ -robustly complete, we have $\mathbf{E}_i[\xi] \leq \xi$. For each sample s chosen in the sampler, let $\xi_{i,s}$ be the fraction of constraints in S (chosen by sampler) that are violated. By regularity of sampler, we have $\mathbf{E}_s[\xi_{i,s}] \leq \xi_i$.

A local view of the composed verifier (corresponding to i, s and the inner dPCP randomness) comprises of the concatenation of the local views of the dPCP encodings corresponding to the constraints in S . Since the the inner dPCP has perfect completeness we have the following. Whenever the constraint is satisfied, the corresponding inner dPCP's encodings satisfies all constraints while we have no guarantee when the constraint is not satisfied. Since for each (i, s) , the fraction of violated constraints is $\xi_{i,s}$, we have

that at least $(1 - \xi_{i,s})$ -fraction of the local inner views corresponding to (i, s) are satisfying and furthermore they all decode to the same $\Pi(i)$. Hence, the local view of the composed verifier corresponding to (i, s) is at least $(1 - \xi_{i,s})$ -close to a satisfying view. Hence, the robust completeness of this honest proof is at least $\mathbf{E}_{i,s}[1 - \xi_{i,s}] \geq 1 - \xi$.

3.4 Label Cover Operations

After the composition, the alphabet reduction step is applied to ensure that the alphabet size is polynomial in the query complexity and the inverse of the soundness. Also, since the basic robust PCP given in Theorem 3.2 is not necessarily regular, we also need to show how to make the initial robust PCP regular. This subsection introduces various such operations and explains why they preserve robust completeness and linearity.

Degree Reduction ([3, Theorem 5.1])

Given an instance of LABEL COVER $G = (A, B, E)$, the degree reduction makes the instance right-regular by appropriately duplicating right vertices and each edge exactly the same number of times. Theorem 5.1 of [3] ensures that by increasing robust soundness by 4μ additively, we can ensure that the right degree is $4/\mu^4$ for all right vertices. We check that this operation preserves linearity and robust completeness.

- Linearity: Linearity is obviously preserved, because there is no change in the constraint.
- Robust completeness: Since each edge is duplicated the same number of times, robust completeness does not decrease.

Alphabet Reduction ([3, Theorem 5.5])

Given an instance of LABEL COVER $G = (A, B, E)$ where Σ_A and Σ_B are the alphabet set of the left (bigger) side and the right (smaller) side respectively, the alphabet reduction replaces Σ_B by a smaller set σ by finding a suitable linear code $C : \Sigma_B \rightarrow \sigma^k$ and replacing each vertex $b \in B$ by k vertices b_1, \dots, b_k . Then assigning $x \in \Sigma_B$ to b corresponds to assigning $(C(x))_i$ to b_1, \dots, b_i . Theorem 5.5 of [3] ensures that if C has a relative distance $1 - \eta^3$, this operation increases robust soundness by at most 3η additively. We check that this operation preserves linearity and robust completeness.

- Linearity: Linearity over \mathbb{F}_2 is preserved if the code $C : \Sigma_B \rightarrow \sigma^k$ is linear with $\sigma = \mathbb{F}_2^a$ as the base field for some $a \in \mathbb{N}$. The code used in Remark 5.4 of [3] is already linear.
- Robust completeness: If an edge (a, b) of the original LABEL COVER instance is preserved and the new instance follows the honest encoding, all k edges of the new instance corresponding to (a, b) will be satisfied. Therefore, robust completeness cannot decrease.

Flip Sides ([3, Section 5.3])

Given an instance of LABEL COVER $G = (A, B, E)$ where each right vertex $b \in B$ has degree d , the flip side is achieved by flipping A and B , and assigning each $v \in B$ a label from Σ_A^d , which is supposed to denote the assignments to its neighbors in the original instance. If $v \in B$ has $u_1, \dots, u_d \in A$ as neighbors, (v, u_i) in the new instance is satisfied (i) if the label $(a_1, \dots, a_d) \in \Sigma_A^d$ for v has $b \in \Sigma_B$ such that the label pair (a_i, b) satisfies the edge (u_i, v) in the old instance, and (ii) if a_i is equal to the label assigned to u_i . This obviously does not change the robust soundness. We check that it also preserves linearity and robust completeness.

9:12 Improved 3LIN Hardness via Linear Label Cover

■ **Table 2** Sequence of steps to regularize the LABEL COVER instance. * denotes irregular instances where the number denotes the average degree.

LABEL COVER (Robust PCPs)	I	Degree Red. ($\rightarrow d$)	Flip	Degree Red. ($\rightarrow d$)	Alphabet Red. ($\rightarrow \sigma$)
# left vertices (randomness)	n	n	mD_B	mD_B	mD_B
# right vertices (proof length)	m	mD_B	n	nD_Ad	$nD_Ad k$
left degree (query complexity)	D_A^*	dD_A^*	d	d^2	$d^2 k$
right degree (proof degree)	D_B^*	d	D_Ad^*	d	d
left alphabet (# accepting conf.)	Σ_A	Σ_A	Σ_A^d	Σ_A^d	Σ_A^d
right alphabet (proof alphabet)	Σ_B	Σ_B	Σ_A	Σ_A	σ
soundness error (rob. soundness error)	δ	$\delta + 4\mu$	$\delta + 4\mu$	$\delta + 8\mu$	$\delta + 8\mu + 3\eta$
rob. completeness (rob. completeness)	$1 - \xi$	$1 - \xi$	$1 - \xi$	$1 - \xi$	$1 - \xi$

- **Linearity:** Linearity is preserved, because for each $v \in B$, the set of (a_1, \dots, a_d) satisfying (i) above is an affine subspace of $(\Sigma_A)^d$, and the new constraint is merely a projection.
- **Robust completeness:** Cannot decrease since if $v \in B$ was assigned $b \in \Sigma_B$ in the original instance, it can be assigned $(a_1, \dots, a_d) \in \Sigma_A$ such that (i) $\pi_{(u_i, v)}(a_i) = b$, and (ii) a_i was assigned to u_i if (u_i, v) was satisfied in the original instance.

We use a combination of the above 3 operations to get a regular LABEL COVER instance, as shown below.

Given an $\varepsilon > 0$, by using $(O(\varepsilon), O(\varepsilon^2))$ -samplers in the composition and doing the above operations with $\eta = O(\varepsilon)$, $d = O(1/\varepsilon^4)$, distance $1 - O(\varepsilon^3)$, $|\sigma| = O(1/\varepsilon^6)$, $k = O(1/\varepsilon^6) \cdot |\Sigma'| \leq O(1/\varepsilon^6) \cdot q|\Sigma|$, we can deduce the following lemma.

► **Lemma 3.7** ([3, Lemma 5.7]). *For all $\varepsilon : \mathbb{N} \rightarrow [0, 1]$, suppose L has a robust linear PCP verifier V with randomness complexity r , query complexity q , proof length m , average proof degree D_B , robust completeness c , robust soundness error δ over a proof alphabet Σ . Then L has a regular reduced linear robust PCP verifier, which we shall denote by $\text{regular}_\varepsilon(V)$ with*

- *randomness complexity $\log m + \log D_B$,*
- *query complexity $O(q \log |\Sigma|/\varepsilon^{14})$,*

- proof length $O(q^2 2^r \log |\Sigma| / \varepsilon^{10})$,
- proof degree $O(1/\varepsilon^4)$,
- proof alphabet σ of size at most $O(1/\varepsilon^6)$,
- robust completeness c ,
- and robust soundness $\delta + \varepsilon$.

3.5 Putting things together

Finally we prove Theorem 1.8 on the hardness of LINEAR LABEL COVER. Let $c > 0$ be an arbitrary constant. Let \mathcal{D} be the PCP decoder from Theorem 3.6 and \mathcal{V} be the robust PCP from Theorem 3.2 with robust completeness $1 - \delta$ with $\delta = \log^c n$, robust soundness error $\varepsilon = 1/\log^{c_0} n$ for some $c_0 > 1$, query complexity $1/\varepsilon^{O(1)}$, randomness complexity $O(\log n)$ and proof length $\text{poly}(n)$.

► **Lemma 3.8** ([3, Lemma 6.6]). *Let \mathcal{D} , \mathcal{V} , ε, δ be as defined above and set $\varepsilon_i = (\varepsilon)^{1/3^i}$. There exist constants $c_0, c_1, c_3 > 0$ such that for every $i \geq 0$ as long as $\varepsilon_i < c_0$, the following holds. GAP LIN($1 - \delta, 0.9$) has a regular linear robust PCP verifier V_i with query complexity $1/\varepsilon_i^{c_1}$, robust completeness $1 - \delta$, robust soundness error $2\varepsilon_i$, proof alphabet Σ_i of size c_3/ε_i^6 , randomness complexity $O(\log n)$ and proof length $\text{poly}(n)$.*

Proof. The proof is similar to [3], and is a sequence of compositions. We start with the regularized robust verifier given by applying the sequence of steps given in Section 3.4 to the robust PCP verifier given in Theorem 3.2. In each subsequent step, we compose the robust verifier obtained in the previous step with a dPCP, and apply the alphabet reduction (Theorem 5.5 of [3]) to reduce the size of the alphabet to c_3/ε_{i+1}^6 . All the parameters remain the same as in [3], and we only need to focus on the two additional properties we need, linearity and robust completeness.

Recall that a PCP with robust completeness $1 - \delta$, when composed with a dPCP with perfect completeness, yields a composed PCP with robust completeness $1 - \delta$. In each step the inner PCP decoder has perfect completeness, therefore the robust completeness of the composed PCP is preserved. Recall that the alphabet reduction step also doesn't affect the perfect completeness.

Linearity is also preserved because all basic components are linear and all steps (e.g., composition, alphabet reduction, and regularization) preserve linearity as previously discussed. ◀

The above lemma shows that we can iteratively reduce the query complexity until some absolute constant while maintaining the soundness and the alphabet size polynomial in the query complexity. (And the total size of the instance always remains polynomial in n .) Only a constant number of iterations is needed until $(\text{proof alphabet size})^{(\text{query complexity})}$, an upper bound on the size of alphabet in the equivalent LABEL COVER instance, becomes polynomial in n . This proves our main Theorem 1.8 for LINEAR LABEL COVER.

Proof of Theorem 1.8. Set i from Lemma 3.8 so that

$$(\text{proof alphabet size})^{(\text{query complexity})} = (c_3/\varepsilon_i^6)^{1/\varepsilon_i^{c_1}} = \exp\left(\frac{1}{\varepsilon_i^{c_1}} \cdot \log\left(\frac{c_3}{\varepsilon_i^6}\right)\right) \leq \text{poly}(n).$$

This ensures that $\varepsilon_i = 1/\log^{c_4} n$ for some $c_4 > 0$. Using the equivalence between LABEL COVER and robust PCP, we have a hardness of LABEL COVER where the number of vertices and the size of label are bounded by $\text{poly}(n)$, and the completeness is at least $1 - 1/\log^c n$, the soundness is $1/\log^{c_4} n$. Applying the parallel repetition of [4] $O(c/c_4)$ times to reduce the soundness to $1/\log^c n$ finishes the proof. ◀

4 Reduction from Linear Label Cover to 3LIN

In this section, we prove our main Theorem 1.6 for 3-LIN. Recall that Theorem 3.3 shows a randomized polynomial reduction from 3-SAT to GAP LINEAR LABEL COVER($1 - \log^c n, \log^c n$) for any constant $c > 0$, where the number of vertices as well as the number of labels are bounded by a polynomial. Therefore, the following theorem finishes the proof of Theorem 1.6. The main idea is to use Hadamard codes instead of long codes using the fact that the LABEL COVER instance is linear. A similar argument was used in [8].

► **Lemma 4.1.** *There is a polynomial time reduction from GAP LINEAR LABEL COVER($1 - \delta, s$) to GAP 3-LIN($1 - \delta, 1/2 + \sqrt{s}/2$), where the size of the 3-LIN instance is polynomial in the number of vertices and the size of label in the LABEL COVER instance.*

Proof. Let $G = (A, B, E), \Sigma_A, \Sigma_B, \{\pi_e\}_{e \in E}$ be an instance of GAP LINEAR LABEL COVER ($1 - \delta, s$). Moreover, since the label cover is linear, let the labels to left hand side vertices come from \mathbb{F}_2^ℓ and the right hand side vertices from \mathbb{F}_2^r , and the mapping on each edge is an affine mapping. Our reduction is described by the following test.

Test

- Consider an edge (u, v) . The labels $x \in \mathbb{F}_2^\ell, y \in \mathbb{F}_2^r$ corresponding to the vertices have to satisfy $x = Ay + b$.
- From the proof, we randomly sample the Hadamard code of x at location α , and that of y at locations β and $\beta + \gamma$, where $\gamma = A^T \cdot \alpha$.
- Check if $\langle \alpha, x \rangle + \langle \beta, y \rangle + \langle \beta + \gamma, y \rangle = \langle \alpha, b \rangle$

Completeness

In the completeness case, if the labels x, y satisfy the edge in the LINEAR LABEL COVER, then we can see that the test will pass.

$$\begin{aligned} & \langle \alpha, x \rangle + \langle \beta, y \rangle + \langle \beta + \gamma, y \rangle \\ &= \langle \alpha, Ay \rangle + \langle \alpha, b \rangle + \langle \beta, y \rangle + \langle \beta + \gamma, y \rangle \\ &= \langle \alpha, Ay \rangle + \langle \alpha, b \rangle + \langle A^T \alpha, y \rangle \\ &= \langle \alpha, b \rangle \end{aligned}$$

Therefore, if $1 - \delta$ edges are satisfiable in the linear LABEL COVER, at least $1 - \delta$ fraction of 3LIN constraints are satisfied.

Soundness

Consider the case where at most s fraction of edges can be satisfied for any labeling in the LINEAR LABEL COVER. Let the Hadamard code encoding function for the left vertices be L and right vertices be R . Consider their Fourier transforms,

$$L(\alpha) = \sum_x \hat{L}(x) \chi_x(\alpha)$$

$$R(\beta) = \sum_y \hat{R}(y) \chi_y(\beta)$$

Let's fix an edge, and analyze the probability that the test will accept. We switch to a $-1,+1$ notation for convenience.

$$\begin{aligned} \Pr[\text{Test accepts}] &= \Pr_{\alpha,\beta}[\langle \alpha, x \rangle + \langle \beta, y \rangle + \langle \beta + A^T \alpha, y \rangle + \langle \alpha, b \rangle = 0] \\ &= \Pr_{\alpha,\beta}[(-1)^{\langle \alpha, x \rangle + \langle \beta, y \rangle + \langle \beta + A^T \alpha, y \rangle + \langle \alpha, b \rangle} = 1] \\ &= \frac{1 + \mathbf{E}_{\alpha,\beta} [L(\alpha)R(\beta)R(\beta + A^T \alpha)(-1)^{\langle \alpha, b \rangle}]}{2} \end{aligned}$$

Consider the expectation on the right hand side of the above equation.

$$\begin{aligned} &\mathbf{E}_{\alpha,\beta} [L(\alpha)R(\beta)R(\beta + A^T \alpha)(-1)^{\langle \alpha, b \rangle}] \tag{3} \\ &\leq \sum_{x,y} \hat{L}(x)\hat{R}(y)^2 \mathbf{E}_{\alpha,\beta} [\chi_x(\alpha)\chi_y(\beta)\chi_z(\beta + A^T \alpha)(-1)^{\langle \alpha, b \rangle}] \\ &\leq \sum_{x,y,x=Ay+b} \hat{L}(x)\hat{R}(y)^2 \\ &\leq \sqrt{\sum_{x,y,x=Ay+b} \hat{R}(y)^2} \sqrt{\sum_{x,y,x=Ay+b} \hat{L}(x)^2 \hat{R}(y)^2} \end{aligned}$$

In the above equation, the first term is bounded by 1, and therefore,

$$(3) \leq \sqrt{\sum_{x,y,x=Ay+b} \hat{L}(x)^2 \hat{R}(y)^2}$$

Consider a random assignment where a left vertex gets a label x with probability $\hat{L}(x)^2$ and a right vertex gets a label y with probability $\hat{R}(y)^2$. The probability that such a random assignment would satisfy the edge, and therefore the expected fraction of edges satisfied, is exactly

$$\sum_{x,y,x=Ay+b} \hat{L}(x)^2 \hat{R}(y)^2$$

If at most s fraction of edges can be satisfied by any assignment, then

$$s \geq \sum_{x,y,x=Ay+b} \hat{L}(x)^2 \hat{R}(y)^2 \geq (2 \cdot \Pr[\text{Test accepts}] - 1)^2$$

or

$$\Pr[\text{Test accepts}] \leq \frac{1}{2} + \frac{\sqrt{s}}{2}$$

Therefore, the expected fraction of 3LIN constraints satisfied is at most $\frac{1}{2} + \frac{\sqrt{s}}{2}$. ◀

Abstract

In this paper we consider the k -server problem where events are generated by selfish agents, known as *the selfish k -server problem*. In this setting, there is a set of k servers located in some metric space. Selfish agents arrive in an online fashion, each has a request located on some point in the metric space, and seeks to serve his request with the server of minimum distance to the request. If agents choose to serve their request with the nearest server, this mimics the greedy algorithm which has an unbounded competitive ratio. We propose an algorithm that associates a surcharge with each server independently of the agent to arrive (and therefore, yields a truthful online mechanism). An agent chooses to serve his request with the server that minimizes the distance to the request *plus* the associated surcharge to the server.

This paper extends [9], which gave an optimal k -competitive dynamic pricing scheme for the selfish k -server problem on the line. We give a k -competitive dynamic pricing algorithm for the selfish k -server problem on tree metric spaces, which matches the optimal online (non truthful) algorithm. We show that an α -competitive dynamic pricing scheme exists on the tree if and only if there exists α -competitive online algorithm on the tree that is *lazy* and *monotone*. Given this characterization, the main technical difficulty is coming up with such an online algorithm.

1 Introduction

Online algorithms were designed to deal with cases where the input arrives piecemeal over time and consists of a sequence of events. Problems such as paging, online matching, online scheduling, etc., are all examples of such problems.

This paper, belongs to a thread of recent research where events are selfish and the goal is to set surcharges on the various decisions that can be made by the agent with some desirable goal in mind such as minimizing social cost, makespan, completion time, flow time, sum of completion times, etc. (See Section 1.1 for some examples.) The prices may change over time, but must be known to the selfish agent upon arrival so that the agent can make an informed decision. Truthfulness is immediate in such settings, the agent gets asked no questions and therefore cannot lie about anything. The agent simply takes the utility maximizing (disutility minimizing) option available.

Specifically, in the dynamic pricing scheme for the k -server problem that we consider, the mechanism sets a surcharge on each server *prior* to an arrival of the next request. The agent that issues the request greedily chooses the server which minimizes the distance between the server and request *plus* the surcharge for the server. Note that the mechanism may update the surcharge of the servers based on *past* requests.

This paper extends the dynamic pricing results obtained for the k -server problem in [9] and deals with servers on a tree rather than restricted to a line. Although the basic idea is the same: use dynamic pricing to “nudge” selfish agents to act as though they were under the control of a centralized online algorithm, the tree metric is much more challenging to deal with than the line.

We show that any α -competitive online algorithm on the tree that is simultaneously (i) *lazy*: moves at most one server and (ii) *monotone*: the set of points served by server (if non-empty) is contiguous and includes the server location, can be converted into a dynamic posted pricing scheme for the selfish k -server problem on the tree with a competitive ratio of α . These properties were defined and in fact proved for the line [9], but they extend naturally to trees; cf. Section 2.2 for formal definitions. Thus, the main challenge in this paper is to give a k -competitive k -server algorithm for the tree that is lazy and monotone.

In the work of Cohen et al. [9], the main idea for obtaining an algorithm with those properties on a line is to run a simulation of the Double Cover (DC) algorithm and serve each request (at point) r with a server that is adjacent to r (i.e., there are no intermediate servers on its path to r) and that can be matched to a simulated Double Cover server which serves r in a min cost matching. This maintains the competitive ratio and ensures laziness and monotonicity. Generalizing this idea to trees is not immediate. In particular, choosing an arbitrary server adjacent to the request which can also be matched to a simulated server in a min cost matching results in non-monotonicity, which cannot be priced. This means that one needs a deeper understanding of the tree topology in deciding which of the servers is to serve the request (We explain this in detail in Section 2.2).

1.1 Related Work

1.1.1 Dynamic Pricing Schemes and Online Mechanisms

Lavi and Nisan [18] initiated the study of competitive analysis of incentive compatible online auctions. In particular, they give an incentive compatible on-line auction for many identical items with a tight competitive ratio. They consider both revenue and social welfare targets.

Awerbuch, Azar, and Myerson [1] give a general scheme that produces posted prices for general combinatorial auctions, with a competitive ratio equal to the logarithm of the ratio between highest and lowest prices, times the underlying competitive ratio for the combinatorial auction.

Although not explicitly stated as a pricing scheme, [14] effectively gives a dynamic pricing scheme for 2 servers in any metric space. Dynamic pricing was used in the context of packets with values and deadlines [12] with the goal of maximizing social welfare. Dynamic subsidies were introduced in [6] in the context selfish agents and facility locations. In [9] selfish agent versions were introduced for metrical task systems [4], for the k -server problem [19] on the line, and for metrical matching [15] on the line, and appropriate dynamic pricing schemes were described for reducing social cost. Dynamic pricing for scheduling selfish agents on related machines to minimize makespan were studied in [11]. In [13] dynamic prices were used to give a good approximation to the maximal flow time. In [10] dynamic prices were used to approximate the sum of weighted completion times. Many problems and extensions remain open.

1.1.2 The k -server problem

The k -server problem was introduced by Manasse et al. [19] as a far reaching generalization of various online problems. The best-studied of those is the paging (caching) problem, which corresponds to k -server problem on a uniform metric space. Sleator and Tarjan [20] gave several k -competitive algorithms for paging and proved that this is the best possible ratio for any deterministic algorithm.

The famous *k -server conjecture* of Manasse et al. [19] hypothesizes that the k -server problem is no harder in other metric spaces, i.e., that k is the optimal ratio for deterministic algorithms in general metrics. A lower bound of k holds in any metric space of at least $k + 1$ points [19], and a nearly matching upper bound of $2k - 1$ was given for the Work Function Algorithm (WFA) by Koutsoupias and Papadimitriou [17], which remains the best known algorithm for general metrics. The conjecture has been settled (exactly) for several special metrics. In particular, Chrobak et al. [7] gave an elegant k -competitive algorithm for the line metric, called Double Coverage (DC), which was later extended and shown to be k -competitive for all tree metrics [8]. Additionally, Bartal and Koutsoupias have shown that WFA is k -competitive for the line, the star, and all metric spaces with $k + 2$ points [3].

Moreover, Bansal et al. [2] have recently shown that the exact competitive ratio of the DC algorithm, which we simulate by dynamic pricing scheme, when it uses k servers but the offline optimum uses only $h \leq k$ servers is $\frac{k(h+1)}{k+1}$. (For such setting, the general lower bound is $\frac{k}{k-h+1}$ [19], which is matched only for the special case of paging [20].)

Most results on the k -server problem can be found in the survey by Koutsoupias [16]. Due to our focus, we ignore the randomized variant, on which there is significant recent progress [5].

1.2 Roadmap to this Paper

The next section, Section 2 gives the model and sufficient condition to give of competitive pricing algorithms on trees. We show that any algorithm that is *lazy* and *monotone* can be used to derive a dynamic pricing scheme, and that a dynamic pricing scheme implies that such an algorithm must exist. Section 3 gives an algorithm that is clearly lazy and monotone, but it remains to show that all points on the tree are associated with some server, i.e., that the algorithm is well defined. This is shown in Section 4. In Section D (in the Appendix) we show that the algorithm of Section 3 can be implemented in polynomial time. The Appendix also contains full proofs of various claims.

2 The Model and Preliminaries

2.1 The Selfish k -server problem

In this problem, there is a set of k -servers located in some metric space defined by an undirected weighted tree $T = (V, E, w)$. A sequence of selfish requests $\sigma = \langle \sigma_1, \sigma_2, \dots \rangle$ arrives online, where each request is issued at some point in the metric space. Before an arrival of each request, a dynamic pricing scheme sets a surcharge (price) on each server, and the arriving request chooses to be served by the server s that minimizes the sum of the distance of s from the request and the surcharge on s ; the server s is then moved to the request. The dynamic pricing scheme's objective is to minimize the total distance moved by all servers.

Formally, given a request sequence $\sigma = \langle \sigma_1, \sigma_2, \dots, \sigma_T \rangle$, each of the requests must be served by one of the k servers, let $\ell = \langle \ell_1, \ell_2, \dots, \ell_T \rangle$ denote the *solution sequence*, where $\ell_i \in \{1, \dots, k\}$ is the index of the server which serves the i -th request. Define the *event prefix* $\sigma^{\prec t}$ to be the sequence of events up to but not including event t : $\sigma^{\prec t} = \langle \sigma_1, \sigma_2, \dots, \sigma_{t-1} \rangle$. The servers location after request t is: $s_i(\sigma^{\prec t+1}) = s_i(\sigma^{\prec t})$ for $i \neq \ell_t$ and $s_{\ell_t}(\sigma^{\prec t+1}) = \sigma_t$. Let $s_i(\sigma^{\prec 1})$ denote the initial server location.

The cost of serving σ by the solution sequence ℓ is

$$\text{COST}(\sigma, \ell) = \sum_{t=1}^T \text{dist}(\sigma_t, s_{\ell_t}(\sigma^{\prec t})).$$

In the selfish setting, the server that serves the request σ_t in step t is chosen so as to minimize the distance of σ_t to the server's current location *plus* the surcharge function $c: \sigma^{\prec t} \times \{1, \dots, k\} \mapsto \mathbb{R}^+$ (i.e., c depends only on past events). The chosen server is:

$$\ell_t^c \in \arg \min_i \text{dist}(\sigma_t, s_i(\sigma^{\prec t})) + c(\sigma^{\prec t}, i).$$

Let $\ell^c = \langle \ell_1^c, \dots, \ell_t^c \rangle$ be the (solution) sequence of server indices chosen by the selfish requests σ , and let $\ell^* = \langle \ell_1^*, \dots, \ell_t^* \rangle$ be the servers that minimize the total cost for σ . A pricing scheme c is α -competitive if for any σ :

$$\frac{\text{COST}(\sigma, \ell^c)}{\text{COST}(\sigma, \ell^*)} \leq \alpha.$$

2.2 A Sufficient Condition for Competitive Pricing Algorithms on trees

In this paper, we focus on tree metrics, where given a weighted tree $T = (V, E, w)$, we define a tree metric space to include the vertices of T along with all points along the edges of T (see Fig. 3a in Appendix A). Given two points $a, b \in T$, we denote by $\mathcal{P}[a, b]$ the [unique] path between a and b including both endpoints. We use $\text{dist}(a, b)$ to denote the distance between a and b defined by the metric. We also use $\mathcal{P}(a, b]$ to denote the path from a to b that is open at a and closed at b .

We avoid reasoning about prices by describing how any online algorithm of a certain form can be converted into a dynamic pricing scheme that nudges the [upcoming] selfish agent do exactly as the online algorithm.

We use the following two properties. We say that an online algorithm is

1. *lazy* if it moves at most one server.
2. *monotone* if a server i , located at s_i , serves a point p , then it also serves all the points along the path $\mathcal{P}[s_i, p]$.

The following lemma shows that any algorithm that satisfies the above properties can be translated into a dynamic pricing scheme with the same competitive ratio. We sketch the proof below for a “degenerate” case, and we defer the full proof to Appendix C.

► **Lemma 1.** *Given a lazy and monotone online algorithm for the k -server problem on tree metrics, with a competitive ratio of α , there is a dynamic pricing scheme for the k -server problem on tree metrics, with the same competitive ratio.*

Proof sketch. Just before the arrival of some request σ_t (and after serving $\sigma^{<t}$), every server s has an associated subtree T_s of points such that for every point $p \in T_s$ if the next request were made at p , then s would serve it; we say that s is *responsible* for T_s (breaking ties lexicographically in case multiple servers are at a request’s location). These subtrees partition the whole tree metric, i.e., they are disjoint and their union is the entire tree.

First, we set the price for servers for which $T_s = \emptyset$ at ∞ . Next, we observe that when setting the surcharges it is sufficient to consider just the endpoints of the subtrees. We say that two non-empty subtrees, T_s and $T_{s'}$, are *touching* at an endpoint p if there is no server s'' such that in the paths from s to p and from s' to p in T contain a point $q (\neq p) \in T_{s''}$. Note that there may be many mutually touching subtrees.

Consider a maximal collection of non-empty subtrees $T_{s_1}, T_{s_2}, \dots, T_{s_k}$, which pairwise touch at an endpoint p . (Clearly, p belongs to one of those subtrees.) The key observation is that a selfish agent requesting service at p must be indifferent between choosing any of the servers s_1, \dots, s_k . This induces a set of linear equations giving the difference in the surcharges, $c(s_i) - c(s_j)$,

$$\begin{aligned} \text{dist}(s_i, p) + c(s_i) &= \text{dist}(s_j, p) + c(s_j) \quad \text{for all } 1 \leq i < j \leq k \\ \Rightarrow c(s_i) - c(s_j) &= \text{dist}(s_j, p) - \text{dist}(s_i, p) \quad \text{for all } 1 \leq i < j \leq k. \end{aligned} \quad (1)$$

The relationship of subtrees “touching” can itself be described as a tree, so the equations above (1) can all be simultaneously satisfied. Any solution gives the prices we need. ◀

The above argument is incomplete, as when subtrees touch at tree vertices, or at a server’s location, the selfish request may deviate from the prescribed behavior of the algorithm. This issue can be treated easily by “nudging” the subtrees to avoid these phenomena. More on this in Appendix C.

How to find a lazy and monotone algorithm

Any non-lazy algorithm can be trivially transformed into a lazy algorithm simply by delaying the motion of a server that is not serving a request. However, this may result in a server serving a non-empty set of points that does not include its location, contradicting monotonicity. Rather than simply following the simulation, we do as in [9]¹, one may move any server matched to the simulated server in a min cost matching – this is guaranteed to preserve the competitive ratio. We show below that monotonicity can be preserved by choosing an appropriate matching. Given an online algorithm A and a set of requests $\bar{\sigma}$, let $\text{cost}(A, \bar{\sigma})$ be the cost of A for serving $\bar{\sigma}$.

► **Lemma 2** ([9], Lemma 4.3). *Let ON be an online algorithm, let $\text{on}_i^{<t}$ be the location of server i after ON serves requests $\sigma^{<t}$, and let LAZY be an algorithm that serves request σ_t by the server ℓ which is matched to σ_t in an arbitrary min-cost matching between $\{\text{on}_i^{<t+1}\}_{i \in [k]}$ and $\mathbf{s}^{<t}$, where the latter is a vector of locations of LAZY’s servers after serving $\sigma^{<t}$. Then $\text{cost}(\text{LAZY}, \sigma^{<t}) \leq \text{cost}(\text{ON}, \sigma^{<t})$ for every t .*

¹ Originally shown for the line, but the proof works for any metric space, which we show in Appendix B for completeness.

The above lemma suggests a natural approach to find an algorithm with the desired properties. The approach is to simulate an algorithm that does not satisfy these properties (in our case, the Double Cover algorithm discussed in Section 2.4), and whenever the simulated algorithm serves the request with one of its *simulated servers*, choose a *real server* that is matched to the simulated server in a min-cost matching. While this solution produces a lazy algorithm with the same competitive ratio, it is not a-priori clear *if such a server can be chosen in a way that results in a monotone algorithm*. We show that for the Double Cover algorithm, this can indeed be done.

2.3 Characterization of min-cost matching on trees

We now give a full characterization of min-cost matchings on trees. As mentioned, the matching between two sets of points P and Q ($|P| = |Q|$) in a tree metric T is more involved than in a line, as given a point $p \in P$, there can be multiple points in Q local to p that can be matched to p in a min-cost matching between P and Q . Figure 1 contains a simple example.

In order to characterize the min-cost matching we use the following definition to “cut” a tree T at point x to two trees: $T_x(p), \bar{T}_x(p)$, where $p \in T_x(p)$. Formally,

► **Definition 3.** *Given a tree T and two distinct points $p, x \in T$, let $T_x(p)$ be the subtree that contains p and does not contain x when splitting T into two subtrees at point x . Let $\bar{T}_x(p)$ be $T \setminus T_x(p)$.*

We define the lowest common ancestor of two points p and q in the tree when rooted at point r .

► **Definition 4.** *The **lowest common ancestor** of two points p, q with respect to a point r , as $\text{LCA}_r(p, q) = \text{argmax}_{x \in T} \{\text{dist}(x, r) : x \in \mathcal{P}(p, r) \cap \mathcal{P}(q, r)\}$.*

The following Lemma gives necessary and sufficient conditions for a point $p \in P$ to be matched to $q \in Q$ in some min cost matching.

► **Lemma 5.** *Let P and Q be two sets of points in T such that $|P| = |Q|$, and let $p \in P$ and $q \in Q$. Then there exists a min-cost matching $\mathcal{M} : P \rightarrow Q$ that matches p to q if and only if the following holds – when considering every point $x \neq q$ on the path from p to q , $|\bar{T}_x(q) \cap P| > |\bar{T}_x(q) \cap Q|$.*

The following structural lemma is used in our proofs (we defer both proofs to Appendix E).

► **Lemma 6.** *Let P, Q be two sets of points in T ($|P| = |Q|$). For points $q, r \in T$, let $T_r(q)$ be a sub-tree such that $|T_r(q) \cap P| > |T_r(q) \cap Q|$. Then there exists $p \in T_r(q) \cap P$ such that for all $x \in \mathcal{P}(p, r)$, $|\bar{T}_x(r) \cap P| > |\bar{T}_x(r) \cap Q|$.*

2.4 The Double Cover algorithm

In order to achieve an optimal deterministic bound, our surcharge algorithm simulates the Double Cover (DC) algorithm on trees [8]. In [8], the following was shown.

► **Theorem 7 ([8]).** *The Double Cover algorithm is k -competitive.*

The algorithm roughly works as follows: When a request is issued at some point r , move all the servers that “see” r (have no other server on the path to r) at the same speed until either (i) a server d is blocked by another server c that moves towards r , in which case d no longer “sees” r and will cease moving towards r (and all servers that see r will continue moving towards r), or (ii) a server d reached r ’s position, in which case, the servers stop moving, and d serves r .

We use the following notation throughout the paper. The locations of the Double Cover servers, $\text{dc}_i(\sigma^{\prec t}) \in M$, $i = 1, \dots, k$, determine the “area of responsibility” for every Double Cover server: should some request occur at point $p \in M$, there is at least one server i at $\text{dc}_i(\sigma^{\prec t})$ that will be used by the Double Cover algorithm to serve the request at p . If the time t and requests $\sigma^{\prec t} = \sigma_1, \dots, \sigma_{t-1}$ are fixed, we can simplify notation as follows:

$$\begin{aligned} s_i &= s_i(\sigma^{\prec t}), & i &= 1, \dots, k, \\ S &= \langle s_1, \dots, s_k \rangle \\ \text{dc}_i &= \text{dc}_i(\sigma^{\prec t}), \\ \text{DC} &= \langle \text{dc}_1, \dots, \text{dc}_k \rangle \\ \text{dc}_i(r) &= \text{dc}_i(\sigma^{\prec t} r) & r &\in T, \\ \text{DC}(r) &= \langle \text{dc}_1(r), \dots, \text{dc}_k(r) \rangle. \end{aligned}$$

In [9], we showed that for the line metric, exactly one of the two adjacent *real* servers to the request can be matched to the simulated server at the request (Lemma 4.2 in [9]). Moreover, if we use DC on the line as ON, serving the request σ_t using the adjacent real server that is matched to σ_t recovers monotonicity (Lemma 4.4 in [9]). For the case where the underlying metric is a tree, this is much more involved, as there can be multiple adjacent real servers that can be matched to σ_t in a min cost matching, and choosing the wrong one might result in a violation of monotonicity, as shown in Figure 1. In Section 3, we define a binary relation \succ_r on pairs of servers that can serve a request at point r such that if $i \succ_r j$, then server i cannot cause a monotonicity issue with respect to server j (more on that in the relevant section). Since \succ_r is a strict order (see Lemma 15), there exists a server that is maximal with respect to \succ_r , and using this server would not cause monotonicity issue.

The following property on the movement of the double cover servers on trees that is used to prove the correctness of our algorithm.

► **Lemma 8.** *For any DC server dc_i , and any point $r \in T$: If dc_i does not serve the request at r ($\text{dc}_i(r) \neq r$), then for any $p \notin T_r(\text{dc}_i)$ we have $\mathcal{P}[\text{dc}_i, \text{dc}_i(p)] \subseteq \mathcal{P}[\text{dc}_i, \text{dc}_i(r)]$.*

Proof. Consider the trail of a DC server moving in response to a request. Observe that every point along the trail was closer to the (former) location of the DC server than to the (former) location of any other DC server. That is:

$$\text{For all } \text{dc}_j, r \in T, \text{ for every } q \in \mathcal{P}[\text{dc}_j, \text{dc}_j(r)], \text{dist}(\text{dc}_j, q) < \text{dist}(\text{dc}_z, q) \text{ for all } z \neq j. \quad (2)$$

Let $\text{dc}_j(r, t)$ be the position of server j after a movement of at most t units for a request r , or the maximum movement the server can make if it is blocked before moving t unites. Let $t_j(r)$ be the distance traversed by dc_j for the request r , i.e., $t_j(r) = \text{dist}(\text{dc}_j, \text{dc}_j(r))$. Since $p \notin T_r(\text{dc}_i)$, the following holds:

$$\text{For all } \text{dc}_j \in T_r(\text{dc}_i), t' \leq t_j(r) : \mathcal{P}[\text{dc}_j, \text{dc}_j(p, t')] \subseteq \mathcal{P}[\text{dc}_j, \text{dc}_j(r, t')]. \quad (3)$$

We will prove that $t_i(p) \leq t_i(r)$ and by (3) the condition holds. Let b be the DC server that blocks i , i.e. $\text{dc}_b(r, t_i(r)) \in \mathcal{P}(\text{dc}_i(r, t_i(r)), r)$, and let $y = \text{dc}_b(r, t_i(r))$.

Case 1: $\text{dc}_b \in T_r(\text{dc}_i)$ and $t_b(p) \geq t_i(r)$. By (3), $\text{dc}_b(p, t_i(r)) = y \in \mathcal{P}(\text{dc}_i(p, t_i(r)), p)$, so dc_b block dc_i at $t_i(r)$ when the request is at p .

Case 2: $\text{dc}_b \in T_r(\text{dc}_i)$ and $t_b(p) < t_i(r)$. Let dc_ℓ the server which blocked dc_b , by (2) we have $\text{dc}_\ell(p, t_b(p)) \notin \mathcal{P}(\text{dc}_b, y)$. Hence, $\text{dc}_\ell(p, t_b(p)) \in \mathcal{P}(y, p) \subseteq \mathcal{P}(\text{dc}_i(p, t_b(p)), p)$ so dc_ℓ block dc_i at $t_b(p) < t_i(r)$ when the request is at p .

Let $x = \text{LCA}_p(r, \text{dc}_b)$ and $t_b^x = \text{dist}(t_b, x)$. Note that if $\text{dc}_b \notin T_r(\text{dc}_i)$ then $t_b^x \leq t_i(r)$.

Case 3: $dc_b \notin T_r(dc_i)$ and $t_b(p) \geq t_b^x$. Hence, $dc_b(p, t_b^x) = x$ and $x \in \mathcal{P}(r, p) \subseteq \mathcal{P}(dc_i(p, t_b^x), p)$ so dc_b blocks dc_i at $t_b^x \leq t_i(r)$ when the request is at p .

Case 4: $dc_b \notin T_r(dc_i)$ and $t_b(p) < t_b^x$. Let dc_ℓ the server which blocked dc_b . By (2), $dc_\ell(p, t_b(p)) \notin \mathcal{P}(dc_b, x)$ hence $dc_\ell(p, t_b(p)) \in \mathcal{P}(x, p) \subseteq \mathcal{P}(dc_i(p, t_b^x), p)$ so dc_ℓ blocks dc_i at $t_b(p) < t_i(r)$ when the request is at p . ◀

3 An Algorithm for Dynamic Pricing on Trees

We now present a lazy and monotone k -competitive algorithm. This is a “new” (optimal) algorithm for the k -server problem on trees. As mentioned, our goal is to find a region for each server, such that for any request in the region, there exists a min cost matching which matches the server to the dc server at the request (*after* the movement of the dc servers). Note that, for some requests more than one server can be matched to the request. Figure 1 contains a simple example. Moreover, the figure shows that the naïve approach that matches an arbitrary min-cost server to the DC server serving the request produces non-monotonicity. We need to select the real server to move more carefully – this is the purpose of the precedence relation, \succ_r .

Recall the the definition of a lowest common ancestor (LCA) (Definition 4). We now define the precedence relation that is used to determined which of the servers in the min-cost matching to the DC server that serves the request can be used to serve the request. Roughly speaking, a server i *precedes* server j with respect to point r ($i \succ_r j$) if, when inspecting the LCA of i and j with respect to point r , there is a DC server ℓ that comes from j 's subtree and leaves the LCA towards r . The intuition behind this definition is as follows. Suppose we choose j as the server that serves r (when j is in the min-cost matching to the DC server that serves r). If the request is at a point r' further away from r , DC server ℓ might not leave the LCA, preventing server j from being in a min-cost matching to the DC server that serves the request at r' , which might result in non-monotonicity. This situation is exactly the one depicted in Figure 1.

► **Definition 9.** We say that server $i \succ_r j$ (i has higher priority than j with respect to r) if (i) $LCA_r(s_i, s_j) \neq s_j$, and (ii) there exists some DC server ℓ such that:

$$LCA_r(s_i, s_j) \in \mathcal{P}[dc_\ell, dc_\ell(r)] \quad \text{and} \quad dc_\ell \in T_{LCA_r(s_i, s_j)}(s_j).$$

► **Definition 10.** We define

$$MC(r) = \{\ell : \exists \text{ min-cost matching } \mathcal{M} : \mathcal{S} \rightarrow DC(r) \text{ such that } \mathcal{M}(s_\ell) = r\}$$

to be the set of servers that can be matched to the DC server serving the next request located at r .

Accordingly, we define:

► **Definition 11.** A point $r \in T$ is ℓ -colorable for some server ℓ :

1. $\ell \in MC(r)$.
2. There is no server j such that $j \in MC(r)$ and $j \succ_r \ell$.

The intuition behind the above definition is that Property 1 ensures that the conditions for Lemma 2 hold and thus the algorithm is k -competitive. Finally, Property 2 ensures that the algorithm is monotone and well-defined, as we will show. See Figure 2 in Section A for illustrations of the various definitions made above.

■ **Algorithm 1** The Monotone Regions algorithm (see Fig. 3 in Appendix A) for illustration.

Input: A tree metric T , initial servers locations $\langle s_1(\emptyset), \dots, s_k(\emptyset) \rangle \in M^k$, and an online sequence of requests $\bar{\sigma} \in T^*$.

1. After serving $\sigma^{\prec t}$, before the current request σ_t is revealed:
 - a. Initialize the forest $F^0 \leftarrow T$
 - b. For $i = 1, \dots, k$:
 - i. $C_i \leftarrow \{p \in F^{i-1} : p \text{ is } i\text{-colorable}\}$
 # C_i is the set of points that are i -colorable in the current forest F^{i-1} .
 - ii. $R_i \leftarrow \{p \in C_i : \text{for all } q \in \mathcal{P}(p, s_i), q \in C_i\}$
 # R_i is the monotone region of C_i around the location of server i .
 - iii. $F^i \leftarrow F^{i-1} \setminus R_i$
 # F^i is the remaining forest after removing R_i .
2. Let σ_t be the current request, and let $\ell \in [k]$ be the server such that $\sigma_t \in R_\ell$
 - Serve σ_t with server ℓ
 - $\text{dc}_{t+1} \leftarrow \text{DC}(\text{dc}_t, \sigma_t)$

Our algorithm is described in Algorithm 1. We remark that it is not obviously poly-time. In particular, it may not be clear how R_i 's can be computed efficiently. However, we describe how to implement the algorithm in poly-time in Appendix D.

We say that our algorithm is *well defined* if for every sequence $\sigma^{\prec t}$, for every point $x \in T$, there exists a server i such that $x \in R_i$.

► **Theorem 12.** *There exists a dynamic pricing scheme for the selfish k -server problem on trees with an optimal competitive ratio of k .*

Proof. Assuming Algorithm 1 is lazy, monotone and well defined, it can be simulated by a pricing scheme by Lemma 1 and it is k -competitive by Lemma 2, because a point $r \in T$ is served by server ℓ only if r is in R_ℓ , and therefore r is ℓ -colorable, which implies $\ell \in \text{MC}(r)$. The algorithm laziness follows by definition and the monotonicity of the algorithm follows by step 1(b)ii of Algorithm 1, since the region contains only points p such that all other points on the path from p to the server are also in the region of the server². To conclude the proof, Lemma 13 below implies the algorithm is well-defined. ◀

4 Algorithm 1 is Well Defined

In this section, we show that Algorithm 1 is well defined, i.e. that every point in the tree would be in some server's region, concluding the proof of Theorem 12. To help the reader in following this section, various figures, depicting important lemmas of this section, are presented in Figure 4 of Section A.

► **Lemma 13** (Well-Defined Lemma). *For any sequence σ , Algorithm 1 is well-defined.*

² We note that C_i itself might not be continuous, and therefore, step 1(b)ii is needed in order to ensure monotonicity.

10:10 Dynamic Pricing of Servers on Trees

■ **Figure 1** In order to maintain double cover's (DC) competitive ratio, we want to serve each request with a real server that “sees” the request (has no intermediate real servers along the path to the request), and is matched to a DC server that serves the request in a min cost matching between the *real* servers and the *simulated* DC servers. Unfortunately, choosing an arbitrary real server that is matched to the DC server might violate monotonicity. In the figure above DC servers are depicted by squares, namely a, b, c , and real servers by circles, namely $1, 2, 3$. Figure I depicts the initial configuration. We consider two possible locations of the next request, r, p . If the next request is at r , depicted in Figure II, then after the DC servers move, server a which served the request can either be matched to the green(2) server (Figure IV), or to the blue(1) server (Figure V) in the min-cost matching. If one chooses to serve the request with the blue(1) server, then it violates monotonicity. This is since if the next request in the initial configuration is on p (Figure III) instead, then the unique min-cost matching matches the green(2) server to server b . Finally, note that in the initial configuration r is *not* blue(1) colorable. According to Definition 11, properties 1 and 2 hold for the blue(1) server, but property 3 does not since $(2) \in MC(r)$ and $(2) \succ_r (1)$ (DC server a traverses $LCA_r(1, 2)$ and “arrives” from the blue(1) server subtree).

We use the following observation:

► **Observation 14** (See Figure 4a). *From the definition, we observe that for every r, p, q in T ($r \neq p$):*

- (1) *For $q \in T_r(p)$, we have: $x \in T_r(p) \iff r \notin \mathcal{P}[x, q]$.*
- (2) *For $q \notin T_r(p)$, we have: $x \in T_r(p) \Rightarrow r \in \mathcal{P}[x, q]$.*

In order to prove Lemma 13, we first show that the relation \succ_r is a strict partial order.

► **Lemma 15.** *\succ_r is a strict partial order relation for every $r \in T$.*

Proof. In order to show that \succ_r is a strict partial order relation, we need to show it is irreflexive and transitive. (Note that these two properties imply asymmetry.) Since it is clear that \succ_r is irreflexive ($LCA_r(s_j, s_j) = s_j$ for every $r \in T$ and j), we show that it is transitive.

Assume that $i \succ_r j$ and $j \succ_r \ell$, we prove that $i \succ_r \ell$. Let $L_{i,j} = LCA_r(s_i, s_j)$ and $L_{j,\ell} = LCA_r(s_j, s_\ell)$ and $L_{i,\ell} = LCA_r(s_i, s_\ell)$. Let $dc_{i,j}$ and $dc_{j,\ell}$ be the respective dc servers which order the servers, i.e., $L_{i,j} \in \mathcal{P}[dc_{i,j}, dc_{i,j}(r)]$ and $dc_{i,j} \in T_{L_{i,j}}(s_j)$, and $L_{j,\ell} \in \mathcal{P}[dc_{j,\ell}, dc_{j,\ell}(r)]$ and $dc_{j,\ell} \in T_{L_{j,\ell}}(s_\ell)$.

Case 1. $L_{i,j} \in \mathcal{P}[L_{j,\ell}, r]$, hence $L_{i,\ell} = L_{i,j}$ and $T_{L_{i,j}}(s_j) = T_{L_{i,j}}(s_\ell)$, and therefore $L_{i,\ell} \in \mathcal{P}[dc_{i,j}, dc_{i,j}(r)]$ and $dc_{i,j} \in T_{L_{i,\ell}}(s_\ell)$. By Definition 9 $i \succ_r \ell$.

Case 2. $L_{j,\ell} \in \mathcal{P}[L_{i,j}, r]$, hence $L_{i,\ell} = L_{j,\ell}$ and therefore $L_{i,\ell} \in \mathcal{P}[dc_{j,\ell}, dc_{j,\ell}(r)]$ and $dc_{j,\ell} \in T_{L_{i,\ell}}(s_\ell)$. By Definition 9 $i \succ_r \ell$. ◀

This allows us to conclude that every point in the tree T is colorable by some server.

► **Corollary 16.** *For any $r \in T$, there exist j such that r is j -colorable.*

Proof. Consider a point $r \in T$. Recall that $\text{MC}(r)$ is the set of servers that can be matched to r in a min-cost matching between S and $\text{DC}(r)$. Since \succ_r is a strict order relation (by Lemma 15), there is a server $\ell \in \text{MC}(r)$ that is maximal with respect to \succ_r in $\text{MC}(r)$, i.e., such that for every server $j \in \text{MC}(r)$, $j \not\succeq_r \ell$. Hence, there is a server ℓ for which Properties 1 and 2 of ℓ -colorability hold. ◀

A subtree \tilde{T} is *fully-colorable* if for any point $p \in \tilde{T}$ there exists a server ℓ such that p is ℓ -colorable and $s_\ell \in \tilde{T}$. Since Algorithm 1 preserves monotonicity, it follows that a server would color points only in the subtree containing this server. Therefore, in order to prove that Algorithm 1 is well-defined we need to show that not only the original tree T is *fully-colorable* (Corollary 16), but also that every $\tilde{T} \in F^{i-1}$ is fully-colorable as well.

For the sake of proving this property (Corollary 22), we characterize properties of the min-cost matching $\text{MC}(p)$ and the relation \succ_p . First, we now show that for any server ℓ the region in which ℓ is in the min-cost matching is monotone.

► **Lemma 17** (See Figure 4b). *For any server ℓ and two points r, p in T such that $p \notin T_r(s_\ell)$, the following holds – if $\ell \in \text{MC}(p)$ then $\ell \in \text{MC}(r)$.*

Proof. We will show that for any point $x \in \mathcal{P}[s_\ell, r]$, if $\text{dc}_j(r) \in T_x(s_\ell)$ then $\text{dc}_j(p) \in T_x(s_\ell)$:

First, we observe that $\text{dc}_j(r) \neq r$ (dc_j does not serve request at r), since $r \notin T_x(s_\ell)$ and $\text{dc}_j(r) \in T_x(s_\ell)$. Then, we observe that $\text{dc}_j \in T_x(s_\ell)$, since $\mathcal{P}(\text{dc}_j(r), x) \subseteq \mathcal{P}(\text{dc}_j, x)$. By Lemma 8, we have $\mathcal{P}[\text{dc}_j, \text{dc}_j(p)] \subseteq \mathcal{P}[\text{dc}_j, \text{dc}_j(r)]$, since $x \notin \mathcal{P}(\text{dc}_j, \text{dc}_j(r))$ ($\text{dc}_j(r) \in T_x(s_\ell)$), we have $x \notin \mathcal{P}(\text{dc}_j, \text{dc}_j(p))$ and we have $\text{dc}_j(p) \in T_x(s_\ell)$.

We get that for every x in $\mathcal{P}[s_\ell, r]$, if $\text{dc}_j(r) \in T_x(s_\ell)$, then $\text{dc}_j(p) \in T_x(s_\ell)$, which implies $|T_x(s_\ell) \cap \text{dc}(p)| \geq |T_x(s_\ell) \cap \text{dc}(r)|$. Since $\ell \in \text{MC}(p)$, for any $x \in \mathcal{P}[s_\ell, r]$ we have $|T_x(s_\ell) \cap S| > |T_x(s_\ell) \cap \text{dc}(p)|$. Which together yields that the condition of Lemma 5 hold also for $\text{dc}(r)$, and therefore $\ell \in \text{MC}(r)$. ◀

Which yields the following lemma which will be used to prove Lemma 21.

► **Lemma 18** (See Figure 4c). *For any two servers b, ℓ and a point x in T such that $b \in \text{MC}(x)$ and $s_\ell \notin T_x(s_b)$ we have for any $p \in \mathcal{P}(s_b, x)$ that $\ell \notin \text{MC}(p)$.*

Proof. Assume towards a contradiction that there exists $p \in \mathcal{P}(s_b, x)$ such that $\ell \in \text{MC}(p)$. Consider a point $y \in \mathcal{P}(x, p)$ which isn't a tree vertex, and in which at most a single DC server will arrive if the request is issued at this point (there exists such a point due to the continuity of the metric space). According to Lemma 17, $\ell, b \in \text{MC}(y)$.

Therefore, by Lemma 6 we have:

$$\begin{aligned} |T_y(s_b) \cap \text{DC}(y)| &< |T_y(s_b) \cap S|, \text{ and} \\ |T_y(s_\ell) \cap \text{DC}(y)| &< |T_y(s_\ell) \cap S|. \end{aligned}$$

Since y is not a tree node, $T = T_y(s_\ell) \cup T_y(s_b) \cup \{y\}$. Moreover, there is at most one DC server at y (by y 's selection), so overall there are more real servers than DC servers, a contradiction. ◀

The following is an important property of the strict partial order \succ_r .

► **Lemma 19** (See Figure 4d). *For any two servers ℓ, j , a point r such that $s_j \in T_r(s_\ell)$, and any point $p \notin T_r(s_\ell)$: If $j \succ_p \ell$, then $j \succ_r \ell$.*

10:12 Dynamic Pricing of Servers on Trees

Proof. First, since $s_j \in T_r(s_\ell)$ then $\text{LCA}_r(s_\ell, s_j) \in T_r(s_\ell)$, therefore we have that $\text{LCA}_r(s_\ell, s_j) = \text{LCA}_p(s_\ell, s_j)$. Second, $j \succ_p \ell$ therefore there exists dc_i such that $\text{dc}_i \in T_{\text{LCA}_p(s_\ell, s_j)}(s_\ell)$, and $\text{LCA}_p(s_\ell, s_j) \in \mathcal{P}[\text{dc}_i, \text{dc}_i(p)]$. Clearly, if the request is on r and dc_i serves point r then $\text{LCA}_r(s_\ell, s_j) \in \mathcal{P}[\text{dc}_i, \text{dc}_i(r)]$. If dc_i does not serve point r , by Lemma 8 we have $\mathcal{P}[\text{dc}_i, \text{dc}_i(p)] \subseteq \mathcal{P}[\text{dc}_i, \text{dc}_i(r)]$, and again $\text{LCA}_r(s_\ell, s_j) \in \mathcal{P}[\text{dc}_i, \text{dc}_i(r)]$. In either case $\text{LCA}_r(s_\ell, s_j) \in \mathcal{P}[\text{dc}_i, \text{dc}_i(r)]$ and by Definition 9 we have $j \succ_r \ell$. \blacktriangleleft

We now prove the main technical lemma used in proving that the algorithm is monotone. The lemma roughly shows the following. Let $r \in T$ be some point that is ℓ colorable by some server ℓ , and let j be another server on the “same side” of ℓ with respect to r . Let p be a point on the other side of ℓ and j with respect to r . The lemma states that if p is j -colorable, then it is also ℓ -colorable (see Figure 4e for a visual depiction).

The significance of this lemma is the following – suppose r is a point that the algorithm decided should be served by some server ℓ (which obviously means r is ℓ -colorable). Since we want our algorithm to be monotone, this immediately disconnects all the points further away from r from the servers that are on the same side as ℓ with respect to r . This would be a problem if there was such a point p that can be served only by servers on the same side as ℓ , but not ℓ itself. The lemma basically shows this situation cannot happen.

► Lemma 20 (See Figure 4e). *For any two servers ℓ, j and two points r, p in T such that $s_j, s_\ell \in \bar{T}_r(p)$: If r is ℓ -colorable and p is j -colorable, then p is ℓ -colorable.*

Proof. Assume for contradiction that p is not ℓ -colorable. We consider the following cases

Case 1. $\ell \in \text{MC}(p)$. By the definition of ℓ -colorable, we have that there is a server i such that $i \in \text{MC}(p)$ and $i \succ_p \ell$. If $s_i \in \bar{T}_r(p)$, then by Lemma 17, $i \in \text{MC}(r)$, and by Lemma 19, $i \succ_r \ell$. Hence r is not ℓ -colorable, a contradiction. Otherwise, $s_i \in T_r(p)$. Let $x = \text{LCA}_p(s_\ell, s_i)$. Note that $r \in \mathcal{P}[s_\ell, p]$, $r \in \mathcal{P}[s_j, p]$ and $r \notin \mathcal{P}[s_i, p]$ by Observation 14. We get that $\mathcal{P}[s_i, p] \cap \mathcal{P}[s_\ell, p] = \mathcal{P}[s_i, p] \cap \mathcal{P}[r, p] = \mathcal{P}[s_i, p] \cap \mathcal{P}[s_j, p]$, hence $\text{LCA}_p(s_j, s_i) = \text{LCA}_p(s_\ell, s_i) = x$. In addition, $T_x(s_\ell) = T_x(r) = T_x(s_j)$, and since $i \succ_p \ell$ we get $i \succ_p j$ by Definition 9. Recall that, $i \in \text{MC}(p)$, therefore p not j -colorable, a contradiction.

Case 2. $\ell \notin \text{MC}(p)$. By Lemma 5, there exists a point x on the path from s_ℓ to p such that

$$|T_x(s_\ell) \cap \mathcal{S}| \leq |T_x(s_\ell) \cap \text{DC}(p)|. \quad (4)$$

Let x be the closest point to r for which (4) holds. Since $j \in \text{MC}(p)$, by Lemma 5, for every point y on the path from s_j to p , $|T_y(s_j) \cap \mathcal{S}| > |T_y(s_j) \cap \text{DC}(p)|$, and hence, $x \in \mathcal{P}[s_\ell, \text{LCA}(s_\ell, s_j)] \subseteq \mathcal{P}[s_\ell, r]$. Moreover, since r is ℓ -colorable, $\ell \in \text{MC}(r)$, so Lemma 5 implies that

$$|T_x(s_\ell) \cap \mathcal{S}| > |T_x(s_\ell) \cap \text{DC}(r)|. \quad (5)$$

Therefore, combining (4) and (5) yields $|T_x(s_\ell) \cap \text{DC}(r)| < |T_x(s_\ell) \cap \text{DC}(p)|$, and there must be a server dc_a such that $\text{dc}_a \in T_x(s_\ell)$ and $\text{dc}_a(r) \notin T_x(s_\ell) \Rightarrow x \in \mathcal{P}[\text{dc}_a, \text{dc}_a(r)]$. In addition, we have

$$|\bar{T}_x(r) \cap \mathcal{S}| > |\bar{T}_x(r) \cap \text{DC}(p)|, \quad (6)$$

since x is the closest point to p for which (4) holds. Combining (4) and (6) yields that in $\hat{T} = \bar{T}_x(r) \setminus T_x(s_\ell)$ we have $|\hat{T} \cap \mathcal{S}| > |\hat{T} \cap \text{DC}(p)|$. Notice that for every $b \neq a$ such that $\text{dc}_b \in \bar{T}_x(r)$, we have that $\text{dc}_b(r) \in \bar{T}_x(r)$ since only a single DC server can cross point x . Since $|\hat{T} \cap \text{DC}(p)| = |\hat{T} \cap \text{DC}|$, by Lemma 8, we get $|\hat{T} \cap \text{DC}(p)| = |\hat{T} \cap \text{DC}(r)|$. Therefore, $|\hat{T} \cap \mathcal{S}| > |\hat{T} \cap \text{DC}(r)|$, and Lemma 6 implies that there exists $s_i \in \hat{T}$ such that for all $z \in \mathcal{P}[s_i, x]$, we have

$$|T_z(s_i) \cap \mathcal{S}| > |T_z(s_\ell) \cap \text{DC}(r)|. \quad (7)$$

In addition, (7) holds also for $z \in (x, r)$ by (5), hence, $i \in \text{MC}(r)$. Moreover, since $x = \text{LCA}_r(s_i, s_\ell)$, $x \in \mathcal{P}[\text{dc}_a, \text{dc}_a(r)]$ and $\text{dc}_a \in T_x(s_\ell)$, we also have $i \succ_r \ell$, which combined with $i \in \text{MC}(r)$ is a contradiction to r being ℓ -colorable. ◀

The main lemma to show the property *fully-colorable* is the following:

► **Lemma 21.** *For a fully-colorable sub-tree \tilde{T} , let $r, p \in \tilde{T}$ be two points and ℓ a server in \tilde{T} such that $p \notin T_r(s_\ell)$. If we have that*

- *r is ℓ -colorable, and*
- *for all servers a such that $s_a \in \tilde{T}$ where p is a -colorable, we have $s_a \in T_r(s_\ell)$,*
then for any $x \in \mathcal{P}(r, p)$, x is ℓ -colorable.

Proof. First, by Lemma 20 we have that p is ℓ -colorable as well. Assume for the purpose of contradiction that it is not true, let $x \in \mathcal{P}(r, p)$ be the closet point to p such that x is not ℓ -colorable. Since \tilde{T} is fully-colorable, there exists a server b , such that $s_b \in \tilde{T}$ and x is b -colorable. Note that, if $s_b \in T_r(s_\ell)$, then $s_b, s_\ell \in \overline{T}_r(x)$, and since r is ℓ -colorable, by Lemma 20, x is ℓ colorable, a contradiction. Let $L = \text{LCA}_r(p, s_b)$

Case 1. One of the following two holds: (i) $x \notin \mathcal{P}(s_b, s_\ell)$, (ii) $x = L$. In this case, $s_b, s_\ell \in \overline{T}_x(p)$ and x is b -colorable. Therefore, by Lemma 20, p is b -colorable, a contradiction.

Case 2. $x \in \mathcal{P}(s_b, s_\ell)$, and $x \neq L$, which implies $s_\ell \notin T_x(s_b)$, and $b \in \text{MC}(x)$ (since x is b -colorable). Therefore, by Lemma 18, we have $\ell \notin \text{MC}(y)$ for any $y \in \mathcal{P}(s_b, x)$, however since $x \neq L$, there exist $z \in \mathcal{P}(x, s_b) \cap \mathcal{P}(x, p)$, on one hand z is ℓ -colorable (by our choice of x), on the other hand $\ell \notin \text{MC}(z)$ (since $z \in \mathcal{P}(s_b, x)$), a contradiction. ◀

The above lemma implies the following corollary, yielding that Algorithm 1 is well-defined.

► **Corollary 22.** *For a fully-colorable subtree \tilde{T} , and i a server such that $s_i \in \tilde{T}$, then for all subtrees $\hat{T} \in \tilde{T} \setminus R_i$ we have that \hat{T} is fully-colorable tree.*

Proof. Let p be the point in \hat{T} for which this does not hold, since \tilde{T} is fully-colorable, let j be the server such that $s_j \in \tilde{T}$ and p is j -colorable. Let $r = \text{argmin}_x \{\text{dist}(p, x) : x \in \mathcal{P}(s_i, p) \cap R_i\}$ be the closest point to p in R_i . Observe that $r \notin \mathcal{P}(s_j, s_i)$ since otherwise $\mathcal{P}(s_j, p) \subseteq \mathcal{P}(s_j, r) \cup \mathcal{P}(r, p)$, where $\mathcal{P}(s_j, r) \cap R_i = \emptyset$ and $\mathcal{P}(r, p) \cap R_i = \emptyset$. Therefore, $\mathcal{P}(s_j, p) \cap R_i = \emptyset$, and thus $s_j \in \hat{T}$, a contradiction. Hence, by Observation 14(1), $s_j \in T_r(s_i)$. Finally, By Lemma 21, the entire $\mathcal{P}(r, p)$ is i -colorable, a contradiction for $p \notin R_i$. ◀

Using this corollary, we can now prove the Well-Defined Lemma.

Proof of Well-Defined Lemma [Lemma 13]. In order for Algorithm 1 to be well-defined, each point in T should be in the R_ℓ region of some server ℓ . We will show that each subtree $\hat{T} \in F^i$ after iteration i in the run of the algorithm execution is fully-colorable. The initial tree, T is fully-colorable by Corollary 16. After each iteration i , every subtree in F^i is fully-colorable by Corollary 22 (Note that, R_i is a subregion of a single subtree of F^{i-1}). Therefore, eventually a sub-tree would contain a single server and it is fully-colored by this server, which yields that $F^k = \emptyset$ as needed. ◀

A Figures

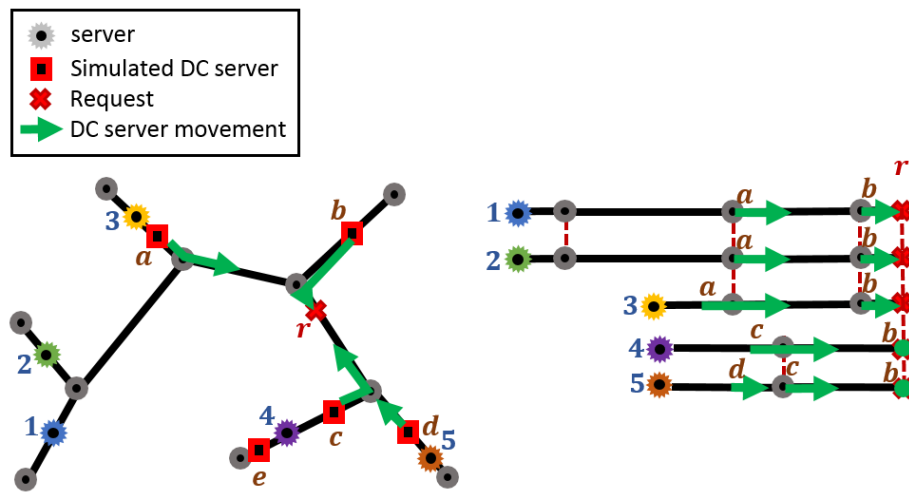

Figure 2 Servers and DC servers are denoted by numbers and letters respectively. Points on the tree are said to be colorable by some set of servers. Colorability of a point r is determined by simulating the double cover (DC) algorithm for a request at r . When DC processes a request, multiple DC servers move towards the request, and one or more arrive to serve it. Imagine a server were to look along the tree towards r when the DC servers were in motion in response to a request at r . Such a server may see a trail left by (at most one) DC server in motion towards r . Different servers may see trails of different DC servers. Two servers see the same trails beyond (above) their lowest common ancestor (when the tree is rooted at r) but for a DC server that traverses their lowest common ancestor, they may observe different trails. We say that server i has higher priority than server j with respect to r , if the trail of the DC server that traverses the lowest common ancestor of i and j is contained in the trail seen by server j (of the same DC server). On the left the movement of the DC servers relative to the real server positions is depicted. On the right, all paths from real servers to r are depicted, with dashed lines indicating vertices seen by more than one real server. In this example, $1 \succ_r 3$ since that trail that server 1 sees of DC server a is contained in the trail that server 3 sees of DC server a . Similarly, $2 \succ_r 3$ (because of a), $5 \succ_r 4$ (because of c), and $4, 5 \succ_r 1, 2, 3$ (because of b). Notice that \succ_r is not defined for all pairs of servers; For example, both $1 \not\succeq_r 2$ and $2 \not\succeq_r 1$. Subsequent to the motion of the DC servers, there are several min cost matching between real servers and DC servers. In one such matching server 1 is matched to server b , in another such min matching server 2 is matched to server b , in a third such min matching server 3 is matched to server b . Therefore, $\text{MC}(r) = \{1, 2, 3\}$. Since $1 \not\succeq_r 2$, $3 \not\succeq_r 2$, $2 \not\succeq_r 1$ and $3 \not\succeq_r 1$. We get that r is 1, 2-colorable. r is not 3-colorable since $1 \succ_r 3$.

■ **Figure 3** Key ingredients for Algorithm 1.

■ **Figure 4** A visual depiction of the lemmas used in order to prove the Well-Defined Lemma.

■ **Figure 5** Issues with the naïve pricing algorithm. In the example on the left, the range served by the blue server has the blue server on its left end. The open interval up to the blue server is served by the green server. By setting the surcharges as in the naïve algorithm, a selfish request (the next request) in the blue zone is indifferent between moving the green and blue servers, so we have no guarantee that selfish agents emulate the online algorithm. The figure on the right shows a similar problem where the green and blue regions touch, and, again, by setting the prices naïvely, selfish agents may choose to move either the green or the blue agent in response to a request. In both cases, a solution to this problem is to break the tie by “pushing” the boundary between the green and blue regions slightly “away” from the blue region. See Figure 6 for details.

B Proof of Lemma 2

Proof of Lemma 2. Given two sets of points P, Q such that $|P| = |Q|$, let $w(P, Q)$ be the weight of the min-cost matching between P and Q .

Let $\text{cost}_t(\text{LAZY})$ and $\text{cost}_t(\text{ON})$ be the respective cost of algorithms LAZY and ON when serving request σ_t . We show that for every t ,

$$\text{cost}_t(\text{LAZY}) + \Delta\Phi \leq \text{cost}_t(\text{ON}), \quad (8)$$

for a non-negative potential function $\Phi = w(\text{S}, \text{on})$, where S and on are the current locations of the servers of LAZY and ON respectively. To prove (8), it suffices to consider the moves of ON and LAZY independently, in this order.

Fix some min-cost matching $\mathcal{M} : \text{S} \rightarrow \text{on}$. We keep \mathcal{M} fixed as ON moves its servers. Clearly, when ON moves a server ℓ by distance d , the cost of \mathcal{M} does not increase by more than d . Hence, the same holds for the min-cost matching. Thus Φ increases by at most d , and (8) holds.

Once ON is done with its moves, we analyze the move of LAZY. Note that at this point $\sigma_t \in \text{on}$, i.e., ON has one of its servers at σ_t . Let \mathcal{M}' be the updated min-cost matching after ON moves, and let ℓ' be some server of LAZY that is matched to σ_t . Upon the move of ℓ' to σ_t , the cost of \mathcal{M}' is decreased by $\text{dist}(s_{\ell'}, \sigma_t)$. Since the cost of the min-cost matching after ℓ' moves is no bigger than that of \mathcal{M}' , Φ decreases by at least $\text{dist}(s_{\ell'}, \sigma_t)$ as well, which is exactly $\text{cost}_t(\text{LAZY})$. Therefore, $\text{cost}_t(\text{LAZY}) + \Delta\Phi \leq 0$, and (8) holds. \blacktriangleleft

C Full Argument for Lemma 1

The proof sketch of Lemma 1 shows that one can set surcharges where for the incoming agent there exists a server that minimizes the distance + surcharge *and* this is the same server that the algorithm would choose. Whenever this server can be matched (in a min cost matching) to the DC server that served the request, Lemma 2 implies that the competitive ratio achieved is optimal. This is enough for a truthful online algorithm with optimal competitive ratio if we can break ties for the agent. However, our goal is to let the agents break ties for themselves.

We first notice there are two scenarios where an agent can have more than one disutility minimizing server – (i) either the transition between the responsibility area of server j and adjacent server i is the location of server i (left side of Figure 5). In this case, setting prices using Equation (1) will result in both server i *and* server j being the disutility minimizing servers for the responsibility area of agent i . (ii) the responsibility area of agent i contains a tree vertex x from which starts the responsibility area of agent j (right side of Figure 5, i is blue and j is green). In this case, if a request is made in the responsibility area of agent i but on the other side of x than server i itself (i.e., in $\overline{T}_x(s_i)$), then both server i *and* server j are the disutility minimizing servers for this request.

To resolve this issue, we “nudge” the responsibility area of agent i slightly to the direction of the responsibility area of agent j by an exponentially decreasing tiny ϵ (see Figure 6). We inspect the proof of Lemma 2 to see why this does not change the competitive ratio. Since we do not necessarily use the server that minimizes the min cost matching at the nudged areas, Equation (8) does not hold if the request is in the nudged area. We notice though that this equation is violated by at most $k\epsilon$. To see this, we first move ON to the request. Using the same argument as in Lemma 2, we see that Equation (8) still holds after doing this.

We now move LAZY. Assume LAZY moves some server ℓ' . If the request would have been in the border between two responsibility areas before the nudge, then the cost of the min cost matching would have decreased by at least $\text{dist}(s_{\ell'}, \sigma_t)$ and this would have paid for the

■ **Figure 6** Modifying the regions for which the DC servers are responsible by pushing their boundaries away from real servers and tree vertices. This prevents indifference between different real servers except for isolated points. The boundaries are pushed by small amounts such that even their sum over all regions and all steps is arbitrarily small, thus having no effect on the competitive ratio. See Appendices B and C for the full argument, which uses a potential function.

cost of moving ℓ' . We notice that if the location of a request in DC moves by ϵ , the locations of all servers change by at most ϵ . Therefore, using the same matching in the nudged area as we would have used in the border before the nudge increases the cost of the min cost matching by at most $k\epsilon$. Hence, moving ℓ' decreases the cost of the min cost matching by at least $\text{dist}(s_{\ell'}, \sigma_t) - k\epsilon$, violating Equation (8) by at most $k\epsilon$.

As we can let ϵ exponentially decay (say by a factor of two at each step t), summing Equation (8) for all t 's yields that the cost of LAZY is at most $2k\epsilon$ larger than the cost of ON. As ϵ is arbitrarily small, so is the difference between LAZY and ON, which thus have the same competitive ratio.

D Implementation in Polynomial Time

Algorithm 1 as defined in Section 3 is continuous in the sense that every point is considered when deciding which set of points should be in the region R_i of some server i . In this section, we show that one can discretize the metric space in a way that only polynomially many points (in the number of servers and vertices of the tree) are considered when determining the regions of each server.

Consider a point $p \in T$, such that there exist $1 \leq i < j \leq k$ such that

$$\text{dc}_i(\sigma^{\prec t} \parallel p) = \text{dc}_j(\sigma^{\prec t} \parallel p)$$

(where \parallel denotes concatenation), then p is called a *boundary point*. That is, a boundary point is a point for which, if a request occurs in p , two DC servers will serve the request. Define the set of all boundary points for Double Cover just before event t arrives (see Fig. 3c in Appendix A):

$$B^{\prec t} = \{p \mid \exists 1 \leq i < j \leq k \text{ such that } \text{dc}_i(\sigma^{\prec t} \parallel p) = \text{dc}_j(\sigma^{\prec t} \parallel p)\}.$$

► **Definition 23.** Given a tree metric $T = (V, E, \text{dist})$, a set of requests $\sigma^{\prec t}$, and the current locations of the servers $S^{\prec t}$, we define the critical tree graph $T_c^{\prec t}$ by subdividing the edges of the tree (V, E) at all the server locations and boundary points, and retaining the distance function dist , see Fig. 3 in Appendix A. Formally:

10:20 Dynamic Pricing of Servers on Trees

- Define the vertex set of the critical tree graph $T_c^{\prec t}$ to be the set $V_c^{\prec t}$, the union of the following point sets on the tree metric
 - Vertices of the tree T .
 - Server locations $\{S_\ell^{\prec t}\}_{\ell=1,\dots,k}$.
 - The set of boundary points $B^{\prec t}$.
- The edge set of $T_c^{\prec t}$ is denoted by $E_c^{\prec t}$. There is an edge $(p, q) \in E_c^{\prec t}$ (where $p \in V_c^{\prec t}$ and $q \in V_c^{\prec t}$) if p and q lie along the same edge of T , and there is no intermediate point $r \in V_c^{\prec t}$ between them. The weight of the edge $(p, q) \in E_c^{\prec t}$ is the distance between p and q in the tree metric T .

The intuition behind the critical graph is that the vertices of the graph are exactly the points in the metric space where the sets of valid colors ($\{\ell : p \text{ is } \ell\text{-colorable}\}$) change.

► **Lemma 24.** *Let $e = \{v_1, v_2\}$ be some edge of $T_c^{\prec t}$, and let ℓ be some server such that $v_1 \in \mathcal{P}[s_\ell, v_2]$ and v_1 is ℓ -colorable. The edge e is ℓ -colorable iff there exists some point p along the edge, excluding the endpoints, such that $\ell \in \text{MC}(p)$.*

Proof. By definition, if e is ℓ -colorable, then for every p along the edge, p is ℓ -colorable, and therefore, $\ell \in \text{MC}(p)$.

Now assume that there exists some p along the edge e such that $\ell \in \text{MC}(p)$. Since there exists some min-cost matching such that s_ℓ is matched to the DC server that serves p , and since p cannot be a vertex of T , by Lemma 5,

$$|T_p(s_\ell) \cap \mathcal{S}| > |T_p(s_\ell) \cap \text{DC}(p)|. \quad (9)$$

Since there are no servers and no tree vertices along edge e , for every point $q \in \mathcal{P}[v_1, v_2] \setminus \{v_1, v_2\}$,

$$|T_q(s_\ell)| = |T_p(s_\ell)|. \quad (10)$$

For a given $q \in \mathcal{P}[v_1, v_2] \setminus \{v_1, v_2\}$ let

$$d_1(q) = |T_q(v_1) \cap \text{DC}(q)| (= |T_q(s_\ell) \cap \text{DC}(q)|)$$

be the set of DC servers in the subtree containing v_1 when splitting T at point q after serving a request at q . Let i be the index of the DC server that serves all the requests along the edge e , excluding its endpoints (there must be a unique such DC server since there are no boundary points along e). Notice that for every $j \neq i$, $\mathcal{P}[\text{dc}_j, \text{dc}_j(q)] \cap \mathcal{P}[v_1, v_2] \setminus \{v_1, v_2\} = \emptyset$. Otherwise, there would have been a point q along e which is closer to server j than server i , which implies the existence of a boundary point along e .

Since there are no tree vertices along e , we get that for every $q, q' \in \mathcal{P}[v_1, v_2] \setminus \{v_1, v_2\}$, $d_1(q) = d_1(q')$. Therefore, for every such point q ,

$$|T_q(s_\ell) \cap \text{DC}(q)| = d_1(q) = d_1(p) = |T_p(s_\ell) \cap \text{DC}(p)|. \quad (11)$$

Combining (9), (10) and (11) yields that for every $q \in \mathcal{P}[v_1, v_2] \setminus \{v_1, v_2\}$, $|T_q(s_\ell) \cap \mathcal{S}| > |T_q(s_\ell) \cap \text{DC}(q)|$. Therefore, $|\overline{T}_q(s_\ell) \cap \mathcal{S}| < |\overline{T}_q(s_\ell) \cap \text{DC}(q)|$, and there exists some point $q' \in \mathcal{P}[q, v_2]$ such that

$$|\overline{T}_{q'}(s_\ell) \cap \mathcal{S}| \leq |\overline{T}_{q'}(s_\ell) \cap \text{DC}(q)| \Rightarrow |\overline{T}_{q'}(q) \cap \mathcal{S}| \leq |\overline{T}_{q'}(q) \cap \text{DC}(q)|.$$

Since there are no servers in $\mathcal{P}[p, v_2]$ (there are no servers along every edge e of $T_c^{\prec t}$), for every server j such that $s_j \in T_q(v_2)$, q' is on the path from s_j to q , and by Lemma 5, $j \notin \text{MC}(q)$. By definition, this implies that for every point q along edge e , and every j such

that $s_j \in \overline{T}_{v_2}(q)$, q is not j -colorable. Since by Corollary 16 every point is colorable by some server, we get that for every q along e , q is ℓ' -colorable by some server ℓ' such that $s_{\ell'} \in \overline{T}_q(v_2) \Rightarrow s_{\ell'} \in \overline{T}_{v_1}(v_2)$. By Lemma 20, since v_1 is ℓ -colorable, we get that every q along the edge e is ℓ -colorable, which implies that e is ℓ -colorable, as desired. \blacktriangleleft

► **Lemma 25.** *Let e be some edge $\{v, v'\} \in E_c^{\prec t}$ such that $\text{color}(v) = j$ and $\text{color}(v') = j'$. There exists $i \in \{j, j'\}$ such that all points in $\mathcal{P}[v, v'] \setminus \{v, v'\}$ are i -colorable which can be determined by inspecting a single point in $\mathcal{P}[v, v'] \setminus \{v, v'\}$.*

Proof. consider some edge $e = \{v, v'\} \in E_c^{\prec t}$ such that $\text{color}(v) = j$ and $\text{color}(v') = j'$. Let p be a point between v and v' . By Corollary 16, it is colorable by some server ℓ . Since there are no servers along x , ℓ must be located either in $\overline{T}_v(p)$ or in $\overline{T}_{v'}(p)$. Assume without loss of generality that $\ell \in \overline{T}_v(p)$. By Lemma 20, p is j -colorable, which implies that $j \in \text{MC}(p)$. By Lemma 24, x is j -colorable. \blacktriangleleft

► **Lemma 26.** *Determining R_i at every iteration i in Step 1b of Algorithm 1 can be done in polynomial time.*

Proof. Consider the graph $T_c^{\prec t}$. This graph has at most $2k - 1 + |V|$ vertices – k servers, at most $k - 1$ boundary points, and $|V|$ original vertices. The boundary points can of course be computed in polynomial time. Consider iteration i of Step 1b of Algorithm 1. To determine R_i , one can start at s_i , which is obviously in R_i , and then expend R_i using any tree traversal algorithm (that runs in linear time) on $T_c^{\prec t}$. The traversal does not go further down the tree if the vertex/edge currently considered is not i -colorable.

To check if a point $r \in T$ is i -colorable can be done in poly-time: Computing $\text{MC}(r)$ can be done in poly-time using the characterization in Lemma 5. Therefore, property 1 can immediately be checked. For Property 2, one should consider each server $j \in \text{MC}(r)$, and check that $j \not\prec_r i$, which again can be done in poly-time.

From the above, it is clear that determining whether a vertex in $T_c^{\prec t}$ is i -colorable can be done in poly-time. As for an edge, by Lemma 25, checking whether the edge is i -colorable can be done by inspecting an arbitrary point in the edge, and checking whether this point is i -colorable, which again, can be done in poly-time. Therefore, the tree-traversal can be made in poly-time, and so does determining R_i . \blacktriangleleft

E Missing Proofs of Section 4

Proof of Lemma 5. \Leftarrow : Let $p \in P$ and $q \in Q$ be two points such that there exists a point $x \in \mathcal{P}(p, q)$ such that $|\overline{T}_x(q) \cap P| \leq |\overline{T}_x(q) \cap Q|$ and let $\mathcal{M} : P \rightarrow Q$ be a matching such that $\mathcal{M}(p) = q$. Since p is matched to a server in $T_x(q)$, $|\overline{T}_x(q) \cap P - \{p\}| < |\overline{T}_x(q) \cap Q|$, and there must be a server $\hat{p} \in T_x(q) \cap P$ that is matched to a server $\hat{q} \in \overline{T}_x(q) \cap Q$. Let $y = \text{LCA}_x(\hat{p}, q)$. Since \hat{p} and q are both in $T_x(q)$, $y \neq x$. Consider the matching \mathcal{M}' in which p is matched to \hat{q} , \hat{p} is matched to q , and for every $\tilde{p} \in P \setminus \{p, \hat{p}\}$, $\mathcal{M}'(\tilde{p}) = \mathcal{M}(\tilde{p})$. We have

$$\begin{aligned} \text{dist}(p, q) + \text{dist}(\hat{p}, \hat{q}) &= \text{dist}(p, x) + \text{dist}(x, y) + \text{dist}(y, q) + \\ &\quad \text{dist}(\hat{p}, y) + \text{dist}(y, x) + \text{dist}(x, \hat{q}) \\ &> \text{dist}(p, x) + \text{dist}(x, \hat{q}) + \text{dist}(\hat{p}, y) + \text{dist}(y, q) \\ &\geq \text{dist}(p, \hat{q}) + \text{dist}(\hat{p}, q), \end{aligned}$$

where that first equality is due to the fact that the path from x to y is contained in both the path from p to q and the path from \hat{q} to \hat{p} , the first strict inequality is due to dropping non-zero terms, and the last inequality follows from the triangle inequality. Therefore, \mathcal{M}' is a matching of a strictly smaller cost than that of \mathcal{M} , and \mathcal{M} cannot be a min-cost matching.

10:22 Dynamic Pricing of Servers on Trees

\Rightarrow : Assume that the condition holds for p, q , let \mathcal{M} be a matching. Let $x = \text{LCA}_q(p, \mathcal{M}(p))$.

Case 1. $x \neq q$, therefore $|\overline{T}_x(q) \cap P| > |\overline{T}_x(q) \cap Q|$. Hence, there exists $\hat{p} \in \overline{T}_x(q)$ s.t. $\mathcal{M}(\hat{p}) \notin \overline{T}_x(q)$. Let $\hat{q} = \mathcal{M}(\hat{p})$, and $q' = \mathcal{M}(p)$. Note that $\text{dist}(p, q') = \text{dist}(p, x) + \text{dist}(x, q')$ and $\text{dist}(\hat{p}, \hat{q}) = \text{dist}(\hat{p}, x) + \text{dist}(x, \hat{q})$. Consider the matching \mathcal{M}' in which p is matched to \hat{q} , \hat{p} is matched to q' , and for every $\tilde{p} \in P \setminus \{p, \hat{p}\}$, $\mathcal{M}'(\tilde{p}) = \mathcal{M}(\tilde{p})$.

$$\begin{aligned} \text{dist}(p, \hat{q}) + \text{dist}(\hat{p}, q') &\leq \text{dist}(p, x) + \text{dist}(x, \hat{q}) + \text{dist}(\hat{p}, x) + \text{dist}(x, q') \\ &= \text{dist}(p, q') + \text{dist}(\hat{p}, \hat{q}), \end{aligned}$$

where the inequality is by the triangle inequality. Therefore, \mathcal{M}' is also a min-cost matching. Let $x' = \text{LCA}_q(p, \mathcal{M}'(p))$ then $\text{dist}(p, x') > \text{dist}(p, x)$ since $x' \notin \overline{T}_x(q)$, therefore we can repeat this process until $x = q$ (**Case 2**).

Case 2. $x = q$, hence $\mathcal{P}(p, q) \subseteq \mathcal{P}(p, \mathcal{M}(p))$. Let $\hat{q} = \mathcal{M}(p)$ and let \hat{p} be such that $q = \mathcal{M}(\hat{p})$. Consider the matching \mathcal{M}' in which p is matched to q , \hat{p} is matched to \hat{q} , and for every $\tilde{p} \in P \setminus \{p, \hat{p}\}$, $\mathcal{M}'(\tilde{p}) = \mathcal{M}(\tilde{p})$.

$$\begin{aligned} \text{dist}(p, q) + \text{dist}(\hat{p}, \hat{q}) &= \text{dist}(p, \hat{q}) - \text{dist}(q, \hat{q}) + \text{dist}(\hat{p}, \hat{q}) \\ &\leq \text{dist}(p, \hat{q}) + \text{dist}(\hat{p}, q) \end{aligned}$$

where the last inequality is by the triangle inequality. Therefore, \mathcal{M}' is also min cost matching and $\mathcal{M}'(p) = q$ as needed. \blacktriangleleft

Proof of Lemma 6. Let v be the closest vertex to r in $T_r(q)$ (recall that $r \notin T_r(q)$, so $v \neq r$). If there exists $p \in \mathcal{P}[v, r) \cap P$, let $p \in \mathcal{P}[v, r) \cap P$ be the closest such point to r . In this case, the condition holds for p since for all $x \in \mathcal{P}(p, r)$, $\overline{T}_x(r) \cap P = T_r(q) \cap P$.

If there is no such p , then

$$|(\overline{T}_v(r) - \{v\}) \cap P| = |T_r(q) \cap P| > |T_r(q) \cap Q| \geq |(\overline{T}_v(r) - \{v\}) \cap Q|.$$

By the pigeonhole principle, there exists $v' \in \overline{T}_v(r)$ such that $|T_v(v') \cap P| > |T_v(v') \cap Q|$. Therefore, by repeating above process, we find $\hat{p} \in P \cap T_v(v')$ for which the condition holds for all $x \in \mathcal{P}(\hat{p}, v)$. Since the condition holds for every $x \in \mathcal{P}(v, r)$ (as $\overline{T}_x(r) \cap P = T_r(q) \cap P$), the lemma follows. \blacktriangleleft

Approximating the Norms of Graph Spanners

Eden Chlamtáč

Ben Gurion University of the Negev, Beersheva, Israel

Michael Dinitz

Johns Hopkins University, Baltimore, MD, USA

Thomas Robinson

Ben Gurion University of the Negev, Beersheva, Israel

Abstract

The ℓ_p -norm of the degree vector was recently introduced by [Chlamtáč, Dinitz, Robinson ICALP '19] as a new cost metric for graph spanners, as it interpolates between two traditional notions of cost (the sparsity ℓ_1 and the max degree ℓ_∞) and is well-motivated from applications. We study this from an approximation algorithms point of view, analyzing old algorithms and designing new algorithms for this new context, as well as providing hardness results. Our main results are for the ℓ_2 -norm and stretch 3, where we give a tight analysis of the greedy algorithm and a new algorithm specifically tailored to this setting which gives an improved approximation ratio.

1 Introduction

Graph spanners are subgraphs which approximately preserve distances: given a graph $G = (V, E)$ (possibly with lengths on the edges), a subgraph H of G is a t -spanner of G if $d_G(u, v) \leq d_H(u, v) \leq t \cdot d_G(u, v)$ for all $u, v \in V$, where d_G denotes shortest-path distances in G (and d_H in H). The value t is called the *stretch* of the spanner.

There have been two traditional ways of studying spanners. The first way is to study universal tradeoffs that can be achieved in all graphs between the stretch and some notion of the “cost” of a spanner, particularly the sparsity [2] or the weight [8]. The second is to study the optimization problem arising from fixing the stretch and trying to optimize the “cost” for the particular given graph. These two lines of work are highly complementary, and have proceeded in parallel. So there is now an extensive line of work on tradeoffs and approximation algorithms for sparsity (total number of edges) and, to a lesser extent, the maximum degree, which are two of the oldest and most well-studied notions of cost.

However, both of these objective functions have drawbacks. If we optimize the sparsity we might end up with a small number of very large degree nodes, which can be a problem for many applications (particularly in distributed systems where the degree is usually related to some notion of “load” on a node). On the other hand, if we try to minimize the maximum degree then we get the opposite problem. If it is unavoidable for there to be some node of large degree d , the maximum degree objective allows us to make every other vertex also of degree d , with no change in the objective function. Since the whole point of using spanners is to get a more compact representation of the graph, this is a significant issue.

In order to remedy these drawbacks, [10] recently proposed a new objective function: the ℓ_p norm of the degree vector. Given a spanner H , we can define $\|H\|_p$ to be the ℓ_p -norm of the n -dimensional vector in which the coordinate corresponding to a node v contains the degree of v in H . Then $\|H\|_1$ is just (twice) the total number of edges, and $\|H\|_\infty$ is precisely the maximum degree. Thus the ℓ_p -norm is an interpolation between these two classical objectives. Moreover, for $1 < p < \infty$, this notion of cost has the properties that we want: it encourages low-degree nodes rather than high-degree nodes, but if high-degree nodes are unavoidable it still encourages the rest of the nodes to be as low-degree as possible. These properties, of interpolating between the average and the maximum, are why the ℓ_p -norm has appeared as a popular objective for a variety of problems, ranging from clustering (the famous k -means problem [17, 19]), to scheduling [6, 5, 1], to covering [16].

The focus of [10] was on universal guarantees rather than approximation algorithms, although they made interesting and suggestive observations about approximation algorithms. In particular, they showed that for stretch 3 and the ℓ_2 -norm, the greedy algorithm performs better than would be expected from its behavior in ℓ_1 and ℓ_∞ (see Section 1.1 for more discussion). In this paper we focus on approximation algorithms, particularly for the special case pointed out by [10] – stretch 3 and the ℓ_2 -norm. We precisely characterize the performance of the greedy algorithm, showing that it does even better than was claimed in [10]. We then design a new algorithm which is specialized to this setting and which, when combined with the greedy algorithm, gives the best known approximation.

1.1 Background on ℓ_p -Norm Spanners

We will be concerned with the following problem.

► **Definition 1.** *In the MINIMUM ℓ_p -NORM t -SPANNER problem we are given an (unweighted) graph $G = (V, E)$ and are asked to find the t -spanner H of G which minimizes $\|H\|_p$.*

In this paper we will focus on MINIMUM ℓ_2 -NORM 3-SPANNER, although many of our techniques can be extended to other stretch values and ℓ_p norms.

Recall the classical greedy algorithm for finding t -spanners in undirected graphs: we add edges to the spanner as long as they do not close a cycle of length at most $t + 1$. In the weighted setting, edges are sorted by non-decreasing order of weight, and added as long as they are not already t -spanned. Here, we focus only on the unweighted setting.

In [10], the authors gave the following tight universal bounds on the ℓ_2 norm of a 3-spanner:

- **Theorem 2** ([10]). *Given an n -vertex connected unweighted undirected graph G :*
1. *There exists a 3-spanner H of G with $\|H\|_2 \leq \min\{O(n), \|G\|_2\}$, and the greedy algorithm returns such a spanner.*
 2. *Any 3-spanner H of G must satisfy $\|H\|_2 \geq \max\{\sqrt{n}, \tilde{\Omega}(\sqrt{\|G\|_2})\}$.*

This immediately implies the following approximation guarantees:

► **Corollary 3.** *Given an n -vertex unweighted graph G , the greedy algorithm gives an $O(\sqrt{n})$ -approximation for MINIMUM ℓ_2 -NORM 3-SPANNER.*

► **Corollary 4.** *Given an n -vertex unweighted graph G , the greedy algorithm gives an $\tilde{O}(n/\sqrt{\|G\|_2})$ -approximation for MINIMUM ℓ_2 -NORM 3-SPANNER.*

Corollary 3 is the strongest approximation guarantee, as a function of n , that follows from the universal bounds in Theorem 2. However, unlike in the ℓ_1 and ℓ_∞ case, the authors of [10] showed that such tight universal upper and lower bounds do not give a tight analysis of the approximation guarantee for ℓ_2 . In particular, the authors showed that the greedy algorithm actually gives a slightly better $O(n^{63/128})$ -approximation.

1.2 Our Results and Techniques

We begin in Section 2 by giving a new analysis of the greedy algorithm, improving on the $O(n^{63/128})$ bound from [10].

► **Theorem 5.** *Given an n -vertex unweighted graph G , the greedy algorithm gives an $\tilde{O}(n^{3/7})$ -approximation for MINIMUM ℓ_2 -NORM 3-SPANNER.*

We also show that this analysis is tight, i.e., there are graphs in which greedy is an $\tilde{\Omega}(n^{3/7})$ -approximation. Thus we resolve the question raised by [10] on the performance of the greedy algorithm for the ℓ_2 -norm and stretch 3.

Interestingly, despite the fact that greedy is purely combinatorial, we analyze it via a constant-size linear program: we show that the problem of finding the worst-case approximation ratio of the greedy algorithm reduces to solving a single LP. To do this, we decompose the input graph into a small collection of nearly-biregular subgraphs. For any such subgraph, this LP has variables describing degree and size parameters in the relevant portion of the greedy spanner and an optimal spanner (and thus has constant size). The objective function in the LP captures the ratio of the upper bound on the ℓ_2 -norm of a greedy spanner to an optimal spanner for any of these subgraphs. We find an optimal solution to this LP, thus giving a tight bound on the approximation ratio.

We then go beyond previously proposed algorithms to give a new algorithm which is specialized to the case of the ℓ_2 -norm and stretch 3. First we rewrite the standard flow-based LP for spanners (from [12]) to have an ℓ_p -norm objective, which leaves it as a convex (rather than linear) program which is polynomial-time solvable via Ellipsoid. We then give two new rounding algorithms, one of which is essentially the algorithm used in [9] for the ℓ_∞ -norm objective, but with different parameters and a different objective, and thus a different analysis. Our second new algorithm draws independent random values for every edge and vertex in the graph, and includes an edge e if these values satisfy one of three conditions relating to the solution of the convex relaxation. Similar ideas have been used for stretch 3 and 4 with the ℓ_1 -objective [12, 7, 13], but this is the first algorithm (to the best of our knowledge) which combines vertex and edge random sampling.

While it is common to trade off two different algorithms at the parameter setting where they have the same approximation ratio (e.g., as was done in the ℓ_1 -objective for spanners [12, 7]), this is not what we do. Instead, the most important question is *correctness*: we carefully parameterize these algorithms so that every edge is spanned in the combined algorithm. Proving that this combined algorithm does yield a 3-spanner, and analyzing its approximation ratio, is surprisingly complex and takes up the bulk of this paper. In the end, we prove the following theorem.

► **Theorem 6.** *There is a polynomial-time algorithm for MINIMUM ℓ_2 -NORM 3-SPANNER with approximation ratio $\tilde{O}(\|G\|_2^{5/16})$.*

Finally, trading our new algorithm off with the greedy guarantee of Corollary 4, we immediately get our strongest approximation guarantee as a function of n :

► **Corollary 7.** *Trying both the algorithm of Theorem 6 and the greedy algorithm and returning the better of the two gives an $\tilde{O}(n^{5/13})$ -approximation.*

In light of all of these upper bound results, a natural question is whether MINIMUM ℓ_2 -NORM 3-SPANNER is also hard to approximate. This is also important because strong hardness results are known for both the ℓ_1 and ℓ_∞ norms. Strong hardness of approximation for the ℓ_1 -norm in directed graphs has been known since [18, 15] (where strong means

11:4 Approximating the Norms of Graph Spanners

the same hardness that is known for the famous LABEL COVER problem, i.e., hard to approximate better than $2^{\log^{1-\epsilon} n}$ for arbitrarily small constant ϵ), and this was recently extended to undirected graphs by [11] by proving hardness for instances of LABEL COVER with some extra structure. For the ℓ_∞ -norm objective, the techniques of [18, 15, 11] were significantly extended in both the directed and undirected settings by [9] in order to prove similar hardness bounds.

It is not hard to see that if we attempt to use the hardness results for ℓ_1 or ℓ_∞ as a “black box” then we will not be able to prove anything useful, simply because the hardness results are subpolynomial (with respect to n) and thus changing the norm loses the entire hardness. In fact, the hardness reduction used in the ℓ_1 case [11] does not seem to work for the ℓ_2 -norm, since it relies on adding many low-degree nodes to amplify the hardness. On the other hand, we show that if we use the ℓ_∞ hardness reduction of [9] (with slightly different parameters), which amplifies hardness by adding a small number of high-degree nodes, we can prove a similar hardness bound.

► **Theorem 8.** *Unless $\text{NP} \subseteq \text{BPTIME}(2^{\text{polylog}(n)})$, for any constant $\epsilon > 0$ there is no polynomial-time algorithm that can approximate MINIMUM ℓ_2 -NORM 3-SPANNER better than $2^{\log^{1-\epsilon} n}$.*

At a very high level, this is obtained by re-analyzing the reduction of [9] more carefully. In [9], since they cared only about the maximum degree, it was not necessary to analyze the (many) nodes with smaller degrees. Moreover, some of the key arguments in [9] are false in the context of the ℓ_2 -norm: there is an argument that we can change the optimal solution to be “canonical” without affecting the ℓ_∞ norm, but in the ℓ_2 -norm there is an effect. So we need to instantiate the reduction with different parameters, perform a more detailed analysis, and replace some key steps with more refined arguments. This all significantly complicates the analysis. Since our main focus is on algorithms rather than hardness, we defer the proof to Appendix A.

2 Greedy

Here, we improve over the the analysis in [10] and give a nearly tight (up to polylogarithmic factors) analysis of the greedy algorithm. We give only a high-level overview here, and defer many of the details to the full version of the paper. We show the following:

► **Theorem 9.** *Given an n -vertex unweighted graph G , the greedy algorithm gives an $\tilde{O}(n^{3/7})$ -approximation for the minimum ℓ_2 -norm 3-spanner.*

This can be seen to be tight by considering the following graph: Let T be a tree of depth 3, where the root has $n^{4/7}$ children, all level 1 nodes have $n^{2/7}$ children, and all level 2 nodes have $n^{1/7}$ children (so the number of leaves is n). Now let G be the graph created by taking T and adding an edge between the root and every leaf. Clearly, T is a 3-spanner of G with $\|T\|_2 = O(n^{4/7})$. However, the greedy algorithm could start by taking all the edges from the root to the leaves of T , right away creating a subgraph with ℓ_2 -norm at least n .

Our analysis will decompose the graph into a small number of well structured subgraphs, and analyze the behavior of the greedy algorithm on each part. The condition on each subgraph is the following.

► **Definition 10.** *We say a graph (L, R, E) with vertex set $L \cup R$ is nearly bi-regular if there exist integers d_L, d_R such that every vertex $u \in L$ has $|\Gamma(u) \cap R| \in [d_L/6, d_L]$ and every vertex $v \in R$ has $|\Gamma(v) \cap L| \in [d_R/(6 \log |R|), d_R]$.*

We use standard regularization techniques to give the following decomposition (the proof is deferred to the full version).

► **Lemma 11.** *Given an undirected graph $G = (V, E)$ with $|V| = n$, there exist $O(\log^3 n)$ subgraphs $H_i = (L_i, R_i, E_i)$ of G such that the edge sets $\{E_i\}$ are a partition of E , and each H_i is nearly bi-regular.*

To analyze the performance of the greedy algorithm on each subgraph in the above partition, we use a specific constant size linear program, similar to the linear program used for the universal lower bound in [10], but with a different objective function: finding the worst-case ratio between the ℓ_2 -norm of the greedy algorithm and an optimal spanner. The linear program assumes that an optimal set of paths of length ≤ 3 that span the edges of any biregular graph H_i has a fairly regular structure. In particular, it assumes that the union of such an extremal set of paths is a four layered graph such that the subgraph induced on every two subsequent layers is bipartite and biregular. Such a graph can be succinctly described by the cardinalities of the different layers and the degrees of the bipartite graphs connecting every two consecutive layers. A pruning argument shows that this assumption is without loss of generality, up to a polylogarithmic factor in the ℓ_2 norm.

We solve this linear program and show that the example graph described after Theorem 5 gives a feasible solution with value $n^{3/7}$, for which there is a dual solution giving the complementary bound. This linear program, its optimal solution, and its connection to the performance of the greedy algorithm are all given in the full version. Here we only mention the conclusion:

► **Lemma 12.** *Let H be an N -vertex nearly bi-regular graph, and let P be a graph (not necessarily a subgraph) which spans every edge in E by a path of length at most 3. Then we have $\min\{N, \|H\|_2\} / \|P\|_2 = \tilde{O}(N^{3/7})$.*

We can now prove our main theorem for this section.

Proof of Theorem 9. Let $\{H_i\}$ be the partition of G into $O(\log^3 n)$ subgraphs given in Lemma 11, and let N_i be the number of vertices in H_i . If H is a spanner returned by the greedy algorithm, we know by Theorem 2 that for each i , we have $\|H \cap H_i\|_2 = \min\{O(N_i), \|H_i\|_2\}$. Choose an i_0 that maximizes this expression. Then we have $\|H\|_2 \leq \sum_i \|H \cap H_i\|_2 = O(\log^3 n) \cdot \min\{N_{i_0}, \|H_{i_0}\|_2\}$.

On the other hand, letting P be an optimal 3-spanner of G , we know in particular that P spans the edges in H_{i_0} . And so our approximation ratio is bounded by

$$\begin{aligned} \frac{\|H\|_2}{\|P\|_2} &\leq \frac{O(\log^3 n) \min\{N_{i_0}, \|H_{i_0}\|_2\}}{\|P\|_2} \\ &= \tilde{O}(N_{i_0}^{3/7}) && \text{by Lemma 12} \\ &= \tilde{O}(n^{3/7}). \end{aligned}$$

3 LP-Based Rounding

We now turn to algorithms based on rounding LP relaxations. In particular, we analyze the performance of the linear programming relaxation (though with a different objective function) suggested by [12, 9] for MINIMUM ℓ_1 3-SPANNER and MINIMUM ℓ_∞ 3-SPANNER, respectively. Focusing on ℓ_2 , we consider the following convex program, noting that it is only the objective function which is nonlinear:

$$\begin{aligned}
 \min \quad & \left(\sum_{v \in V} \left(\sum_{e \sim v} x_e \right)^2 \right)^{1/2} \\
 \text{s.t.} \quad & \sum_{p: u \rightsquigarrow v, |p| \leq 3} y_p = 1 & \forall (u, v) \in E & (1) \\
 & x_e \geq \sum_{\substack{p: u \rightsquigarrow v, |p| \leq 3 \\ p \ni e}} y_p & \forall (u, v), e \in E & (2) \\
 & x_e, y_p \geq 0 & \forall e, p & (3)
 \end{aligned}$$

While the objective function is not linear, it is convex, and so this LP can be efficiently solved by standard techniques (e.g., the Ellipsoid Method). Let us briefly see why this is a relaxation. In the intended (integral) solution, for every edge $e \in E$, x_e is an indicator for whether e appears in our spanner. Thus the objective function describes the ℓ_2 norm of our spanner. Furthermore, for every edge (u, v) we can pick a unique path p of length at most 3 between u and v in our spanner, and set $y_p = 1$, while setting $y_{p'} = 0$ for every other path p' between u and v . This is clearly a feasible solution.

3.1 Independent Edge Sampling

Given an optimum solution to the linear program, consider the following simple rounding algorithm, which slightly generalizes the rounding suggested in [9], parametrized by a constant $\alpha \in (0, 1)$:

Edge-Round(α): Independently add each edge $e \in E$ to the spanner with probability x_e^α .

One part of our rounding algorithm will use this rounding for a specific value of α , though it will not necessarily return a spanner. We would like to bound the ℓ_2 norm of the subgraph returned by this algorithm. For our analysis of this and other rounding algorithms, we will need the following standard Chernoff bound (cf. [14], Theorem 1.1):

► **Theorem 13.** *Let $X = \sum_{i=1}^n X_i$, where X_i are independently distributed in $[0, 1]$. Then for all $t > 2e\mathbb{E}[X]$, we have $\text{Prob}[X > t] \leq 2^{-t}$.*

We have the following bound on the ℓ_p -norm of the subgraph returned by Algorithm Edge-Round:

► **Lemma 14.** *Let H be the output of Edge-Round(α). Then with probability at least $1 - 2^{\log n - \log^2 n}$, we have $\|H\|_2 \leq \log^2(n) \|G\|_2^{1-\alpha} \text{LP}^\alpha$.*

Proof. First note that for every vertex $v \in V$ the expected degree of v in H is

$$\mathbb{E}[d_H(v)] = \sum_{e \sim v} x_e^\alpha \geq 1,$$

where the inequality follows since the x_e 's support a flow of 1 from v to any neighbor. Thus, by Theorem 13, and taking a union bound over all vertices, we have that with probability at least $1 - n2^{-\log^2 n}$ all vertices $v \in V$ satisfy

$$\begin{aligned}
 \mathbb{E}[d_H(v)] & \leq \log^2 n \cdot \sum_{e \sim v} x_e^\alpha \\
 & \leq \log^2 n \cdot d_G(v)^{1-\alpha} \left(\sum_{e \sim v} x_e \right)^\alpha. & \text{(by Hölder's inequality)}
 \end{aligned}$$

Thus if we define vectors f, g as $f_v = d_G(v)^{2(1-\alpha)}$ and $g_v = (d_{\text{LP}}(v))^{2\alpha}$, then we get

$$\begin{aligned}
\|H\|_2^2 &\leq \log^4 n \sum_{v \in V} d_G(v)^{2(1-\alpha)} (d_{\text{LP}}(v))^{2\alpha} \\
&= \log^4 n f \cdot g \\
&\leq \log^4 n \|f\|_{1/(1-\alpha)} \|g\|_{1/\alpha} && \text{(by Hölder's inequality)} \\
&= \log^4 n \left(\sum_{v \in V} d_G(v)^2 \right)^{1-\alpha} \left(\sum_{v \in V} (d_{\text{LP}}(v))^2 \right)^\alpha \\
&= \log^4 n \|G\|_2^{2(1-\alpha)} \text{LP}^{2\alpha} \quad \blacktriangleleft
\end{aligned}$$

The above lemma on its own does not give a clear approximation guarantee. However, when combined with the known lower bounds on OPT, we can get the following bound:¹

► **Lemma 15.** *Let H be the output of Edge-Round(α). Then with probability at least $1 - 2^{\log n - \log^2 n}$, we have $\|H\|_2 = \tilde{O}\left(\|G\|_2^{(1-\alpha)/2}\right) \cdot \text{OPT}$.*

Proof. With the stated probability, by Lemma 14 we have

$$\begin{aligned}
\|H\|_2 &\leq \log^2 n \|G\|_2^{1-\alpha} \text{LP}^\alpha \leq \log^2 n \|G\|_2^{1-\alpha} \text{OPT}^\alpha = \log^2 n \left(\frac{\|G\|_2}{\text{OPT}} \right)^{1-\alpha} \cdot \text{OPT} \\
&\leq \log^2 n \left(\frac{\|G\|_2}{\tilde{\Omega}(\sqrt{\|G\|_2})} \right)^{1-\alpha} \cdot \text{OPT},
\end{aligned}$$

where the final inequality is from the lower bound in Theorem 2, which proves the lemma. ◀

3.2 A New Rounding Algorithm

We now present a new rounding algorithm for the same linear programming relaxation, which we have designed specifically for the ℓ_2 -norm, and which gives our best approximation guarantee (when traded off with the greedy algorithm).

In fact, we will round our LP solution by trying two different algorithms, and returning the union of the edge sets returned by the two algorithms. We will show that every edge will be spanned by at least one of the two algorithms with high probability. Our first algorithm is simply Edge-Round(3/7).

■ **Algorithm 1** Edge-Round(3/7).

-
- Independently add each edge $e \in E$ to the spanner with probability $x_e^{3/7}$.
-

Lemma 15 directly implies that with high probability this algorithm returns a subgraph with ℓ_2 norm at most $\text{OPT} \cdot \tilde{O}(\|G\|_2^{2/7})$, which is even better than our final guarantee (see Lemma 17). However, it is not guaranteed to return a valid spanner.

Our second algorithm takes a different approach. We balance the need in our objective function for both few edges overall and low degrees for individual vertices by simultaneously limiting which vertices can buy edges and what edges they can buy.

¹ In [9], it was shown that this algorithm gives a 3-spanner for $\alpha = 1/3$, which already gives an $\tilde{O}(\|G\|_2^{1/3})$ -approximation via Lemma 15. However, this is weaker than our final $\tilde{O}(\|G\|_2^{5/16})$ guarantee.

Algorithm 2 Edge/Vertex Sampling.

- For every vertex $v \in V$, and for every edge $e \in E$, independently sample uniformly random variables $z_v^- \in_R [0, 1]$, $z_v^+ \in_R [0, 1]$, and $z_e \in_R [0, 1]$.
 - For every edge $e = (u, v) \in E$, add e to the spanner if at least one of the following three conditions holds:
 1. $z_e \leq x_e^{1/4}$ and $z_v^- \leq x_e^{1/4}$.
 2. $z_u^- \leq x_e^{1/4}$ and $z_v^+ \leq x_e^{1/4}$.
 3. $z_u^+ \leq x_e^{1/4}$ and $z_e \leq x_e^{1/4}$.
-

► **Remark 16.** The algorithm is formulated for directed graphs. If the graph is undirected, run the algorithm on the directed graph where every original edge is considered with both possible orientations.

Both showing that these algorithms give a good approximation, and showing that together they give a valid 3-spanner, requires a technically involved argument. We separate these two arguments in the next two subsections.

In Section 3.2.2, we will show that every edge has a probability of $\Omega(1/\text{polylog} n)$ of being spanned by at least one of the two algorithms. Thus, the complete algorithm will be

- For some constant $c > 0$, run both Algorithm 1 and Algorithm 2 $O(\log^c n)$ times, and output the union of all the edges chosen by either algorithm over the various iterations.

Thus, for an approximation guarantee of $\tilde{O}(f)$, it suffices to show that the probability that either algorithm returns a subgraph with ℓ_2 norm greater than $\tilde{O}(\text{OPT} \cdot f)$ is at most $O(1/\log^c n)$ for some sufficiently large constant $c > 0$. This approximation guarantee (for $f = \|G\|_2^{5/16}$) is given in Section 3.2.1.

3.2.1 Approximation guarantee

As mentioned earlier, Lemma 15 implies that Algorithm 1 returns a subgraph with ℓ_2 norm at most $\text{OPT} \cdot \tilde{O}(\|G\|_2^{2/7})$ with probability at least $1 - 2^{-(1-o(1)) \log^2 n}$. This is in fact better than our final approximation guarantee, so we will focus now on Algorithm 2.

We give the following upper bound on the ℓ_2 norm of the subgraph given by Algorithm 2.

► **Lemma 17.** *For any $b = b(n) > 1$, Algorithm 2 outputs a graph with ℓ_2 norm at most $\text{OPT} \cdot \tilde{O}(b^{1/2} \|G\|_2^{5/16})$ with probability at least $1 - \exp(-\Omega(\log^2 n)) - 1/b$.*

Proof. We will bound the contribution to the ℓ_2 norm of every kind of edge added by the algorithm. In particular, we define the three corresponding edge sets

$$\begin{aligned} E_1 &= \left\{ (u, v) \in E \mid z_{(u,v)} \leq x_{(u,v)}^{1/4}, z_v^- \leq x_{(u,v)}^{1/4} \right\} \\ E_2 &= \left\{ (u, v) \in E \mid z_u^- \leq x_{(u,v)}^{1/4}, z_v^+ \leq x_{(u,v)}^{1/4} \right\} \\ E_3 &= \left\{ (u, v) \in E \mid z_u^+ \leq x_{(u,v)}^{1/4}, z_{(u,v)} \leq x_{(u,v)}^{1/4} \right\} \end{aligned}$$

Now consider the various degrees defined by these edge sets:

$$\begin{aligned} d_1(u) &= |\{v \in V \mid (u, v) \in E_1\}| & d_2(v) &= |\{u \in V \mid (u, v) \in E_1\}| \\ d_3(u) &= |\{v \in V \mid (u, v) \in E_2\}| & d_4(v) &= |\{u \in V \mid (u, v) \in E_2\}| \\ d_5(u) &= |\{v \in V \mid (u, v) \in E_3\}| & d_6(v) &= |\{u \in V \mid (u, v) \in E_3\}| \end{aligned}$$

To bound the ℓ_2 norm of the subgraph returned by the algorithm, we bound each of $\sum_{u \in V} (d_i(u))^2$ separately for each $i \in [6]$. However, we only analyze the contribution for $i = 1$ and $i = 3$. The analysis for $i = 6$ is identical to the analysis for $i = 1$, and the analysis for $i \in \{2, 4, 5\}$ is essentially identical to the analysis for $i = 3$.

Let us start by analyzing $\sum_{u \in V} (d_1(u))^2$. Note that for every $u \in V$, $d_1(u)$ is a sum of independent Bernoulli random variables with success probabilities

$$\text{Prob}[z_{(u,v)} \leq x_{(u,v)}^{1/4}] \cdot \text{Prob}[z_v^- \leq x_{(u,v)}^{1/4}] = x_{(u,v)}^{1/2}.$$

Thus, individual degrees behave exactly as in Edge-Round(1/2). Therefore, the proof of Lemma 15 (which did not use any property of the correlation between different degrees) shows that with high probability the total contribution to the ℓ_2 norm from these degrees is at most $\text{OPT} \cdot \tilde{O}(\|G\|_2^{1/4})$ (which is even smaller than our claim).

Now let us analyze the contribution from the d_3 degrees. First, for every vertex $u \in V$, let us define

$$\hat{\Gamma}(u) := \left\{ v \in V \mid (u, v) \in E, z_v^+ \leq x_{(u,v)}^{1/4} \right\}.$$

Note, as before, that $|\hat{\Gamma}(u)|$ is a sum of independent Bernoulli random variables with probabilities $x_{(u,v)}^{1/4}$, and so with high probability, using Hölder's inequality, we have

$$|\hat{\Gamma}(u)| \leq \log^2 n \cdot \sum_{v:(u,v) \in E} x_{u,v}^{1/4} \leq \log^2 n \cdot d_G(u)^{3/4} d_{\text{LP}}(u)^{1/4}.$$

We will also need to bound (in expectation and with high probability) the following expression:

$$\begin{aligned} \mathbb{E} \left[\sum_{v \in \hat{\Gamma}(u)} x_{(u,v)}^{1/4} \right] &= \sum_{v:(u,v) \in E} x_{(u,v)}^{1/2} \\ &\leq d_G(u)^{1/2} d_{\text{LP}}(u)^{1/2} \quad \text{(by Cauchy-Schwarz).} \end{aligned}$$

This is not a sum of Bernoulli random variables, but it is a sum of independent random variables distributed in $[0, 1]$, where the expectation of the sum is at least 1, so we can use Theorem 13 and get that with probability at least $1 - 2^{-\log^2 n}$ we have

$$\sum_{v \in \hat{\Gamma}(u)} x_{(u,v)}^{1/4} \leq \log^2 n \cdot d_G(u)^{1/2} d_{\text{LP}}(u)^{1/2}.$$

Suppose we have sampled the z^+ variables, so the sets $\hat{\Gamma}(u)$ are fixed and the two bounds on $\hat{\Gamma}(u)$ above hold for all $u \in V$. Note that this high probability event is completely independent of the z^- variables. Conditioned on this event, for every $u \in V$, $(d_3(u))^2$ is a random variable distributed in $[0, |\hat{\Gamma}(u)|^2]$ that depends only on z_u^- . The expected contribution from a single vertex $u \in V$ is

$$\begin{aligned} \mathbb{E}[(d_3(u))^2] &= \sum_{v_1, v_2 \in \hat{\Gamma}(u)} \text{Prob}[z_u^- \leq x_{(u,v_1)}^{1/4}, z_u^- \leq x_{(u,v_2)}^{1/4}] \\ &\leq \sum_{v_1 \in \hat{\Gamma}(u)} \sum_{v_2 \in \hat{\Gamma}(u)} x_{(u,v_2)}^{1/4} \\ &= |\hat{\Gamma}(u)| \cdot \sum_{v \in \hat{\Gamma}(u)} x_{(u,v)}^{1/4} \\ &\leq \log^4 n \cdot d_G(u)^{5/4} d_{\text{LP}}(u)^{3/4} \quad \text{by our bounds on } \hat{\Gamma}(u) \end{aligned}$$

11:10 Approximating the Norms of Graph Spanners

Thus, by Markov's inequality, with probability at least $1 - 1/b$ we have

$$\begin{aligned}
\sum_{u \in V} \mathbb{E}[d_3(u)^2] &\leq b \log^4 n \cdot \sum_{u \in V} d_G(u)^{5/4} d_{\text{LP}}^{3/4} \\
&\leq b \log^4 n \| (d_G(u)^{5/4})_{u \in V} \|_{8/5} \| d_{\text{LP}}(u)^{3/4} \|_{8/3} && \text{by Hölder's inequality} \\
&= b \log^4 n \left(\sum_{u \in V} d_G(u)^2 \right)^{5/8} \left(\sum_{u \in V} d_{\text{LP}}(u)^2 \right)^{3/8} \\
&= b \log^4 n \cdot \text{LP}^{3/4} \|G\|_2^{5/4} \\
&\leq b \log^4 n \cdot \text{OPT}^{3/4} \|G\|_2^{5/4} \\
&\leq b \text{polylog}(n) \cdot \text{OPT}^{3/4} \cdot \frac{\text{OPT}^{5/4}}{\|G\|_2^{5/8}} \cdot \|G\|_2^{5/4} && \text{by Theorem 2} \\
&= \tilde{O}(b \|G\|_2^{5/8}) \cdot \text{OPT}^2
\end{aligned}$$

Thus the contribution of the d_3 degrees to the ℓ_2 norm is at most $\tilde{O}(\sqrt{b} \|G\|_2^{5/16}) \cdot \text{OPT}$, as claimed. \blacktriangleleft

3.2.2 Correctness

We will use the following regularization lemma (simplified form of Lemma 2.6 in [9]):

► **Lemma 18.** *There exists a constant $C > 0$ such that for any vertices $u, v \in V$ and set P of paths from u to v of length at most 3 such that $\sum_{p \in P} y_p = 1$, there exists a subset $P' \subseteq P$ satisfying the following conditions.*

- *For some $1 \leq k \leq 3$, all paths in P' have length k .*
- *There exists some $y_0 > 0$ such that every path $p \in P'$ has weight $y_p \in [y_0, 2y_0]$. Furthermore, $1 \geq y_0 |P'| \geq 1/(\log^C n)$.*
- *If $k = 3$, then all the paths in P' are tuples in $E_1 \times E_2 \times E_3$ for some pairwise disjoint collection of edge sets $E_1, E_2, E_3 \subset E$.*
- *If $k = 3$, then there exist positive integers d_L, d_R such that:*
 - *For every edge $e_1 \in E_1$, the number of paths in P' which include e_1 is in the range $[d_L, d_L \log^C n]$. Note that this gives $|E_1| \leq |P'|/d_L \leq 1/(d_L y_0)$.*
 - *Every edge $e_2 \in E_2$ participates in exactly one path in P' .*
 - *For every edge $e_3 \in E_3$, the number of paths in P' which include e_3 is in the range $[d_R, d_R \log^C n]$. Note that this gives $|E_3| \leq |P'|/d_R \leq 1/(d_R y_0)$.*

Note that given a solution to our LP relaxation, for every edge $(u, v) \in E$ there does exist such a set of paths P , and so there exists a set of paths P' of length k as in the lemma. If $k = 1$, this is just the edge (u, v) which then has LP value $y_{(u,v)} \geq 1/(\log^C n)$, and will be added by Algorithm 1 w.p. $\tilde{\Omega}(1)$. It is also easy to see that Algorithm 1 will span (u, v) if $k = 2$. Indeed, we have:

► **Lemma 19.** *Let P' be a set of paths of length k for an edge $(u, v) \in E$ as in Lemma 18. Then if $k = 2$, then w.p. $\tilde{\Omega}(1)$ at least one of these paths will be added by Algorithm 1.*

Proof. Since the paths in P' are of length 2, they are also edge disjoint. By the capacity constraints, every edge e in these paths must have LP value $x_e \geq y_0$. Thus, the probability that at least one path in P' will be added by Algorithm 1 is bounded by

$$\begin{aligned}
 \text{Prob}[\text{Some path in } P' \text{ is added}] &= 1 - \prod_{p \in P'} \text{Prob}[P' \text{ is not added}] \\
 &= 1 - \prod_{p=(e_1, e_2) \in P'} (1 - \text{Prob}[e_1 \text{ is added}]\text{Prob}[e_2 \text{ is added}]) \\
 &\geq 1 - \prod_{p \in P'} \left(1 - \left(y_0^{3/7}\right)^2\right) \\
 &= 1 - \left(1 - y_0^{6/7}\right)^{|P'|} \\
 &\geq 1 - \exp\left(-y_0^{6/7}|P'|\right) \\
 &\geq 1 - \exp\left(1/\log^C n\right) = \tilde{\Omega}(1),
 \end{aligned}$$

where the last inequality follows from the fact that $y_0^{6/7}|P'| \geq y_0|P'| \geq 1/\log^C n$. ◀

Thus it remains to deal with edges for which P' is a set of paths of length 3. We will show that every such edge is spanned with probability $\Omega(1)$ by either Algorithm 1 or Algorithm 2, depending on the parameters d_L, d_R from Lemma 18. In both cases, we show that the relevant algorithm adds a large number of paths from P' in expectation, and that outside some easy special cases, the number of paths added is (at least mildly) concentrated around the expectation by Chebyshev's inequality. The following lemma describes the correctness property of Algorithm 1.

► **Lemma 20.** *Let $(u, v) \in E$ be an edge and P' be a set of paths of length 3 as in Lemma 18 with corresponding parameters y_0, d_L, d_R . Then if $\max\{d_L, d_R\} \geq y_0^{-2/3}/\log^{C'} n$ for some constant $C' > 0$, Algorithm 1 will add at least one path in P' with probability $\tilde{\Omega}(1)$.*

Proof. First, consider the case where $d_L = \tilde{\Omega}(1/y_0)$. In this case, every edge $e_1 = (u, u') \in E_1$ that participates in any path in P' has LP value $x_{e_1} = \tilde{\Omega}(1)$. Thus, such an edge is added by Algorithm 1 w.p. $\tilde{\Omega}(1)$. Moreover, there are $\tilde{\Omega}(1/y_0)$ paths of length 2 from u' to v with LP value at least y_0 (suffixes of paths in P' starting with e_1), and by Lemma 19, w.p. $\tilde{\Omega}(1)$ Algorithm 1 will add at least one of these, and this event is independent of e_1 being added. Thus, in this case the lemma follows. The lemma follows similarly when $d_R = \tilde{\Omega}(1/y_0)$.

Assume therefore that for some arbitrarily large constant $C'' > 0$ we have

$$d_L, d_R \leq 1/(y_0 \log^{C''} n). \tag{4}$$

Now assume w.l.o.g. that $d_L > d_R$. Thus, by our assumption, we have

$$d_L \geq y_0^{-2/3}/\log^{C'} n. \tag{5}$$

Consider the case where $(d_L \leq) d_L d_R \leq y_0^{-2/3} \log^{C''} n$, which in particular implies $d_R \leq \log^{C''+C'} n$. In this case define a new set of paths $P'' \subseteq P'$ by taking for every edge $e_3 \in E_3$ a single path in P' containing e_3 . Note that $|P''| \geq |P'|/(d_R \log^C n)$. Since $|E_1| \leq |P'|/d_L$ and every edge in E_1 participates in at most $d_L \log^C n$ paths in P' , this implies that at least $|P''|/(2d_L d_R \log^{2C} n)$ edges in E_1 each participate in at least $d_L/(2d_R \log^C n)$ paths in $|P''|$. Let $E'_1 \subseteq E_1$ be this set of edges. So we have

$$|E'_1| \geq \frac{|P''|}{2d_L d_R \log^{2C} n} \geq \frac{1}{2d_L d_R y_0 \log^{3C} n} \geq \frac{1}{2y_0^{1/3} \log^{3C+C''} n}.$$

11:12 Approximating the Norms of Graph Spanners

Now, for every $e_1 \in E'_1$, denote by $P''(e_1)$ the set of paths in P'' containing e_1 . By definition of E'_1 , for every such e_1 we have $|P''(e_1)| \geq d_L/(2d_R \log^C n)$. Note that by capacity constraints we have $x_{e_1} \geq d_L y_0 \geq y_0^{1/3}/\log^{C'} n$. Thus, as in the proof of Lemma 19, the probability that at least one path in $P''(e_1)$ is added is bounded by

$$\begin{aligned}
& \text{Prob}[\text{Some path in } P''(e_1) \text{ is added}] \\
&= \text{Prob}[e_1 \text{ is added}] \cdot \left(1 - \prod_{p \in P''(e_1)} (1 - \text{Prob}[p \setminus e_1 \text{ is added}]) \right) \\
&\geq (d_L y_0)^{3/7} \left(1 - (1 - y_0^{6/7})^{|P''(e_1)|} \right) \\
&\geq y_0^{1/7} \log^{-3C'/7} n \left(1 - (1 - y_0^{6/7})^{d_L/(2d_R \log^C n)} \right) \\
&\geq y_0^{1/7} \log^{-3C'/7} n \left(1 - (1 - y_0^{6/7})^{y_0^{-2/3}/(2 \log^{C+C''-C'} n)} \right) \\
&\geq y_0^{1/7} \log^{-3C'/7} n \left(1 - \exp(-y_0^{4/21}/(2 \log^{C+C''-C'} n)) \right) \\
&= \tilde{\Omega}(y_0^{1/3})
\end{aligned}$$

By definition of P'' , the paths in $P''(e_1)$ are completely edge disjoint from the paths in $P''(e'_1)$ for any $e_1, e'_1 \in E'_1$. Thus, there is a probability of $\tilde{\Omega}(y_0^{1/3})$ that at least one path in $P''(e_1)$ is added, and these are independent events for the different edges $e_1 \in E'_1$. By our bound on $|E'_1|$, there are $\tilde{\Omega}(y_0^{-1/3})$ such edges, and so the probability that at least one of them will contribute a path in P'' to the spanner is at least $\tilde{\Omega}(1)$. This concludes our analysis of the case where $d_L d_R \leq y_0^{-2/3} \log^{C''} n$. From this point on, we assume that

$$d_L d_R \geq y_0^{-2/3} \log^{C''} n \quad (6)$$

Now define new LP values for $E_1 \cup E_2 \cup E_3$ as follows:

$$x'_e = \begin{cases} d_L y_0 & \text{if } e \in E_1 \\ y_0 & \text{if } e \in E_2 \\ d_R y_0 & \text{if } e \in E_3. \end{cases}$$

Then by capacity constraints, for every edge $e \in E_1 \cup E_2 \cup E_3$, we have $x_e \geq x'_e$. Consider an algorithm that adds edges $e \in E_1 \cup E_2 \cup E_3$ independently with probability $(x'_e)^{3/7}$ instead of $x_e^{3/7}$. Clearly, the probability that Algorithm 1 adds at least one path from P' is at least the probability that the algorithm with modified LP values does so. Let us now analyze the probability that the modified algorithm adds at least one path from P' , and denote by Y the number of paths from P' added by the modified algorithm. We start by analyzing the expectation of Y . By definition of the modified algorithm, every path $p \in P'$ is added with probability

$$\text{Prob}[p \text{ is added}] = (d_L y_0)^{3/7} y_0^{3/7} (d_R y_0)^{3/7} = (d_L d_R)^{3/7} y_0^{9/7}.$$

Since $|P'| = y_0^{-1}/(\log^c n)$ for some $c \in [0, C]$, for an appropriate choice of C'' , the expected number of paths added by the modified algorithm satisfies

$$\begin{aligned}
\mathbb{E}[Y] &= |P'| (d_L d_R)^{3/7} y_0^{9/7} \\
&= \log^{-c} n \cdot (d_L d_R)^{3/7} y_0^{2/7} \\
&\geq \log^{3C''/7-c} n && \text{by (6)} \\
&\geq \log^{1+c/2+3C/2} n,
\end{aligned} \quad (7)$$

where the last inequality follows if we choose, say,

$$C'' = 7/3 + 7c/2 + 7C/2.$$

Thus, the expected number of paths in P' added is (relatively) large. However, since the paths in P' are not disjoint, this does not guarantee that at least one path will be added with probability $\tilde{\Omega}(1)$. To show this, we need to show concentration. As in [9], we use Chebyshev's inequality, which guarantees that $\text{Prob}[Y = 0] < \frac{1}{2}$ as long as

$$\text{Var}[Y] = \mathbb{E}[Y^2] - (\mathbb{E}[Y])^2 < \frac{1}{8}(\mathbb{E}[Y])^2. \quad (8)$$

To show that (8) holds, consider the contribution of edge-disjoint versus non-edge-disjoint paths:

$$\begin{aligned} \mathbb{E}[Y^2] &= \sum_{p_1, p_2 \in P'} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] \\ &= \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 \neq \emptyset}} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] + \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \emptyset}} \text{Prob}[p_1 \text{ is added}] \text{Prob}[p_2 \text{ is added}] \\ &\leq \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 \neq \emptyset}} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] + \sum_{p_1, p_2 \in P'} \text{Prob}[p_1 \text{ is added}] \text{Prob}[p_2 \text{ is added}] \\ &= \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 \neq \emptyset}} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] + \mathbb{E}[Y]^2 \end{aligned}$$

Thus, to show (8), it suffices to bound the contribution from pairs of non-edge-disjoint paths. These fall into three categories: pairs of identical paths, pairs sharing only the first edge (in E_1), and pairs sharing only the third edge (in E_3). The contribution from paths in the first category is at most

$$\sum_{p_1=p_2 \in P'} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] = \mathbb{E}[Y] = o(\mathbb{E}[Y]^2). \quad (\text{since } \mathbb{E}[Y] > \log n)$$

The analysis for the second and third categories is identical, so let us focus only on pairs of paths sharing only the first edge. These pairs contribute

$$\begin{aligned} \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} \text{Prob}[p_1 \text{ and } p_2 \text{ are added}] &= \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} (d_L y_0)^{3/7} y_0^{6/7} (d_R y_0)^{6/7} \\ &= \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} d_L^{3/7} d_R^{6/7} y_0^{15/7} \\ &\leq |E_1| (d_L \log^C n)^2 \cdot d_L^{3/7} d_R^{6/7} y_0^{15/7} \\ &\leq \frac{1}{d_L y_0} \cdot (\log^{2C} n) d_L^{17/7} d_R^{6/7} y_0^{15/7} \\ &= (\log^{2C} n) d_L^{10/7} d_R^{6/7} y_0^{8/7} \\ &\leq (\log^{2C-4C''/7} n) d_L^{6/7} d_R^{6/7} y_0^{4/7} \quad (\text{by (4)}) \\ &= \log^{2C+2c-4C''/7} n \cdot \mathbb{E}[Y]^2 \quad (\text{by (7)}) \\ &= \log^{-4/3} n \cdot \mathbb{E}[Y]^2 \end{aligned}$$

Thus, all three categories contribute at most $o(\mathbb{E}[Y]^2)$, and this concludes the proof. \blacktriangleleft

11:14 Approximating the Norms of Graph Spanners

Finally, we examine edges that will be spanned by Algorithm 2. Note that the trade-off between the two algorithms has nothing to do with the approximation guarantee. In fact, at the parameter threshold between the two algorithms (where $\max\{d_L, d_R\} \approx y_0^{-2/3}$), both algorithms either give or could be easily modified to give a better approximation than $\|G\|_2^{5/16}$. The reason for trading off the two algorithms is that beyond the threshold, Algorithm 2 will still give a large number of spanning paths for each edge in expectation, but in reality will only span such an edge with very low probability (in which event it will span it with many paths). The following lemma gives the parameter regime for edges spanned by Algorithm 2.

► **Lemma 21.** *Let $(u, v) \in E$ be an edge and P' be a set of paths of length 3 as in Lemma 18 with corresponding parameters y_0, d_L, d_R . Then there exists a constant $C' > 0$ such that if $d_L, d_R \leq y_0^{-2/3} / \log^{C'} n$, Algorithm 2 will add at least one path in P' with probability $\tilde{\Omega}(1)$.*

Proof. First consider the case where $d_L d_R \leq \log^{C''} n$ for some constant $C'' > 0$. This is an easy special case, but also the tight case of our entire analysis. In this case, define a new set of paths $P'' \subseteq P'$ by taking for every edge $e_3 \in E_3$ a single path in P' containing e_3 , and then out of these, choosing for every edge $e_1 \in E_1$ used in these paths a single path containing e_1 . Note that $|P''| \geq |P'| / \log^{2C+C''} n$, and all the paths in P'' are edge disjoint. For any path $p = (u, u', v', v) \in P''$, we can bound the probability that p is added by Algorithm 1 by

$$\begin{aligned} \text{Prob}[p \text{ is added}] &\geq \text{Prob}[z_{(u,u')} \leq x_{(u,u')}^{1/4}] \cdot \text{Prob}[z_{u'}^- \leq x_{(u,u')}^{1/4}, x_{(u',v')}^{1/4}] \\ &\quad \cdot \text{Prob}[z_{v'}^+ \leq x_{(u',v')}^{1/4}, x_{(v',v)}^{1/4}] \cdot \text{Prob}[z_{(v,v')} \leq x_{(v,v')}^{1/4}] \\ &\geq \text{Prob}[z_{(u,u')} \leq y_0^{1/4}] \cdot \text{Prob}[z_{u'}^- \leq y_0^{1/4}] \cdot \text{Prob}[z_{v'}^+ \leq y_0^{1/4}] \cdot \text{Prob}[z_{(v,v')} \leq y_0^{1/4}] \\ &= y_0. \end{aligned}$$

Since the paths in P'' are completely edge-disjoint, and share no interior vertices, the above events are independent for the various paths, and so the probability that at least one path in P'' is added is at least

$$\begin{aligned} 1 - (1 - y_0)^{|P''|} &\geq 1 - \exp(-y_0 |P''|) \geq 1 - \exp(-y_0 |P'| / \log^{2C+C''} n) \\ &\geq 1 - \exp(-1 / \log^{3C+C''} n) = \tilde{\Omega}(1). \end{aligned}$$

Now consider the remaining case. That is, assume from now on that

$$d_L d_R \geq \log^{C''} n. \tag{9}$$

As in the proof of Lemma 20, consider the result of running Algorithm 2 with LP values $\{x'_e\}$ as defined in that proof. As before, modifying the LP values in such a way can only decrease the probability that one of the paths in P' will be chosen. Let Y be the following set of paths, added by Algorithm 2 using the modified LP values:

$$\begin{aligned} Y = \left\{ (u, u', v', v) \in P' \mid \left(z_{(u,u')} \leq (x'_{(u,u')})^{1/4} \right) \wedge \left(z_{u'}^- \leq (x'_{(u,u')})^{1/4}, (x'_{(u',v')})^{1/4} \right) \right. \\ \left. \wedge \left(z_{v'}^+ \leq (x'_{(u',v')})^{1/4}, (x'_{(v',v)})^{1/4} \right) \wedge \left(z_{(v,v')} \leq (x'_{(v,v')})^{1/4} \right) \right\} \end{aligned}$$

Since $d_L, d_R \geq 1$, the probability that a single path $p \in P'$ is added to Y is exactly

$$(d_L y_0)^{1/4} \cdot \min\{(d_L y_0)^{1/4}, y_0^{1/4}\} \cdot \min\{y_0^{1/4}, (d_R y_0)^{1/4}\} \cdot (d_R y_0)^{1/4} = (d_L d_R)^{1/4} y_0.$$

Since $|P'| = y_0^{-1}/(\log^c n)$ for some $c \in [0, C]$, for an appropriate choice of C'' , the expected number of paths added by the modified algorithm satisfies

$$\begin{aligned} \mathbb{E}[Y] &= |P'| (d_L d_R)^{1/4} y_0 = \log^{-c} n \cdot (d_L d_R)^{1/4} & (10) \\ &\geq \log^{C''-c} n & \text{by (9)} \\ &\geq \log n, \end{aligned}$$

where the last inequality follows if we choose $C'' = 1 + c$.

As before, it is not enough to show that the expected number of paths is large, we also need to show concentration. As in the proof of Lemma 20, it suffices to show that

$$\sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 \neq \emptyset}} \text{Prob}[p_1, p_2 \subseteq Y] = o((\mathbb{E}[Y])^2).$$

These pairs of non-edge-disjoint paths fall into three categories: pairs of identical paths, pairs sharing only the first edge (in E_1), and pairs sharing only the third edge (in E_3). As before, the contribution from identical paths is $\mathbb{E}[Y] = o((\mathbb{E}[Y])^2)$ (where the final bound follows since $\mathbb{E}[Y] \geq \log n$). Since the analysis for the second and third categories is essentially the same, we focus on pairs of paths sharing only the first edge. These pairs contribute

$$\begin{aligned} \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} \text{Prob}[p_1, p_2 \subseteq Y] &= \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} (d_L y_0)^{1/4} y_0^{1/4} y_0^{1/2} (d_R y_0)^{1/2} \\ &= \sum_{e_1 \in E_1} \sum_{\substack{p_1, p_2 \in P' \\ p_1 \cap p_2 = \{e_1\}}} d_L^{1/4} d_R^{1/2} y_0^{3/2} \\ &\leq \frac{1}{d_L y_0} \cdot (d_L \log^C n)^2 \cdot d_L^{1/4} d_R^{1/2} y_0^{3/2} \\ &= (\log^{2C} n) d_L^{5/4} d_R^{1/2} y_0^{1/2} \\ &\leq (\log^{2C-3C'/4} n) d_L^{1/2} d_R^{1/2} \quad (\text{since } d_L \leq y_0^{-2/3} / \log^{C'} n) \\ &= \log^{2C+2c-3C'/4} n \cdot \mathbb{E}[Y]^2 \quad (\text{by (10)}) \\ &\leq \log^{-3/4} n \cdot \mathbb{E}[Y]^2, \end{aligned}$$

where the final bound follows if we choose $C' \geq 1 + 8C/3 + 8c/3$. Thus, all three categories contribute at most $o(\mathbb{E}[Y]^2)$, and this concludes the proof. \blacktriangleleft

4 Generalizations and Open Questions

While we provided approximation and hardness bounds for MINIMUM ℓ_2 -NORM 3-SPANNER, the true approximability still remains open. Perhaps more interesting, though, is the question of the more general MINIMUM ℓ_p -NORM k -SPANNER problem. Some of our techniques easily extend to this more general setting, but some do not. The linear-programming based framework we use to analyze the greedy algorithm should basically work for other values of p and k , but the details become more complicated.

Recall that our strongest approximation algorithm (from Section 3) is a careful tradeoff between greedy, independent edge sampling (**Edge-Round**), and a combined vertex and edge sampling (Algorithm 2). Independent edge sampling (**Edge-Round**) can also be analyzed for other values of p and k , where the right α to use depends on the value of k (indeed, this is the main technique used by [9] for $p = \infty$, and correctness for other values of k

follows directly from [9]). Our more tailored algorithm (Algorithm 2), which combines edge and vertex sampling, seems harder to generalize for larger values of k . Algorithm 2 is a generalization of the ideas used for $k = 3, 4$ in the ℓ_1 case (due to [12, 7, 13]), and it is a fascinating open question to extend these techniques to larger stretch values. For stretch $k = 3$ and other values of p , Algorithm 2 can be reanalyzed with appropriate parameters and seems to give nontrivial guarantees. In general, designing and analyzing approximation algorithms for other values of p and k remains an exciting challenge which may require new algorithmic ideas.

With respect to hardness, our results in Appendix A already include other values of p . For larger stretch values, the basic construction can be extended by including “outer paths” in the same way as has been done for many other spanner hardness results ([15, 9] in particular).

A Hardness Results

Since the analysis is simpler in the directed setting, we follow [9] and begin with it. We will also prove hardness for the more general ℓ_p -norm version, and hardness when $p = 2$ will follow as a corollary. First, though, we give some notation and background necessary for the reduction.

A.1 Background: Min-Rep and Spanner Hardness

Our hardness bounds rely on the Min-Rep problem. In Min-Rep we are given a bipartite graph $G = (A, B, E)$ where A is partitioned into groups A_1, A_2, \dots, A_r and B is partitioned into groups B_1, B_2, \dots, B_r , with the additional property that every set A_i and every set B_j has the same size (which we will call $|\Sigma|$ due to its connection to the alphabet of a 1-round 2-prover proof system). This graph and partition induces a new bipartite graph G' called the *supergraph* in which there is a vertex a_i for each group A_i and similarly a vertex b_j for each group B_j . There is an edge between a_i and b_j in G' if there is an edge in G between some node in A_i and some node in B_j . A node in G' is called a supernode, and similarly an edge in G' is called a superedge.²

A REP-cover is a set $C \subseteq A \cup B$ with the property that for all superedges $\{a_i, b_j\}$ there are nodes $a \in A_i \cap C$ and $b \in B_j \cap C$ where $\{a, b\} \in E$. We say that $\{a, b\}$ covers the superedge $\{a_i, b_j\}$. The goal is to construct a REP-cover of minimum size.

For any fixed constant $\epsilon > 0$, we say that an instance of Min-Rep is a YES instance if $OPT = 2r$ (i.e. a single node is chosen from each group) and is a NO instance if $OPT \geq 2^{\log^{1-\epsilon} n} r$. We will sometimes refer to the hardness gap (in this case $2^{\log^{1-\epsilon} n}$) as the *soundness* s , due to the connection between Min-Rep and proof systems. The following theorem is due to Kortsarz [18] (the polynomial relations between the parameters are implicit rather than explicit in his proof, but are straightforward to verify since the instances used in [18] are obtained by parallel repetition [20] applied to instances of 3SAT-5 which have a constant gap $[4, 3]$).

² Rather than G being the graph and G' being the supergraph, sometimes G' is referred to as the graph and G is called the *label-extended graph*.

► **Theorem 22** ([18]). *Unless $\text{NP} \subseteq \text{DTIME}(2^{\text{polylog}(n)})$, for any constant $\epsilon > 0$ there is no polynomial-time algorithm that can distinguish between YES and NO instances of Min-Rep. This is true even when the graph and the supergraph are regular, and both the supergraph degree and $|\Sigma|$ are polynomial in the soundness.*

A.2 Directed Hardness

A.2.1 Reduction

We first consider the directed setting (note that here the “degree” in the degree vector is the sum of the in-degree and the out-degree). Suppose we are given a Min-Rep instance $\tilde{G} = (A, B, \tilde{E})$ with associated supergraph $G' = (U, V, E')$ from Theorem 22. For any vertex $w \in U \cup V$ we let $\Gamma(w)$ denote its group. So $\Gamma(u) \subseteq A$ for $u \in U$, and $\Gamma(v) \subseteq B$ for $v \in V$. Similarly, for $a \in A \cup B$, we let $\Gamma^{-1}(a)$ be the unique $w \in U \cup V$ such that $a \in \Gamma(w)$. We will assume without loss of generality that G' is regular with degree $d_{G'}$ and \tilde{G} is regular with degree $d_{\tilde{G}}$. Our reduction will also use a special bipartite regular graph $H = (X, Y, E_H)$, which will simply be the directed complete bipartite graph with $|X| = |Y|$. Let d_H denote the degree of a node in H , so $d_H = |X| = |Y|$ (later when we move to the undirected setting H will not just be the complete bipartite graph). We will set all of these values to $(d_{G'} + |\Sigma| + 1)^{p/(p-1)}$ (for the undirected setting we will set d_H to this value, but $|X| = |Y|$ will be larger).

Our instance $G = (V_G, E_G)$ of MINIMUM ℓ_p -NORM 3-SPANNER will be a combination of these three graphs. The four sets of vertices are

$$\begin{aligned} V_{out}^L &= U \times X & V_{out}^R &= V \times Y \\ V_{in}^L &= A \times E_H & V_{in}^R &= B \times E_H. \end{aligned}$$

The actual vertex set V_G of our instance G will be $V_{out}^L \cup V_{out}^R \cup V_{in}^L \cup V_{in}^R$. Defining the edge set is a little more complex, as there are a few different types of edges. We first create *outer edges*, which are incident on outer nodes:

$$E_{out} = \{((u, x), (v, y)) : u \in U \wedge v \in V \wedge x \in X \wedge y \in Y \wedge \{u, v\} \in E' \wedge (x, y) \in E_H\}.$$

Note that if we fix x and y the corresponding outer edges form a copy of the supergraph G' . Thus these edges essentially form $|E_H|$ copies of the supergraph.

We also have *inner edges*, which correspond to $|E_H|$ copies of the Min-Rep instance (note that unlike the supergraph copies, these copies are vertex disjoint):

$$E_{in} = \{((a, e), (b, e)) : a \in A \wedge b \in B \wedge e \in E_H \wedge \{a, b\} \in \tilde{E}\}.$$

We will now add *connection edges*, i.e., edges that connect some of the outer nodes to some of the inner nodes. Let

$$\begin{aligned} E_{con}^L &= \{((u, x), (a, (x, y))) : u \in U \wedge a \in \Gamma(u) \wedge x \in X \wedge (x, y) \in E_H\}, \text{ and} \\ E_{con}^R &= \{((b, (x, y)), (v, y)) : v \in V \wedge b \in \Gamma(v) \wedge y \in Y \wedge (x, y) \in E_H\}. \end{aligned}$$

In other words, the outer node (u, x) (resp. (v, y)) is connected to the inner nodes in its group in each copy of \tilde{G} that corresponds to an E_H edge that involves x (resp. y).

Finally, for technical reasons we need to add *group edges* internally in each group in each copy of \tilde{G} : let $E_{group}^L = \{((a, e), (a', e)) : e \in E_H \wedge a, a' \in A \wedge \Gamma^{-1}(a) = \Gamma^{-1}(a')\}$, and let $E_{group}^R = \{((b, e), (b', e)) : e \in E_H \wedge b, b' \in B \wedge \Gamma^{-1}(b) = \Gamma^{-1}(b')\}$.

Our final edge set is the union of all of these, namely $E_G = E_{out} \cup E_{in} \cup E_{con}^L \cup E_{con}^R \cup E_{group}^L \cup E_{group}^R$.

A.2.2 Analysis

We first consider the YES case. We can use almost the same spanner as was used to prove the equivalent lemma in [9] (Lemma 3.3). Unfortunately, since in [9] only the maximum degree mattered, they did not need to optimize the degrees of non-extremal vertices, while we do. So we actually use a slightly sparser spanner construction.

► **Lemma 23.** *If \tilde{G} is a YES instance of Min-Rep, then there is a 3-spanner S of G with $\|S\|_p \leq 3d_H(|U||X| + |V||Y|)^{1/p}$*

Proof. Since \tilde{G} is a YES instance, for each $u \in U$ there is some $f(u) \in \Gamma(u)$ and for each $v \in V$ there is some $f(v) \in \Gamma(v)$ so that $\{f(u), f(v)\} \in \tilde{E}$ for all $\{u, v\} \in E'$. Our spanner S the connection edges suggested by the REP-cover: for every $u \in U$ and $x \in X$ and $(x, y) \in E_H$, it contains the connection edge $((u, x), (f(u), (x, y)))$. Similarly, for every $v \in V$ and $y \in Y$ and $(x, y) \in E_H$, it contains the connection edge $((f(v), (x, y)), (v, y))$. It also contains a star of group edges centered at the chosen node in every group: for every $u \in U$ and $e \in E_H$ and $a \in \Gamma(u)$ it includes the group edges $((f(u), e), (a, e))$ and $((a, e), (f(u), e))$, and for every $v \in V$ and $e \in E_H$ and $b \in \Gamma(v)$ it includes the group edges $((f(v), e), (b, e))$ and $((b, e), (f(v), e))$. Finally, it contains the appropriate inner edges: for every $\{u, v\} \in E'$ with $u \in U$ and $v \in V$ and every $e \in E_H$, we add the inner edge $((f(u), e), (f(v), e))$.

This is precisely the spanner from [9, Lemma 3.3] but with fewer group edges (we include stars in each group, while [9, Lemma 3.3] included all group edges). It is easy to verify that this change does not affect the correctness of the spanner: all edges in G not in S are still spanned. So we rely on [9, Lemma 3.3] for correctness.

So we just need to analyze $\|S\|_p$. To do this, we can just count the degrees in S of each type of nodes. There are $|U||X| + |V||Y|$ outer nodes, each of which has degree at most d_H in S . For the inner nodes, we divide into those that are chosen (those that are $(f(u), e)$ or $(f(v), e)$ for some u or v in $U \cup V$) and those that are not. There are at most $|E_H|(|A| + |B|)$ inner nodes which are not chosen, and in S they all have degree 2 (an incoming and outgoing group edge from the node in the same group that is chosen). There are at most $|E_H|(|U| + |V|)$ inner nodes which are chosen, each of which has degree in S of at most $|\Sigma| + d_{G'} + 1$ (the group edges, inner edges, and connection edges that it is incident with respectively). Putting all this together, we get that

$$\begin{aligned} \|S\|_p &\leq ((|U||X| + |V||Y|) \cdot d_H^p \\ &\quad + |E_H|(|A| + |B|) \cdot 2^p + |E_H|(|U| + |V|)(|\Sigma| + d_{G'} + 1)^p)^{1/p} \\ &\leq ((|U||X| + |V||Y|) \cdot d_H^p + 2|E_H|(|U| + |V|)(|\Sigma| + d_{G'} + 1)^p)^{1/p} \\ &\leq (3(|U||X| + |V||Y|) \cdot d_H^p)^{1/p} \\ &\leq 3d_H(|U||X| + |V||Y|)^{1/p}, \end{aligned}$$

where we have used our setting of d_H and the fact that $|A| + |B| = (|U| + |V|)|\Sigma|$. ◀

Now we analyze the NO setting.

► **Lemma 24.** *If \tilde{G} is a NO instance of Min-Rep, then every 3-spanner S of G has $\|S\|_p \geq sd_H(|U||X| + |V||Y|)^{1/p}$.*

Proof. Suppose for the sake of contradiction that this is false. Let S be a 3-spanner of G with $\|S\|_p < sd_H(|U||X| + |V||Y|)^{1/p}$. For every outer node (u, x) in V_{out}^L and edge $(x, y) \in E_H$, let $d_{out}^{x,y}(u, x)$ be the number of outer edges in S that are incident on (u, x) and have the other

11:20 Approximating the Norms of Graph Spanners

endpoint of the form (v, y) for some $v \in V$. Similarly, for every outer node (v, y) in V_{out}^R and edge $(x, y) \in E_H$, let $d_{out}^{x,y}(v, y)$ be the number of outer edges in S that are incident with (v, y) and have the other endpoint of the form (u, y) . For every outer node (u, x) in V_{out}^L and edge $(x, y) \in E_H$, let $d_{con}^{x,y}(u, x)$ be the number of connection edges in S that are incident with (u, x) and have the other endpoint of the form $(a, (x, y))$ for some $a \in \Gamma(u)$. Similarly, for every outer node (v, y) in V_{out}^R and edge $(x, y) \in E_H$, let $d_{con}^{x,y}(v, y)$ be the number of connection edges in S that are incident with (v, y) and have the other endpoint of the form $(b, (x, y))$ for some $b \in \Gamma(v)$.

Now with this notation in hand, the fact that $\|S\|_p \leq sd_H(|U||X| + |V||Y|)^{1/p}$ implies that

$$\begin{aligned} & \sum_{(x,y) \in E_H} \left(\sum_{u \in U} ((d_{out}^{x,y}(u, x))^p + (d_{con}^{x,y}(u, x))^p) + \sum_{v \in V} ((d_{out}^{x,y}(v, y))^p + (d_{con}^{x,y}(v, y))^p) \right) \\ & \leq (sd_H)^p (|U||X| + |V||Y|) \end{aligned}$$

Now a simple application of Hölder's inequality gives us the following.

$$\begin{aligned} & \sum_{(x,y) \in E_H} \left(\sum_{u \in U} (d_{out}^{x,y}(u, x) + d_{con}^{x,y}(u, x)) + \sum_{v \in V} (d_{out}^{x,y}(v, y) + d_{con}^{x,y}(v, y)) \right) \\ & \leq (sd_H)(|U||X| + |V||Y|) && \text{(Hölder's inequality)} \\ & \leq 2sd_H(|U||X|) && (H \text{ and } G' \text{ are both balanced)} \\ & \leq |E_H|2s|U| && (H \text{ is regular with degree } d_H) \\ & \leq |E_H|s(|U| + |V|) && (G' \text{ is balanced)} \end{aligned}$$

Thus averaging now implies that there is some $(x, y) \in E_H$ such that

$$\sum_{u \in U} (d_{out}^{x,y}(u, x) + d_{con}^{x,y}(u, x)) + \sum_{v \in V} (d_{out}^{x,y}(v, y) + d_{con}^{x,y}(v, y)) \leq s(|U| + |V|) \quad (11)$$

Fix this (x, y) . We create a set $C_1(u) \subseteq \Gamma(u)$ for each $u \in U$ by adding all $a \in \Gamma(u)$ such that there is a connection edge $((u, x), (a, (x, y)))$ which contributes to $d_{con}^{x,y}(u, x)$. Similarly, we create a set $C_1(v) \subseteq \Gamma(v)$ for each $v \in V$ by adding all $b \in \Gamma(v)$ such that there is a connection edge $((b, (x, y)), (v, y))$ which contributes to $d_{con}^{x,y}(v, y)$.

Now we create similar sets for the outer edges. For each $u \in U$ we create a set $C_2(u) \subseteq \Gamma(u)$ and for each $v \in V$ we create a set $C_2(v)$ as follows. For every outer edge $((u, x), (v, y))$ in S (i.e., every outer edge which contributes to $d_{out}^{x,y}(u) + d_{out}^{x,y}(v)$), we pick an arbitrary $a \in \Gamma(u)$ and $b \in \Gamma(v)$ such that $\{a, b\} \in \tilde{E}$ and add a to $C_2(u)$ and b to $C_2(v)$.

Let $C(u) = C_1(u) \cup C_2(u)$ for all $u \in U$, and let $C(v) = C_1(v) \cup C_2(v)$ for all $v \in V$. Let $C = (\cup_{u \in U} C(u)) \cup (\cup_{v \in V} C(v))$. Clearly by construction we know that

$$\begin{aligned} |C| & \leq \sum_{u \in U} ((d_{out}^{x,y}(u, x)) + (d_{con}^{x,y}(u, x))) + \sum_{v \in V} ((d_{out}^{x,y}(v, y)) + (d_{con}^{x,y}(v, y))) \\ & \leq s(|U| + |V|). && \text{(by (11))} \end{aligned}$$

Now we claim that C is a valid REP-cover. This will prove the lemma, since it will imply that S is not a NO instance, giving a contradiction and thus implying that no such S can exist. To see that C is a REP-cover, consider an arbitrary superedge $\{u, v\} \in E'$. It is not hard to see (and was proved in [9]) that the only way that S can span the outer edge $((u, x), (v, y))$ is to either include that edge in S or include a *canonical path* between the endpoints: a path which uses a connection edge to get to some $(a, (x, y))$, then an inner

edge to get to some $(b, (x, y))$, then a connection edge to get to (v, y) . If the outer edge is included in S , then when we constructed $C_2(u)$ and $C_2(v)$ we explicitly added some $a \in \Gamma(u)$ and $b \in \Gamma(v)$ that cover $\{u, v\}$. Otherwise S spans the outer edge using a canonical path, which from the construction of $C_1(u)$ and $C_1(v)$ means that there is some $a, b \in C$ which covers $\{u, v\}$. Thus C is a REP-cover, which proves the lemma. \blacktriangleleft

Now we can prove our hardness bound using these lemmas.

► **Theorem 25.** *Unless $\text{NP} \subseteq \text{DTIME}(2^{\text{poly}(\log(n))})$, for any constant $\epsilon > 0$ and $p \geq 1$ there is no polynomial-time algorithm that can approximate MINIMUM ℓ_p -NORM 3-SPANNER in directed graphs better than $2^{\left(\frac{p-1}{3p-1}\right)^{1-\epsilon} \log^{1-\epsilon} n}$.*

Proof. Lemmas 23 and 24, together with Theorem 22, imply that under the complexity assumption, there is no polynomial-time algorithm with approximation ratio better than

$$\frac{sd_H(|U||X| + |V||Y|)^{1/p}}{3d_H(|U||X| + |V||Y|)^{1/p}} = \frac{s}{3}.$$

The only thing that remains is to argue about the increase in the size: the n in the value of s is really $|A| + |B|$, while our graph G is larger. But it is not too much larger: the number of vertices in G is $|V_G| = |U||X| + |V||Y| + |A||E_H| + |B||E_H| = O(n(|\Sigma| + d_{G'})^{2p/(p-1)}) \leq O(n^{1+\frac{2p}{p-1}}) = O(n^{(3p-1)/(p-1)})$. Thus the overall hardness that we obtain is

$$\frac{s}{3} = \frac{1}{3} 2^{\log^{1-\epsilon} n} = \frac{1}{3} 2^{\log^{1-\epsilon}(N^{(p-1)/(3p-1)})} = \frac{1}{3} 2^{\left(\frac{p-1}{3p-1}\right)^{1-\epsilon} \log^{1-\epsilon} N}.$$

The extra $1/3$ factor can be absorbed by using a smaller ϵ . \blacktriangleleft

Our claimed hardness theorem for $p = 2$, the directed version of Theorem 8, is a corollary of this theorem for $p = 2$.

A.3 Undirected Hardness

We extend the directed hardness to the undirected setting in the same way that it was extended for LDKS in [9]. First, we start with a slightly different Min-Rep instance with some useful extra properties (from [11] instead of from [18], and with some extra analysis from [9]). Then we combine it with a graph H which is the finite projective plane of degree $d_H = (d_{G'} + |\Sigma| + 1)^{p/(p-1)}$, which is a graph of girth 6 with $|X| = |Y| = d_H^2$. Then we further subsample G to ensure that there are no cycles of length less than 5 consisting of outer edges (some were introduced via the way we combined \tilde{G} with H). All of this is necessary in order to ensure that in any 3-spanner of G , the only ways of spanning an outer edge are through the outer edge itself or through a canonical path (and in particular, there is no way to span it using just other outer edges).

We give a sketch of the analysis and proof here, since it is simply re-analyzing the construction of [9] using the ideas from the previous section. It is straightforward to prove the analog of Lemma 23, since we use the same spanner suggested by the existence of a good REP-cover and analyze all degrees in the same way. This implies that in a YES instance, there will be a k -spanner S with $\|S\|_p \leq O((|U||X| + |V||Y|)^{1/p} \cdot d_H)$.

The NO setting is more difficult to analyze, since it requires arguing directly about the subsampling process. But if we follow the analysis in [9] but with the notation from the previous section, we get that in a NO instance,

$$\sum_{u \in U} (d_{out}^{x,y}(u, x) + d_{con}^{x,y}(u, x)) + \sum_{v \in V} (d_{out}^{x,y}(v, y) + d_{con}^{x,y}(v, y)) \geq s^{1/8}(|U| + |V|)$$

11:22 Approximating the Norms of Graph Spanners

for every $\{x, y\} \in E_H$. This is the equivalent of Equation (11) but as a direct proof rather than by contradiction. Then as in the directed case, we can combine these to get the following theorem (the dependence on p is slightly worse since the graph that we build is larger due to using the finite projective plane rather than the complete bipartite graph).

► **Theorem 26.** *Unless $\text{NP} \subseteq \text{BPTIME}(2^{\text{poly} \log(n)})$, for any constant $\epsilon > 0$ and $p \geq 1$ there is no polynomial-time algorithm that can approximate $\text{MINIMUM } \ell_p\text{-NORM } 3\text{-SPANNER}$ better than $2^{\left(\frac{p-1}{4p-1}\right)^{1-\epsilon} \log^{1-\epsilon} n}$.*

Theorem 8 is now a corollary of this theorem when $p = 2$.

Conditional Hardness of Earth Mover Distance

Dhruv Rohatgi

MIT, Cambridge, Massachusetts, USA
drohatgi@mit.edu

Abstract

The Earth Mover Distance (EMD) between two sets of points $A, B \subseteq \mathbb{R}^d$ with $|A| = |B|$ is the minimum total Euclidean distance of any perfect matching between A and B . One of its generalizations is asymmetric EMD, which is the minimum total Euclidean distance of any matching of size $|A|$ between sets of points $A, B \subseteq \mathbb{R}^d$ with $|A| \leq |B|$. The problems of computing EMD and asymmetric EMD are well-studied and have many applications in computer science, some of which also ask for the EMD-optimal matching itself. Unfortunately, all known algorithms require at least quadratic time to compute EMD exactly. Approximation algorithms with nearly linear time complexity in n are known (even for finding approximately optimal matchings), but suffer from exponential dependence on the dimension.

In this paper we show that significant improvements in exact and approximate algorithms for EMD would contradict conjectures in fine-grained complexity. In particular, we prove the following results:

- Under the Orthogonal Vectors Conjecture, there is some $c > 0$ such that EMD in $\Omega(c^{\log^* n})$ dimensions cannot be computed in truly subquadratic time.
- Under the Hitting Set Conjecture, for every $\delta > 0$, no truly subquadratic time algorithm can find a $(1 + 1/n^\delta)$ -approximate EMD matching in $\omega(\log n)$ dimensions.
- Under the Hitting Set Conjecture, for every $\eta = 1/\omega(\log n)$, no truly subquadratic time algorithm can find a $(1 + \eta)$ -approximate asymmetric EMD matching in $\omega(\log n)$ dimensions.

1 Introduction

In the *Earth Mover Distance (EMD) problem*, we are given two sets A and B each with n vectors in \mathbb{R}^d , and want to find the minimum cost of any perfect matching between A and B , where an edge between $a \in A$ and $b \in B$ has cost $\|a - b\|_2$.

In a harder variant of the problem (“EMD matching”), we want to actually *find* a perfect matching with the optimal cost. This is a special case of the *geometric transportation problem*, in which each vector of A has a positive supply and each vector of B has a positive demand, and the goal is to find an optimal “transportation map”, i.e., match each unit of supply with a unit of demand while minimizing the total distance, summed over all units of supply.

A more general variant of the EMD problem (with an analogous extension to arbitrary supplies/demands) allows for the possibility that $|A| < |B|$, and requires the map from A to B to be an injection. We refer to this variant as the *asymmetric EMD problem*.

Earth Mover Distance is a discrete analogue of the Monge-Kantorovich metric for probability measures, which has connections to various areas of mathematics [26]. Furthermore, computing distance between probability measures is an important problem in machine learning [23, 20, 7, 13] and computer vision [22, 10, 25], to which Earth Mover Distance is often applied. To provide a few specific examples, computing geometric transportation cost has applications in image retrieval [22], where asymmetric EMD allows the distance to deal with occlusions and clutter. In computer graphics, computing the actual transportation map is useful for interpolation between distributions, though the metric may be non-Euclidean [10].

For the exact geometric transportation problem, the best known algorithm simply formulates the problem in terms of minimum cost flow, yielding a runtime of $O(n^{2.5} \cdot \text{polylog}(U))$ where U is the total supply (assuming that d is subpolynomial in n) [18, 19]. Even for EMD, the best known algorithm follows directly from the general graph algorithms for maximum matching in $O(m\sqrt{n})$ time [14].

The situation is better for approximation algorithms. There has been considerable work on both estimating the transportation cost [15, 6] and computing the actual map [24, 3, 5] in time nearly linear in n but exponential in dimension d . Most recently, it was shown [17] that there is an $O(n\epsilon^{-O(d)} \log(U)^{O(d)} \log^2 n)$ time algorithm which outputs a transportation map with cost at most $(1 + \epsilon)$ times the optimum. This algorithm is very efficient when the dimension d is constant or nearly constant, and when ϵ is not too small – say, constant or $O(1/\text{polylog}(n))$. However, when $d = \omega(\log n)$, the algorithm is not guaranteed to find even a constant-factor approximation in quadratic time.

Despite considerable progress on improving the *algorithms* for geometric matching problems over the last two decades, little is known about *lower bounds* on their computational complexity. In particular, we do not have any evidence that a running time of the form $O(n \cdot \text{poly}(d, \log n, 1/\epsilon))$ is not achievable. This is the question we address in this paper.

1.1 Our Results

In this paper we provide evidence that geometric transportation problems in high-dimensional spaces cannot be solved in (truly) subquadratic time. This applies to both exact and approximate variants of the problem, and even in the special case of unit supplies. In particular we show a conditional quadratic hardness for the exact EMD problem, as well as the approximate variant of EMD when the (approximately) optimal matching must be reported.

Our hardness results are based on two well-studied conjectures in fine-grained complexity: Orthogonal Vectors Conjecture and Hitting Set Conjecture (see [29] for a comprehensive survey).

1.1.1 Exact EMD and Orthogonal Vectors Conjecture

The *Orthogonal Vectors (OV) problem* takes as input two sets $A, B \subseteq \{0, 1\}^{d(n)}$ where $|A| = |B| = n$ and asks whether there are some vectors $a \in A$ and $b \in B$ such that $a \cdot b = 0$. The popular *Orthogonal Vectors Conjecture* hypothesizes that in sufficiently large dimensions, the obvious quadratic time algorithm for OV is nearly optimal:

► **Orthogonal Vectors Conjecture.** *Let $d(n) = \omega(\log n)$. For every constant $\epsilon > 0$, no randomized algorithm can solve $d(n)$ -dimensional OV in $O(n^{2-\epsilon})$ time.*

A plethora of problems have been shown to have nontrivial lower bounds under the Orthogonal Vectors Conjecture; often these lower bounds are essentially tight (e.g. [1, 2, 8, 11, 28]; see [29] for a comprehensive survey). It is known that if the conjecture fails, then the Strong Exponential Time Hypothesis (SETH) fails as well [27], providing evidence for hardness of OV, and by extension of these problems to which OV can be reduced.

Our first result shows that EMD in “nearly constant” dimension is hard to compute exactly in truly subquadratic time, under the Orthogonal Vectors Conjecture:

► **Theorem 1.** *There is a constant $c > 0$ under which the following holds. If there exists $\epsilon > 0$ and $d(n) = \Omega(c^{\log^* n})$ such that EMD on $O(\log n)$ -bit vectors in $d(n)$ dimensions can be computed in $O(n^{2-\epsilon})$ time, then the Orthogonal Vectors Conjecture is false.*

Using techniques similar to those for the above theorem, we also address a question raised in [9] about the complexity of the maximum/minimum weighted assignment problem when the weight matrix has low rank. The minimum weighted assignment problem is defined as follows: given an $n \times n$ weight matrix which determines a complete bipartite graph, find the cost of the minimum weight perfect matching. Motivated by the observation that the problem can be solved in $O(n \log n)$ time if the weight matrix is rank-1, it is asked whether there is an $O(nr^2 \log n)$ time algorithm for rank- r matrices [9]. We can answer this question in the negative, under the Orthogonal Vectors Conjecture. In fact, we can show something stronger (see Appendix A for the proof):

► **Theorem 2.** *There is a constant $c > 0$ under which the following holds. If there exists $\epsilon > 0$ and $r(n) = \Omega(c^{\log^* n})$ such that the minimum assignment problem with rank- r weight matrices can be solved in $O(n^{2-\epsilon})$ time, then the Orthogonal Vectors Conjecture is false.*

1.1.2 Approximate EMD and the Hitting Set Conjecture

The second conjecture on which we base some of our results is hardness of the *Hitting Set (HS) problem*. This problem, similar to OV, takes two sets of vectors $A, B \subseteq \{0, 1\}^d$ as input, and asks whether there exists some $a \in A$ such that $a \cdot b \neq 0$ for every $b \in B$.

► **Hitting Set Conjecture.** *Let $d(n) = \omega(\log n)$. For every constant $\epsilon > 0$, no randomized algorithm can solve $d(n)$ -dimensional HS in $O(n^{2-\epsilon})$ time.*

It is known that HS reduces to OV, but the reverse reduction is unknown, so the Hitting Set Conjecture is “stronger” than the Orthogonal Vectors Conjecture [2]. The Hitting Set Conjecture has been used to prove conditional hardness of the Radius problem in sparse graphs [2]. The utility of the Hitting Set problem in conditional hardness results comes from the difference between its “ $\exists\forall$ ” logical structure and the “ $\exists\exists$ ” logical structure of the Orthogonal Vectors problem, which makes it more natural for some types of problems.

Under the Hitting Set Conjecture, we prove hardness of approximation for the EMD matching problem (in which we want to find the optimal or nearly-optimal matching). Simultaneously we obtain stronger hardness of approximation for asymmetric EMD matching.

► **Theorem 3.** *For any $\delta > 0$ and $d(n) = \omega(\log n)$, if $(1 + 1/n^\delta)$ -approximate EMD matching can be solved in $d(n)$ dimensions in truly subquadratic time, then the Hitting Set conjecture is false.*

► **Theorem 4.** *For any $d(n) = \omega(\log n)$ and $\eta = 1/\omega(\log n)$, if $(1 + \eta)$ -approximate asymmetric EMD matching can be solved in $d(n)$ dimensions in truly subquadratic time, then the Hitting Set Conjecture is false.*

Finally, motivated by the question of how hard Hitting Set really is, compared to Orthogonal Vectors, we generalize the result that Hitting Set reduces to Orthogonal Vectors by finding a set of approximation problems that lie between Orthogonal Vectors and Hitting Set in difficulty. For a positive integer function $k(n) \leq n/2$, we define the $(k, 2k)$ -Find-OV

(a) Structure of Theorem 1.

(b) Structure of Theorem 3.

■ **Figure 1** Summary of reductions.

problem: given two sets $A, B \subseteq \{0, 1\}^{d(n)}$ with $|A| = |B| = n$ and the guarantee that there exist at least $2k$ orthogonal pairs between A and B , find k pairs $\{(a_i, b_i)\}_{i=1}^k$ such that $a_i \cdot b_i = 0$ for every i .

We prove the following theorem in Appendix C.

► **Theorem 5.** *Let $k(n) \leq n/2$. If $(k, 2k)$ -Find-OV can be solved in truly subquadratic time, then the Hitting Set conjecture is false.*

See Figure 1 for an overview of the structure of our main results (Theorems 1 and 3 respectively; the proof of Theorem 4 has the same structure as the latter). We provide the remaining definitions of the relevant problems in the next section.

2 Preliminaries

Before diving into the reductions, we formally define the remainder of the problems which we’re studying. Each problem we study takes sets of vectors as input, so one parameter of a problem is the dimension d , which is a function of the input size n . That is, every function $d : \mathbb{N} \rightarrow \mathbb{N}$ defines a $d(n)$ -dimensional EMD problem, and a $d(n)$ -dimensional OV problem, and so forth. We gloss over this choice of d in the subsequent definitions.

2.1 Earth Mover Distance

The *Earth Mover Distance (EMD)* problem is defined as follows: given two sets $A, B \subseteq \mathbb{R}^{d(n)}$ with $|A| = |B|$, find

$$\min_{\pi: A \rightarrow B} \sum_{a \in A} \|a - \pi(a)\|_2$$

where π is a bijection. We’ll restrict our attention to the special cases where $A, B \subseteq \mathbb{Z}^{d(n)}$ with polynomially bounded entries (for hardness of exact EMD) and $A, B \subseteq \{0, 1\}^{d(n)}$ (for hardness of approximate EMD).

We can define the *asymmetric EMD* problem as above, except we relax the constraint $|A| = |B| = n$ to $|A| \leq |B| = n$, and require π to be an injection rather than a bijection.

The *EMD matching* problem is the variant of the EMD problem in which the desired output is the optimal matching π . Similarly we can define the *asymmetric EMD matching* problem. An algorithm “solves” EMD matching (or its asymmetric variant) up to a certain additive or multiplicative factor if the cost of the bijection it outputs differs from the optimal cost by at most that additive or multiplicative factor.

2.2 Variants of Orthogonal Vectors

The reduction from Hitting Set to approximate EMD matching will go through the variants of OV defined next.

The *Maximum Orthogonal Matching (MOM)* problem is defined as follows: given two sets $A, B \subseteq \{0, 1\}^{d(n)}$, with $|A| \leq |B| = n$, find an injection $\pi : A \rightarrow B$ which maximizes

$$|\{a \in A \mid a \cdot \pi(a) = 0\}|.$$

And the *Find-OV* problem is defined as follows: given two sets $A, B \subseteq \{0, 1\}^{d(n)}$ with $|A| = |B| = n$, find the set $S \subseteq A$ of vectors $a \in A$ such that there exists some $b \in B$ with $a \cdot b = 0$. An algorithm solves Find-OV up to an additive error of t if it returns a set $S' \subseteq S$ for which $|S'| \geq |S| - t$.

2.3 Relevant prior work

We will apply the following theorem from [12] to our low-dimensional hardness result of exact EMD:

► **Theorem 6** ([12]). *Assuming OVC, there is a constant $c > 0$ such that Bichromatic ℓ_2 -Closest Pair in $c^{\log^* n}$ dimensions requires $n^{2-o(1)}$ time, with vectors of $O(\log n)$ bit entries.*

3 Exact EMD in low dimensions

To prove hardness of the exact EMD problem under the Orthogonal Vectors Conjecture, we reduce to the bichromatic closest pairs problem, and then apply Theorem 6 due to [12]. The intuition for the reduction is as follows: given two sets A and B of n vectors, we’d like to augment set A with $n - 1$ copies of a vector that is equidistant from all of B , and much closer to B than A is. Similarly, we’d like to augment set B with $n - 1$ copies of a vector that is equidistant from all of A , and much closer to A than B is. If this were possible, then the minimum cost matching between the augmented sets would only match one pair of the original sets: the desired closest pair.

Unfortunately, it is in general impossible to find a vector equidistant from n vectors in $d \ll n$ dimensions. But this can be circumvented by embedding the vectors in a slightly higher-dimensional space, and adjusting coordinates in the “free” dimensions to ensure that an equidistant vector exists. So long as the free dimensions used to adjust set A are disjoint from the free dimensions used to adjust set B , the inner products between A and B are unaffected, and the distances change in an accountable way.

Since we are working in the ℓ_2 norm, we will need the following simple lemma which shows that any integer can be efficiently decomposed as a sum of a constant number of perfect squares.

► **Lemma 7.** *For any $\rho > 0$ and any positive integer m , there is an $O(m^\rho)$ time algorithm to decompose m as a sum of $O(\log 1/\rho)$ perfect squares.*

12:6 Conditional Hardness of Earth Mover Distance

Proof. Here is the algorithm: repeatedly find the largest square which does not push the total above m , until the remainder does not exceed $O(m^{\rho/2})$. Then compute the minimal square decomposition for the remainder by dynamic programming.

The first, greedy phase takes $O(\text{polylog}(m))$ time and finds $O(\log 1/\rho)$ perfect squares which sum to some m' with $m - m^{\rho/2} \leq m' \leq m$. The second, dynamic programming phase takes $O(m^\rho)$ time (even naively). By Lagrange's four-square theorem, a decomposition of $m - m'$ into at most four perfect squares is found. ◀

Now we describe the main reduction of this section. We'll use a shorthand notation to define vectors more concisely: for example, $a^x b^y c^z$ refers to an $(x + y + z)$ -dimensional vector with value a in the first x dimensions, b in the next y dimensions, and c in the next z dimensions.

► **Theorem 8.** *Let $d = d(n) \leq n$ be a dimension, and let $k > 0$ be a constant. There is a constant $c = c(k)$ for which the following holds. Suppose that there is an algorithm which computes the ℓ_2 earth mover distance between sets $A', B' \subseteq [1, n^{16k}]^{2d+2c+2}$ of size n in $O(n^{2-\epsilon})$ time. Then bichromatic closest pair between sets $A, B \subseteq [1, n^k]^d$ of size n can be computed in $O(n^{2-\epsilon})$ time as well.*

Proof. Set $\rho = 1/(16k)$, and let $c = O(\log 1/\rho)$ be the constant in Lemma 7 for the number of perfect squares in a decomposition. Let A and B be two sets of vectors from $\{1, \dots, n^k\}^d$. Let $N = n^{16k}$. Our goal is to compute

$$\min_{a \in A, b \in B} \|a - b\|_2.$$

We can assume without loss of generality that $\|a\|_2^2$ and $\|b\|_2^2$ are odd for all $a \in A$ and $b \in B$: for instance, we can replace each vector $z = (z_1, \dots, z_d)$ by $(2z_1, \dots, 2z_d, 1)$.

We construct sets A' and B' of $(2d + 2c + 2)$ -dimensional vectors as follows. Let $u = 0^d(10^c)0^{c+1}0^d$ (parentheses for clarity). Let $v = N^d 0^{c+1}(10^c)0^d$. Add $n - 1$ copies of u to B' and add $n - 1$ copies of v to A' . For each $a \in A$, add the following vector to A' , where we'll define vector $\text{adj}_a \in \mathbb{Z}^{c+1}$ later:

$$a' = f(a) = 0^d(\text{adj}_a)0^{c+1}a.$$

Similarly, for each $b \in B$, add the following vector to B' , where we'll define $\text{adj}_b \in \mathbb{Z}^{c+1}$ later:

$$b' = g(b) = N^d 0^{c+1}(\text{adj}_b)b.$$

Now pick any $a \in A$. We'll construct adj_a so that the following equalities are both satisfied:

$$\|a' - u\|_2^2 = n^{4k}d^2 = \|\text{adj}_a\|_2^2.$$

Define the first element $\text{adj}_a(0) = (\|a\|_2^2 + 1)/2$. Since $\|a\|_2^2 \leq n^{2k}d$, we can then use Lemma 7 to find c integers $\text{adj}_a(1), \dots, \text{adj}_a(c)$ so that $\|\text{adj}_a\|_2^2 = n^{4k}d^2$. Furthermore,

$$\begin{aligned} \|a' - u\|_2^2 &= \|\text{adj}_a - 10^c\|_2^2 + \|a\|_2^2 \\ &= \|\text{adj}_a\|_2^2 - 2 \cdot \text{adj}_a(0) + 1 + \|a\|_2^2 \\ &= n^{4k}d^2. \end{aligned}$$

For each $b \in B$, we can similarly construct adj_b so that $\|b' - v\|_2^2 = \|\text{adj}_b\|_2^2 = n^{4k}d^2$.

We claim that

$$\text{EMD}(A', B') = 2(n-1)n^{2k}d + \min_{a \in A, b \in B} \sqrt{N^2d + 2n^{4k}d^2 + \|a - b\|_2^2}.$$

To prove this claim, notice that $\|u - v\|_2 \geq N\sqrt{d}$ and $\|a' - b'\|_2 \geq N\sqrt{d}$ for every $a' \in A' \setminus \{v\}$ and $b' \in B' \setminus \{u\}$, whereas $\|a' - u\|_2 \ll N\sqrt{d}/n$ and $\|b' - v\|_2 \ll N\sqrt{d}/n$. This means that the optimal matching between A' and B' will minimize the number of (u, v) and (a', b') edges. Hence, exactly one element of $A' \setminus \{v\}$ will be matched to an element in $B' \setminus \{u\}$. So if M denotes this optimal matching, and $x' = f(x) \in A'$ is matched with $y' = g(y) \in B'$, then the cost of M is

$$\begin{aligned} \text{cost}(M) &= \left(\sum_{a' \in A' \setminus \{v, x'\}} \|a' - u\|_2 + \sum_{b' \in B' \setminus \{u, y'\}} \|b' - v\|_2 \right) + \|x' - y'\|_2 \\ &= 2(n-1)n^{2k}d + \sqrt{N^2d + \|\text{adj}_x\|_2^2 + \|\text{adj}_y\|_2^2} + \|x - y\|_2^2 \\ &= 2(n-1)n^{2k}d + \sqrt{N^2d + 2n^{4k}d^2 + \|x - y\|_2^2}. \end{aligned}$$

The claim follows. So the algorithm is simply: run the EMD algorithm on (A', B') and use the computed matching cost to find the closest pair distance, according to the above formula.

The time complexity of constructing A', B' is $O(n^{5/4}d^{1/8})$, dominated by computing a square decomposition for each vector. Since A' and B' are sets of $O(n)$ vectors in $\mathbb{Z}^{2d+2c+2}$ with entries bounded by $\max(N, n^{2k}d) \leq n^{16k}$, the EMD between A' and B' can be computed in $O(n^{2-\epsilon})$ time. Thus, the overall algorithm takes $O(n^{2-\epsilon})$ time. \blacktriangleleft

Theorem 1 follows from the above reduction and Theorem 6.

4 Approximate EMD under the Hitting Set Conjecture

In this section we prove hardness of approximation for the EMD matching problem when the approximately optimal matching must be reported. Note that the techniques from the previous section do not immediately generalize to this scenario, since the reduction in Theorem 8 is not approximation-preserving. A multiplicative error of $1 + \epsilon$ in the EMD algorithm would induce an additive error of $\tilde{O}(\epsilon n^{16k})$ in the closest pair algorithm, due to the large integers constructed in the reduction. A bucketing scheme, to ensure that the diameter of the input point set is within a constant factor of the closest pair, could eliminate the dependence on the values of the input coordinates, yielding a multiplicative error of only $1 + \tilde{O}(\epsilon n)$.

However, $(1 + \epsilon)$ -approximate closest pair is only quadratically hard for $\epsilon = o(1)$ [21]; for any constant $\epsilon > 0$, there is a subquadratic $(1 + \epsilon)$ -approximation algorithm [16, 4]. Thus, the above arguments would only yield $(1 + \tilde{O}(1/n))$ -approximate hardness. Furthermore, the factor of n loss intuitively feels intrinsic to the approach of reducing from closest pair, since the EMD is the sum of n distances. Thus, a different approach seems necessary if we are to achieve hardness for $\epsilon = \omega(1/n)$.

Our method broadly consists of two steps. First, we show that EMD can encode orthogonality, by reducing approximate Maximum Orthogonal Matching (the problem of reporting a maximum matching in the implicit graph with an edge for each orthogonal pair) to approximate EMD matching. Second, we show that approximate Maximum Orthogonal matching can solve an instance (A, B) of Hitting Set by finding an orthogonal pair (a, b) for every $a \in A$ if possible, even if the set of orthogonal pairs does not constitute a matching.

12:8 Conditional Hardness of Earth Mover Distance

We start by proving that asymmetric EMD matching reduces to EMD matching for the appropriate choices of error bounds. The reduction pads the smaller set of vectors A with a vector that is equidistant from the opposite set B , so that its contribution to the earth mover distance can be accounted for. Of course, it is first necessary to transform the vectors so that an equidistant vector exists.

► **Lemma 9.** *Suppose that $(1 + \epsilon)$ -approximate EMD matching in D dimensions can be solved in $T(n, D)$ time. Then $(1 + \epsilon)$ -approximate asymmetric EMD matching in d dimensions can be solved with an additional additive factor of $n\epsilon\sqrt{d}$ in $T(n, 2d)$ time.*

Proof. Let $A, B \subseteq \{0, 1\}^d$ with $|A| \leq |B|$. Define sets $A', B' \subseteq \{0, 1\}^{2d}$ by mapping $a \in A$ to the vector

$$(a_1, \dots, a_d, 1 - a_1, \dots, 1 - a_d)$$

and similarly mapping $b \in B$ to

$$(b_1, \dots, b_d, 1 - b_1, \dots, 1 - b_d).$$

Then add $|B| - |A|$ copies of the zero vector to A' .

Now $|A'| = |B'|$, so we can run the approximate EMD algorithm on A' and B' to find some bijection $\pi : A' \rightarrow B'$ such that

$$\sum_{a' \in A'} \|a' - \pi(a')\|_2 \leq (1 + \epsilon)EMD(A', B').$$

Each vector $b' \in B'$ has $\|b'\|_2^2 = d$, so the distance from the zero vector to each match is exactly \sqrt{d} . And for any $a \in A$ and $b \in B$ which map to $a' \in A'$ and $b' \in B'$,

$$\|a' - b'\|_2^2 = 2\|a - b\|_2^2.$$

Hence, the cost of π is

$$\sum_{a' \in A'} \|a' - \pi(a')\|_2 = (|B| - |A|)\sqrt{d} + \sqrt{2} \cdot \sum_{a \in A} \|a - \pi(a)\|_2$$

and the optimal cost is

$$EMD(A', B') = (|B| - |A|)\sqrt{d} + \sqrt{2} \cdot EMD(A, B).$$

It follows that

$$\sum_{a \in A} \|a - \pi(a)\|_2 \leq \frac{\epsilon}{\sqrt{2}}(|B| - |A|)\sqrt{d} + (1 + \epsilon)EMD(A, B),$$

which is the stated error bound. ◀

Next, we reduce approximate Maximum Orthogonal Matching to approximate asymmetric EMD matching. The general idea, given input sets (A, B) , is to deform A and B so that orthogonal pairs (a, b) are mapped to pairs (a'', b'') with distance d_0 , and all other pairs are mapped to pairs with distance at least $d_1 > d_0$. Then add $|A|$ auxiliary vectors to B , each with distance exactly d_1 from all vectors in A . Thus, in an optimal matching, each vector of A is either matched with an orthogonal vector at distance d_0 , or some vector with distance exactly d_1 . This introduces a nonlinearity, ensuring that in the additive matching cost, an

orthogonal pair's contribution is not “cancelled out” by the contribution of a pair with dot product 2, for instance. A similar trick was used by [8] in the context of edit distance, another “additive” metric.

The following simple lemma will be useful:

► **Lemma 10.** *There are maps $\phi_1, \phi_2 : \{0, 1\}^d \rightarrow \{0, 1\}^{3d}$ such that for any $a, b \in \{0, 1\}^d$,*

$$\phi_1(a) \cdot \phi_2(b) = d - (a \cdot b).$$

Furthermore, the maps can be evaluated in $O(d)$ time.

Proof. Each dimension expands into three dimensions as follows:

$$a_i \mapsto (\phi_1(a)_{3i}, \phi_1(a)_{3i+1}, \phi_1(a)_{3i+2}) = (a_i, 1 - a_i, 1 - a_i)$$

$$b_i \mapsto (\phi_2(b)_{3i}, \phi_2(b)_{3i+1}, \phi_2(b)_{3i+2}) = (1 - b_i, b_i, 1 - b_i).$$

Then for each i ,

$$\sum_{j=3i}^{3i+2} \phi_1(a)_j \phi_2(b)_j = a_i(1 - b_i) + (1 - a_i)b_i + (1 - a_i)(1 - b_i) = 1 - a_i b_i.$$

Summing over $i = 1, \dots, d$ we get $\phi_1(a) \cdot \phi_2(b) = d - (a \cdot b)$ as desired. ◀

► **Lemma 11.** *Suppose that $(1 + \epsilon)$ -approximate asymmetric EMD in D dimensions can be solved with an additional additive factor of $n\epsilon\sqrt{D}$ in $T(n, D)$ time. Then the Maximum Orthogonal Matching problem in d dimensions can be solved up to an additive factor of $O(n\epsilon d)$ in $T(2n, 12d + 1)$ time.*

Proof. Let $A, B \subseteq \{0, 1\}^d$ with $|A| \leq |B| = n$. Define $A', B' \subseteq \{0, 1\}^{3d}$ by $A' = \phi_1(A)$ and $B' = \phi_2(B)$, where ϕ_1, ϕ_2 are as defined in Lemma 10.

Let $d' = 3d$ for convenience. Now we construct sets $A'', B'' \subseteq \{0, 1\}^{4d'+1}$ as follows, starting from sets A' and B' . We add $2d'$ dimensions to ensure that $\|a''\|_2^2 = \|b''\|_2^2 = d'$ for every $a'' \in A''$ and $b'' \in B''$ without changing the inner products. Add another $d' + 1$ dimensions, extending each $a'' \in A''$ so that $a''_{3d'+1} = 1$ and $a''_i = 0$ otherwise; and extend each $b'' \in B''$ so that $b''_{3d'+2} = 1$ and $b''_i = 0$ otherwise. Finally augment B'' with $|A|$ copies of the vector $v \in \{0, 1\}^{4d'+1}$ with $3d'$ zeros followed by $d' + 1$ ones.

Notice that for every $a \in A$ and $b \in B$ corresponding to some $a'' \in A''$ and $b'' \in B''$,

$$\|a'' - b''\|_2^2 = \|a''\|_2^2 + \|b''\|_2^2 - 2a'' \cdot b'' = 2(d' + 1) - 2a'' \cdot b'' = 2a \cdot b + 4d + 2,$$

and

$$\|a'' - v\|_2^2 = 2(d' + 1) - 2a'' \cdot v = 4d + 4.$$

Now we run the approximate asymmetric EMD matching algorithm on A'' and B'' , yielding an injection $\pi : A'' \rightarrow B''$ such that

$$\sum_{a'' \in A''} \|a'' - \pi(a'')\|_2 \leq |B''| \epsilon \sqrt{4d' + 1} + (1 + \epsilon) \text{EMD}(A'', B'').$$

For each $a'' \in A''$, if $\|a'' - \pi(a'')\|_2^2 > 4d + 4$, then we can set $\pi(a'') = v$, preserving injectivity and decreasing the cost of the matching. Therefore every edge has cost either $\sqrt{4d + 2}$ or $\sqrt{4d + 4}$. In particular, if there are m orthogonal pairs in the matching, the total cost is

$$\sum_{a'' \in A''} \|a'' - \pi(a'')\|_2 = m\sqrt{4d + 2} + (|A| - m)\sqrt{4d + 4}.$$

12:10 Conditional Hardness of Earth Mover Distance

By the same argument as above, the minimum cost matching is obtained by maximizing the number of orthogonal pairs. If the maximum possible number of orthogonal pairs in a matching is m_{OPT} , then

$$\text{EMD}(A'', B'') = m_{\text{OPT}}\sqrt{4d+2} + (|A| - m_{\text{OPT}})\sqrt{4d+4}.$$

Substituting these expressions into the approximation guarantee and solving, we get that $m \geq m_{\text{OPT}} - O(\epsilon nd)$ as desired. \blacktriangleleft

In the above lemma we assumed that we are given an algorithm for asymmetric EMD matching which has both a multiplicative error of $1 + \epsilon$ and an additive error of $n\epsilon\sqrt{d}$, since this is the error introduced by the reduction to (symmetric) EMD. However, we are also interested in the hardness of $(1 + \epsilon)$ -approximate asymmetric EMD matching in its own right. Removing the additive error from the hypothesized algorithm in Lemma 11 directly translates to an improved Maximum Orthogonal Matching algorithm, with an additive error of $O(\epsilon|A|d)$ instead of $O(\epsilon nd)$, where $n = |A| + |B|$:

► **Lemma 12.** *Suppose that there is an algorithm which solves $(1 + \epsilon)$ -approximate asymmetric EMD matching in $T(|A| + |B|, d)$ time, where the input is $A, B \subseteq \{0, 1\}^d$. Then the Maximum Orthogonal Matching problem can be solved up to an additive error of $O(\epsilon|A|d)$ in $T(2n, 12d + 1)$ time.*

Now we could reduce OV to approximate Maximum Orthogonal Matching. The proof of the following theorem is given in Appendix B for completeness.

► **Theorem 13.** *Let $d = \omega(\log n)$. Under the Orthogonal Vectors Conjecture, for any $\epsilon > 0$ and $\delta \in (0, 1)$, $(1 + 1/n^\delta)$ -approximate EMD matching in $\{0, 1\}^d$ cannot be solved in $O(n^{2\delta-\epsilon})$ time.*

However, Theorem 13 does not prove quadratic hardness for any approximation factor larger than $(1 + 1/n)$, and in fact breaks down completely for $(1 + 1/\sqrt{n})$ -approximate EMD matching.

Instead, we reduce Hitting Set to approximate Maximum Orthogonal Matching, through approximate Find-OV. These two problems are structurally similar; the technical difficulty is that Find-OV may require finding many orthogonal pairs even when the largest orthogonal matching may be small, in which case applying the Maximum Orthogonal Matching algorithm would result in little progress. We resolve this with the following insight: if many vectors in set A are orthogonal to at least one vector in set B but there is not a large orthogonal matching, then some vector in set B is orthogonal to *many* vectors in A . But these vectors can be found efficiently by sampling.

In the proof of the following theorem we formalize the above idea.

► **Theorem 14.** *Let $d = d(n)$ be a dimension. Suppose that the Maximum Orthogonal Matching problem can be solved up to an additive error of $E(|A|, |B|)$ in $O(n^{2-\epsilon}\text{poly}(d))$ time, where the input is $A, B \subseteq \{0, 1\}^d$. Then for any (sufficiently small) $\alpha > 0$ there is some $\gamma > 0$ such that Find-OV can be solved with high probability up to an additive error of $E(|A|, 2|B|^{1+\alpha})$ in $O(n^{2-\gamma}\text{poly}(d))$ time.*

Proof. Let $A, B \subseteq \{0, 1\}^d$ with $|A| = |B| = n$. Let $\alpha > 0$ be a constant we choose later. We may safely assume that $\alpha < 1$. Let the degree of a vector $a \in A$, denoted $d(a)$, be the number of $b \in B$ which are orthogonal to a . The algorithm for Find-OV consists of three steps:

1. For every $a \in A$, sample $n^{1-\alpha/4}$ vectors from B to get an estimate $\hat{d}(a)$ of $d(a)$. Mark and remove the vectors for which $\hat{d}(a) \geq n^{\alpha/2}$.
2. Next, for every $b \in B$, sample $n^{1-\alpha/2}$ vectors from A to get an estimate $\hat{d}(b)$ of $d(b)$. Let $B_{\text{large}} \subseteq B$ be the set of vectors for which $\hat{d}(b) \geq n^{\alpha}$. For each $b \in B_{\text{large}}$, iterate over A and mark and remove each $a \in A$ for which $a \cdot b = 0$. Now remove B_{large} from B .
3. Run the Maximum Orthogonal Matching algorithm on the remaining set A , and the multiset consisting of $2n^{\alpha}$ copies of each remaining $b \in B$. This produces a set of pairs (a_i, b_i) where $a_i \cdot b_i = 0$. Output the union of $\{a_i\}_i$ and the set of all vectors marked and removed from A in the previous steps.

In the first step, a Chernoff bound shows that with high probability, every vector for which $d(a) \geq 2n^{\alpha/2}$ is marked and removed. Now summing over the remaining vectors,

$$\sum_{a \in A} d(a) = \sum_{b \in B} d(b) \leq 2n^{1+\alpha/2}.$$

In the second step, with high probability B_{large} contains no $b \in B$ for which $d(b) \leq \frac{1}{2}n^{\alpha}$, by a Chernoff bound on each such $b \in B$. Therefore $|B_{\text{large}}| \leq 4n^{1-\alpha/2}$. Furthermore, with high probability B_{large} contains every $b \in B$ for which $d(b) \geq 2n^{\alpha}$.

So after the first two steps, every remaining vector $b \in B$ has degree at most $2n^{\alpha}$. Suppose there are t vectors $a \in A$ with positive degree, and t' of these are found in the first two steps. Then by the degree bound, the remaining $t - t'$ vectors inject into $2n^{\alpha}$ copies of B . Therefore there is an orthogonal matching of size at least $t - t'$. By the approximation guarantee of the Maximum Orthogonal Matching algorithm, we find an orthogonal matching of size at least $t - t' - 2n^{(1+\alpha)\delta}$ in step 3. Overall, we find at least $t - 2n^{(1+\alpha)\delta}$ vectors with positive degree, which gives the desired approximation guarantee.

The time complexity is $O((n^{2-\alpha/4} + n^{(2-\epsilon)(1+\alpha)})\text{poly}(d))$. This is subquadratic in n for sufficiently small α . ◀

As the final step of the reduction, we show that approximate Find-OV can solve Hitting Set. Note that exact Find-OV obviously solves Hitting Set. It's also clear that Find-OV with an additive error of $n^{1-\epsilon}$ solves Hitting Set: simply run Find-OV, and then exhaustively check the remaining unpaired vectors of A – unless there are more than $n^{1-\epsilon}$ unpaired vectors, in which case there must be a hitting vector.

To reduce Hitting Set to Find-OV with additive error of $\Theta(n)$, the essential idea is simply to repeatedly run Find-OV on the remaining unpaired vectors. If the Find-OV algorithm has an additive error of $n/2$, then given an input A, B with no hitting vector, the algorithm will find orthogonal pairs for at least $n/2$ vectors of A . Naively, we'd like to recurse on the remaining half of A . Unfortunately, the set B cannot similarly be halved, so the error bound in the next step would not be halved. Thus, the algorithm might make no further progress.

The workaround is to duplicate every unpaired vector of A before recursing. If $n/2$ orthogonal pairs are found but every vector of A has been duplicated once, then matches are found for at least $n/4$ distinct vectors. This suffices to terminate the recursion in $O(\log n)$ steps.

► **Theorem 15.** *Suppose that Find-OV in d dimensions can be solved up to additive error of $n/2$ in $T(n, d)$ time. Then Hitting Set in d dimensions can be solved in $O((T(n, d) + nd) \log n)$ time.*

Proof. Let $A, B \subseteq \{0, 1\}^d$ with $|A| = |B| = n$. Our hitting set algorithm consists of $t = \lceil \log n \rceil + 1$ phases. Initialize $R_1 = A$.

12:12 Conditional Hardness of Earth Mover Distance

In phase $i \geq 1$, run Find-OV on $(2^{i-1}R_i, B)$, where $2^i R_i$ is the multiset with 2^i copies of each vector in R_i . Let $P \subseteq A$ be the output multiset and let P' be the corresponding set (removing duplicates). Set $R_{i+1} = R_i \setminus P'$. If $|R_{i+1}| > n/2^i$, report failure (i.e. there is a hitting vector). Otherwise, proceed to the next phase. If phase t is complete, report success (i.e. no hitting vector).

Suppose that the algorithm reports success. Then after phase t , we have $R_{t+1} \leq n/2^t < 1$. Then for every $a \in A$ there was some phase i in which a was removed from R_i , and therefore was orthogonal to some $b \in B$. So there is no hitting vector.

Suppose that the algorithm reports failure in phase i . Then $|R_i| \leq n/2^{i-1}$ and $|R_{i+1}| > n/2^i$, so $|P'| < n/2^i$. Therefore $|P| \leq 2^{i-1}|P'| < n/2$. By the Find-OV approximation guarantee, not every element of R_i is orthogonal to an element of B . So there is a hitting vector.

The time complexity is dominated by $O(\log n)$ applications of Find-OV on inputs of size $O(n)$, along with $O(nd)$ extra processing in each phase. Thus, the time complexity is $O((T(n, d) + nd) \log n)$. ◀

The next theorem shows that hardness for approximate EMD matching (conditioned on the Hitting Set Conjecture) follows from chaining together the above reductions.

► **Theorem 16.** *If there are any $\epsilon, \delta > 0$ such that $(1+1/n^\delta)$ -approximate EMD matching can be solved in $O(n^{2-\epsilon})$ time for some dimension $d = \omega(\log n)$, then the Hitting Set Conjecture is false.*

Proof. Fix $d = \omega(\log n)$, and assume without loss of generality that $d(n)$ is polylogarithmic. Let $\epsilon, \delta > 0$ and suppose that $(1+1/n^\delta)$ -approximate EMD matching can be solved in $O(n^{2-\epsilon})$ time. Then $(1+1/n^\delta)$ -approximate asymmetric EMD can be solved with an additional additive error of $n^{1-\delta}\sqrt{d}$ with the same time complexity, by Lemma 9. Hence, the Maximum Orthogonal Matching problem can be solved with an additive error of $n^{1-\delta}d$ in the same time, by Lemma 11.

Applying Theorem 14 with parameter $\alpha = \delta$, we get a randomized algorithm for Find-OV with an additive error of $O(n^{1-\delta^2}d^{1+\delta})$ and time complexity $O(n^{2-\gamma})$ for some $\gamma > 0$. For sufficiently large n , the error is at most $n/2$. Thus, we can apply Theorem 15 to get a randomized algorithm for Hitting Set with time complexity $\tilde{O}(n^{2-\gamma})$, which contradicts the Hitting Set Conjecture. ◀

Furthermore, we obtain stronger hardness of approximation for asymmetric EMD matching:

► **Theorem 17.** *Let $d = \omega(\log n)$ and $\eta = 1/\omega(\log n)$. If there is a truly subquadratic $(1+\eta)$ -approximation algorithm for asymmetric EMD matching in d dimensions, then the Hitting Set Conjecture is false.*

Proof. Fix $d' = \omega(\log n)$ and $\eta = 1/\omega(\log n)$ and $\epsilon > 0$. Suppose that there is an $O(n^{2-\epsilon})$ time algorithm which achieves a $(1+\eta)$ approximation for asymmetric EMD matching in d' dimensions. Set $d = \min(d', \sqrt{(\log n)/\eta})$. Since \mathbb{R}^d embeds isometrically in $\mathbb{R}^{d'}$, the algorithm also achieves a $(1+\eta)$ approximation for asymmetric EMD in d dimensions.

By Lemma 12, the Maximum Orthogonal Matching problem can be solved up to an additive error of $O(\eta|A|d)$ in $O(d)$ dimensions and $O(n^{2-\epsilon})$ time. By Theorem 14 there is some $\gamma > 0$ such that Find-OV can be solved up to an additive error of $O(\eta nd)$ in $O(d)$ dimensions and $O(n^{2-\gamma})$ time. By choice of d we have $\eta nd = o(n)$, so for sufficiently large n the algorithm achieves additive error of at most $n/2$. Therefore by Theorem 15, Hitting Set can be solved in $O(d)$ dimensions and $\tilde{O}(n^{2-\epsilon})$ time. Since $d = \omega(\log n)$, this contradicts the Hitting Set Conjecture. ◀

A Hardness of Low-Rank Minimum Weighted Assignment

The methods we used to prove hardness of exact EMD in low dimensions can be adapted to prove hardness of minimum weighted assignment with low-rank weight matrices, under the Orthogonal Vectors Conjecture. In particular, we show in the following theorem that bichromatic closest pair in d dimensions can be reduced to minimum weighted assignment with a rank- $O(d)$ weight matrix. The reduction algorithm uses the same input transformation as Theorem 8, and then solves minimum weighted assignment on the matrix M with entries $M_{ij} = \|A'_i - B'_j\|_2^2$, where A' and B' are the transformed input sets. The key is that M has rank $O(d)$, and its minimum weight assignment encodes the squared closest pair distance of the input – just as the EMD of the transformed input in Theorem 8 encoded the closest pair distance of the input.

► **Theorem 18.** *Fix a dimension $d = d(n) \leq n$, and let $\epsilon > 0$. Suppose that there is an algorithm which solves minimum weighted assignment in $O(n^{2-\epsilon})$ time, if the weight matrix has rank at most $O(d)$. Then bichromatic closest pair in d dimensions can be solved in $O(n^{2-\epsilon})$ time.*

Proof. Let A and B be two sets of n vectors in d dimensions, with entries in $\{1, \dots, n^k\}$ for some constant $k > 0$. Apply the transformation described in Theorem 8 to construct sets $A', B' \in \{0, \dots, n^{16k}\}^{2d+2c+2}$ where c is as defined in the proof of the theorem. Define

$$\text{SQEMD}(A', B') = \min_{\sigma: A' \rightarrow B'} \sum_{a' \in A'} \|a' - \sigma(a')\|_2^2$$

where σ ranges over all bijections from A' to B' . Since $\|u - v\|_2^2 \geq N^2 d$ and $\|a' - b'\|_2^2 \geq N^2 d$ for every $a' \in A' \setminus \{v\}$ and $b' \in B' \setminus \{u\}$, whereas $\|a' - u\|_2^2 \ll N^2 d/n$ and $\|b' - v\|_2^2 \ll N^2 d/n$, the optimal matching σ minimizes the number of (u, v) and (a', b') edges. In particular, exactly one element of $A' \setminus \{v\}$ is matched to an element of $B' \setminus \{u\}$. Thus, paralleling the proof of Theorem 8, we get

$$\text{SQEMD}(A', B') = 2(n-1)n^{4k}d^2 + \left(N^2 d + 2n^{4k}d^2 + \min_{a \in A, b \in B} \|a - b\|_2^2 \right).$$

Hence, to compute the bichromatic closest pair distance between A and B , it suffices to compute $\text{SQEMD}(A', B')$. Representing A' and B' as $n \times (2d + 2c + 2)$ matrices, let M be the $n \times n$ matrix defined by $M_{ij} = \|A'_i - B'_j\|_2^2$. Then observing that

$$M_{ij} = \sum_{k=1}^{2d+2c+2} (A'_{ik} - B'_{jk})^2 = \sum_{k=1}^{2d+2c+2} (A'_{ik})^2 + \sum_{k=1}^{2d+2c+2} (B'_{jk})^2 - 2 \sum_{k=1}^{2d+2c+2} A'_{ik} B'_{jk},$$

we can write M as the sum of $2d + 2c + 4$ rank-1 matrices, so $\text{rank}(M) \leq 2d + 2c + 4$. So by assumption, the minimum weight perfect matching in the complete bipartite graph determined by M can be found in $O(n^{2-\epsilon} \text{poly}(d))$ time. But the cost of the optimal matching is precisely $\text{SQEMD}(A', B')$. ◀

Applying Theorem 6 completes the proof of Theorem 2.

B Proof of Theorem 13

The theorem follows immediately from the reduction from Maximum Orthogonal Matching to EMD matching shown in section 4, and this next proposition.

12:16 Conditional Hardness of Earth Mover Distance

► **Proposition 19.** *Suppose the Maximum Orthogonal Matching problem can be solved up to an additive factor of n^δ in $O(n^\gamma)$ time where $\delta < 1/2$. Then OV can be solved in $O(n^{\gamma/(1-\delta)})$ time.*

Proof. Let $A, B \subseteq \{0, 1\}^d$ with $|A| = |B| = n$. We construct multisets A' and B' which consist of $2n^{\delta/(1-\delta)}$ copies of each $a \in A$, and $2n^{\delta/(1-\delta)}$ copies of each $b \in B$, respectively. We then run our approximate Maximum Orthogonal Matching algorithm on A' and B' . If any orthogonal pair is found, we return it; otherwise we return that there is no orthogonal pair.

Since $|A'| = |B'| = 2n^{1/(1-\delta)}$, the time complexity of this algorithm is $O(n^{\gamma/(1-\delta)})$. It is clear that if A and B have no orthogonal pair, then A' and B' have no orthogonal pair, so the algorithm correctly returns “no pair”.

Suppose that there are $a \in A$ and $b \in B$ with $a \cdot b = 0$ but the algorithm returns “no pair”. Then the matching found by the algorithm had no orthogonal pairs. However, there is a matching consisting of $2n^{\delta/(1-\delta)}$ pairs. Since $|B'|^\delta < 2n^{\delta/(1-\delta)}$, this contradicts the approximation guarantee of the Maximum Orthogonal Matching algorithm. ◀

C Hardness of $(k, 2k)$ -Find-OV

The $(k, 2k)$ -Find-OV problem provides some sense of the relative “powers” of the Orthogonal Vectors Conjecture and the Hitting Set Conjecture, as well as another example of how the Hitting Set Conjecture can be used to explain hardness of approximation problems. Reducing from OV, we get the following hardness result, and it is not clear how to make any improvement. Note that this proof extends to the $(1, 2k)$ -Find-OV problem, for which this lower bound is tight, due to a random sampling algorithm.

► **Proposition 20.** *Fix $\delta \in (0, 1)$. Assuming OVC, any algorithm for $(n^\delta, 2n^\delta)$ -Find-OV requires $\Omega(n^{2-\delta-o(1)})$ time.*

Proof. Suppose that there exists an $O(n^{2-\delta-\epsilon})$ time algorithm FIND for $(n^\delta, 2n^\delta)$ -Find-OV. Here is an algorithm for OV: given sets $A, B \subseteq \{0, 1\}^d$ with $|A| = |B| = n$, duplicate each $a \in A$ and each $b \in B$ exactly $2n^{\delta/(2-\delta)}$ times. If the original number of orthogonal pairs was r , then the new number is $4rn^{2\delta/(2-\delta)}$. For $r \geq 1$, this exceeds $2(n \cdot 2n^{\delta/(2-\delta)})^\delta$, so applying FIND yields a positive number of orthogonal vectors if and only if $r > 0$. It’s easy to check that the time complexity is subquadratic. ◀

On the other hand, under the Hitting Set Conjecture, we can obtain quadratic hardness. When $k = n/2$, hardness follows from Theorem 15, but it holds in greater generality. In particular, we provide a proof of conditional hardness for $k = \sqrt{n}$, and it extends naturally to any $k = n^\gamma$ for $\gamma \in (0, 1)$. The proof takes inspiration from the reduction from Hitting Set to OV [2], with a few extra twists.

► **Theorem 21.** *If the $(\sqrt{n}, 2\sqrt{n})$ -Find-OV problem can be solved in $O(n^{2-\epsilon})$ time for some $\epsilon > 0$, then Hitting Set can be solved in $O(n^{2-\delta})$ time for some $\delta > 0$.*

Proof. Let FIND be the presupposed algorithm for $(\sqrt{n}, 2\sqrt{n})$ -Find-OV. Set $\alpha = \epsilon/7$. Let $A, B \subseteq \{0, 1\}^d$ with $|A| = |B| = n$. Without loss of generality, assume that no vector is all-zeroes. Here is an algorithm:

1. For each $a \in A$, randomly sample $n^{1-\alpha}$ vectors from B . If any of these is orthogonal to a , mark a and remove it from A , replacing it with an all-ones vector.
2. Set $k = n^{1/3-\alpha}$. Partition A into sets A_1, \dots, A_k of approximately equal size, and similarly partition B into sets B_1, \dots, B_k . For each pair (A_i, B_j) :

- a. Apply FIND to (A_i, B_j) .
 - b. If the output is not $\sqrt{n/k}$ orthogonal pairs, then continue to the next pair (A_i, B_j) .
 - c. Otherwise, suppose that the output is $\{(a_m, b_m)\}_{m=1}^{\sqrt{n/k}}$. For each vector $a \in \{a_m\}_{m=1}^{\sqrt{n/k}}$, mark a and remove it from A_i (and from A), replacing it with an all-ones vector.
 - d. Go to (a).
3. If the number of unmarked input vectors exceeds $2n^{1-3\alpha/2}$, return “NO” and exit.
 4. For each $a \in A$, if a is not the all-ones vector, iterate over all $b \in B$, and mark a if any $b \in B$ is orthogonal.
 5. Return “YES” if every vector originally in A is now marked, and “NO” otherwise.

We claim that this algorithm solves Hitting Set in strongly subquadratic time. Correctness is relatively simple: a vector $a \in A$ is only marked by the above algorithm if some $b \in B$ is found for which $a \cdot b = 0$. Thus, if some $a \in A$ is a hitting vector for B , then it is never marked, so the algorithm returns “NO”.

Conversely, suppose that every $a \in A$ is orthogonal to some $b \in B$. Then the number of unmarked input vectors in Step 3 is at most the number of remaining orthogonal pairs. But each (A_i, B_j) contains at most $2\sqrt{n/k}$ orthogonal pairs after Step 2 finishes, so the number of remaining orthogonal pairs in Step 3 is at most $k^2(2\sqrt{n/k}) = 2n^{1-3\alpha/2}$. Thus, the algorithm continues to Step 4. Every $a \in A$ which has not been marked by the end of Step 2 is tested against every $b \in B$ in Step 4. Therefore every vector is marked, so the algorithm returns “YES”.

Turning to time complexity, Step 1 takes $O(n^{2-\alpha})$ time. The complexity of Step 2 is dominated by the calls to FIND. For each pair (A_i, B_j) there is at most one call to FIND for which the output is not $\sqrt{n/k}$ orthogonal pairs. Hence, there are $k^2 = n^{2/3-2\alpha}$ such “failed” calls. To bound the number of “successful” calls to FIND, for which the output is $\sqrt{n/k}$ orthogonal pairs, note that after Step 1, with high probability each $a \in A$ is orthogonal to at most $n^{2\alpha}$ vectors $b \in B$, so the total number of orthogonal pairs is at most $n^{1+2\alpha}$. Each successful call eliminates $\sqrt{n/k} = n^{1/3+\alpha/2}$ orthogonal pairs, so there are at most $n^{2/3+3\alpha/2}$ successful calls. This bound dominates the bound on failed calls. Each call takes time $O((n/k)^{2-\epsilon})$, so the time complexity of Step 2 is asymptotically

$$n^{(\frac{2}{3}+\alpha)(2-\epsilon)} n^{\frac{2}{3}+\frac{3\alpha}{2}} = n^{2-\frac{\epsilon}{6}-\frac{\epsilon^2}{7}}.$$

Step 3 takes negligible time. Finally, in Step 4, there are at most $2n^{1-3\alpha/2}$ vectors $a \in A$ which are not the all-ones vector (since each of these is unmarked), so the complexity is $O(n^{2-3\alpha/2})$.

Hence, the overall time complexity is bounded by $O(n^{2-\epsilon/7})$. ◀

Single-Elimination Brackets Fail to Approximate Copeland Winner

Abstract

Single-elimination (SE) brackets appear commonly in both sports tournaments and the voting theory literature. In certain tournament models, they have been shown to select the unambiguously-strongest competitor with optimum probability. By contrast, we reevaluate SE brackets through the lens of approximation, where the goal is to select a winner who would beat the most other competitors in a round robin (i.e., maximize the Copeland score), and find them lacking. Our primary result establishes the approximation ratio of a randomly-seeded SE bracket is $2^{-\Theta(\sqrt{\log n})}$; this is underwhelming considering a $\frac{1}{2}$ ratio is achieved by choosing a winner uniformly at random. We also establish that a generalized version of the SE bracket performs nearly as poorly, with an approximation ratio of $2^{-\Omega(\sqrt[3]{\log n})}$, addressing a decade-old open question in the voting tree literature.

1 Introduction

The *round robin* and the *single-elimination bracket* are two common formats for sporting competitions. In a round robin, every competitor plays against every other competitor once. The outcome of a round robin can be represented as a *tournament graph*, a directed complete graph where an edge from A to B means A defeats B . A single-elimination bracket can be represented by a balanced binary tree with the leaves labeled by a permutation of the competitors. Each internal node is then labeled with the winner of a game between the two children of that node, with the root node indicating the overall winner. (For simplicity, assume no ties, deterministic game outcomes, and $n = 2^m$ competitors for some integer $m \geq 2$.)

A round robin effectively gives us complete information; we learn the outcome of all $\binom{n}{2}$ possible games. However, it is not immediately clear how to translate this into a single winner unless one competitor beats every other competitor (known as a *Condorcet winner*). There are various possible solution concepts – such as the Slater set, the uncovered set, and the top cycle – but we will focus on the (far more popular) Copeland solution. Each competitor’s *Copeland score* equals its out-degree in the tournament graph, i.e., the number of other competitors it defeats. This gives us a natural, quantitative measure of competitor strength; thus the Copeland winner(s), or Copeland set, is the competitor(s) with the maximum Copeland score.

An SE bracket leaves no such ambiguity in determining a unique winner. It also requires fewer games, and each game has higher stakes, which may explain the popularity of this format! But what are we trading off in exchange for these desirable qualities? Can we still expect a strong competitor to win? We will address this question by considering how well SE brackets approximate the maximum Copeland score, for both worst-case and random seeding.

1.1 Related Work

A slightly different version of this question is long resolved. Namely, that line of work assumes the game outcomes are probabilistic *but* there exists an unambiguously strongest competitor (who beats every other competitor with probability $> 1/2$). Competition formats can then be evaluated based on their probability of selecting this strongest competitor, relative to the number of games or rounds played. This evaluation criteria has variously been referred to as “predictive power” or “effectiveness” [12, 1, 14]. Under certain models in this setting, a balanced SE bracket has the highest predictive power of any competition format with at most $n - 1$ games [12]. However, the predictive power of *any* knockout format (where a competitor is eliminated after a single loss) will in general be sub-constant in the number of competitors. This is one motivation for evaluating formats based on the expected “strength” of the winner, rather than just the (vanishing) probability of selecting a single strongest competitor.

The question of *seeding* an SE bracket has also received significant attention in the probabilistic setting, both in terms of *designing* a fair seeding [21] and *manipulating* the seeding to help a particular competitor [14, 20] – in general, it is NP-hard to find a seeding which maximizes a given competitor’s win probability. Perhaps surprisingly, it is even NP-hard to determine whether there exists a winning seeding for a given competitor with *deterministic* game outcomes [2], although many special cases have been identified where a polynomial time algorithm exists [19, 16, 18, 17, 2, 10, 9]. We ignore questions of seeding in the present work, considering only worst-case and random seeding. However, it is worth noting that a winning seeding *does* exist for any Copeland winner [19].

Finding or approximating the Copeland winner(s) of a tournament graph with deterministic game outcomes has been studied more generally, although not specifically for SE brackets. Finding the whole Copeland set requires all $\binom{n}{2}$ games to be played in the worst-case [4, 7]. If we only wish to select a single Copeland winner, that still requires at least $\binom{n}{2} - 2$ games (for odd n) [7]. By contrast, finding the Condorcet winner (or determining none exists) requires only $2n - \lfloor \log n \rfloor - 2$ games to be played [3, 13]. The number of games required to *approximate* the Copeland winner is not well studied, but it is known that finding a competitor with Copeland score *exactly* $k \leq (n - 1)/2$ requires $\Theta(nk)$ games to be played in the worst-case [3].

The most direct predecessor of the present work concerns approximating the Copeland winner using a broad category of tournament formats known as *voting trees*, which include SE brackets. Whereas an SE bracket corresponds to a balanced binary tree with n leaves, a voting tree can be any binary tree with any number of leaves (the same competitor can label multiple leaves). For $n \leq 7$ competitors, there exists a voting tree which can select a Copeland winner, but not so for 8 or more competitors [15]. However, voting trees can *approximate* the maximum Copeland score, with an approximation ratio of $2/3$ [8], although this result is non-constructive. The best-known upper bound on the approximation ratio achievable by voting trees is $3/4$ [5, 6]. The situation changes slightly if, instead of a single voting tree, we are allowed to specify a distribution over voting trees. For instance, we could consider a randomly-seeded SE bracket. In this case, we want the *expected* Copeland score of the winner to approximate the maximum Copeland score. Naturally, the $2/3$ lower bound still applies, but the best-known upper bound for randomized voting trees is $5/6$ [5]. In addition, for randomized voting trees there is a constructive lower bound with certain nice properties which obtains an approximation ratio approaching $1/2$ [5]. The relevant paper concludes by conjecturing that SE brackets, or certain sizes of balanced voting trees more generally, may be able to obtain good approximation ratios, although they note “[t]he analysis of this type of randomization is closely related to the theory of dynamical systems, and we expect it to be rather involved” [5]. We answer this conjecture in the negative.

It is worth noting that randomly-seeded single-elimination brackets have previously been assumed to select “strong” winners. The probability of a competitor winning such a bracket has variously been referred to as “a natural notion of player strength” [10], and proposed as a way to select a winner from a tournament graph [11]. This makes it especially surprising that SE brackets fail to approximate the maximum Copeland score.

1.2 Contributions

We divide our contributions into three primary categories.

In Section 3, we analyze SE brackets with worst-case seeding. Although it will be straightforward to see that they achieve an approximation ratio of only $\frac{\log n}{n-2}$, we provide context for this result by calculating the query complexity (number of games that must be played) to approximate the maximum Copeland score with a given approximation ratio. We argue that, for worst-case seeding, SE brackets can actually be considered optimal among formats with at most $n - 1$ games satisfying a basic fairness criterion, in close analogy to the work of [12]. Additionally, our results suggest a “single-elimination into round robin” format as an optimal generalization of SE brackets to more than n games.

Our main result is described in Section 4. Namely, we establish that the approximation ratio of a randomly-seeded SE bracket is $2^{-\Theta(\sqrt{\log n})}$. (For comparison, this is not as bad as the worst non-zero approximation ratio $\Theta(\frac{1}{n})$ but is worse than, say, $\Theta(\frac{1}{\log n})$.) A central lemma used in this proof is based on a result of [5], although we have to redo their analysis more precisely for our purposes. Essentially, we consider a class of tournament graphs where the competitors fall into three categories: “weak”, “mediocre”, and “strong”. We construct a randomized distribution over such tournament graphs, which allows us to use the lemma to show that “weak” competitors usually win the corresponding SE brackets. Additionally, we show that most of the probability mass concentrates on tournament graphs where the “weak” competitors really do have low Copeland score, and thus there exists a specific tournament graph with low approximation ratio. We obtain the corresponding lower bound on the approximation ratio by showing that sufficiently low-scoring competitors are few in number and likely to be eliminated early in an SE bracket.

Finally, in Section 5, we reuse the aforementioned lemma to upper-bound the approximation ratio of *all* randomly-seeded, balanced voting trees of sufficient size as $2^{-\Omega(\sqrt[4]{\log n})}$. This refutes the hope expressed in [5] that carefully choosing the size of a balanced voting tree could result in a good approximation ratio.

2 Preliminaries

Let $S = \{1, \dots, n = 2^m\}$ be a set of competitors. A *tournament graph*, or just *tournament*, on S is a directed complete graph where S is the vertex set. For any two competitors $c_1, c_2 \in S$, $c_1 \neq c_2$, the corresponding edge is directed from the winner to the loser in a hypothetical game between the two. If c_1 is the winner, we say c_1 beats c_2 , or $c_1 \rightarrow c_2$. Note that this implies there are no ties, and the game outcomes are deterministic, i.e., if $c_1 \rightarrow c_2$, then c_1 beats c_2 always. We use $\mathcal{T}(n)$ to denote the set of all tournaments on n competitors.

Given a tournament graph T , the *Copeland score* of a competitor c is the out-degree of the corresponding vertex, i.e., $d_+(c) = |\{s \in S \mid c \rightarrow s\}|$. The *Copeland winner(s)* of a tournament is the competitor(s) with the highest Copeland score. If some competitor has Copeland score $n - 1$, she is called the *Condorcet winner*.

13:4 Single-Elimination Brackets Fail to Approximate Copeland Winner

We will be considering various *competition formats*, which are (deterministic or randomized) algorithms that query edges of the tournament graph by running games between pairs of competitors, and return a single winner. For a competition format F , the *query complexity* is the worst-case number of games played under F . For a given set of n competitors S , we also define the *approximation ratio* for the maximum Copeland score as

$$\min_{T \in \mathcal{T}(n)} \frac{\mathbb{E}[d_+(F(T))]}{\max_{s \in S} d_+(s)}$$

where $F(T)$ denotes the winner of tournament T under format F (possibly randomized).

A *single-elimination bracket* is a competition format represented by a balanced binary tree with $n = 2^m$ leaves labeled by a permutation or *seeding* of the competitors. For each level of the tree, moving up from the leaves – that is, for each round of the bracket – for each internal node, it labels the node with the winner of a game between the node’s two children. The root node’s label indicates the winner. We will analyze both worst-case seeding (i.e., the deterministic competition format with an arbitrary labeling of the leaves) and random seeding (i.e., the randomized competition format where a random permutation of competitors is chosen to label the leaves).

3 Deterministic Approximation of Copeland Winner

We first consider how well SE brackets with worst-case seeding approximate the Copeland winner, and for comparison, we establish the deterministic query complexity required for any competition format with a given approximation ratio. This reveals that SE brackets require significantly more games than the optimal query complexity. However, in Section 3.1, we reanalyze the query complexity of approximation subject to a basic fairness constraint, the “Condorcet property.” Under this constraint, SE brackets actually achieve optimal query complexity, and can be generalized into an asymptotically optimal “single-elimination into round robin” format for more than $n - 1$ games.

We begin by calculating the approximation ratio of SE brackets.

► **Theorem 1.** *The single-elimination bracket on $n = 2^m$ competitors achieves a deterministic approximation ratio of exactly $\frac{\log n}{n-2}$ for the maximum Copeland score.*

Proof. Observe that (1) the SE winner must have a Copeland score of at least $\log n$, since she must beat one competitor per level for $\log n$ levels, and (2) if a Condorcet winner exists, he must be the SE winner, or conversely, a non-SE-winner has Copeland score at most $n - 2$. Taken together, these observations imply that the approximation ratio of the SE bracket is at least $\frac{\log n}{n-2}$.

Now, we construct a tournament graph showing that the approximation ratio is at most $\frac{\log n}{n-2}$. Consider any tournament graph G on $n - 1$ competitors with a Condorcet winner, c . Let the n^{th} competitor be s . Fix any seeding for the bracket. In order to win the bracket, s must defeat $\log n$ competitors, whose identities are fully determined by the graph G and the seeding. Thus we may assume s defeats exactly this set of $\log n$ competitors, loses to every other competitor, and wins the bracket. By construction, s has Copeland score $\log n$ and the maximum Copeland score is (at least) $n - 2$, so the approximation ratio is (at most) $\frac{\log n}{n-2}$, as desired. ◀

In order to evaluate how good or bad this approximation ratio is, we will consider how well an arbitrary competition format can approximate the maximum Copeland score, trading off against the total number of games played. This can be thought of as the query complexity

of approximation. I.e., if we are allowed arbitrary and adaptive “queries”, how many games must be played (outcomes queried) to find a competitor with at least $0 < r \leq 1$ times the maximum Copeland score?

► **Theorem 2.** *The deterministic query complexity to find a competitor with at least $0 < r \leq 1$ times the maximum Copeland score in a tournament on n vertices is $\Theta(\max(1, rn)^2)$.*

Proof. We will use the fact that, for any tournament on n vertices, the maximum Copeland score M lies in $[\frac{n-1}{2}, n-1]$, i.e., between the average Copeland score and the maximum possible.

The upper bound is simple: to obtain an approximation ratio r , pick an arbitrary $n' = \min(2\lceil r(n-1) \rceil, n)$ competitors, and query all games within this sub-tournament. If $n' = n$, you find the true Copeland winner, so the approximation ratio is $1 \geq r$. Otherwise, $n' = 2\lceil r(n-1) \rceil$, so the average Copeland score within this sub-tournament is $\frac{2\lceil r(n-1) \rceil - 1}{2} = \lceil r(n-1) \rceil - \frac{1}{2}$. The maximum Copeland score within this sub-tournament is at least the average score rounded up, so at least $\lceil r(n-1) \rceil \geq r(n-1) \geq rM$, as desired. The total number of games played is at most

$$\binom{2\lceil r(n-1) \rceil}{2} \leq 2\lceil rn \rceil^2 = O(\max(1, rn)^2).$$

For the lower bound, we will define a simple adversarial strategy for answering the queries: when two competitors are queried, give the win to whichever has *fewer* wins so far, breaking ties arbitrarily. The competitor c returned by the optimal algorithm must have been shown to beat at least $k = \lceil \frac{r(n-1)}{2} \rceil$ distinct other competitors, since any un-queried game could be a loss for c . Now, because of the adversary’s strategy, when the algorithm discovers the i^{th} win for c , it must be beating a competitor which already had $i-1$ wins queried. Thus, counting the number of wins for c and for the k competitors she defeats, the algorithm must have queried at least

$$k + \sum_{i=1}^k (i-1) = \frac{k(k+1)}{2} \geq \left\lceil \frac{r(n-1)}{2} \right\rceil^2 \div 2 = \Omega(\max(1, rn)^2)$$

games. ◀

As a sanity check, we know that finding a competitor with maximum Copeland score requires at least $\binom{n}{2} - 2$ games to be played (for odd n) [4], and indeed plugging in $r = 1$ we get a query complexity of $\Theta(n^2)$.

Numerically, SE brackets do not look very good at this point! The sub-tournament strategy described above can obtain the same approximation ratio $r = \frac{\log n}{n-2}$ in only $\Theta(\log^2 n) \ll n-1$ games. Conversely, if we allow ourselves $n-1$ games, we should be able to obtain an approximation ratio of $\Theta(\frac{1}{\sqrt{n}}) \gg \frac{\log n}{n-2}$.

Of course, this sub-tournament strategy is a deeply unsatisfying format for any kind of competition or election. 64 teams qualify for March Madness; should we suggest the NCAA just pick 12 at random and then play a round robin?

3.1 “Fair” Deterministic Approximation

There are multiple reasons why we might prefer an SE bracket over this strange sub-tournament round robin, but the most glaring is fairness. An SE bracket may be more or less “fair” depending on how the competitors are seeded, but at least it doesn’t eliminate a majority of the competitors from the get-go.

13:6 Single-Elimination Brackets Fail to Approximate Copeland Winner

In this section, we will investigate the complexity of approximation restricted to *Condorcet* competition formats. That is, if one competitor beats every other competitor in the underlying tournament graph (i.e., if there is a Condorcet winner) then he must be chosen as the winner of the competition. This is only a slightly stronger requirement than insisting that no competitor be eliminated a priori, since it specifies an intuitively obvious win condition. Additionally, this “Condorcet property” is well-studied in voting theory, has previously been described for tournaments under the name “unbiasedness” [12], and is closely related to the concept of “admissibility” from the voting tree literature [5]. Clearly, the SE bracket is a Condorcet competition format, while the sub-tournament round robin discussed above is not.

As a warm-up, observe that any Condorcet format must query at least $n - 1$ game outcomes. This holds because every competitor except the winner must have been observed to lose at least one game; otherwise, a non-winner could violate the Condorcet property. Thus if we want to obtain an approximation ratio of $\frac{\log n}{n-2}$ for the maximum Copeland score, the SE bracket is optimal among Condorcet competition formats. In fact, the following result implies that SE brackets achieve the optimal approximation ratio among all Condorcet formats with exactly $n - 1$ games.

► **Theorem 3.** *The deterministic query complexity, restricted to Condorcet competition formats, to find a competitor with at least $0 < r \leq 1$ times the maximum Copeland score in a tournament on $n = 2^m \geq 4$ vertices is $n - 1$ if $r \leq \frac{\log n}{n-2}$ or $n - 1 + \Theta(\max(1, r(n-2) - \log n)^2)$ otherwise.*

Proof. As noted above, $n - 1$ games are required for any Condorcet format, so when $r \leq \frac{\log n}{n-2}$, the desired approximation ratio is achieved in the optimal $n - 1$ games by an SE bracket. For the remainder of the proof, we consider $r > \frac{\log n}{n-2}$.

The upper bound is similar to the sub-tournament round robin approach from Theorem 2, except that we use a partial single-elimination bracket to select the competitors for the sub-tournament. Define $\delta = \max(1, r(n-2) - \log n)$. If $\delta \geq \frac{n}{8}$, then we simply run a round robin on all n competitors and return the Copeland winner. This is clearly a Condorcet format, achieves approximation ratio $1 \geq r$, and requires $\binom{n}{2} \leq \frac{n^2}{2} = n - 1 + O(\delta^2)$ games.

Otherwise, we will play the first $\log n - \lceil \log \delta \rceil - 3$ rounds of a single-elimination bracket, then run a round robin among the remaining $2^{\lceil \log \delta \rceil + 3}$ competitors and return a competitor with highest number of wins. Observe that this is a Condorcet format, and it returns a competitor with Copeland score at least $\log n - \lceil \log \delta \rceil - 3 + 2^{\lceil \log \delta \rceil + 2} \geq \log n + 2^{\lceil \log \delta \rceil} \geq \log n + \delta \geq r(n-2)$. Therefore, we obtain an r -approximation of the maximum Copeland score, because either (1) there is a Condorcet winner, she wins the tournament, and the ratio is $1 \geq r$, or (2) there is no Condorcet winner, so the maximum Copeland score is $M \leq n - 2$. Finally, the number of games played is less than

$$n - 1 + \binom{8\delta}{2} = n - 1 + O(\delta^2).$$

For the lower bound, we will reuse the adversarial strategy from Theorem 2: whenever a query is made, the winner of the game will be whichever competitor has *fewer* wins so far, with ties broken arbitrarily. Suppose the competitor c chosen as the winner of the competition has had k wins queried. Because of the adversary’s strategy, these k competitors must have already had $0, 1, 2, \dots, k - 1$ wins (out-edges), respectively, at the time they were beaten. In fact, the same logic extends to these k competitors and their wins, etc., forming a cascade of 2^k vertices. However, these 2^k vertices need not necessarily be distinct competitors (except the top $k + 1$, which must). Moreover, every vertex except the winner must have at

least one in-edge (otherwise it could be a Condorcet winner), so the number of vertex-reuses in this cascade is at most the query complexity less $n - 1$, since every reuse increases the in-degree of some vertex by 1.

We would like to lower-bound the query complexity in terms of n ; to do this, we will initially frame it as lower-bounding n in terms of the query complexity, for fixed k . Let $i \in \mathbb{R}_{\geq 0}$ be such that the total number of games played will be $n - 1 + \lceil i(i + 1)/2 \rceil$. Since k is fixed, we need a cascade of 2^k vertices; however $\lceil i(i + 1)/2 \rceil$ can be “reuses.” Note that if a vertex is reused, it *and* its children appear only once in the resulting cascade. Any valid reuse can be captured by “erasing” a sub-tree, with the interpretation that the dangling edge that led to that sub-tree now points somewhere else. However, none of the top $k + 1$ vertices can be erased in this way, since they must be distinct. (Other vertices can be erased and have their edges pointed to one of these vertices, however.)

Thus, to lower-bound n , we can equivalently upper-bound the number of vertices erased with $\lceil i(i + 1)/2 \rceil$ reuses, since there need to be at least enough distinct vertices to constitute all the non-erased vertices in the cascade. How can we maximize the number of vertices erased? The top two layers (top $k + 1$ vertices) cannot be erased, so the optimal strategy is to erase vertices from the layer directly below, in order of decreasing size of their sub-trees, since it always removes more vertices to erase the root of a sub-tree than any of its children. In particular, we would first erase the 3^{rd} level sub-tree of size 2^{k-2} , then the two sub-trees of size 2^{k-3} , then the three sub-trees of size 2^{k-4} , etc. For ease of accounting, let us assume we remove all the 3^{rd} -level sub-trees of size at least $2^{k-\lceil i \rceil - 1}$. Observe that this comes to $1 + 2 + \dots + \lceil i \rceil \geq \lceil i(i + 1)/2 \rceil$ reuses. We need to erase at least $2^k - n$ vertices from the cascade, so

$$\begin{aligned} 2^k - n &\leq 2^{k-2} + 2 \times 2^{k-3} + \dots + \lceil i \rceil \times 2^{k-\lceil i \rceil - 1} \\ &= 2^{k-\lceil i \rceil - 1} \left(2^{\lceil i \rceil - 1} + 2 \times 2^{\lceil i \rceil - 2} + \dots + \lceil i \rceil \times 2^0 \right) \\ &= 2^{k-\lceil i \rceil - 1} \left(2^{\lceil i \rceil + 1} - \lceil i \rceil - 2 \right) \\ &= 2^k - (\lceil i \rceil + 2) 2^{k-\lceil i \rceil - 1} \\ \log n &\geq \log(\lceil i \rceil + 2) + k - \lceil i \rceil - 1 \\ \lceil i \rceil &\geq k - \log n + \log(\lceil i \rceil + 2) - 1 \geq k - \log n. \end{aligned}$$

Note that this means any Condorcet competition format using $n - 1 + \lceil i(i + 1)/2 \rceil$ games returns a winner with at most $k \leq \log n + \lceil i \rceil$ wins queried. What does this mean for our approximation ratio? By the pigeonhole principle, there is some non-winner with no more than $1 + \left\lfloor \frac{\lceil i(i+1)/2 \rceil}{n-1} \right\rfloor$ losses queried. Thus the maximum Copeland score could be as high as $M \geq n - 2 - \left\lfloor \frac{\lceil i(i+1)/2 \rceil}{n-1} \right\rfloor$. In particular, observe that if only $n - 1$ games are played, then $i = 0$ and $r = \frac{k}{M} \leq \frac{\log n}{n-2}$. This confirms that for $r > \frac{\log n}{n-2}$, $n - 1 + \Omega(1)$ games are required, implying SE brackets achieve the optimal approximation ratio for Condorcet formats with $n - 1$ games.

We have essentially calculated a bound on the approximation ratio in terms of i , but we want to turn this into an asymptotic bound on query complexity for a given approximation ratio. Assuming $0 < i \leq n - 1$ (since we can only have $\binom{n}{2}$ games in total), we have

$$\begin{aligned}
 r &\leq \frac{\log n + \lceil i \rceil}{n - 2 - \lfloor \frac{\lceil i(i+1)/2 \rceil}{n-1} \rfloor} \\
 r(n-2) - \log n &\leq r \left\lfloor \frac{\lceil i(i+1)/2 \rceil}{n-1} \right\rfloor + \lceil i \rceil \\
 (r(n-2) - \log n)^2 &\leq \left(r \left\lfloor \frac{\lceil i(i+1)/2 \rceil}{n-1} \right\rfloor + \lceil i \rceil \right)^2 \\
 &\leq \lceil i(i+1)/2 \rceil^2 \left(\frac{1}{n-1} + \frac{\lceil i \rceil}{\lceil i(i+1)/2 \rceil} \right)^2 \\
 &\leq \lceil i(i+1)/2 \rceil^2 \left(\frac{1}{n-1} + \min \left(1, \frac{2}{i} \right) \right)^2 \\
 &\leq \lceil i(i+1)/2 \rceil^2 \left(2 \min \left(1, \frac{2}{i} \right) \right)^2 \\
 &\leq 4 \lceil i(i+1)/2 \rceil \left(\frac{i(i+1)}{2} + 1 \right) \min \left(1, \frac{4}{i^2} \right) \leq 16 \lceil i(i+1)/2 \rceil.
 \end{aligned}$$

Thus the query complexity is at least

$$n - 1 + \lceil i(i+1)/2 \rceil \geq n - 1 + \frac{1}{16}(r(n-2) - \log n)^2 = n - 1 + \Omega(\max(1, r(n-2) - \log n)^2)$$

as desired. \blacktriangleleft

Interestingly, this implies that a “single-elimination into round robin” format achieves asymptotically optimal query complexity, with very simple structure. The initial single-elimination rounds could still benefit from seeding (to make stronger competitors more likely to survive the early rounds), while the round-robin phase ensures the eventual winner is reasonably strong, regardless of any manipulation in the seeding. Both single-elimination and round robin are common formats for sporting competitions, but they are rarely if ever employed together in this order.

In the following section, we move on to analyze SE brackets with random seeding (rather than worst-case). Note, however, that coming up with a good *randomized* approximation of the Copeland winner is much easier than the deterministic case considered above. In fact, we can achieve an approximation ratio of $r = \frac{1}{2}$ with a query complexity of *zero* – the average Copeland score is $\frac{n-1}{2}$, so simply returning a random competitor achieves this objective! This makes it especially surprising that randomly-seeded SE brackets cannot even achieve a constant approximation of the maximum Copeland score.

4 SE Brackets Fail to Approximate Copeland Winner

In this section, we prove our main result: the approximation ratio of SE brackets for the maximum Copeland score is $2^{-\Theta(\sqrt{\log n})}$.

To obtain our upper bound on the approximation ratio, we consider tournament graphs consisting of 3 groups (“components”) of competitors: a small set of “strong” competitors, a small set of “weak” competitors, and a majority of “mediocre” competitors. We assume every strong competitor beats every mediocre competitor, who beats every weak competitor; however, the weak beat the strong (a related concept has been analyzed under the term “choking” [10]). Note that the weak competitors will have low Copeland scores, while the strong have high scores. The idea is that, even though weak competitors have low scores,

they can beat the strongest competitors in the tournament and thus come out on top. In fact, the key observation follows one made in Theorem 5 of [5]: as the depth of a balanced bracket grows, the likely winner oscillates between these three components.

The construction of this upper bound is similar to the proof of Theorem 5 in [5], with a few key differences. First, they consider a tournament with only a single “strong” and a single “weak” competitor, and label each leaf of the bracket *independently and uniformly at random*. Since an SE bracket must be labeled with a random *permutation* of the competitors, we instead have to construct a distribution over tournament graphs with varying numbers of strong and weak competitors in order to simulate each leaf being labeled independently. Because of this, even after showing that a “weak” competitor is likely to win the bracket, we have to prove this still holds when we restrict our distribution to tournaments where the “weak” competitors really have low Copeland score, and thus there exists some specific tournament graph where the SE bracket has a poor approximation ratio.

Second, [5] shows that the winner of a bracket oscillates between these three components, but does not establish the rate of oscillation. Because we need to show a weak competitor is likely to win after *precisely* $\log n$ rounds, we have to repeat their analysis with significant additional bookkeeping.

The result of this bookkeeping is the following lemma, analogous to Lemma G.1 from [5]. Roughly, it says: Suppose after some number of rounds of an SE bracket, practically all the remaining competitors come from the “strong” component. Nevertheless, after a specific number of additional rounds, practically all the remaining competitors will come from the “weak” component. Furthermore, the “weak” competitors continue to dominate for many rounds before the oscillation repeats. The proof consists of analyzing a simple recursive formula for the likelihood of a “strong”, “mediocre”, or “weak” player winning an SE bracket after k rounds, in order to give painstaking bounds on the magnitude and rate of oscillation of these probabilities.

The rather lengthy and unenlightening proof has been relegated to the appendix.

► **Lemma 4.** *Let S be a set of competitors partitioned into three components C_1, C_2, C_3 such that every member of component C_i beats every member of component $C_{(i \bmod 3)+1}$. Fix probabilities $p_i^{(0)}$ summing to 1, and let $p_i^{(k)}$ denote the probability that a member of component C_i wins a balanced bracket of height k where each leaf is labeled independently according to $p_i^{(0)}$. If for some $K \in \mathbb{N}$ and $0 < \epsilon \leq 2^{-10}$, $\epsilon^2 \leq p_3^{(K)} \leq \epsilon$ and $\epsilon \leq p_1^{(K)} \leq 2\epsilon$, then there exists $K + \log(\frac{1}{\epsilon}) \leq K' \leq K + 3 \log(\frac{1}{\epsilon})$ and $\epsilon^{2 \log(\frac{1}{\epsilon})} \leq \delta \leq \epsilon^{\log(\frac{1}{\epsilon})/4}$ such that $\delta^2 \leq p_2^{(K')} \leq \delta$ and $\delta \leq p_3^{(K')} \leq 2\delta$. Furthermore, if $\epsilon \leq 2^{-75}$ then for any $K'' \in [K', K' + 2^5 \log(\frac{1}{\epsilon})]$, $p_2^{(K'')}, p_3^{(K'')} \leq \epsilon^{\log(\frac{1}{\epsilon})/2^5}$.*

We are now ready to prove our upper bound on the approximation ratio for SE brackets.

► **Theorem 5.** *The approximation ratio of a randomly-seeded single-elimination bracket on $n = 2^m$ competitors for the maximum Copeland score is $O(2^{-\sqrt{\log(n)}/7})$.*

Proof. For any $n = 2^m$ with $\log n \geq 2^{12}$, pick $0 < \delta \leq 2^{-18}$ such that $7 \log^2 \frac{1}{\delta} \leq \log n \leq 8 \log^2 \frac{1}{\delta}$. Define a distribution over tournaments $D(n, \delta)$, with $p_s^{(0)} = p_w^{(0)} = \delta, p_m^{(0)} = 1 - 2\delta$. $D(n, \delta)$ is supported over tournaments of size n with three (possibly empty) components s, m, w where s beats m , m beats w , and w beats s . Internally each component is a regular tournament, meaning the difference between the maximum and minimum Copeland scores is 1 or 0. For any fixed size of the components, summing to n , the weight of the corresponding tournament in $D(n, \delta)$ is equal to the probability that those fixed sizes are achieved by assigning each of n competitors independently to a component according to $p_s^{(0)}, p_m^{(0)}, p_w^{(0)}$.

13:10 Single-Elimination Brackets Fail to Approximate Copeland Winner

We will now analyze the winner of a bracket where each leaf is labeled independently with a component according to $p_s^{(0)}, p_m^{(0)}, p_w^{(0)}$. Observe that this is equivalent to choosing a random tournament according to $D(n, \delta)$ and then labeling n leaves with a random permutation of the competitors. In particular, for any given tournament graph in $D(n, \delta)$, every permutation of the competitors appears with equal probability.

Letting $C_1 = s, C_2 = m$, and $C_3 = w$ we apply Lemma 4. Since $0 < \delta \leq 2^{-10}$ and $\delta^2 \leq p_w^{(0)} \leq \delta \leq p_s^{(0)} \leq 2\delta$, we obtain that $(\delta')^2 \leq p_m^{(K)} \leq \delta' \leq p_w^{(K)} \leq 2\delta'$ for some $\delta^{2 \log(\frac{1}{\delta})} \leq \delta' \leq \delta^{\log(\frac{1}{\delta})/4}$ and $\log(\frac{1}{\delta}) \leq K \leq 3 \log(\frac{1}{\delta})$. We apply Lemma 4 once more, now with $C_1 = w, C_2 = s$, and $C_3 = m$ and starting from K , to find that a weak competitor wins with overwhelming probability after K' rounds, with

$$0 \leq K' \leq K + 3 \log\left(\frac{1}{\delta'}\right) \leq 3 \log\left(\frac{1}{\delta}\right) + 6 \log^2\left(\frac{1}{\delta}\right).$$

We will use the final part of Lemma 4 to increase this to a bracket of depth $\log n$. Observe that no more than $8 \log^2(\frac{1}{\delta})$, but more than 0, additional rounds are required. Furthermore, note that

$$\delta' \leq \delta^{\log(\frac{1}{\delta})/4} \leq 2^{-18^2/4} < 2^{-75}$$

as required for this part of the lemma. Finally, the number of additional rounds required is at most

$$8 \log^2\left(\frac{1}{\delta}\right) \leq 2^5 \log\left(\frac{1}{\delta'}\right)$$

and thus by Lemma 4, after $\log n$ rounds we have

$$p_s^{(\log n)}, p_m^{(\log n)} \leq \delta'^{\log(\frac{1}{\delta'})/2^5} \leq 2^{-\log^2(2^{\log^2(\delta)/4})/2^5} = 2^{-(\log^2(\delta)/4)^2/2^5} = 2^{-\log^4(\delta)/2^9}$$

so also $p_3^{(\log n)} \geq 1 - 2 \times 2^{-\log^4(\delta)/2^9}$.

We have established the winning probability of a “weak” competitor, over distribution $D(n, \delta)$. However, some tournaments with non-zero weight in the distribution have “weak” competitors with high Copeland score (those in which either the weak or strong component is large). Next, we bound the probability that this happens in order to establish a distribution $D'(n, \delta)$, where a “weak” competitor still wins almost always *and* the weak competitors all have low Copeland score.

First, we separate out the high-scoring weak and low-scoring weak cases from $D(n, \delta)$, where $\Pr[w]$ represents the probability of a weak competitor winning:

$$\begin{aligned} \Pr[w] &= \Pr[w : |w|, |s| < 10\delta n] \Pr[|w|, |s| < 10\delta n] + \\ &\quad \Pr[w : |w| \text{ or } |s| \geq 10\delta n] \Pr[|w| \text{ or } |s| \geq 10\delta n] \end{aligned}$$

Rearranging,

$$\begin{aligned} \Pr[w \text{ wins} : |w|, |s| < 10\delta n] &\geq \Pr[w \text{ wins} : |w|, |s| < 10\delta n] \Pr[|w|, |s| < 10\delta n] \\ &= \Pr[w \text{ wins}] - \Pr[w \text{ wins} : |w| \text{ or } |s| \geq 10\delta n] \Pr[|w| \text{ or } |s| \geq 10\delta n] \\ &\geq 1 - 2 \times 2^{-\log^4(\delta)/2^9} - \Pr[|w| \text{ or } |s| \geq 10\delta n] \\ &\geq 1 - 2 \times 2^{-\log^4(\delta)/2^9} - \Pr[|s| \geq 10\delta n] - \Pr[|w| \geq 10\delta n] \\ &\geq 1 - 2 \times 2^{-\log^4(\delta)/2^9} - 2e^{-\frac{9\delta n}{3}} := p \end{aligned}$$

using the Chernoff bound $\Pr[|C| \geq 10\delta n] \leq e^{-\frac{9\delta n}{3}}$ (since the expectation of $|w|, |s|$ is δn).

Let $D'(n, \delta)$ equal $D(n, \delta)$ restricted to tournaments where $|w|, |s| < 10\delta n$. A weak competitor wins the SE bracket on a tournament graph drawn from $D'(n, \delta)$ with probability at least p .

Finally, we observe that the Copeland score of any member of the weak component of any tournament with non-zero support on $D'(n, \delta)$ is less than $\frac{3}{2}10\delta n$ (consisting of less than $10\delta n$ edges to the strong component and less than $10\delta n/2$ edges within the weak component). Thus the expected Copeland score of the winner of a randomly-seeded SE bracket over a tournament drawn from $D'(n, \delta)$ is less than

$$\begin{aligned} & p \frac{30\delta n}{2} + (1-p)(n-1) \\ & \leq 15\delta n + 2n \times 2^{-\log^4(\delta)/2^9} + 2ne^{-3\delta n}; \end{aligned}$$

recall $\log n \leq 8 \log^2(\frac{1}{\delta})$, so $\delta \leq 2^{-\sqrt{\log(n)/8}}$:

$$\begin{aligned} & \leq 15 \times 2^{\log n - \sqrt{\log(n)/8}} + 2n \times 2^{-\log^4(2^{-\sqrt{\log(n)/8})/2^9} + 2ne^{-3 \times 2^{\log n - \sqrt{\log(n)/8}}} \\ & \leq 15 \times 2^{\log n - \sqrt{\log(n)/8}} + 2n \times 2^{-(\sqrt{\log(n)/8})^4/2^9} + 2ne^{-3 \times 2^{\log(n)/2}} \\ & \leq 15 \times 2^{\log n - \sqrt{\log(n)/8}} + 2 \times 2^{\log n - (\sqrt{\log(n)/8})^4/2^9} + 2ne^{-3\sqrt{n}} \\ & \leq 15 \times 2^{\log n - \sqrt{\log(n)/8}} + 2 \times 2^{\log n - \sqrt{\log(n)/8}} + 2 \end{aligned}$$

This implies that some *individual* tournament with non-zero support on $D'(n, \delta)$ achieves expected Copeland score at most $O(2^{\log n - \sqrt{\log(n)/8}})$. Thus the approximation ratio is $O(2^{-\sqrt{\log(n)/8}})$, completing the proof. \blacktriangleleft

In fact, the upper bound shown above is “nearly” tight, as the following theorem establishes.

► **Theorem 6.** *The approximation ratio of a randomly-seeded single-elimination bracket on $n = 2^m$ competitors for the maximum Copeland score is $\Omega(2^{-\sqrt{2 \log n}})$.*

Proof. For any $k < n$, at most $2k$ competitors in the tournament can have Copeland score less than k – otherwise, the average score amongst these competitors alone would be at least $\frac{(2k+1)-1}{2} = k$, a contradiction. If k is sufficiently small, it becomes quite likely that these few competitors will be eliminated early in a randomly-seeded SE bracket.

We will capture this idea by union-bounding over the probability that an individual competitor c with Copeland score $d_+(c) < k$ survives $\lceil \log(\frac{n}{k}) \rceil + 1$ rounds. Each round, c must face one of the $< k$ competitors he can beat (not including those he has already beaten) – even assuming every other competitor he can beat advances. Therefore,

$$\begin{aligned} & \Pr \left(c \text{ survives } \left\lceil \log \left(\frac{n}{k} \right) \right\rceil + 1 \text{ rounds} : d_+(c) < k \right) \\ & \leq \prod_{i=0}^{\lceil \log(\frac{n}{k}) \rceil} \frac{k-i-1}{\frac{n}{2^i} - 1} \\ & \leq \prod_{i=0}^{\lceil \log(\frac{n}{k}) \rceil} 2^i \frac{k}{n} \\ & \leq 2^{\frac{\log(\frac{n}{k})(\log(\frac{n}{k})+1)}{2}} \left(\frac{k}{n} \right)^{\log(\frac{n}{k})+1} \\ & = \left(\frac{k}{n} \right)^{\frac{-1 - \log(\frac{n}{k})}{2}} \left(\frac{k}{n} \right)^{\log(\frac{n}{k})+1} = \left(\frac{k}{n} \right)^{\frac{\log(\frac{n}{k})+1}{2}} \end{aligned}$$

13:12 Single-Elimination Brackets Fail to Approximate Copeland Winner

Even if we assume that every one of these low-scoring competitors wins with the probability calculated above, and contributes nothing to the expected Copeland score of the SE winner, we still know that the remaining probability belongs to competitors with Copeland score at least k . Thus,

$$\mathbb{E}[d_+(\text{winner})] \geq k \left(1 - 2k \left(\frac{k}{n} \right)^{\frac{\log(\frac{n}{k})+1}{2}} \right).$$

Let us plug in $k = n2^{-\sqrt{2\log n}} = 2^{\log n - \sqrt{2\log n}}$. Then,

$$\begin{aligned} \mathbb{E}[d_+(\text{winner})] &\geq 2^{\log n - \sqrt{2\log n}} \left(1 - 2 \times 2^{\log n - \sqrt{2\log n}} \left(2^{-\sqrt{2\log n}} \right)^{\frac{\sqrt{2\log n}+1}{2}} \right) \\ &\geq 2^{\log n - \sqrt{2\log n}} \left(1 - 2 \times 2^{\log n - \sqrt{2\log n}} \times 2^{-\log n - \sqrt{\frac{\log n}{2}}} \right) \\ &\geq 2^{\log n - \sqrt{2\log n}} \left(1 - 2^{-3\sqrt{\frac{\log n}{2}}+1} \right) \\ &\geq n \left(2^{-\sqrt{2\log n}} - 2^{-5\sqrt{\frac{\log n}{2}}+1} \right) \geq n2^{-\sqrt{2\log n}-1} \end{aligned}$$

which establishes that the approximation ratio is $\Omega(2^{-\sqrt{2\log n}})$, as desired. \blacktriangleleft

Taken together, these bounds establish that the approximation ratio of randomly-seeded SE brackets for the maximum Copeland score is $2^{-\Theta(\sqrt{\log n})}$.

5 Balanced Voting Trees Fail to Approximate Copeland Winner

In this section, we derive an upper bound on the approximation ratio for the maximum Copeland score of a generalized version of SE brackets from the voting tree literature. Recall that a voting tree is any binary tree with leaves labeled by the n competitors. The *randomized perfect voting tree* of depth k (k -RPT) is a class of voting trees introduced by [5], consisting of a balanced binary tree of depth k , with each leaf labeled uniformly at random from the set of n competitors. The k -RPT is similar to an SE bracket, except (1) the number of leaves may be larger (or smaller) than the number of competitors, and (2) the random seeding process does not require every competitor to appear on the leaves. However, as noted by [5], as k grows, the probability of any competitor not appearing on the leaves vanishes.

[5] established that, for infinitely many k , the k -RPT has an approximation ratio of $O(1/n)$ for the maximum Copeland score – essentially the worst possible! However, they left open the question of whether, for some carefully chosen $k = f(n)$, the k -RPT might achieve a good approximation ratio. We certainly shouldn't expect the approximation ratio to be as low as $O(1/n)$ for *every* k , since technically the 1-RPT corresponds to randomly choosing a winner and so has approximation ratio $\frac{1}{2}$, while the $(\log n)$ -RPT is closely related to the SE bracket which has a ratio of $2^{-\Theta(\sqrt{\log n})}$. However, we can at least show that the approximation ratio of a k -RPT for any $k \geq \log n$ is sub-constant.

► **Theorem 7.** *The approximation ratio of the k -RPT with $k \geq \log n$ is $O(2^{-\sqrt[4]{\log n}})$*

Proof. We use the same tournament structure as in the previous section, with strong, mediocre, and weak components s, m, w . Because the labeling of leaves in a k -RPT is uniformly random, there is no need to define a distribution over such tournaments; the components have fixed proportions $p_s^{(0)}, p_m^{(0)}, p_w^{(0)}$ to be specified later.

We again make repeated use of Lemma 4. In this setting, however, we do not have arbitrary control over ϵ , the probability of a competitor being weak; it must initially be some integer multiple of $1/n$. Thus we will first establish, for any sufficiently small ϵ , an infinite set of ranges for which the probability of a weak competitor winning must be high. We will then argue that for sufficiently large n , we can vary $\epsilon = \ell/n$ enough that these ranges collectively cover every $k \geq \log n$.

Let $\epsilon_0 \leq 2^{-2^6}$ equal $p_w^{(0)}$, i.e., it will represent the fraction of competitors that are weak; note that this satisfies the requirement $\epsilon_0 \leq 2^{-10}$ for Lemma 4. Each time we apply Lemma 4, we will obtain a new ϵ_i , so for instance, $\epsilon_1 \in [2^{-2 \log^2(\epsilon_0)}, 2^{-\log^2(\epsilon_0)/4}]$. We claim that

$$\log \epsilon_i \in \left[-2^{2^i-1} \left(\log \frac{1}{\epsilon_0} \right)^{2^i}, -\left(\frac{1}{4} \right)^{2^i-1} \left(\log \frac{1}{\epsilon_0} \right)^{2^i} \right]$$

We can verify this by induction – it clearly holds for $i = 0$. Assume it holds for $i - 1$. By Lemma 4,

$$\begin{aligned} \log \epsilon_i &\in \left[-2 \log^2 \left(\frac{1}{\epsilon_{i-1}} \right), -\frac{1}{4} \log^2 \left(\frac{1}{\epsilon_{i-1}} \right) \right] \\ &\in \left[-2 \left(-2^{2^{i-1}-1} \left(\log \frac{1}{\epsilon_0} \right)^{2^{i-1}} \right)^2, -\frac{1}{4} \left(-\left(\frac{1}{4} \right)^{2^{i-1}-1} \left(\log \frac{1}{\epsilon_0} \right)^{2^{i-1}} \right)^2 \right] \\ &\in \left[-2 \times 2^{2^i-2} \left(\log \frac{1}{\epsilon_0} \right)^{2^i}, -\frac{1}{4} \left(\frac{1}{4} \right)^{2^i-2} \left(\log \frac{1}{\epsilon_0} \right)^{2^i} \right], \end{aligned}$$

as desired.

Let t_i be the step (bracket depth) at which the i^{th} application of Lemma 4 begins, $t_0 = 0$. Note that $p_w^{(t_i)}$ is high when $i \bmod 3 = 2$. We claim that

$$t_{i+1} \in \left[\log \left(\frac{1}{\epsilon_i} \right), 4 \log \left(\frac{1}{\epsilon_i} \right) \right].$$

The lower bound is immediate from Lemma 4 because the i^{th} oscillation takes at least $\log(\frac{1}{\epsilon_i})$ steps. The upper bound we again prove inductively; for t_1 it likewise holds directly from Lemma 4. Assuming it holds for t_i , and since $\log \epsilon_i \in [-2 \log^2(\epsilon_{i-1}), -\frac{1}{4} \log^2(\epsilon_{i-1})]$,

$$\begin{aligned} t_{i+1} &\leq t_i + 3 \log \left(\frac{1}{\epsilon_i} \right) \\ &\leq 4 \log \left(\frac{1}{\epsilon_{i-1}} \right) + 3 \log \left(\frac{1}{\epsilon_i} \right) \\ &\leq 4 \sqrt{4 \log \left(\frac{1}{\epsilon_i} \right) + 3 \log \left(\frac{1}{\epsilon_i} \right)} \\ &\leq 4 \log \left(\frac{1}{\epsilon_i} \right) \end{aligned}$$

where the last line holds because $\log(\frac{1}{\epsilon_i}) \geq \log(\frac{1}{\epsilon_0}) \geq 2^6$ by assumption.

Next, recall that by Lemma 4, the two smaller probabilities at t_{i+1} sum to at most $3\epsilon_{i+1}$. If we allow this sum to increase slightly, say to ϵ_i , we can go additional steps beyond t_{i+1} . Specifically, knowing the probability at most doubles each time step, for any $t \leq \frac{1}{8} \log^2(\frac{1}{\epsilon_i})$ we have

13:14 Single-Elimination Brackets Fail to Approximate Copeland Winner

$$\begin{aligned}
\log(2^t \times 3\epsilon_{i+1}) &\leq t - 1 + \log(\epsilon_{i+1}) \\
&\leq \frac{1}{8} \log^2\left(\frac{1}{\epsilon_i}\right) - 1 - \frac{1}{4} \log^2\left(\frac{1}{\epsilon_i}\right) \\
&\leq -\log\left(\frac{1}{\epsilon_i}\right)
\end{aligned}$$

where the last line holds because $\log(\frac{1}{\epsilon_i}) \geq \log(\frac{1}{\epsilon_0}) \geq 2^6$. Removing the logarithm, the above implies that for any $t \leq \frac{1}{8} \log^2(\frac{1}{\epsilon_i})$, the two smaller probabilities at time t_{i+1} still sum to at most ϵ_i at time $t_{i+1} + \lceil t \rceil$. Also, for $t = \frac{1}{8} \log^2(\frac{1}{\epsilon_i})$, observe that

$$\begin{aligned}
t_{i+1} &\leq 4 \log\left(\frac{1}{\epsilon_i}\right) \leq 2 \left(2 \log \frac{1}{\epsilon_0}\right)^{2^i} \\
t_{i+1} + \lceil t \rceil &\geq \log\left(\frac{1}{\epsilon_i}\right) + \frac{1}{8} \log^2\left(\frac{1}{\epsilon_i}\right) - 1 \\
&\geq \frac{1}{8} \log^2\left(\frac{1}{\epsilon_i}\right) \geq 2 \left(\frac{\log(1/\epsilon_0)}{4}\right)^{2^{i+1}}.
\end{aligned}$$

Thus for any $\epsilon_0 \leq 2^{-2^6}$ and $i \in \mathbb{N}$, we have established an interval on which the largest probability is at least $1 - \epsilon_i$. In particular, whenever $i + 1 = 2 \pmod{3}$, this gives an interval on which a weak competitor wins with overwhelming probability.

Next, we want to show that, for any sufficiently large n , these intervals can be made to cover every depth $k \geq \log n$, even with the limitation that ϵ_0 must equal ℓ/n for some $\ell \in \mathbb{N}$. In fact, we claim that letting ℓ take on values $1, 2, \dots, \lceil 2^{\log n - \sqrt[4]{\log n/4}} \rceil := L$ covers every $k \geq \log n$ for any n sufficiently large that $\lceil 2^{\log n - \sqrt[4]{\log n/4}} \rceil / n \leq 2^{-2^6}$ – this is necessary to ensure that $\epsilon_0 \in [1/n, L/n]$ will be at most 2^{-2^6} as assumed above.

First, let us verify that the lowest k contained in one of these intervals is sufficiently small. k will be smallest when i is small ($i + 1 = 2$) and when ϵ_0 is large ($\epsilon_0 = L/n$). Thus the first interval will start at

$$2 \left(2 \log \frac{n}{L}\right)^2 \leq 2 \left(\log(2^{\sqrt[4]{\log n/4}})\right)^2 = \sqrt{\log n}/8 \ll \log n,$$

so indeed our overlapping intervals start below $k = \log n$.

Next, we need to establish that for a fixed i , the adjacent intervals with $\epsilon_0 = \ell/n, \epsilon_0 = (\ell - 1)/n$ overlap. That is, the lower bound of the later interval needs to be below the upper bound of the earlier. I.e., we require

$$\begin{aligned}
2 \left(2 \log\left(\frac{n}{\ell - 1}\right)\right)^2 &\leq 2 \left(\log\left(\frac{n}{\ell}\right)/4\right)^4 \\
2^5 \log\left(\frac{n}{\ell - 1}\right) &\leq \log^2\left(\frac{n}{\ell}\right)
\end{aligned}$$

and indeed,

$$2^5 \log\left(\frac{n}{\ell - 1}\right) \leq 2^5 \left(1 + \log \frac{n}{\ell}\right) \leq \log^2\left(\frac{n}{\ell}\right)$$

where the final inequality holds because $\log(\frac{n}{\ell}) \geq 2^6$.

Finally, we will show that the latest interval for i , $\epsilon_0 = 1/n$, overlaps with the earliest interval for $i + 3$, $\epsilon_0 = L/n$, and thus that there is no gap between intervals where a weak competitor can win with high probability. We require

$$2 \left(2 \log \frac{n}{L}\right)^{2^{i+3}} \leq 2 \left(\frac{\log n}{4}\right)^{2^{i+1}}$$

$$\left(2 \log \frac{n}{L}\right)^4 \leq \frac{\log n}{4}$$

and indeed,

$$\left(2 \log \frac{n}{L}\right)^4 \leq \left(2^{\sqrt[4]{\log n/4}}\right)^4 = \frac{\log n}{16} < \frac{\log n}{4}$$

as desired.

Having shown that a weak competitor can win with overwhelming probability for sufficiently large n and any $k \geq \log n$, we can upper-bound the expected Copeland score of the winner as

$$\mathbb{E}[d_+(\text{winner})] \leq (1-\epsilon_i)(\ell+\ell/2)+\epsilon_i(n-1) \leq L+L/2+\frac{L}{n}(n-1) \leq 3L = 3 \left\lceil 2^{\log n - \sqrt[4]{\log n/4}} \right\rceil.$$

Equivalently, the approximation ratio of any k -RPT is $O(2^{-\sqrt[4]{\log n/4}})$. \blacktriangleleft

Interestingly, although this bound holds for all $k \geq \log n$, significantly tighter bounds can be obtained for certain k by the same method. In particular, the bound is made much looser by increasing the size of the weak component up to L/n , which is only necessary when trying to cover every possible k . When the weak component has size $1/n$, we recover the $O(1/n)$ approximation ratio of [5]. Without matching lower bounds, it is unclear to what extent this oscillating approximation ratio is real versus an artifact of the proof method. Regardless, this upper bound settles the question of whether any k -RPT can obtain a decent approximation ratio.

6 Conclusion

In this work, we establish that randomly-seeded single-elimination brackets are surprisingly bad at approximating the maximum Copeland score, as is a generalized version of SE brackets from the voting theory literature, the k -RPT. However, we show that SE brackets have optimal approximation ratio for *worst-case*/deterministic seeding among Condorcet competition formats.

Despite their sub-constant approximation ratio, single-elimination brackets are widely used; perhaps quirks of their occurrence in practice could improve the approximation ratio? For instance, one could consider the impact of seeding based on some measure of competitor ability, or investigate whether SE brackets perform better on tournament graphs generated from some random model. Alternatively, one could investigate other existing competition formats (e.g., double-elimination, Swiss-system) to see if they better approximate the Copeland winner.

A Proof of Lemma 4

► **Lemma 4.** *Let S be a set of competitors partitioned into three components C_1, C_2, C_3 such that every member of component C_i beats every member of component $C_{(i \bmod 3)+1}$. Fix probabilities $p_i^{(0)}$ summing to 1, and let $p_i^{(k)}$ denote the probability that a member of component C_i wins a balanced bracket of height k where each leaf is labeled independently according to $p_i^{(0)}$. If for some $K \in \mathbb{N}$ and $0 < \epsilon \leq 2^{-10}$, $\epsilon^2 \leq p_3^{(K)} \leq \epsilon$ and $\epsilon \leq p_1^{(K)} \leq 2\epsilon$, then there exists $K + \log(\frac{1}{\epsilon}) \leq K' \leq K + 3 \log(\frac{1}{\epsilon})$ and $\epsilon^{2 \log(\frac{1}{\epsilon})} \leq \delta \leq \epsilon^{\log(\frac{1}{\epsilon})/4}$ such that $\delta^2 \leq p_2^{(K')} \leq \delta$ and $\delta \leq p_3^{(K')} \leq 2\delta$. Furthermore, if $\epsilon \leq 2^{-75}$ then for any $K'' \in [K', K' + 2^5 \log(\frac{1}{\epsilon})]$, $p_2^{(K'')}, p_3^{(K'')} \leq \epsilon^{\log(\frac{1}{\epsilon})/2^5}$.*

Proof. Since we have labeled each leaf independently, the two children of a node are independent, so we can easily calculate $p_i^{(k)}$ recursively. For all $k \geq 0$,

$$p_i^{(k+1)} = \left(p_i^{(k)}\right)^2 + 2p_i^{(k)} p_{(i \bmod 3)+1}^{(k)} = p_i^{(k)} \left(p_i^{(k)} + 2p_{(i \bmod 3)+1}^{(k)}\right).$$

We will proceed by phases. Phase 1 will be the time during which $p_2^{(k)}$ shrinks to $1/2$; phase 2 will extend from there to the time when $p_2^{(k)}$ shrinks to less than $p_3^{(k)}$ (this will be K'); and phase 3 will be the additional $2^5 \log(\frac{1}{\epsilon})$ steps after K' .

Phase 1. Let $K_1 > K$ be the first step for which $p_1^{(k)} + p_3^{(k)} > 1/2$. Such a step must exist because for $K \leq k < K_1$, $p_1^{(k)} + p_3^{(k)} \leq 1/2$, and thus

$$p_3^{(k+1)} = p_3^{(k)} \left(p_3^{(k)} + 2p_1^{(k)}\right) \leq p_3^{(k)} \leq \epsilon,$$

i.e., $p_3^{(k)}$ is weakly decreasing on this interval. Thus also,

$$p_1^{(k+1)} = p_1^{(k)} \left(p_1^{(k)} + 2p_2^{(k)}\right) = p_1^{(k)} (1 - p_3^{(k)} + p_2^{(k)}) \geq p_1^{(k)} (1.5 - \epsilon) \geq p_1^{(k)} \sqrt{2}$$

for k in this interval, since $p_1^{(k)} + p_3^{(k)} \leq 1/2$ implies $p_2^{(k)} \geq 1/2$, and since $\epsilon \leq 2^{-10} < 1.5 - \sqrt{2}$. Therefore, $p_1^{(k)}$ is increasing by at least a constant factor every step, and so eventually $p_1^{(k)} + p_3^{(k)}$ will exceed $1/2$. Note also that $p_i^{(k+1)} \leq 2p_i^{(k)}$ for all i, k , so $p_1^{(k)}$ is increasing by at least a factor of $\sqrt{2}$ and at most a factor of 2 on this interval.

This leads to the following observations about phase 1:

1. $\epsilon^{2^{(k-K)/2}} \leq p_1^{(k)} \leq \epsilon^{2^{k-K+1}}$ for any $k \in [K, K_1]$
2. $\epsilon^2 \left(\epsilon^{2^{(K_1-K+3)/4}}\right)^{K_1-K} \leq p_3^{(K_1)} \leq \epsilon \left(\epsilon^{2^{(K_1-K+5)/2}}\right)^{K_1-K}$
3. $\log(\frac{1}{\epsilon}) - 3 \leq K_1 - K \leq 2 \log(\frac{1}{\epsilon})$

Observation 1 follows directly from our initial assumption on $p_1^{(K)}$ and the bounds on the factor by which it increases each step.

13:18 Single-Elimination Brackets Fail to Approximate Copeland Winner

Observation 2 can be shown via observation 1 and our initial assumptions as follows, using the fact that $0 \leq p_3^{(k)} \leq p_1^{(k)}$ on this interval.

$$\begin{aligned}
 p_3^{(K_1)} &= p_3^{(K)} \prod_{t=K}^{t=K_1-1} (p_3^{(t)} + 2p_1^{(t)}) \\
 p_3^{(K)} \prod_{t=K}^{t=K_1-1} 2p_1^{(t)} &\leq p_3^{(K_1)} \leq p_3^{(K)} \prod_{t=K}^{t=K_1-1} 3p_1^{(t)} \\
 p_3^{(K)} \prod_{t=0}^{t=K_1-K-1} 2p_1^{(K)} 2^{t/2} &\leq p_3^{(K_1)} \leq p_3^{(K)} \prod_{t=0}^{t=K_1-K-1} 3p_1^{(K)} 2^t \\
 p_3^{(K)} (2p_1^{(K)})^{K_1-K} 2^{(K_1-K-1)(K_1-K)/4} &\leq p_3^{(K_1)} \leq p_3^{(K)} (3p_1^{(K)})^{K_1-K} 2^{(K_1-K-1)(K_1-K)/2} \\
 \epsilon^2 (\epsilon 2^{(K_1-K+3)/4})^{K_1-K} &\leq p_3^{(K_1)} \leq \epsilon (\epsilon 2^{(K_1-K+5)/2})^{K_1-K}
 \end{aligned}$$

Finally, observation 3 is obtained from observation 1 based on how long it would take for $p_1^{(k)}$ to get to $1/2$ (or rather in the range $[1/2 - \epsilon, 1]$). Specifically, plugging in $k = K_1$ to observation 1 and taking the log of both sides:

$$\begin{aligned}
 \log \epsilon + \frac{K_1 - K}{2} &\leq \log p_1^{(K_1)} \leq \log \epsilon + K_1 - K + 1 \\
 \log p_1^{(K_1)} - \log \epsilon - 1 &\leq K_1 - K \leq 2 \log p_1^{(K_1)} - 2 \log \epsilon \\
 \log\left(\frac{1}{2} - \epsilon\right) - \log \epsilon - 1 &\leq K_1 - K \leq 2 \log 1 - 2 \log \epsilon \\
 \log\left(\frac{1}{\epsilon}\right) - 3 &\leq K_1 - K \leq 2 \log\left(\frac{1}{\epsilon}\right)
 \end{aligned}$$

Phase 2. Let $K_2 > K_1$ be the first step for which $p_3^{(k)} > p_2^{(k)}$. We claim that $K' = K_2$ is as required in the statement of the lemma.

To show that such a step must exist, note that at step K_1 , we have $1/4 < p_2^{(K_1)} < 1/2$, $p_3^{(K_1)} \leq \epsilon$, and therefore $p_1^{(K_1)} > 1/2 - \epsilon$. Furthermore, since $p_3^{(k)} \leq p_2^{(k)}$ on this interval, for $K_1 \leq k < K_2$,

$$p_1^{(k+1)} = p_1^{(k)} (p_1^{(k)} + 2p_2^{(k)}) = p_1^{(k)} (1 - p_3^{(k)} + p_2^{(k)}) \geq p_1^{(k)}$$

i.e., $p_1^{(k)}$ is weakly increasing. In particular,

$$p_1^{(K_1+1)} = p_1^{(K_1)} (p_1^{(K_1)} + 2p_2^{(K_1)}) \geq (1/2 - \epsilon)(1/2 - \epsilon + 1/4) > 0.6 > 1/2.$$

Thus for every step after the first, $p_3^{(k)}$ is increasing by a factor of $p_3^{(k)} + 2p_1^{(k)} > 1.2$, while $p_2^{(k)}$ is multiplied by a factor of $p_2^{(k)} + 2p_3^{(k)} = 1 - p_1^{(k)} + p_3^{(k)} < 1$, and they will eventually cross.

We make the following observations about phase 2:

1. $(\frac{1}{4})^{2^{k-K_1}} \leq p_2^{(k)} \leq (\frac{1}{2})^{2^{k-K_1-1}}$ for any $k \in [K_1 + 1, K_2]$
2. $1.5^{k-K_1-2} p_3^{(K_1)} \leq p_3^{(k)} \leq 2^{k-K_1} p_3^{(K_1)}$ for any $k \in [K_1 + 2, K_2]$
3. $\log \log(\frac{1}{\epsilon}) \leq K_2 - K_1 \leq \log(\frac{1}{\epsilon})$

Observation 1 follows from the fact that $\frac{1}{4} \leq p_2^{(K_1)} \leq \frac{1}{2}$ and $p_3^{(K_1)} \leq \epsilon \leq 2^{-10}$. Recall that no probability can more than double in a single step. Thus

$$\begin{aligned} p_2^{(K_1+1)} &\leq p_2^{(K_1)} \left(p_2^{(K_1)} + 2p_3^{(K_1)} \right) \leq \frac{1}{2} \left(\frac{1}{2} + 2^{-9} \right) \leq 0.251 \\ p_2^{(K_1+2)} &\leq p_2^{(K_1+1)} \left(p_2^{(K_1+1)} + 2p_3^{(K_1+1)} \right) \leq 0.251(0.251 + 2^{-8}) \leq 0.064 \\ p_2^{(K_1+3)} &\leq p_2^{(K_1+2)} \left(p_2^{(K_1+2)} + 2p_3^{(K_1+2)} \right) \leq 0.064(0.064 + 2^{-7}) \leq 0.0046. \end{aligned}$$

Therefore, since $p_2^{(k+1)} = p_2^{(k)} \left(p_2^{(k)} + 2p_3^{(k)} \right)$, we have for any $k \geq K_1 + 3$,

$$\begin{aligned} \left(p_2^{(k)} \right)^2 &\leq p_2^{(k+1)} \leq 3 \left(p_2^{(k)} \right)^2 \\ \left(\frac{1}{4} \right)^{2^{k-K_1}} &\leq p_2^{(k+1)} \leq (3 \times 0.0046)^{2^{k-K_1-3}} \leq \left(\frac{1}{2} \right)^{2^{k-K_1-1}}. \end{aligned}$$

Since $p_2^{(k)}$ is decreasing we have $p_3^{(k)} \leq p_2^{(k)} \leq \frac{1}{8}$ for $K_1 + 2 \leq k \leq K_2$. Thus $p_3^{(k)}$ increases by at most a factor of 2, and at least a factor of $2p_1^{(k)}$ which is at least 1.5 after the first two steps. ($p_3^{(k)}$ may decrease by a factor no smaller than $1 - \epsilon$ in the first step, but the next step more than cancels this out.) This yields observation 2.

Observation 3 we'll just show by plugging in the given values for $K_2 - K_1$ into the bounds for $p_2^{(k)}$ and $p_3^{(k)}$ and showing that they either must have, or must not have crossed by the given time.

First let us verify that after another $\log(\frac{1}{\epsilon})$ steps it must be the case that $p_3^{(k)} > p_2^{(k)}$. Specifically, if we assume that $K_1 + \log(\frac{1}{\epsilon}) < K_2$, we obtain the following contradiction:

$$\begin{aligned} p_3^{(K_1 + \log(\frac{1}{\epsilon}))} &\geq 1.5^{\log(\frac{1}{\epsilon})-2} p_3^{(K_1)} \geq 1.5^{\log(\frac{1}{\epsilon})-2} \epsilon^2 \left(\epsilon^{2(K_1-K+3)/4} \right)^{K_1-K} \\ &\geq 1.5^{\log(\frac{1}{\epsilon})-2} \epsilon^2 \left(\epsilon \left(\frac{1}{\epsilon} \right)^{1/2} 2^{3/4} \right)^{2 \log(\frac{1}{\epsilon})} \\ &= \left(\frac{2}{3} \right)^2 \left(\frac{3}{2} \right)^{\log(\frac{1}{\epsilon})} \epsilon^{\log(\frac{1}{\epsilon})+2} 2^{3 \log(\frac{1}{\epsilon})/2} \\ &> \left(\frac{1}{2} \right)^{\log(\frac{1}{\epsilon})(\log(\frac{1}{\epsilon})+2)} > \left(\frac{1}{2} \right)^{1/2\epsilon} \geq p_2^{(K_1 + \log(\frac{1}{\epsilon}))} \end{aligned}$$

since $1/2\epsilon > \log^2(\frac{1}{\epsilon}) + 2 \log(\frac{1}{\epsilon})$ for $\epsilon \leq 2^{-7}$. This establishes the upper bound on $K_2 - K_1$.

To establish that $K_2 - K_1 \geq \log \log(\frac{1}{\epsilon})$, we need to show that after that many steps, it still holds that $p_3^{(k)} \leq p_2^{(k)}$.

$$\begin{aligned} p_3^{(K_1 + \log \log(\frac{1}{\epsilon}))} &\leq 2^{\log \log(\frac{1}{\epsilon})} p_3^{(K_1)} \leq 2^{\log \log(\frac{1}{\epsilon})+2} \epsilon \left(\epsilon^{2(\log(\frac{1}{\epsilon})-3+5)/2} \right)^{\log(\frac{1}{\epsilon})-3} \\ &= \log\left(\frac{1}{\epsilon}\right) \epsilon \left(2\epsilon^{1/2} \right)^{\log(\frac{1}{\epsilon})-3} \\ &= \frac{1}{8} \log\left(\frac{1}{\epsilon}\right) \epsilon^{\log(\frac{1}{\epsilon})/2-3/2} \\ &\leq \epsilon^{\log(\frac{1}{\epsilon})/4} \leq \left(\frac{1}{4} \right)^{\log(\frac{1}{\epsilon})} \leq p_2^{(K_1 + \log \log(\frac{1}{\epsilon}))} \end{aligned}$$

where the last line holds for $\epsilon \leq 2^{-10}$. Thus phase 2 must proceed for more than $\log \log(\frac{1}{\epsilon})$ steps.

13:20 Single-Elimination Brackets Fail to Approximate Copeland Winner

Note also that observation 3 (together with observation 3 of phase 1) implies that $K + \log(\frac{1}{\epsilon}) \leq K' \leq K + 3 \log(\frac{1}{\epsilon})$, as required.

Finally, we need to establish that there exists a δ as required in the statement of the lemma. If $p_3^{(K'-1)} \leq p_2^{(K')} \leq p_3^{(K')}$, let $\delta = p_3^{(K')}$. Then trivially $\delta \leq p_3^{(K')} \leq 2\delta$ and also

$$\delta^2 \leq \delta/2 \leq p_3^{(K'-1)} \leq p_2^{(K')} \leq p_3^{(K')} = \delta$$

since $\delta \leq 1/2$. Otherwise, $p_2^{(K')} < p_3^{(K'-1)}$; in this case, let $\delta = p_3^{(K'-1)}$. Again trivially, $\delta \leq p_3^{(K')} \leq 2\delta$. Additionally,

$$\delta^2 = \left(p_3^{(K'-1)}\right)^2 \leq \left(p_2^{(K'-1)}\right)^2 \leq p_2^{(K')} \leq p_3^{(K'-1)} = \delta.$$

Now to lower-bound δ , using observations 2 and 3, we have

$$\begin{aligned} 2\delta &\geq p_3^{(K')} \geq 1.5^{\log \log(\frac{1}{\epsilon}) - 2} p_3^{(K_1)} \\ &\geq \left(\frac{2}{3}\right)^2 \log\left(\frac{1}{\epsilon}\right)^{1/2} \epsilon^2 \left(\epsilon 2^{(2 \log(\frac{1}{\epsilon}) + 1)/4}\right)^{2 \log(\frac{1}{\epsilon})} \\ &\geq \left(\frac{2}{3}\right)^2 \log\left(\frac{1}{\epsilon}\right)^{1/2} \epsilon^{\log(\frac{1}{\epsilon}) + 3/2} \geq 2\epsilon^{2 \log(\frac{1}{\epsilon})} \\ \delta &\geq \epsilon^{2 \log(\frac{1}{\epsilon})} \end{aligned}$$

where the penultimate line holds for $\epsilon \leq 2^{-4}$.

As for an upper bound:

$$\begin{aligned} \delta &\leq p_3^{(K')} \leq p_3^{(K_1)} 2^{\log(\frac{1}{\epsilon})} \\ &\leq \epsilon \left(\epsilon 2^{(\log(\frac{1}{\epsilon}) - 3 + 5)/2}\right)^{\log(\frac{1}{\epsilon}) - 3} 2^{\log(\frac{1}{\epsilon})} \\ &= \left(2\epsilon^{1/2}\right)^{\log(\frac{1}{\epsilon}) - 3} = 2^{-3} \epsilon^{(\log(\frac{1}{\epsilon}) - 5)/2} \leq \epsilon^{\log(\frac{1}{\epsilon})/4} \end{aligned}$$

where the last line holds for $\epsilon \leq 2^{-10}$. Thus we have shown that $K' = K_2$ is as required in the statement of the lemma.

Phase 3. Finally, we want to establish that $p_3^{(k)}$ and $p_2^{(k)}$ stay relatively small for $2^5 \log(\frac{1}{\epsilon})$ steps past K' , provided ϵ is small enough. In particular, we know that $p_3^{(K')} > p_2^{(K')}$, and that no probability can more than double at each time step. Thus

$$\begin{aligned} p_3^{(K'+t)}, p_2^{(K'+t)} &\leq 2^t p_3^{(K')} \leq 2^t \left(2\epsilon^{1/2}\right)^{\log(\frac{1}{\epsilon}) - 3} \\ &= 2^{t-3} \epsilon^{(\log(\frac{1}{\epsilon}) - 5)/2} \\ &\leq \epsilon^{\log(\frac{1}{\epsilon})/2^5} \end{aligned}$$

where the last line holds if

$$\begin{aligned} 2^{t-3} \epsilon^{-5/2} &\leq \epsilon^{-(2^4 - 1) \log(\frac{1}{\epsilon})/2^5} \\ t - 3 - \frac{5}{2} \log(\epsilon) &\leq (2^4 - 1) \log^2(\epsilon)/2^5 \\ t &\leq \frac{2^4 - 1}{2^5} \log^2(\epsilon) + \frac{5}{2} \log(\epsilon) + 3 \end{aligned}$$

In particular, since we want this to hold up to $t = 2^5 \log(\frac{1}{\epsilon})$, $\epsilon \leq 2^{-75}$ suffices. This completes the proof. \blacktriangleleft

Routing Symmetric Demands in Directed Minor-Free Graphs with Constant Congestion

Abstract

The problem of routing in graphs using node-disjoint paths has received a lot of attention and a polylogarithmic approximation algorithm with constant congestion is known for undirected graphs [Chuzhoy and Li 2016] and [Chekuri and Ene 2013]. However, the problem is hard to approximate within polynomial factors on directed graphs, for any constant congestion [Chuzhoy, Kim and Li 2016].

Recently, [Chekuri, Ene and Pilipczuk 2016] have obtained a polylogarithmic approximation with constant congestion on directed planar graphs, for the special case of symmetric demands. We extend their result by obtaining a polylogarithmic approximation with constant congestion on arbitrary directed minor-free graphs, for the case of symmetric demands.

1 Introduction

Routing in graphs along disjoint paths is a fundamental problem with numerous applications in various domains [1, 2, 3, 23, 24]. Disjoint path problems have been well-studied in both the directed and undirected setting, and it is known that the directed formulations of these problems are generally more difficult to approximate [14, 11]. The recent work of [5, 6] has brought to light a more tractable formulation of the directed version of these problems by considering routing symmetric demand pairs with constant congestion.

Two of the most well-known and studied disjoint path problems are the node-disjoint paths problem (NDP) and the edge-disjoint paths problems (EDP). In these problems, the goal is to connect a set of node pairs through node- or edge-disjoint paths in an undirected graph. It is known that the decision version of NDP is NP-complete [20], and it has been shown to be fixed parameter tractable [26]. But there remain gaps in our understanding of their approximability. For both EDP and NDP on n -node graphs, the state of the art is an $O(\sqrt{n})$ -approximation [9], [22]. For planar graphs, a slightly better bound of $\tilde{O}(n^{9/19})$ -approximation is known [13]. Even for the case of the grid, only a $\tilde{O}(n^{1/4})$ -approximation for NDP is known [12]. For hardness of approximation, it is known that both NDP and EDP are $2^{\Omega(\sqrt{\log n})}$ -hard to approximate, unless all problems in NP have algorithms with running time $n^{\log n}$ [14].

Progress has been made on relaxed versions of these problems. One such relaxation is the all-or-nothing flow problem (ANF), where a subset $\mathcal{M}' \subseteq \mathcal{M}$ is routed if there is a feasible multicommodity flow routing one unit of flow for each pair in \mathcal{M}' . Poly-logarithmic approximations are known for ANF [8, 7]. Another relaxation is to allow some small constant congestion on the nodes or edges. For this relaxation, poly-logarithmic approximations have been obtained for EDP with congestion 2 [15], and for NDP with congestion $O(1)$ [4].

It is natural to extend the study of disjoint path problems to directed graphs. However, these problems are known to be significantly harder on directed graphs. Even the case of ANF with constant congestion c allowed has an $n^{\Omega(1/c)}$ inapproximability bound [11]. However, a more tractable case is found by considering symmetric demand pairs. The study of maximum throughput routing problems in directed graphs with symmetric demand pairs began in [5]. In this setting the graph G is directed, and routing a source-destination pair (s_i, t_i) requires finding a path from s_i to t_i and a path from t_i to s_i . We let Sym-Dir-ANF be the analogue of ANF, and Sym-Dir-NDP be the analogue of NDP in this setting. A poly-logarithmic approximation for Sym-Dir-ANF is obtained in [5]. Subsequently, in [6] a randomized poly-logarithmic approximation with constant congestion on planar graphs for Sym-Dir-NDP is obtained.

1.1 Our contribution

We consider the problem of routing symmetric demands along node-disjoint paths in directed graphs. We refer to this problem as Sym-Dir-NDP. Letting $G = (V, E)$ be a directed graph with unit node capacities and $\mathcal{M} = \{(s_1, t_1), \dots, (s_k, t_k)\} \subseteq V \times V$ be a set of source-destination pairs, we say that (G, \mathcal{M}) is an instance of Sym-Dir-NDP. Routing a pair (s_i, t_i) requires finding a path from s_i to t_i , and from t_i to s_i . A solution to an instance of Sym-Dir-NDP is a routing strategy maximizing the number of pairs routed through disjoint paths. We refer to a solution having congestion ζ , if no vertex is used in more than ζ paths. Our contribution generalizes the result from [6] from the class of directed planar graphs to arbitrary directed minor-free graphs. We now formally state our results and briefly highlight the methods used. Our main result is the following.

► **Theorem 6.** *Let G be an H -minor free graph. There is a polynomial time randomized algorithm that, with high probability, achieves an $\Omega\left(\frac{1}{h^7 \sqrt{h} \log^{5/2}(n)}\right)$ -approximation with congestion 5 for Sym-Dir-NDP instances in G , where h is an integer dependent only on H .*

The approximation algorithm in this theorem is obtained by extending the algorithm of [6]. For an instance $(G, \{(s_1, t_1), \dots, (s_k, t_k)\})$ of Sym-Dir-NDP, we say that the set $\mathcal{T} = \{s_1, \dots, s_k\} \cup \{t_1, \dots, t_k\}$ is the set of terminals. Speaking broadly, the algorithm obtained in Theorem 6 consists of the following steps.

1. Using a multicommodity flow based LP relaxation and the well-linked decomposition of [6], reduce to an instance in which the terminals \mathcal{T} are α -well-linked for a fixed constant α .
2. Find a large routing structure connected to a large proportion of the terminals.
3. Use the routing structure to connect a large number of the source-destination pairs.

From here on, we shall refer to the routing structure as the crossbar. The reduction we use in Step 1 allows us to reduce an instance of Sym-Dir-NDP to an instance on an Eulerian graph of small maximum degree, and where the terminals are α -well-linked. This comes at the cost of then having a randomized algorithm for the original instance. This reduction comes from [6], and while there it is used for planar graphs, we were fortunate in that it

can also be used for general graphs. The routing scheme of Step 3 is also thanks to [6], and relies on a similar crossbar construction. Our main contribution to this line of research is in finding an appropriate crossbar construction for Step 2.

To build our crossbar, we would ideally find a “flat” grid minor so that some constant fraction of the terminal pairs can be routed along node-disjoint paths to the interface of the grid minor (a “flat” grid minor is one in which the grid minor is connected with the rest of the graph only through the outer face). Then we would have the following sets of node-disjoint paths along which to route the terminal pairs: the paths from the terminals to the interface, the paths from terminals to terminals implied by the node-well-linked property of the terminals, the concentric cycles of the grid minor, and the paths connecting the outermost and innermost cycles of the grid minor. From these, just as in [6] we can construct a routing scheme with congestion 5. To find a suitable flat grid minor, we combine results of [10] and [28] to show that flat grid minors of a suitable size can be found. We then show that if for the flat grid minor produced we cannot route a large enough fraction of the terminals to the interface then there exists some vertex which can be eliminated from the graph without destroying a potential solution to the problem. Thus, we find and test flat grid minors until one suitable to be used in the crossbar is found.

2 Notation and Preliminaries

We now introduce some notation and definitions that are used throughout the paper.

Directed and undirected graphs

From any directed graph G we can obtain an undirected graph G^{UN} as follows. We set $V(G^{\text{UN}}) = V(G)$ and $E(G^{\text{UN}}) = \{\{u, v\} : (u, v) \in E(G) \vee (v, u) \in E(G)\}$. We refer to G^{UN} as the *underlying undirected graph* of G .

Flat subgraphs

We say that a planar subgraph H of an undirected graph G is *flat* if there exists a planar drawing Φ of H such that for any $\{u, v\} \in E(G)$, with $u \in V(H)$ and $v \in V(G) \setminus V(H)$, we have that u is on the outer face of Φ .

Well-linked sets

Let G be a directed (resp. undirected) graph. A set $X \subseteq V(G)$ is node-well linked in G if for any two disjoint subsets $Y, Z \subset X$ of equal size, there exist $|Y|$ node-disjoint directed (resp. undirected) paths from Y to Z , such that each vertex in Y is the start of exactly one path, and each vertex in Z is the end of exactly one path. For some $\alpha \in (0, 1)$, we say that X is α -node well-linked if for any two disjoint subsets $Y, Z \subset X$ of equal size, there exist $|Y|$ directed (resp. undirected) paths from Y to Z such that no vertex is in more than $1/\alpha$ of these paths; In other words, we allow a node congestion of $1/\alpha$ for these paths.

Directed and undirected treewidth

For a directed graph G , we will denote by $\text{dtw}(G)$ the *directed treewidth* of G , and we will denote by $\text{tw}(G^{\text{UN}})$ the (undirected) *treewidth* of G^{UN} . Directed treewidth is a global connectivity measure introduced in [19, 25], and just as undirected treewidth is defined by the minimum width tree decomposition, directed treewidth is defined by the minimum size of

14:4 Routing Symmetric Demands in Directed Minor-Free Graphs

what is termed an arboreal decomposition. Instead of providing the full definitions of directed and undirected treewidth here, we only ask the reader to make a note of the following two important facts:

- If G is an Eulerian directed graph with max degree Δ , then $\text{tw}(G^{\text{UN}}) \leq \text{dtw}(G) = O(\Delta \cdot \text{tw}(G^{\text{UN}}))$ [19].
- If a directed graph G contains an α -well-linked set X , then $\text{dtw}(G) = \Omega(\alpha|X|)$ [25].

Clique-sums

Let G_1 and G_2 be two graphs. A *clique-sum* of G_1 and G_2 is any graph that is obtained by identifying a clique in G_1 with a clique of the same size in G_2 , and then possibly removing some edges in the resulting shared clique. An *h -clique-sum*, or *h -sum* for short, is a clique-sum where the identified cliques have at most h vertices.

Nearly-embeddable and minor-free graphs

We say that a graph is (a, g, k, p) -*nearly embeddable* if it is obtained from a graph of Euler genus g by adding a apices and k vortices of pathwidth p . We say that a graph is h -*nearly embeddable* if it is (a, g, k, p) -nearly embeddable for some $a, g, k, p \leq h$. The following is implicit in [27].

► **Theorem 1** (Robertson and Seymour [27]). *Let H be any graph. Every H -minor-free graph can be obtained by at most h -clique-sums of graphs that are h -nearly embeddable graphs, where h is a non-negative integer dependent on H .*

Note that the result of the above theorem is existential. Demaine, Hajiaghayi, and Kawarabayashi in [16] provide an algorithm to compute this decomposition in polynomial time, for any fixed minor H .

3 The Algorithm for Minor-Free Graphs

We first use the following result of [6] to reduce the problem to the case of Eulerian graphs with small degrees. Note that this result is stated for planar graphs in [6], but the proof does not use planarity, and thus can be stated for general graphs.

► **Lemma 2** (Chekuri, Ene & Pilipczuk [6]). *Suppose that there is a polynomial time algorithm for $\Omega(1)$ -node-well-linked instances of Sym-Dir-NDP in directed Eulerian graphs of maximum degree Δ that achieves a $\beta(\Delta)$ -approximation with congestion c . Then there is a polynomial time randomized algorithm that, with high probability, achieves a $\beta(O(\log^2 k)) \cdot O(\log^6 k)$ -approximation with congestion c for arbitrary instances of Sym-Dir-NDP in directed graphs, where k is the number of pairs in the instance.*

Now we describe how to construct the crossbar in minor-free graphs, assuming that we are given a $m \times m$ flat grid minor Γ , for some large enough m , and a family of λm node-disjoint paths connecting the set of terminals and the interface of Γ , for some constant λ . The following is our main technical result, which is similar to the one in [6] for planar graphs. We use here a generalized notion of *enclosed* for flat grids in non-planar graphs. Let H be a directed graph with a flat grid minor η . Let u^{out} be an arbitrary vertex not contained in η . Let C be some cycle contained within η . We say a vertex u is *enclosed* by C if all paths in H^{UN} from u to u^{out} intersect C . We now find the desired concentric cycles in G . The proof is deferred to Section 4.

■ **Figure 1** An example for case (1) of Theorem 3. The red paths are the node disjoint paths in P^+ , going from Y^+ to the innermost of the concentric cycles, and the blue paths correspond to the node disjoint paths in P^- , going from Y^- to the innermost of the concentric cycles.

► **Theorem 3.** *Let G be a directed minor-free graph of maximum in-degree of at most Δ . Let X be an α -node-well-linked set in G with $|X| = \Omega\left(\frac{\Delta^2}{\alpha}\right)$. Let $m = \Omega\left(\frac{\alpha|X|}{\beta}\right)$, where β is a non-negative number dependent on G . Suppose that we can find a $m \times m$ flat grid minor Γ of G^{UN} , and a family of λm node-disjoint paths connecting X and the interface of Γ in G^{UN} , for some $0 < \lambda \leq 1$. One can in polynomial time find a set of $\Omega\left(\frac{\alpha|X|}{\beta\Delta}\right)$ concentric directed cycles going in the same direction w.r.t. a planar embedding of Γ (all clockwise or counter-clockwise), sets $Y^+, Y^- \in X$ with $|Y^+| = |Y^-| = \Omega\left(\frac{\alpha^2|X|}{\beta\Delta^2}\right)$, and families P^+ and P^- of node-disjoint paths such that one of the following holds.*

- (1) *None of the cycles enclose any vertex of $Y^+ \cup Y^-$, the family P^+ consists of $|Y^+|$ node-disjoint paths from Y^+ to the innermost cycle, and the family P^- consists of $|Y^-|$ node-disjoint paths from the innermost cycle to Y^- (See Figure 1).*
- (2) *All cycles enclose $Y^+ \cup Y^-$, the family P^+ consists of $|Y^+|$ node-disjoint paths from $|Y^+|$ to the outermost cycle, and the family P^- consists of $|Y^-|$ node-disjoint paths from the outermost cycle to Y^- .*

In order to obtain such a crossbar, we need to find a flat grid minor of large enough size. The following Lemma provides us the desired flat grid minor, and the proof is deferred to Section 6.2.

► **Lemma 4.** *Let H be any graph and let G be an H -minor-free directed graph with treewidth t . Let X be an α -node-well-linked set in G with $|X| = \Omega\left(\frac{\Delta^2}{\alpha}\right)$. One can in polynomial time find a $r \times r$ flat grid minor Γ in G^{UN} , with $r = \Omega\left(\frac{t}{h^7 \sqrt{h \log^{5/2}(n)}}\right)$, and a family of r node-disjoint paths connecting X and the interface of Γ , where h is an integer dependent only on the structure of H .*

Once we obtain a crossbar as described above, we can route a large subset of terminal pairs.

► **Lemma 5.** *Given the crossbar described in Theorem 3, one can get an $O\left(\frac{\Delta^2}{\beta\alpha^3}\right)$ -approximation algorithm with congestion 5 for Sym-Dir-NDP in instances for which the input graph is minor-free and Eulerian with maximum in-degree Δ , the set of terminals is α -node-well-linked for some $\alpha \leq 1$, and β is dependent only on H .*

Proof. By applying the same routing scheme as in the one in [6], we get the desired result. ◀

Now we are ready to state the main result of this paper.

► **Theorem 6.** *Let G be a H -minor-free graph. There is a polynomial time randomized algorithm that, with high probability, achieves an $\Omega\left(\frac{1}{h^7 \sqrt{h} \log^{5/2}(n)}\right)$ -approximation with congestion 5 for Sym-Dir-NDP instances in G , where h is an integer dependent only on H .*

Proof. This is immediate by Lemmas 2, 4, 5, and Theorem 3. ◀

4 The Crossbar Construction

In this section we discuss the construction of the crossbar stated in Theorem 3. Before we give the proof of this Theorem we establish some auxiliary facts. Throughout this subsection, we assume that we are given the input of Theorem 3.

► **Lemma 7.** *One can in polynomial time find an integer $r = \Omega\left(\frac{\alpha|X|}{\beta}\right)$ and a sequence of node-disjoint concentric undirected cycles C_1, C_2, \dots, C_r in G^{UN} , with C_1 being the outermost and C_r being the innermost cycle.*

Proof. Let t be the treewidth of G^{UN} . Since X is α -node-well-linked in G , X is also α -node-well-linked in G^{UN} . Thus, $t = \Omega(\alpha|X|)$. Let Γ be a flat $m \times m$ grid minor of G^{UN} , as given in the input of Theorem 3. By losing a constant factor, we can construct a flat sub-divided $r \times r$ wall in G^{UN} , with $r = \Omega\left(\frac{\alpha|X|}{\beta}\right)$. Let C_1 be the outermost cycle of Γ , and for each $i \in \{2, \dots, r\}$, let C_i be the outermost cycle of $\Gamma \setminus \cup_{1 \leq j < i} V(C_j)$. ◀

As in [6], for a vertex set $Q \subseteq V(G^{\text{UN}})$, a vertex $v \notin Q$, and an integer $\ell \geq 2\Delta$, we say that a vertex set S is a (v, Q, ℓ) -isle if $v \in S$, $G^{\text{UN}}[S]$ is connected, $S \cap Q = \emptyset$, and $|N_{G^{\text{UN}}}(S)| \leq \ell$. Let C_1, \dots, C_r be the sequence of node-disjoint concentric undirected cycles in G^{UN} obtained from Lemma 7. We set isles S^{out} and S^{in} by choosing an arbitrary vertex v^{out} in C_1 , and an arbitrary vertex v^{in} in C_r . Letting $\ell = \lfloor r/(4\Delta + 2) \rfloor$, then S^{out} is the $(v^{\text{out}}, X, \ell)$ -isle and S^{in} is the (v^{in}, X, ℓ) -isle obtained. We also need that S^{out} and S^{in} are separated by many cycles. For this, we use the following Lemma of [6], the proof of which is slightly modified.

► **Lemma 8.** *The isle S^{out} does not contain any vertex that is enclosed by $C_{\ell+1}$, and the isle S^{in} does not contain any vertex that is not strictly enclosed by $C_{r-\ell}$.*

Proof. The proofs for S^{in} and S^{out} are symmetrical, so we focus on the case of S^{out} . Assume that S^{out} contains a vertex enclosed by $C_{\ell+1}$, and we will find a contradiction. Since $v^{\text{out}} \in S^{\text{out}}$, S^{out} is connected in G^{UN} , and Γ is a flat wall, it must be that S^{out} contains a vertex from every cycle C_i , $1 \leq i \leq \ell + 1$. Since $|N_{G^{\text{UN}}}(S^{\text{out}})| \leq \ell$, for some $1 \leq i \leq \ell + 1$ we have that $V(C_i)$ is completely contained in S^{out} . However, there are $r > \ell$ vertex-disjoint paths in G^{UN} connecting C_i with X . Thus, either $S^{\text{out}} \cap X \neq \emptyset$ or $|N_{G^{\text{UN}}}(S^{\text{out}})| > \ell$, both of which are contradictions. ◀

We are almost ready to prove the main result of this section. We will make use of the following Lemma, which is implicit in [6]. Note that sets S'^{in} and S'^{out} , the concentric cycles $C'_1, \dots, C'_{r'}$, and integers r' and Δ' in the next Lemma are defined for a planar graph G' as described in [6].

► **Lemma 9.** *Let G' be an Eulerian, planar directed graph, with sets $S'^{\text{in}}, S'^{\text{out}}$ separated by concentric cycles $C'_1, \dots, C'_{r'}$, and let $\ell' = \lfloor r'/(4\Delta' + 2) \rfloor$, where Δ' is the maximum in-degree of G' . Then one can in polynomial time find $\lfloor \ell'/2 \rfloor$ node-disjoint directed concentric*

■ **Figure 2** Maintaining an Eulerian graph with bounded degree.

cycles, all going in the same direction (all clockwise or all counter-clockwise), such that all vertices of S^{in} are strictly enclosed by the innermost cycle, and all vertices of S^{out} are not enclosed by the outermost cycle, or vice versa, with the roles of S^{in} and S^{out} swapped.

We will use Lemma 9 to find concentric cycles in minor-free graphs. We first generalize the notion of *enclosed* for flat grids in non-planar graphs. Let H be a directed graph with a flat grid minor η . Let u^{out} an arbitrary vertex not contained in η . Let C be some cycle contained within η . We say a vertex u is *enclosed* by C if all paths in H^{UN} from u to u^{out} intersect C . We now find the desired concentric cycles in G .

► **Lemma 10.** *One can in polynomial time find $\lceil \ell/2 \rceil$ node-disjoint directed concentric cycles in G , all going in the same direction (all clockwise or all counter-clockwise), such that all vertices of S^{in} are enclosed by the innermost cycle, and all vertices of S^{out} are not enclosed by the outermost cycle, or vice versa, with the roles of S^{in} and S^{out} swapped.*

Proof. We proceed by creating G' from G as follows. Let

$$Z = \{v \in V(G) : v \in V(C_1) \text{ or } v \text{ is not in the component of } G \setminus V(C_1) \text{ containing } C_2\}.$$

Let $G' = G/Z$, i.e. G' is the graph created by identifying all vertices in Z to a single vertex z . Since G is Eulerian, G' is also Eulerian. Furthermore, we can delete any self-loops on z , and G' is still Eulerian. Since C_1, \dots, C_r are contained within a flat grid minor of G , G' is therefore a planar graph. The only impediment to directly applying Lemma 9 is that the in-degree δ of z might be greater than Δ . We can eliminate this by replacing z with a path P of length δ , with edges directed both ways between adjacent vertices. We then connect the vertices formerly connected to z to vertices in P , maintaining the planarity of G' . Then, to restore G' as an Eulerian graph, for the vertices in P with an imbalance between in- and out-degree we can create a new edge (See Figure 2).

After these modifications, G' is an Eulerian, planar digraph with maximum in-degree Δ . Let $S'_{\text{in}} = S^{\text{in}}$ and $S'_{\text{out}} = (S^{\text{out}} \cap V(G')) \cup \{z\}$. We now apply Lemma 9 using G' , S'_{in} , and S'_{out} to find $\lceil \ell/2 \rceil$ node-disjoint directed concentric cycles, all going in the same direction, and all vertices of S'_{in} are strictly enclosed by the innermost cycle, and all vertices of S'_{out} are not enclosed by the outermost cycle. Clearly, each of these cycles exists in G , all vertices of S^{in} are strictly enclosed by the innermost cycle, and all vertices of S^{out} are not enclosed by the outermost cycle. ◀

We are now ready to obtain the proof of Theorem 3.

Proof of Theorem 3. By Lemma 10, we can finish the construction of the crossbar with the same argument as in [6]. ◀

■ **Figure 3** Decomposition of the grid minor.

5 Graphs of Bounded Genus

In this section we describe an algorithm to construct a flat grid minor Γ of large enough size in graphs of bounded genus. The following is implicit in the work of Chekuri and Sidiropoulos [10].

► **Lemma 11.** *Let G be an undirected graph of Euler genus $g \geq 1$, with treewidth $t \geq 1$. There is a polynomial time algorithm that computes a $r' \times r'$ -grid as a minor, with $r' = \Omega\left(\frac{t}{g^3 \log^{5/2} n}\right)$. Furthermore, the algorithm does not require a drawing of G as part of the input.*

We need to find a flat grid minor for our purpose. Thomassen in [28] shows that if a graph of genus g contains a $m \times m$ -grid as a minor, then it contains a $k \times k$ flat grid minor, where $m > 100k\sqrt{g}$. With some minor modifications, we can use this result to obtain the following.

► **Lemma 12.** *Let G be an undirected graph of Euler genus $g \geq 1$, and let H be a $m \times m$ grid minor of G . Let $k < \frac{m}{100\sqrt{g}}$ be an integer. Then one can compute a $k \times k$ flat grid minor of G in polynomial time.*

Proof. Thomassen in [28] shows that in order to find the desired flat grid minor, it is enough to construct a family of pairwise disjoint subgraphs $Q_1, Q_2, \dots, Q_{2g+2}$ of H , satisfying the following conditions.

- (1) Each Q_i is a $k \times k$ sub-grid of H .
- (2) For any i, j with $1 \leq i < j \leq 2g + 2$, we have the following. If x_i and x_j are on the outer cycles of Q_i and Q_j respectively, and they have neighbors $y_i \in V(H) \setminus V(Q_i)$ and $y_j \in V(H) \setminus V(Q_j)$ respectively, then H has a path P_{ij} from x_i to x_j such that

$$V(P_{ij}) \cap \left(\bigcup_{r=1}^{2g+2} V(Q_r) \right) = \{x_i, x_j\}.$$

Since we have $m > 100k\sqrt{g}$, this construction can be easily done as shown in Figure 3, and thus one of the Q_i 's is flat, as desired. ◀

► **Lemma 13.** *Let G be an undirected graph of Euler genus $g \geq 1$, with treewidth $t \geq 1$. There exists a polynomial time algorithm that computes a $r \times r$ -grid as a minor, with $r = \Omega\left(\frac{t}{g^3 \sqrt{g} \log^{5/2} n}\right)$. Moreover, the algorithm does not require a drawing of G as part of the input.*

Proof. This is immediate by Lemmas 11 and 12. ◀

Note that computing a large grid minor in the graph is not enough. We need to make sure that a large number of terminals can reach the interface of the grid minor. The following Lemma will provide for us the desired grid minor. The proof of this Lemma is deferred to Appendix A.

► **Lemma 14.** *Let \mathcal{F} be some minor-closed family of graphs, let $\alpha \leq 1$, and $\beta > 0$. Suppose that there exists a polynomial-time algorithm which given, some $G' \in \mathcal{F}$ and some α -node-well-linked set X' in G' , outputs some $r' \times r'$ flat grid minor Γ' in G' , for some $r' = \Omega(\alpha|X'|/\beta)$. Then there exists a polynomial-time algorithm which, given some $G \in \mathcal{F}$ and some α -node-well-linked set X in G , outputs some $r \times r$ flat grid minor Γ in G , for some integer $r = \Omega(\alpha|X|/\beta)$, and a family of λr node-disjoint paths in G connecting X to the interface of Γ , for some constant $0 < \lambda < 1$.*

► **Lemma 15.** *Let G be an undirected graph of genus g , and let $\alpha \leq 1$. Let X be an α -node-well-linked set in G . One can, in polynomial time, find some $r \times r$ flat grid minor Γ in G , for some integer $r = \Omega\left(\frac{\alpha|X|}{g^3\sqrt{g}\log^{5/2}n}\right)$, and a family of λr node-disjoint paths connecting X and the interface of Γ , for some $0 < \lambda \leq 1$.*

Proof. This is immediate by combining Lemmas 13 and 14. ◀

Now by Lemmas 2, 5, and 15 we get the following result.

► **Theorem 16.** *Let G be a graph of genus g . There is a polynomial time randomized algorithm that, with high probability, achieves an $\Omega\left(\frac{1}{g^3\sqrt{g}\log^{5/2}(n)}\right)$ -approximation with congestion 5 for Sym-Dir-NDP instances in G .*

6 Minor Free Graphs

In this section we present the flat grid minor construction for minor-free graphs. We first consider the problem on nearly embeddable graphs, and we extend our solution to arbitrary minor-free graphs by dealing with sums of constant size.

6.1 Nearly Embeddable Graphs

In this subsection we work on nearly embeddable graphs. First we reduce the problem to the case of zero apices.

► **Lemma 17 (Reduction to $(0, g, k, p)$ -nearly embeddable graphs).** *Suppose that there is a polynomial time algorithm for Sym-Dir-NDP in $(0, g, k, p)$ -nearly embeddable graphs that achieves a β -approximation with congestion c . Then there is a polynomial time algorithm for Sym-Dir-NDP in (a, g, k, p) -nearly embeddable graphs that achieves a β/a -approximation with congestion c .*

Proof. Let G be an (a, g, k, p) -nearly embeddable graph, and suppose that we are given a Sym-Dir-NDP instance $M = \{s_1t_1, \dots, s_mt_m\}$ in G . Let $A \subseteq V(G)$ be the set of apices in G . Let $G' = G \setminus A$. Clearly, G' is a $(0, g, k, p)$ -nearly embeddable graph. Let $M' \subseteq M$ be the subset of source-terminal pairs that do not intersect A . M' forms a Sym-Dir-NDP instance in G' , and thus we can get a β -approximation solution S' with congestion c . Since $|M| \leq |M'| + a$, we have that S' is a β/a -approximation solution with congestion c for M in G , as desired. ◀

14:10 Routing Symmetric Demands in Directed Minor-Free Graphs

Next we provide an algorithm for Sym-Dir-NDP in $(0, g, k, p)$ -nearly embeddable graphs. Let G be an $(0, g, k, p)$ -nearly embeddable graph, and let S be the bounded genus subgraph of G on the surface; that is, S is obtained from G by deleting all vortices. Let $X \subseteq V(G)$ be the set of terminals. Note that by using Lemma 2 we can reduce the problem to the case where X is α -well-linked for some $\alpha \leq 1$. The following is implicit in [17].

► **Lemma 18** (Demaine and Hajiaghayi [17]). *Let $t \geq 1$ be the treewidth of G^{UN} , and let t' be the treewidth of S^{UN} . Then we have $t' \geq \frac{t}{(p+k)^3}$.*

► **Lemma 19.** *One can in polynomial time find a $r \times r$ flat grid minor Γ in G^{UN} , with $r = \Omega\left(\frac{t}{g^3 \sqrt{g}(p+k)^3 \log^{5/2} n}\right)$.*

Proof. By Lemma 18 we have that the treewidth of S^{UN} is at least $\frac{t}{(p+k)^3}$. S^{UN} is a graph of Euler genus g , and thus by Lemma 13 we get the desired result. ◀

► **Lemma 20.** *One can in polynomial time find some $r \times r$ flat grid minor Γ in G^{UN} , for some integer $r = \Omega\left(\frac{t}{g^3 \sqrt{g}(p+k)^3 \log^{5/2} n}\right)$, and a family of r node-disjoint paths connecting X and the interface of Γ .*

Proof. This is immediate by Lemmas 19 and 14. ◀

Now by combining Lemmas 2, 3, 20, the crossbar construction and routing scheme in Section 4, we get the following result.

► **Lemma 21.** *Let G be a $(0, g, k, p)$ -nearly embeddable graph. There is a polynomial time randomized algorithm that, with high probability, achieves an $\Omega\left(\frac{1}{g^3 \sqrt{g}(p+k)^3 \log^{5/2} n}\right)$ -approximation with congestion 5 for Sym-Dir-NDP instances in G .*

► **Theorem 22.** *Let G be a (a, g, k, p) -nearly embeddable graph. There is a polynomial time randomized algorithm that, with high probability, achieves an $\Omega\left(\frac{1}{ag^3 \sqrt{g}(p+k)^3 \log^{5/2} n}\right)$ -approximation with congestion 5 for Sym-Dir-NDP instances in G .*

Proof. This follows immediately by Lemmas 21 and 17. ◀

6.2 Dealing with h -sums

In this subsection we are going to prove Lemma 4. Let G be a minor-free graph, with treewidth t . Let $X \subseteq V(G)$ be the set of terminals. The following is implicit in [18].

► **Lemma 23** ([18]). *Let G_1, G_2 be two undirected graphs, and let G_3 be an h -sum of G_1 and G_2 for some integer $h > 0$. Let t_1, t_2 , and t_3 be the treewidth of G_1, G_2 , and G_3 respectively. Then we have $t_3 \leq \max\{t_1, t_2\}$.*

We are now ready to prove our result for computing flat grid minors in minor-free graphs.

Proof of Lemma 4. By using Theorem 1, we get a decomposition of G^{UN} into h -sums of h -nearly-embeddable graphs. By Lemma 23, we have that at least one summand G' has treewidth at least t . Now G' is a h -nearly-embeddable graph with treewidth t , and thus by Lemma 20 we get the desired flat grid minor. ◀

A Missing Proofs

Proof of Lemma 14. Let t be the treewidth of G . Since X is α -node-well-linked in G , we have that $t = \Omega(\alpha|X|)$. Let Γ_0 be an $r' \times r'$ flat grid minor in G , for some $r' = \Omega(\alpha|X|/\beta)$. If there is a family of λr_0 node-disjoint paths connecting X and the the interface of Γ_0 , then we are done. Otherwise, we will find an *irrelevant* vertex; that is a vertex $v \in V(G)$ such that deleting v from G does not affect the well-linkedness of X . Therefore, we can delete v from G , and recursively call the process for finding flat grid minors, until we get the desired one.

Suppose that there is not a family of λr_0 node-disjoint paths connecting X and the interface of Γ_0 . First we find a $r'_0 \times r'_0$ sub-grid Γ'_0 of Γ_0 such that $r'_0 = O(r_0)$ and Γ'_0 contains at most $\frac{\lambda r_0}{\alpha}$ terminals. For any minor H of G , and for every $v \in V(H)$, let $\eta(v) \subseteq V(G)$ be the subset of vertices in G corresponding to v . Let also $X_H = X \cap \eta(H)$. Since there is not a family of λr_0 node-disjoint paths connecting X and the interface of Γ_0 , we can find a cut $C \subseteq E(G)$ in G , separating X_{Γ_0} and the interface of Γ_0 , with $|C| < \lambda r_0$. Now let A_1, A_2, \dots, A_m be the connected components of $G \setminus C$ that contain vertices of X_{Γ_0} (See Figure 4). We may assume w.l.o.g. that $|V(A_1)| \geq |V(A_2)| \geq \dots \geq |V(A_m)|$. Now let $Y, Z \subset X$ be two disjoint subsets of X of equal size such that $X_{A_1} \subset Y$ and $X_{A_i} \subset Z$ for any $i \in \{2, 3, \dots, m\}$. Since X is α -node-well-linked, there exist a family \mathcal{P} of $|Y|$ paths from Y

■ **Figure 4** The connected components of $G \setminus C$ in Γ'_0 .

to Z such that no vertex is in more than $1/\alpha$ of these paths. However, we have $X_{A_1} \subset Y$ and $X_{A_i} \subset Z$ for any $i \in \{2, 3, \dots, m\}$, and thus we have $|V(X_{A_2}) \cup \dots \cup V(X_{A_m})| \leq |C| \frac{1}{\alpha} < \frac{\lambda r_0}{\alpha}$. Therefore, we can find a $\frac{r_0}{4} \times \frac{r_0}{4}$ sub-grid Γ'_0 of Γ_0 such that Γ'_0 does not intersect X_{A_1} , and moreover there are at most $\frac{\lambda r_0}{\alpha}$ number of terminals in $\eta(\Gamma'_0)$.

If there is a family of $\lambda r'_0$ node-disjoint paths connecting X and the interface of Γ'_0 , then we are done. Otherwise, we find an irrelevant vertex. We use a similar technique as in [21]. Let Γ''_0 be the $r''_0 \times r''_0$ sub-grid of Γ'_0 obtained by deleting the first and last $r'_0/4$ rows and columns of Γ'_0 . By the construction, we know that Γ''_0 contains at most $\frac{\lambda r_0}{\alpha}$ terminals. We may assume w.l.o.g. that r'_0 is a power of 2, and thus r''_0 is a power of 2 as well. We construct a hierarchical partitioning of Γ''_0 into smaller sub-grids as follows. For every $i, j \in \{1, 2, \dots, r''_0\}$, let $v_{i,j}$ be the vertex in the i 'th row and j 'th column of Γ''_0 . For any $i, j, h \in \{1, 2, \dots, r''_0\}$, let

$$H_{i,j,h} = \bigcup_{a=\max\{1, i-h-1\}}^{\min\{i+h, r''_0\}} \bigcup_{b=\max\{1, j-h-1\}}^{\min\{j+h, r''_0\}} \{v_{a,b}\}.$$

We also define $\ell(H_{i,j,h}) = 2h$. For every $q \in \{0, 1, \dots, \log r''_0\}$, we define two partitions of Γ''_0 into $q \times q$ sub-grids as follows. Let

$$\mathcal{H}_{q,1} = \bigcup_{i=0}^{r''_0/2^{q+1}-1} \bigcup_{j=0}^{r''_0/2^{q+1}-1} \{H(i2^{q+1}, j2^{q+1}, 2^q)\},$$

and

$$\mathcal{H}_{q,2} = \bigcup_{i=0}^{r''_0/2^{q+1}-1} \bigcup_{j=0}^{r''_0/2^{q+1}-1} \{H(i2^{q+1} + 2^q, j2^{q+1} + 2^q, 2^q)\}.$$

Let $\mathcal{H} = \bigcup_{q=0}^{\log r''_0} \bigcup_{i=1}^2 \mathcal{H}_{q,i}$. For every $H \in \mathcal{H}$, let $w(H)$ be the number of terminals in $\eta(H)$.

Let also $w(\Gamma''_0)$ be the number of terminals in $\eta(\Gamma''_0)$. We say that some $H \in \mathcal{H}$ is *dense* if $w(H) \geq \ell(H)/100$. Let $\delta(\Gamma''_0)$ be the interface of Γ''_0 . We say that some $v \in V(\Gamma''_0)$ is *good* if v is not contained in any dense $H \in \mathcal{H}$, and there is no terminals in $\eta(v)$. First we

■ Figure 5 Sets C_q .

show that there exists a good vertex in Γ''_0 . We count the number of vertices in Γ''_0 that are contained in at least one dense $H \in \mathcal{H}$. Let $\mathcal{H}_{q,j} \in \mathcal{H}$ for some $q \in \{0, \dots, \log r''_0\}$ and $j \in \{1, 2\}$, and let $H \in \mathcal{H}_{q,j}$. H is dense if and only if $w(H) \geq \ell(H)/100 = 2^{q+1}/100$. We know that $w(\Gamma''_0) \leq r''_0/10000$, and thus if $2^{q+1} > r''_0/100$, then there are no dense $H \in \mathcal{H}_{q,j}$. Now suppose that $2^{q+1} \leq r''_0/100$, and thus $q < \log r''_0 - 7$. Let $i \in \{8, \dots, \log r''_0\}$, and let $q = \log r''_0 - i$. Let $H' \in \mathcal{H}_{q,1}$. We have that $\ell(H') = 2^{q+1} = r''_0/2^{i-1}$. In order for H' to be dense it must be that $w(H') \geq \frac{\ell(H')}{100} = \frac{r''_0}{100 \cdot 2^{i-1}}$. Note that we have $w(\Gamma''_0) \leq r''_0/10000$, and therefore there can be at most $2^{i-1}/100$ dense $H' \in \mathcal{H}_{q,1}$. With a similar argument, we can show that there can be at most $2^{i-1}/100$ dense $H' \in \mathcal{H}_{q,2}$. Now we have

$$\begin{aligned} \left| \bigcup_{H \in \mathcal{H}: H \text{ is dense}} H \right| &\leq 2 \cdot \sum_{i=8}^{\log r''_0} \left(\frac{r''_0}{2^{i-1}} \right)^2 \cdot \frac{2^{i-1}}{100} \\ &= \frac{(r''_0)^2}{50} \cdot \sum_{i=8}^{\log r''_0} \frac{1}{2^{i-1}} \\ &< \frac{(r''_0)^2}{50}. \end{aligned}$$

This means that there exist at least $\frac{49(r''_0)^2}{50}$ vertices in Γ''_0 that are not contained in any dense $H \in \mathcal{H}$, and since there are at most $r''_0/10000$ terminals in $\eta(\Gamma''_0)$, there must exist a good vertex in Γ''_0 , as desired. Furthermore, this vertex can be found in polynomial time. Let $v \in V(\Gamma''_0)$ be a good vertex.

We claim that vertices in $\eta(v)$ are irrelevant. For every $q \in \{0, 1, \dots, \log r''_0\}$ and $i \in \{1, 2\}$, let $H_{q,i} \in \mathcal{H}_{q,i}$ be a sub-grid that contains v . By the construction, for every $q \in \{0, 1, \dots, \log r''_0\}$, we have that either $d_{\Gamma''_0}(v, \delta(H_{q,1})) \geq 2^{q-1}$ or $d_{\Gamma''_0}(v, \delta(H_{q,2})) \geq 2^{q-1}$. Let $B_q \in \{H_{q,1}, H_{q,2}\}$ be such that $d_{\Gamma''_0}(v, \delta(B_q)) \geq 2^{q-1}$. For every $q \in \{1, \dots, \log r''_0\}$, let $C_q = B_q \setminus B_{q-1}$, and let also $C_{\log r''_0+1} = V(\Gamma''_0) \setminus V(\Gamma''_0)$ (See Figure 5).

Let $Y, Z \subset X$ be two disjoint subsets of X of equal size. Since X is α -node well-linked, we know that there exists a family \mathcal{P} of $|Y|$ paths from Y to Z such that no vertex is in more than $1/\alpha$ of these paths. If none of these paths use v , then we are done. Otherwise, we try to re-route these paths to obtain a new family \mathcal{P}' of paths, such that no path is using

v , and no vertex is in more than $1/\alpha$ of the paths in \mathcal{P}' . First we look at the paths $P \in \mathcal{P}$ with both endpoints outside of Γ'_0 ; that is the endpoints of P do not belong to $\eta(\Gamma'_0)$. Let $\mathcal{P}^* \subseteq \mathcal{P}$ be the set of all such paths. We re-route them in a way such that they do not intersect $\eta(\Gamma''_0)$. Note that by the construction, at most $\lambda r'_0$ of paths in \mathcal{P}^* can intersect $\eta(\Gamma'_0)$. For these paths, we can re-route their intersection with $\eta(\Gamma'_0)$ in $\eta(\Gamma'_0) \setminus \eta(\Gamma''_0)$, and thus they will not intersect $\eta(\Gamma''_0)$. Now let $\mathcal{P}^{**} \subseteq \mathcal{P}$ be the set of paths with one endpoint outside of $\eta(\Gamma'_0)$, and one endpoint inside of $\eta(\Gamma'_0)$. Let $P = (a_1, a_2, \dots, a_p) \in \mathcal{P}^{**}$, where $a_1 \notin \eta(\Gamma'_0)$ and $a_p \in \eta(\Gamma'_0)$. Let $a_f \in V(P)$ be the first intersection of P and $\eta(\Gamma'_0)$; that is $f \in \{1, 2, \dots, p\}$ is the minimum number such that $a_f \in \eta(\Gamma'_0)$. Let $P' = (a_f, \dots, a_p)$. We replace P with P' in \mathcal{P} . Note that again there are at most $\lambda r'_0$ such paths in \mathcal{P} . Now we are only dealing with paths with both endpoints in $\eta(\Gamma'_0)$. For all such paths, we use an inductive argument to re-route them. For any $i, j \in \{1, 2, \dots, \log r''_0 + 1\}$, let $\mathcal{P}_{i,j} \subseteq \mathcal{P}$ be the paths with one endpoint in $\eta(C_i)$, and the other endpoint in $\eta(C_j)$. By the construction, for any $i \in \{1, 2, \dots, \log r''_0 + 1\}$, we know that there are at most $2^i/20$ terminals in $\eta(C_i)$, and thus $|\mathcal{P}_{i,i}| \leq 2^i/20$. For all such paths, we can re-route them such that they stay inside C_i . We start with $\mathcal{P}_{\log r''_0+1, \log r''_0+1}$, and re-route all these paths such that they only use vertices

in $C_{\log r''_0+1}$. Again, by the construction, we have that $\left| \bigcup_{j=1}^{\log r''_0} \mathcal{P}_{\log r''_0+1, j} \right| \leq r''_0/10$. For all

$P \in \bigcup_{j=1}^{\log r''_0} \mathcal{P}_{\log r''_0+1, j}$, similar to the paths in \mathcal{P}^{**} , we can replace them with paths with one endpoint on the boundary of $C_{\log r''_0}$, and recursively follow the same argument for paths with both endpoints in $\eta\left(\bigcup_{j=1}^{\log r''_0} C_j\right)$ and so on. Therefore, by applying the same re-routing pattern, we can get a new set of paths \mathcal{P}' such that no path uses vertex v , as desired.

Now let $G_1 = G \setminus v$. Since v is an irrelevant vertex in G , we have that X is α -node-well-linked in G_1 , and thus we have that the treewidth of G_1 is $\Omega(\alpha|X|)$. Therefore, we can find a $r'_1 \times r'_1$ flat grid minor Γ_1 in G_1 , for some $r'_1 = \Omega\left(\frac{\alpha|X|}{\beta}\right)$. If there exists a family of $\lambda r'_1$ node-disjoint paths connecting X and the interface of Γ_1 , we are done. Otherwise, we recursively follow the same approach to find an irrelevant vertex v_1 in G_1 , and let $G_2 = G_1 \setminus v_1$ and so on. This recursive call stops in $O(n)$ steps, because for each $i \geq 1$, G_i is a graph of treewidth $\alpha|X|$. Therefore, for some $j \geq 1$, we can find a $r_j \times r_j$ flat grid minor Γ_j of G_j , for some $r_j = \Omega\left(\frac{\alpha|X|}{\beta}\right)$, such that there exists a family of λr_j node-disjoint paths connecting X and the interface of Γ_j . Note that Γ_j is also a flat grid minor of G , and this completes the proof. \blacktriangleleft

Rainbow Coloring Hardness via Low Sensitivity Polymorphisms

Abstract

A k -uniform hypergraph is said to be r -rainbow colorable if there is an r -coloring of its vertices such that every hyperedge intersects all r color classes. Given as input such a hypergraph, finding a r -rainbow coloring of it is NP-hard for all $k \geq 3$ and $r \geq 2$. Therefore, one settles for finding a rainbow coloring with fewer colors (which is an easier task). When $r = k$ (the maximum possible value), i.e., the hypergraph is k -partite, one can efficiently 2-rainbow color the hypergraph, i.e., 2-color its vertices so that there are no monochromatic edges. In this work we consider the next smaller value of $r = k - 1$, and prove that in this case it is NP-hard to rainbow color the hypergraph with $q := \lceil \frac{k-2}{2} \rceil$ colors. In particular, for $k \leq 6$, it is NP-hard to 2-color ($k - 1$)-rainbow colorable k -uniform hypergraphs.

Our proof follows the algebraic approach to promise constraint satisfaction problems. It proceeds by characterizing the polymorphisms associated with the approximate rainbow coloring problem, which are rainbow colorings of some product hypergraphs on vertex set $[r]^n$. We prove that any such polymorphism $f : [r]^n \rightarrow [q]$ must be C -fixing, i.e., there is a small subset S of C coordinates and a setting $a \in [q]^S$ such that fixing $x_{|S} = a$ determines the value of $f(x)$. The key step in our proof is bounding the sensitivity of certain rainbow colorings, thereby arguing that they must be juntas. Armed with the C -fixing characterization, our NP-hardness is obtained via a reduction from smooth Label Cover.

1 Introduction

Graph and hypergraph coloring are one of the most studied problems in Graph Theory and Theoretical Computer Science. Even though there is a simple algorithm to check if a given graph is 2-colorable or not, checking if a 3-uniform hypergraph can be colored with two colors so that no hyperedge is monochromatic is one of the classic NP-hard problems. This raises the question of identifying if 2-coloring is easy on special hypergraphs of interest. For example, if a k -uniform hypergraph is k -partite, i.e., the vertices can be partitioned into k parts so

that every hyperedge intersects each part, then there are simple algorithms to properly color the hypergraph with two colors. Suppose we know that a k -uniform hypergraph is promised to be $k - 1$ -partite, can we color it with two colors?

An equivalent way to formulate this question is in terms of rainbow coloring. A k -uniform hypergraph is said to be r -rainbow colorable if there is a coloring of vertices with r colors such that all the r colors appear in every edge. Unlike usual coloring, rainbow coloring becomes harder as we have more colors. Note that r -partiteness is the same thing as r -rainbow colorability. As mentioned above, a k -uniform hypergraph that is promised to be k -rainbow colorable can be efficiently colored with two colors. One big hammer approach for this is to use semidefinite programming and find a unit vector for each vertex such that the sum of the vectors in each edge sum to zero, and then use random hyperplane rounding. But the 2-coloring can also be performed by a simple random walk algorithm – start with an arbitrary coloring, and as long as there is a monochromatic edge, pick an arbitrary one and flip the color of a random vertex in it. This process will converge to a 2-coloring in a quadratic number of iterations with high probability [26].

If we relax the k -rainbow colorability assumption slightly to that of $(k - 1)$ -rainbow colorability, there are no known efficient algorithms for 2-coloring. It is tempting to conjecture that in fact this task is hard (in fact, even if we are allowed c colors for any constant c ; this was shown assuming the V Label Cover conjecture in [9]). If we relax the rainbow colorability assumption further, Austrin, Bhangale, and Potukuchi proved that it is NP-hard to 2-color a k -uniform hypergraph when it is promised to be $(k - 2\sqrt{k})$ -rainbow colorable [2]. They also showed that it is NP-hard to 2-color a 4-uniform hypergraph even if it is 3-rainbow colorable. In this work, we focus on hardness results for the $(k - 1)$ -rainbow colorable case, as this promise is the closest to k -partiteness which makes 2-coloring easy. While we can't show hardness of 2-coloring, we show that rainbow coloring with $\lceil \frac{k-2}{2} \rceil$ colors is hard. Formally, our main result is the following.

► **Theorem 1.** *Fix an integer $k \geq 4$. Given a k -uniform hypergraph that is promised to be $(k - 1)$ -rainbow colorable, it is NP-hard to rainbow color it with $\lceil \frac{k-2}{2} \rceil$ colors.*

As a corollary, we also get the following, which extends the similar result of [2] for the $k = 4$ case (their techniques did not generalize beyond the 4-uniform case).

► **Theorem 2.** *For $k \leq 6$, given a k -uniform hypergraph that is promised to be $(k - 1)$ -rainbow colorable, it is NP hard to 2-color it.*

1.1 Techniques

There have been broadly three lines of attack on proving hardness for graph and hypergraph coloring problems.

1. The first line of work gives reductions from Label Cover analyzed using Fourier-analytic techniques of the sort originally pioneered by Håstad [19]. Early applications of this method showed strong hardness results for coloring 2-colorable hypergraphs of low uniformity with any constant number of colors [15, 20, 22, 31]. This approach, augmented with the invariance principle of [28] and some of its extensions such as [13, 27, 33], was used to prove further hardness results for hypergraph coloring [5, 16] and strong conditional hardness results for graph coloring [13]. These methods usually also prove a stronger statement about finding independent sets in the graphs or hypergraphs. For rainbow

coloring, it is proved in [16] by combining together many of these techniques that a $(k/2)$ -rainbow colorable k -uniform hypergraph cannot be colored with any constant number of colors in polynomial time unless $P = NP$.

2. A less extensive line of work proceeds via combinatorial gadgets that are analyzed using ideas based on the chromatic number of Kneser graphs and similar results. The first exemplar of this approach was the hardness of $O(1)$ -coloring 2-colorable 3-uniform hypergraphs shown in [14]. Unlike the analytic results for 4-uniform hypergraphs mentioned above, this result does not show hardness of finding large independent sets. (This was later shown in [23] using the analytic approach, albeit under the d -to-1 conjecture.) A few recent results have revived this combinatorial approach, by re-deriving and improving some previous hardness results for hypergraph coloring using simpler proofs [3, 6].
3. The third and most recent line of work adapts the universal algebraic method behind the complexity classification of constraint satisfaction problems that culminated in the resolution of the Feder-Vardi CSP dichotomy conjecture [11, 35]. Here, the coloring problem is viewed as a Promise Constraint Satisfaction Problem (PCSP), and its associated “polymorphisms” are then analyzed.¹ In the cases when the polymorphisms are severely limited, one can show hardness via a reduction from Label Cover. The approach to study PCSP using polymorphisms originated in [4] and was used to show hardness results for graph and hypergraph coloring in [8]. The algebraic theory was further developed significantly in [12] leading among other results to a proof of NP-hardness of 5-coloring 3-colorable graphs. Recently, [24] and [34] used topological ideas to make further progress.

In this work, we follow the algebraic approach to prove Theorem 1. In fact, our main motivation is to understand Promise CSPs better. A promise CSP (defined formally in Section 2) is a relaxation of the traditional CSP where one is allowed to find an assignment that satisfies a relaxed version of the predicates underlying the CSP. Approximate graph coloring with more colors than the promised chromatic number is a quintessential example of a promise CSP. Rainbow coloring with fewer colors also naturally falls in this framework. As proved in [10, 12], as with normal CSP, the complexity of a promise CSP is captured by its associated polymorphisms. Polymorphisms (defined formally in Section 2) of a PCSP are ways to combine multiple solutions of an instance satisfying the stronger predicate to obtain a solution to the instance satisfying the weaker predicate. The high-level principle behind the algebraic approach is that the problem should be easy when it has a rich enough set of polymorphisms that include functions with strong symmetries, and hard when all its polymorphisms are somehow skewed and lack symmetries. This has been fully established for CSPs – when there are polymorphisms which obey weak near-unanimity, the CSP is polytime solvable, and otherwise NP-complete.² The hardness part of this dichotomy is easier and was known for a while [25]; the much harder algorithmic part was established only recently in [11, 35].

For promise CSPs, which form a much richer class, our current understanding is rather limited, for both the algorithmic and hardness sides. It is not clear (to even conjecture) what kind of lack in symmetries in the polymorphisms might dictate hardness, and how one might show the corresponding hardness. A simple (but rather limited) sufficient condition

¹ The proof in [13] also implicitly studies polymorphisms and proves that they must have a small number of coordinates with sizeable influence and thus are not too symmetric. This influence-type characterization interfaces better with Unique Games or other highly structured forms of Label Cover.

² For the case of Boolean CSPs, the CSP is hard iff all polymorphisms are essentially at most unary, i.e., either the dictator function, its complement or a constant function.

for hardness is when all the polymorphisms are dictators that depend on a single coordinate. In [4], it has been proved that if all the polymorphisms of a PCSP are juntas³, then the PCSP is NP-hard. This is the basis of the hardness results for $(2 + \epsilon)$ -SAT [4] and 3-coloring graphs that admit a homomorphism to C_k for any fixed odd integer k [24]. The recent hardness of 5-coloring 3-colorable graphs in [12] proceeds by showing that the absence of arity 6 polymorphisms with the so-called Olšák symmetry implies NP-hardness, and then verifying that 3 vs. 5-coloring lacks such polymorphisms.

It turns out that the polymorphisms of rainbow coloring can have Olšák symmetries *and* be non-juntas. We will get around this by proving that these polymorphisms are C -fixing in the sense that there exists a constant number of coordinates and an assignment to them such that if we fix these coordinates to the assignment, the value of the function is fixed. This is also studied as certificate complexity in Boolean function analysis [1]. We then prove that if the polymorphisms of a PCSP are C -fixing, then the PCSP is NP-hard.

In order to prove that the polymorphisms have low certificate complexity, we use the connection between sensitivity and certificate complexity of functions. These two ways of characterizing the complexity of functions are well studied in the context of Boolean functions. It is worth emphasizing that for our purposes, all we need is to show that low sensitivity (even sensitivity 2 suffices) implies constant certificate complexity, and thus we are not interested in optimal gaps between sensitivity and certificate complexity. The famous sensitivity vs. block sensitivity conjecture [29] states that these two parameters are in fact polynomially related. In one of the earliest works related to this problem, Simon [32] proved that certificate complexity is at most exponential in sensitivity. We extend this to larger domains and then use it to prove that the polymorphisms that we study have low certificate complexity. We remark that in a striking breakthrough, Huang [21] recently proved the sensitivity vs block sensitivity conjecture for Boolean domains.

The second step is to then use the C -fixing property to show NP-hardness of the PCSP. This is done by the usual paradigm of reducing from Label Cover using polymorphism tests (better known as long code tests) of functions associated with vertices of the Label Cover instance. A more structured form of the C -fixing property where the C variables are fixed to the same value, is used in [10] to show NP-hardness of certain Boolean PCSPs. However, in order to prove NP-hardness using our more general notion of C -fixing, we end up needing stronger properties of the Label Cover instance. As a result, our reduction is from the *smooth* Label Cover problem that was introduced and shown to be NP-hard in [22], and has found many applications in inapproximability since.

A natural question is to understand how far we can push these techniques. Our NP hardness reduction from smooth Label Cover works when the polymorphisms of the PCSP in hand are C -fixing for some constant C . As k increases, the polymorphisms of PCSP of 2-coloring a k -uniform hypergraph that is promised to be $(k - 1)$ -rainbow colorable get richer. When k is at most 6, the polymorphisms are C -fixing. At $k = 7$, we show that there is a polymorphism that is not C -fixing for any constant C . In fact, one would need C to be linear in the arity of polymorphisms which also rules out using smooth Label Cover with very strong soundness.

1.2 Prior work on rainbow coloring and related problems

Various notions of approximate coloring with rainbow colorability guarantees have been studied in the literature. Bansal and Khot [5] prove that when the input hypergraph is promised to be almost k -rainbow colorable, it is Unique Games hard to color it with

³ A C -junta is a function that depends on at most C inputs.

$O(1)$ colors. Sachdeva and Saket [30] establish NP-hardness of $O(1)$ coloring a k -uniform hypergraph when it is promised to be almost $(k/2)$ -rainbow colorable. This was extended by Guruswami and Lee [16] to perfectly $(k/2)$ -rainbow colorable hypergraphs. Guruswami and Saket [17] prove similar results assuming stronger forms of rainbow colorability in the completeness case. In [2], Austrin, Bhangale, and Potukuchi proved that it is NP-hard to 2-color a k -uniform hypergraph when it is promised to be $(k - 2\sqrt{k})$ -rainbow colorable. On the other hand, when the hypergraph is promised to be $(k - \sqrt{k})$ -rainbow colorable, Bhattiprolu, Guruswami and Lee [7] give algorithms to color the hypergraph with two colors that miscolors at most $k^{-\Omega(k)}$ fraction of edges; this beats the 2^{k+1} fraction achieved by random coloring that is the best possible for general 2-colorable hypergraphs [19]. Brakensiek and Guruswami [9] put forth a problem called V label cover (to possibly serve as a perfect completeness variant surrogate for Unique games), and under its conjectured inapproximability proved that it is hard to color a k -uniform $(k - 1)$ -rainbow colorable hypergraph with $O(1)$ colors.

A related notion of hypergraph coloring is strong coloring where we color a k -uniform hypergraph with $s > k$ colors such that in any edge, all the k vertices are colored with distinct colors. Brakensiek and Guruswami [8] prove that it is NP-hard to 2-color a k -uniform hypergraph that is promised to be strongly colorable with $\lceil \frac{3k}{2} \rceil$ colors. Assuming the V Label Cover conjecture, it is hard to $O(1)$ -color k -uniform hypergraphs with strong chromatic number at most $k + \sqrt{k}$ [9].

1.3 Outline

We start with a few notations and definitions in Section 2. In Section 3, we study polymorphisms of rainbow coloring. We first prove a result on sensitivity and certificate complexity and use it to prove properties of polymorphisms of the PCSP that we are studying. Then, we use these in Section 4 to prove NP hardness. Finally, we conclude in Section 5 by mentioning some open questions.

2 Preliminaries

2.1 Notations

We use $[n]$ to denote the set $\{1, 2, \dots, n\}$. Vectors are represented using bold face letters. We abuse the notation of k -ary relation A to use it both as a set $A \subseteq [q]^k$ and indicator function $A : [q]^k \rightarrow \{0, 1\}$.

2.2 PCSP and Polymorphisms

We will now formally define CSP, PCSP, and Polymorphisms.

► **Definition 3 (CSP).** *Given a k ary relation $A : [q]^k \rightarrow \{0, 1\}$ over $[q]$, the Constraint Satisfaction problem associated with A takes input as a set of variables $V = \{a_1, a_2, \dots, a_n\}$ which are to be assigned values from $[q]$. There are m constraints (e_1, e_2, \dots, e_m) each consisting of $e_i = ((e_i)_1, (e_i)_2, \dots, (e_i)_k) \subseteq V^k$ that indicate that the corresponding assignment should belong to A . The problem is to check if we can satisfy all the constraints or not.*

In general, we can have multiple relations A_1, A_2, \dots, A_m , and different constraints can use different relations. We denote such a CSP by $\text{CSP}(A_1, A_2, \dots, A_m)$.

Promise CSP (PCSP) is a gap or promise version of CSP. Here, we have a pair of relations such that one is a relaxed form of other and given a CSP instance, and the objective is to decide if there is a satisfying assignment from stronger relation or we cannot even satisfy

the CSP using the relaxed relation. One canonical example of PCSP is the promise graph coloring: Given a graph G , distinguish between the case that G can be 3-colored versus G cannot even be colored with five colors. We can formally define PCSP as below:

► **Definition 4** (Promise CSP). *In the promise CSP problem, we have a set of pairs of relations $(A_1, B_1), (A_2, B_2), \dots, (A_m, B_m)$ such that for every i , A_i is a subset of $[q_1]^{k_i}$ and B_i is a subset of $[q_2]^{k_i}$. Furthermore, there is a homomorphism $h : [q_1] \rightarrow [q_2]$ such that, for all i , $x \in A_i$ implies $h(x) \in B_i$ for all $x \in [q_1]^{k_i}$. Given a CSP (A_1, A_2, \dots, A_m) instance, the goal is to distinguish between the two cases:*

1. *There is a solution to the instance assigning values from $[q_1]$ that satisfies every constraint when viewed as CSP (A_1, A_2, \dots, A_m) .*
2. *There is no solution to the instance assigning values from $[q_2]$ that satisfies every constraint when viewed as CSP (B_1, B_2, \dots, B_m) .*

We now turn our attention towards rainbow coloring which is the PCSP that we study in this paper. In RAINBOW (k, r, q) problem, the input is a k -uniform hypergraph. The goal is to distinguish between the cases when the hypergraph is rainbow colorable with r colors and when it cannot be rainbow colorable with q colors. More formally, we can define the problem as below:

► **Definition 5** (RAINBOW (k, r, q)). *In the RAINBOW (k, r, q) promise CSP, $q \leq r \leq k$, we have the relation pair (A, B) defined as follows:*

- $A : [r]^k \rightarrow \{0, 1\} : A(x_1, x_2, \dots, x_k) = 1$ if and only if $\{x_1, x_2, \dots, x_k\} = [r]$.
- $B : [q]^k \rightarrow \{0, 1\} : B(y_1, y_2, \dots, y_k) = 1$ if and only if $\{y_1, y_2, \dots, y_k\} = [q]$.

Note that we need q, r to be at most k since we cannot rainbow color a k -uniform hypergraph with more than k colors. We also need the condition that $q \leq r$ for the promise problem to make sense: If the hypergraph is r rainbow colorable, we can infer that it is already $q < r$ rainbow colorable too. Thus, the promise problem is to identify if the hypergraph is r rainbow colorable or it *cannot even be* rainbow colorable with q colors. Furthermore, in this paper we will be only dealing with near perfect completeness case when hypergraph is $(k - 1)$ -partite i.e. $r = k - 1$.

Associated with every promise CSP, there are polymorphisms. Polymorphisms capture the symmetries in the PCSP. They are ways in which we combine solutions to obtain new solutions that are still valid.

► **Definition 6** (Polymorphisms). *For a PCSP problem (A, B) , $A : [q_1]^k \rightarrow \{0, 1\}$, $B : [q_2]^k \rightarrow \{0, 1\}$, a polymorphism is a function f from $[q_1]^n \rightarrow [q_2]$, where n is the arity of the polymorphism that satisfies the property $(f(\mathbf{v}_1), f(\mathbf{v}_2), \dots, f(\mathbf{v}_k)) \in B$ for all $(\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k)$ such that for all $i \in [n]$, $((\mathbf{v}_1)_i, (\mathbf{v}_2)_i, \dots, (\mathbf{v}_k)_i) \in A$.*

In the above, we defined polymorphisms for a single relation PCSP. When the PCSP has multiple relations, the polymorphism should satisfy the above property for all the relations. Informally, the arity n polymorphisms are precisely the functions $f : [q_1]^n \rightarrow [q_2]$ such that for every $k \times n$ matrix M with elements from $[q_1]$ whose columns are satisfying tuples of A , the k tuple obtained by applying f to the rows of M should be in B . We refer the reader to [10, 12] for a detailed introduction to PCSP and various examples of polymorphisms.

We now direct our attention to polymorphisms of RAINBOW (k, r, q) . By definition, the polymorphisms of hypergraph coloring PCSPs turn out to be colorings of certain tensor product hypergraphs. Fix n to be arity of the polymorphisms. We can infer that the polymorphisms of RAINBOW (k, r, q) are proper q -rainbow colorings of the following k -uniform hypergraph $\text{RH}_n(k, r)$:

- The vertex set of hypergraph is the set $V = [r]^n$.
- A k element set $\{\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k\}$, where each $\mathbf{v}_i \in [r]^n$ is an edge if and only if for every $j \in [n]$, the set $\{(\mathbf{v}_1)_j, (\mathbf{v}_2)_j, \dots, (\mathbf{v}_k)_j\}$ is equal to $[r]$.

That is, a set of k vectors from $[r]^n$ forms an edge if in the matrix obtained by plugging these vectors as rows, all the r elements from $[r]$ occur in every column.

2.3 Complexity measures of functions

Finally, we define the notions of sensitivity and C -fixing of functions.

► **Definition 7** (Sensitivity at \mathbf{x}). For a function $f : [r]^n \rightarrow [q]$, and an input $\mathbf{x} \in [r]^n$, the sensitivity of f at \mathbf{x} , denoted by $S(f, \mathbf{x})$ is defined as the number of coordinates i such that changing \mathbf{x} at i can change the value of f i.e. $S(f, \mathbf{x}) = |\{i \in [n] \mid \exists a : f(\mathbf{x}) \neq f(\mathbf{x} : x_i \leftarrow a)\}|$.

► **Definition 8** (Sensitivity). The sensitivity of a function $f : [r]^n \rightarrow [q]$, denoted by $S(f)$ is defined as the maximum sensitivity of f over all \mathbf{x} in $[r]^n$ i.e. $S(f) = \max_{\mathbf{x}} S(f, \mathbf{x})$.

► **Definition 9** (C -fixing). A function f from $[r]^n$ to $[q]$ is said to be C -fixing for some integer C if there exists a set $S = \{s_1, s_2, \dots, s_C\} \subseteq [n]$ and a vector $\alpha \subseteq [r]^n$ such that $f(\mathbf{x}) = c$ whenever $\mathbf{x}_{s_i} = \alpha_{s_i}$ for all integers $1 \leq i \leq C$, for some fixed $c \in [q]$.

3 Polymorphisms

In this section, we will analyze the properties of polymorphisms of rainbow coloring. In order to do so, we will prove that low sensitivity implies low certificate complexity. Using this, we will establish that the polymorphisms for $\text{RAINBOW}(k, k-1, \lceil \frac{k-2}{2} \rceil)$ are C -fixing. Along the way, we will study rainbow colorings of various hypergraphs related to $\text{RH}_n(k, r)$. Finally, we will show that our techniques cannot prove hardness of $\text{RAINBOW}(7, 6, 2)$ by presenting a polymorphism that is not C -fixing for any constant C .

3.1 Sensitivity vs certificate complexity

We extend a lemma of [32] that proves that if a function has low sensitivity then the function is C fixing, to larger domains. The proof is along the same lines as the original proof.

► **Lemma 10.** Let $f : [r]^n \rightarrow [q]$ be a function with sensitivity s , and let $b \in [q]$ such that $f^{-1}(b)$ is non empty. Then, $|f^{-1}(b)| \geq r^{n-s}$.

Proof. Fix s , and induct on n . The case $n = s$ is trivial. Let $\mathbf{x} \in [r]^n$ be such that $f(\mathbf{x}) = b$. Since $s < n$, there is a coordinate in \mathbf{x} that is not sensitive. Without loss of generality, let it be 1, and let $\mathbf{x} = (x_1, \mathbf{y})$. As the first coordinate is not sensitive for \mathbf{x} , we can conclude that $f(\alpha, \mathbf{y}) = b$ for all $\alpha \in [r]$.

Consider the set of functions $g_i : [r]^{n-1} \rightarrow [q]$, $g_i(\mathbf{u}) = f(i, \mathbf{u})$, $i \in [r]$. Note that for each such g_i , the set $g_i^{-1}(b)$ is non-empty. In addition, for every $i \in [r]$, sensitivity of g_i is at most the sensitivity of f . Thus, by induction, we know that each such g_i has at least r^{n-1-s} elements \mathbf{u} in $[r]^{n-1}$ such that $g_i(\mathbf{u}) = b$. Note that every such \mathbf{u} gives $f(i, \mathbf{u}) = b$. By combining over all i s, we can conclude that there are at least $r \cdot r^{n-1-s} = r^{n-s}$ elements $\mathbf{x} \in [r]^n$ such that $f(\mathbf{x}) = b$. ◀

► **Lemma 11.** Let $f : [r]^n \rightarrow [q]$ be a function with sensitivity $s < n/2$. Then, it is C -fixing for $C = s(r-1)r^{2s+1}$.

Proof. We will actually prove a stronger statement that f is a C -junta. Let A denote the set of coordinates with non-zero influence in f i.e. the coordinates that are sensitive for some input. Our goal is to upper bound the cardinality of A .

For a function $f : [r]^n \rightarrow [q]$, let the set of sensitive edges $E(f)$ be defined as the set of pairs of elements $\mathbf{x}, \mathbf{y} \in [r]^n$ such that $f(\mathbf{x}) \neq f(\mathbf{y})$, and \mathbf{x}, \mathbf{y} differ on exactly one coordinate. From the sensitivity bound on f , we can deduce that

$$|E(f)| \leq s(r-1)r^n \quad (1)$$

Fix an arbitrary coordinate $i \in A$. There are elements $\mathbf{x}, \mathbf{y} \in [r]^n$ such that $x_i = \alpha, y_i = \beta, \alpha \neq \beta, f(\mathbf{x}) \neq f(\mathbf{y})$, and \mathbf{x}, \mathbf{y} differ only in i th coordinate. Define a function $g : [r]^{n-1} \rightarrow \{0, 1\}$ as $g(\mathbf{z})$ is 1 if and only if $f(\alpha, \mathbf{z}) = f(\mathbf{x})$, and $f(\beta, \mathbf{z}) = f(\mathbf{y})$ where we use the notation (α, \mathbf{z}) to denote the vector in $[r]^n$ obtained by inserting α in i th position to $\mathbf{z} \in [r]^{n-1}$. Now, since $f(\alpha, \mathbf{z})$ and $f(\beta, \mathbf{z})$ are both sensitive to at most s coordinates, $g(\mathbf{z})$ is sensitive to at most $2s$ coordinates. Also note that $g^{-1}(1)$ is non-empty. Thus, by Lemma 10, we can conclude that $|g^{-1}(1)|$ is at least r^{n-1-2s} . In other words, each sensitive coordinate contributes at least r^{n-2s-1} edges to $E(f)$. Thus, we can conclude that

$$|E(f)| \geq |A|r^{n-2s-1} \quad (2)$$

Combining Equation (1) and Equation (2), we get

$$|A| \leq s(r-1)r^{2s+1} \quad (3)$$

which proves the required claim. \blacktriangleleft

3.2 Low sensitivity polymorphisms of rainbow coloring

We now turn our attention towards our main goal in this section: to show that polymorphisms of $\text{RAINBOW}(k, k-1, q)$ are C -fixing for $q = \lceil \frac{k-2}{2} \rceil$. As we have already mentioned earlier, the polymorphisms of rainbow coloring themselves are rainbow colorings of certain tensor product hypergraphs. To be precise, the n -ary polymorphisms of $\text{RAINBOW}(k, r, q)$ are precisely q -rainbow colorings of $\text{RH}_n(k, r)$. Thus our new goal is to prove that for any integer $q \geq 2$, any q -rainbow coloring of $\text{RH}_n(2q+2, 2q+1)$ is a C -fixing function.

In order to achieve this, we will first define certain hypergraphs similar to $\text{RH}_n(k, r)$.

► **Definition 12.** $\text{H}_n(r, s) = (V, E)$ is a r -uniform hypergraph where the vertex set V is equal to $[r]^n$. A set of vectors $(\mathbf{u}_1, \mathbf{u}_2, \dots, \mathbf{u}_r)$ is an edge if and only if

1. In every coordinate $i \subseteq [n]$, at least $r-1$ elements occur i.e. $|\bigcup_j (\mathbf{u}_j)_i| \geq r-1 \quad \forall i \in [n]$.
2. All the r elements occur in at least $n-s$ coordinates i.e. $|\bigcup_j (\mathbf{u}_j)_i| = r$ for at least $n-s$ choices of i in $[n]$.

The reason behind studying these hypergraphs is that the q -rainbow colorings of $\text{RH}_n(2q+2, 2q+1)$ are very closely related to q -rainbow colorings of $\text{H}_n(2q+1, c)$ for any absolute constant c . In fact if we can prove that q -rainbow colorings of $\text{H}_n(2q+1, c)$ are C -fixing, it implies that q -rainbow colorings of $\text{RH}_n(2q+2, 2q+1)$ are $\max(C, c)$ -fixing. This is formally proved in Lemma 16. Thus our modified objective is to argue that q -rainbow colorings of $\text{H}_n(2q+1, c)$ are C -fixing. In order to do so, we inductively relate q -rainbow colorings of $\text{H}_n(t, c)$ and $\text{H}_n(t-1, c-1)$. As a base case, we have the following lemma:

► **Lemma 13.** For all integers $q \geq 2$ and $n \geq 1$, the hypergraph $\text{H}_n(2q-1, 1)$ cannot be rainbow colored with q colors.

Proof. We will use induction on q . For the case $q = 2$, rainbow coloring with 2 colors is the same as proper coloring the hypergraph with 2 colors. The fact that $H_n(3, 1)$ cannot be two colored follows from [2] (Lemma 3.2 with $d = 3$).

Suppose for contradiction that f is a valid q -rainbow coloring of $H_n(2q - 1, 1)$. Let $r = 2q - 1$ denote the uniformity of the hypergraphs. Consider the set of r vectors in $[r]^n$: $\{\bigcup_{i \in [r]}(i, i, \dots, i)\}$. As there are at most $q < r$ colors, some two elements of this set should have same f value. Without loss of generality, let $f(r - 1, r - 1, \dots, r - 1) = f(r, r, \dots, r) = c$ for some $c \in [q]$. Consider the $(r - 2)$ -uniform hypergraph $H = H_n(r - 2, 1)$. Note that every edge in H together with $\mathbf{u} = (r - 1, r - 1, \dots, r - 1)$ and $\mathbf{v} = (r, r, \dots, r)$ forms an edge in $H_n(r, 1)$. Thus, all the $q - 1$ colors in $[q] \setminus \{c\}$ occur in every edge of coloring of $H_n(r - 2, 1)$ using f . This implies that we can get a a valid $(q - 1)$ -rainbow coloring of $H_n(r - 2 = 2(q - 1) - 1, 1)$ by restricting f to $[r - 2]^n$, and replacing the color c using arbitrary color from $[q] \setminus \{c\}$. However, by the induction hypothesis, such a coloring cannot exist, and thus we have arrived at a contradiction. \blacktriangleleft

Now, we will use this to argue about q -rainbow colorings of $H_n(2q + 1, 3)$ via q -rainbow colorings of $H_n(2q, 2)$. Consider the hypergraph $H_n(2q, 2)$. A trivial way to q -rainbow color this hypergraph is to pick a coordinate $i \in [n]$, and partition the set $[2q]$ into q disjoint sets of size two, let's say A_1, A_2, \dots, A_q and assign the value $p \in [q]$ to $f(\mathbf{x})$ for $\mathbf{x} = (x_1, x_2, \dots, x_n)$ if and only if $x_i \in A_p$. It turns out that this is the only way to q -rainbow color $H_n(2q, 2)$. We prove it in the lemma below:

► Lemma 14. *Let f be a q -rainbow coloring of $H_n(r = 2q, 2)$. Then, there exists an index $i \in [n]$, sets $A_1, A_2, \dots, A_q \subseteq [r]$ mutually disjoint and each of size 2, such that $f(\mathbf{x}) = j$ iff $x_i \in A_j$.*

Proof. First we will prove that the sensitivity of f is at most 1. Let $\mathbf{x} = (x_1, x_2, \dots, x_n)$ be an arbitrary vector in $[r]^n$. Consider a $(r - 1)$ -uniform hypergraph $H(\mathbf{x})$ defined on $([r] \setminus \{x_1\}) \times ([r] \setminus \{x_2\}) \times \dots \times ([r] \setminus \{x_n\})$. We add a $r - 1$ vector set as edge of $H(\mathbf{x})$ if and only if it has at most one coordinate where there are missing elements i.e. all the $[r] \setminus \{x_i\}$ occur in all but one coordinate i , and in that coordinate, at most one value is missing.

Note that $H(\mathbf{x})$ is isomorphic to $H_n(2q - 1, 1)$. From Lemma 13, we know that $H(\mathbf{x})$ cannot be rainbow colored with q colors. Thus, when we view f as a coloring of $H(\mathbf{x})$, there is an edge that has a color missing. Let it be denoted by $e = (\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_{r-1})$. Let j be the coordinate where there is a missing element in e . If there is no coordinate with a missing element, j can be arbitrary. Without loss of generality, let color $1 \subseteq [q]$ be missing in e . Note that $\{\mathbf{x}\} \cup e$ is an edge of $H_n(r, 1)$, and thus an edge of $H_n(r, 2)$ as well. Since f is a proper q -rainbow coloring of $H_n(2q, 2)$, we can conclude that $f(\mathbf{x}) = 1$. In fact, we can actually deduce something stronger. Let $\mathbf{y} \in [r]^n$ such that \mathbf{x} and \mathbf{y} differ on exactly one coordinate $j' \in [r]^n, j' \neq j$. Note that $\{\mathbf{y}\} \cup e$ is also a valid edge of $H_n(2q, 2)$ since it has at most two coordinates where there are missing elements i.e. j' and j . Thus, $f(\mathbf{y}) = 1 = f(\mathbf{x})$. Thus, for every \mathbf{x} , in except for one coordinate, changing the value of the coordinate preserves the value of \mathbf{x} . In other words, the sensitivity of f is at most 1.

Using this, we will now prove that f is a dictator. Let i be an influential coordinate of f i.e. there exists $\mathbf{x}, \mathbf{y} \in [r]^n$ differing only in i th coordinate such that $f(\mathbf{x}) \neq f(\mathbf{y})$. We claim that $f(\mathbf{u}) = f(\mathbf{x})$ for all $\mathbf{u} = (u_1, u_2, \dots, u_n) \in [r]^n$ such that $u_i = x_i$, and $f(\mathbf{u}) = f(\mathbf{y})$ if $u_i = y_i$. We will prove this by induction on the number of coordinates in which \mathbf{x} and \mathbf{u} differ excluding i . Since f has sensitivity at most 1, the only sensitive coordinate of \mathbf{x} and \mathbf{y} is i . Thus, for any \mathbf{u} differing only in one coordinate from \mathbf{x} (other than i) such that $u_i = x_i$ or y_i will have corresponding f value. Suppose that the statement holds for all \mathbf{u} differing from \mathbf{x} in t coordinates excluding i .

15:10 Rainbow Coloring Hardness via Low Sensitivity Polymorphisms

Now, let \mathbf{u} differ from \mathbf{x} in $t + 1$ coordinates excluding i . We can find $\mathbf{v} \in [r]^n, \mathbf{w} \in [r]^n$ such that \mathbf{v} and \mathbf{x} differ in t coordinates excluding $i, v_i = x_i$; \mathbf{w} and \mathbf{y} differ in t coordinates excluding $i, w_i = y_i$, and one of \mathbf{v} and \mathbf{w} differs from \mathbf{u} in at most one coordinate. By the induction hypothesis, $f(\mathbf{v}) = f(\mathbf{x}), f(\mathbf{w}) = f(\mathbf{y})$. Since \mathbf{v} and \mathbf{w} differ in a single coordinate i, i is the only sensitive coordinate of \mathbf{v} and \mathbf{w} . Thus, $f(\mathbf{u})$ is equal to either $f(\mathbf{v})$ or $f(\mathbf{w})$ depending on $u_i = x_i$ or y_i . This completes the inductive proof.

To complete the proof that f is a dictator, we will use this to show that there cannot be two influential coordinates. Suppose that there are two influential coordinates i and j . From the previous argument, we can infer that there are assignments $i_1, i_2, j_1, j_2 \in [r]$ such that assigning these to corresponding coordinates fixes the value of f . Also note that assigning i as i_1 and i_2 fixes f to different values. Similarly, assigning j as j_1 and j_2 fixes f to different values. This gives rise to contradiction since if we set coordinate i to i_1, f should be fixed irrespective of j is equal to j_1 or j_2 . Thus, there can be only one influential coordinate for f , or in other words, f is a dictator.

Let p be the dictator coordinate of f i.e. there exists a function $g : [r] \rightarrow [q]$ such that $f(\mathbf{x}) = g(x_p)$. From the definition of the hypergraph $\mathbb{H}_n(r, 2)$, for every $j \in [r]$, the set $\{\bigcup_i g(x_i)\} \setminus \{g(x_j)\}$ should be equal to $[q]$. This proves that there exists sets $A_1, A_2, \dots, A_q \subseteq [r]$ each of size two, and mutually disjoint such that $g(\alpha) = j$ if and only if $\alpha \in A_j$, which proves the required claim. \blacktriangleleft

We finish the chain of inductive arguments by proving a key property of q -rainbow colorings of $\mathbb{H}_n(2q + 1, 3)$.

► Lemma 15. *Let $f : [2q + 1]^n \rightarrow [q]$ be a q -rainbow coloring of $\mathbb{H}_n(r = 2q + 1, 3)$. Then, there exists an index $i \in [n]$, and $\alpha \in [r]$ such that $S(f, \mathbf{x}) \leq 2$ for all $\mathbf{x} \in [r]^n$ such that $x_i = \alpha$.*

Proof. Let $\mathbf{x} = (x_1, x_2, \dots, x_n) \in [r]^n$ be an arbitrary vector in $[r]^n$. Similar to the previous lemma, we define the complement hypergraph associated with \mathbf{x} . Consider a $(r - 1)$ -uniform hypergraph $H(\mathbf{x})$ defined on $([r] \setminus \{x_1\}) \times ([r] \setminus \{x_2\}) \times \dots \times ([r] \setminus \{x_n\})$. We add a $r - 1$ vector set as edge of $H(\mathbf{x})$ if and only if it has at most two coordinates where there are missing elements i.e. all the $[r] \setminus \{x_i\}$ occur in all but two coordinates i , and in these two coordinates, at least $r - 2$ values occur. Note that $H(\mathbf{x})$ is isomorphic to $\mathbb{H}_n(r - 1, 2)$.

We can view $f : [2q + 1]^n \rightarrow [q]$ as a q -coloring of $H(\mathbf{x})$. If f is not a valid q -rainbow coloring of $H(\mathbf{x})$, by the same argument as in Lemma 14, we can deduce that $S(f, \mathbf{x}) \leq 2$. If f is a valid q -rainbow coloring of $H(\mathbf{x})$, we will use the properties proved in Lemma 14. Let us define a function $g : [r]^n \rightarrow [n] \cup \{\perp\}$ such that for a vector $\mathbf{x} \in [r]^n$,

1. If f is a valid q -rainbow coloring of $H(\mathbf{x})$, then Lemma 14 implies that there exists a coordinate $i \in [n]$ such that f is a dictator in i th coordinate in $H(\mathbf{x})$. In this case, set $g(\mathbf{x}) = i$.
2. If f is not a valid q -rainbow coloring of $H(\mathbf{x})$, let $g(\mathbf{x}) = \perp$.

First, we will prove that there exists an index $i \in [n]$ such that $g(\mathbf{x}) \in \{i, \perp\}$ for all $\mathbf{x} \in [r]^n$. Suppose $g(\mathbf{x}) = i \in [n]$, and $g(\mathbf{y}) = j \in [n]$ where $\mathbf{x}, \mathbf{y} \in [r]^n$ and $i \neq j$. Since $g(\mathbf{x}) = i$, there exist sets $S_1, S_2, \dots, S_n \subseteq [r]$ such that f is a dictator on i th coordinate in $S = S_1 \times S_2 \times \dots \times S_n \subseteq [r]^n$. In particular, there is a subset $A \subseteq S_i$ such that $|A| = 2$, and $f(\mathbf{x}), \mathbf{x} \in S$, is equal to 1 if and only if $x_i \in A$. Similarly, there exist sets $T_1, T_2, \dots, T_n \subseteq [r]$ such that f is a dictator on j th coordinate in $T = T_1 \times T_2 \times \dots \times T_n \subseteq [r]^n$. There exists a subset $B \subseteq T_j$ such that $|B| = 2$, and $f(\mathbf{x}), \mathbf{x} \in T$ is equal to $c \neq 1$ if and only if $x_j \in B$ for some $c \in [q]$. Combining the both, let $U_i = S_i \cap T_i, |U_i| \geq r - 2 \forall i \in [n]$. We can deduce

that f is a dictator in both i and j coordinates in $U = U_1 \times U_2 \times \dots \times U_n$. This implies that f is a constant function in U . Recall that there are two assignments in S_i that make f equal to 1 and two assignments in T_j that make f equal to $c \neq 1$. Thus, $f(\mathbf{x}')$ is equal to 1 for some $\mathbf{x}' \in U$ and $f(\mathbf{y}') = c \neq 1$ for some $\mathbf{y}' \in U$. This contradicts the fact that f is a constant function in U . Thus, there exists an index $i \in [n]$ such that $g(\mathbf{x})$ is either equal to i or is equal to \perp for all $\mathbf{x} \in [r]^n$. Without loss of generality let that be the first coordinate i.e. for all $\mathbf{x} \in [r]^n$, $g(\mathbf{x}) \in \{1, \perp\}$.

Consider the case when $g(\mathbf{x}) = \perp$ for every $\mathbf{x} \in [r]^n$. In this case, we know that $S(f, \mathbf{x}) \leq 2$ for all $\mathbf{x} \in [r]^n$. In particular, we can set α arbitrary and say that $S(f, \mathbf{x}) \leq 2$ whenever $x_1 = \alpha$. So we are only left with the case when there exists a $\mathbf{x} \in [r]^n$ such that $g(\mathbf{x}) = 1$. We will now prove that there exists $\alpha \in [r]$ such that $g(\mathbf{x}) = \perp$ whenever $x_1 = \alpha$, thus proving the required sensitivity bound.

Suppose for contradiction that for every $\alpha \in [r]$, there exists $\mathbf{x} \in [r]^n$ such that $x_1 = \alpha$, and $g(\mathbf{x}) = 1$. Consider a pair $\mathbf{u}, \mathbf{v} \in [r]^n$ such that $u_1 = \alpha, v_1 = \beta \neq \alpha$ and $g(\mathbf{u}) = g(\mathbf{v}) = 1$. Let $\mathbf{u} = (u_1, u_2, \dots, u_n)$, $S_i = [r] \setminus \{u_i\}$ and f is dictator on 1st coordinate in $S = S_1 \times S_2 \times \dots \times S_n$. There is a function $h_1 : S_1 \rightarrow [q]$ such that $f(\mathbf{x}) = h_1(x_1)$ if $\mathbf{x} \in S$ and $|h_1^{-1}(c)| = 2 \forall c \in [q]$. Similarly, let $\mathbf{v} = (v_1, v_2, \dots, v_n)$, $T_i = [r] \setminus \{v_i\}$ and f is dictator on first coordinate in $T = T_1 \times T_2 \times \dots \times T_n$. There is a function $h_2 : T_1 \rightarrow [q]$ such that $f(\mathbf{x}) = h_2(x_1)$ if $\mathbf{x} \in T$ and $|h_2^{-1}(c)| = 2 \forall c \in [q]$. Let $U_i = S_i \cap T_i$. Note that $U = U_1 \times U_2 \times \dots \times U_n$ is non empty and f is dictator on 1st coordinate in U as well. Note that $|U_i| \geq r - 2$ for all $i \in [n]$. Thus, we can conclude that if $\gamma \in U_1$, then $h_1(\gamma) = h_2(\gamma)$.

Applying this to all pairs \mathbf{u}, \mathbf{v} such that $g(\mathbf{u}) = g(\mathbf{v}) = 1$, we can infer that there exists a function $h : [r] \rightarrow [q]$ that satisfies the property that for all $\mathbf{x} \in [r]^n$ such that $g(\mathbf{x}) = 1$, let $\mathbf{x} = (x_1, x_2, \dots, x_n)$, $S_i = [r] \setminus \{x_i\}$, $S = S_1 \times S_2 \times \dots \times S_n$, then $f(\mathbf{y}) = h(y_1)$ for all $\mathbf{y} \in S$. As $r = 2q + 1 > 2q$, there exists $b \in [q]$ such that $|h^{-1}(b)| \geq 3$. Let $\gamma \in [r]$ be such that $h(\gamma) \neq b$. From our assumption that for every $\alpha \in [r]$ there exists $\mathbf{x} \in [r]^n$ such that $g(\mathbf{x}) = 1$ and $x_1 = \alpha$, there exists $\mathbf{u} \in [r]^n$ such that $u_1 = \gamma$ and $g(\mathbf{u}) = 1$. Now, let $\mathbf{u} = (u_1, u_2, \dots, u_n)$, $S_i = [r] \setminus \{u_i\}$, $S = S_1 \times S_2 \times \dots \times S_n$, and we know that $f(\mathbf{x}) = h(x_1)$ if $\mathbf{x} \in S$, and $|h^{-1}(c) \cap S_1| = 2 \forall c \in [q]$. However, this contradicts the fact that $h(u_1) = h(\gamma) \neq b$, and $|h^{-1}(b)| = 3$. Thus, there exists $\alpha \in [r]$ such that $g(\mathbf{x}) = \perp$ for all $\mathbf{x} \in [r]^n$ such that $x_1 = \alpha$. \blacktriangleleft

Finally, we will use the previous hypergraph coloring properties to argue about polymorphisms of rainbow coloring.

► Lemma 16. *There exist constant $C = C(q)$ independent of n such that every $f : [2q+1]^n \rightarrow [q]$ that is an n -ary polymorphism of $\text{RAINBOW}(2q+2, 2q+1, q)$ i.e. f is a proper q -rainbow coloring of $\text{RH}_n(2q+2, 2q+1)$ is C -fixing.*

Proof. Let $r = 2q + 1$. Let $f : [r]^n \rightarrow [q]$ be a polymorphism of $\text{RAINBOW}(2q+2, 2q+1, q)$. We can view f as a q -rainbow coloring of $H_n(r, 3)$ as the vertex set of $\text{RH}_n(r+1, r)$ and of $H_n(r, 3)$ is equal to $[r]^n$. If it is not a valid q -rainbow coloring, there is an edge in which not all q colors appear. Let that edge be $e = (\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_r)$ and $c \in [q]$ be a missing color in $\{f(\mathbf{v}_1), f(\mathbf{v}_2), \dots, f(\mathbf{v}_r)\}$. Since this edge is part of $H_n(r, 3)$, except for 3 values of i , for all other i , the set $((\mathbf{v}_1)_i, (\mathbf{v}_2)_i, \dots, (\mathbf{v}_r)_i)$ is equal to $[r]$. Let the missing coordinates be the set $S = \{i_1, i_2, i_3\}$. Now consider an element \mathbf{u} of $[r]^n$ such that it has missing values of e in S . From the definition of $\text{RH}_n(r+1, r)$, we can deduce that the set $e \cup \mathbf{u}$ is an edge of $\text{RH}_n(r+1, r)$. Since f is a valid q -rainbow coloring of $\text{RH}_n(r+1, r)$, $f(\mathbf{u})$ is equal to c . Note that this should hold irrespective of what values \mathbf{u} has in coordinates outside S . This proves that f is C -fixing with $C = 3$.

15:12 Rainbow Coloring Hardness via Low Sensitivity Polymorphisms

On the other hand if f is a valid q -rainbow coloring of $\mathbb{H}_n(r, 3)$, using Lemma 15, we can deduce that there exists an index $i \in [n]$, and $\alpha \in [r]$ such that $S(f, \mathbf{x}) \leq 2$ whenever $x_i = \alpha$. Now, we can consider a function $g : [r]^{n-1} \rightarrow [q]$ which on an input $\mathbf{y} \in [r]^{n-1}$, is equal to $f(\mathbf{x}), \mathbf{x} = \mathbf{y}, x_i \leftarrow \alpha \in [r]^n$ i.e. we first insert α in i th position to \mathbf{y} and then apply f . Note that g has sensitivity at most 2. From Lemma 11, we can conclude that g is C -fixing for $C = 2(r-1) \cdot r^5$. In other words, g is fixed by assigning values to a set of C indices. This implies that f is also $C' = C + 1$ -fixing since we can first assign i th index to α , then use C -fixing property of g . ◀

3.3 High sensitivity polymorphism of RAINBOW(7, 6, 2)

We show that there exists a function $f : [6]^n \rightarrow \{0, 1\}$ that is a polymorphism of RAINBOW(7, 6, 2) that is not C -fixing for any constant C . We start with a dictator but add just enough noise such that the function still remains being a polymorphism, but it is no longer C -fixing. Let $wt(\mathbf{x})$ denote the number of $i \in [n], i > 1$ such that $x_i = 1$. Let $S \subseteq [6]^n$ denote the set of $\mathbf{x} \in [6]^n$ such that $wt(\mathbf{x}) > \frac{2n}{3}$. Let $h : [6]^n \rightarrow \{0, 1\}$ be noise function defined below. For a given $\mathbf{x} \in [6]^n$, we define $f(\mathbf{x})$ as follows:

1. If $\mathbf{x} \notin S$
 - a. If $x_1 \leq 3$, $f(\mathbf{x}) = 0$
 - b. Else, $f(\mathbf{x}) = 1$
2. Else $f(\mathbf{x}) = h(\mathbf{x})$.

A choice of noise function that works is inverting the original function: $h(\mathbf{x})$ is defined as 1 if and only if $x_1 \leq 3$.

► **Proposition 17.** *The function $f : [6]^n \rightarrow \{0, 1\}$ defined above is a polymorphism of RAINBOW(7, 6, 2) and it is not C -fixing for any $C < \frac{n}{3}$.*

Proof. Any polymorphism of RAINBOW(7, 6, 2) is a proper 2-rainbow coloring of $\mathbb{RH}_n(7, 6)$. Recall that rainbow coloring with two colors is the same as standard hypergraph coloring with two colors.

Polymorphism. In any set of 7 vectors E in $[6]^n$ such that all the 6 elements occur in all the coordinates, at most two vectors can be in S . This is because, in any set of three vectors in S , there exists a coordinate in which all three values are equal to 1. Thus, there are vectors $\mathbf{x} \notin S$ with $x_1 \leq 3$ and vector $\mathbf{y} \notin S$ such that $y_1 \geq 3$ in E , which together ensures that E is not monochromatic.

C -fixing. Suppose that there exists a set $T = \{t_1, t_2, \dots, t_m\} \subseteq [n]$ and $(\alpha_1, \alpha_2, \dots, \alpha_m) \subseteq [6]^m$ such that $f(\mathbf{x}) = b$ for all \mathbf{x} such that $x_i = \alpha_i$ for all $1 \leq i \leq m$, for some fixed $b \in \{0, 1\}$. We will prove that $|T| \geq \frac{n}{3}$. Suppose for contradiction that $|T| < \frac{n}{3}$. First, if $1 \notin T$, we can set all coordinates outside T to be equal to $\beta \neq 1$, and in this case $f(\mathbf{x}) = x_1$, which cannot be fixed if $1 \notin T$. Thus $1 \in T$. Next, if all the coordinates outside T are all equal to 1, then $f(\mathbf{x})$ is equal to noise function, which is different from the case when the rest are equal to $\beta \neq 1$. Thus, if f is indeed a C -fixing function, for the C -fixing assignment, the value of f should be independent of the assignment to the coordinates outside T . However, that is not the case as the value of f changes when we set all the coordinates outside T to be 1 or $\beta \neq 1$. ◀

4 NP-Hardness

In this section, we will use the properties of polymorphisms proved so far to argue about NP hardness of rainbow coloring PCSP. We will prove the below theorem:

► **Theorem 18.** *Suppose that there exists a constant C such that for all integers $n \geq 1$, every n -ary polymorphism of $\text{RAINBOW}(k, k-1, q)$ is C -fixing. Then, the corresponding decision problem $\text{RAINBOW}(k, k-1, q)$ is NP hard.*

Before delving into the proof of Theorem 18, we first mention that this theorem together with Lemma 16 implies Theorem 1. In Lemma 16, we have proved that for every $q \geq 2$, the polymorphisms of $\text{RAINBOW}(2q+2, 2q+1, q)$ are C -fixing. This fact combined with Theorem 18 implies that $\text{RAINBOW}(2q+2, 2q+1, q)$ is NP hard for every $q \geq 2$. This already proves Theorem 1 when k is even. When k is odd, we can combine Lemma 14 and Lemma 16 to prove that the polymorphisms of $\text{RAINBOW}(k=2q+1, 2q, q)$ are C -fixing. We can combine this with Theorem 18 to prove Theorem 1 when k is odd.

The rest of this section is dedicated to proving Theorem 18. Like various other hardness of approximation results, we will use the standard label cover with long code framework. We reduce *smooth* label cover introduced in [22] to rainbow coloring PCSP. First we define Label Cover problem below:

► **Definition 19 (Label Cover).** *In an instance of Label Cover problem, we are given a tuple $(G = (L, R, E), \Sigma, \Pi)$ where*

1. G is a bipartite multi graph between vertex sets L and R
2. Each vertex in G has to be assigned a label from Σ
3. For each edge $e = (u, v) \in E$, there is a projection constraint Π_e from u to v that is a function from Σ to itself. This corresponds to a constraint between u and v .

A labelling of graph is a function $\sigma : L \cup R \rightarrow \Sigma$ that assigns a label to each vertex of G . A labelling σ is said to satisfy constraint Π_e if and only if $\Pi_e(\sigma(u)) = \sigma(v)$.

We refer to L and R as left and right vertices respectively. We are now ready to define Gap Label Cover.

► **Definition 20 ($(1, \epsilon_{LC})$ Gap Label Cover).** *In $(1, \epsilon_{LC})$ Gap Label Cover, we are given a Label Cover instance $(G = (L, R, E), \Sigma, \Pi)$, and the goal is to distinguish between the following two cases:*

1. There is a labelling $\sigma : G \rightarrow \Sigma$ that satisfies all the constraints.
2. No labelling can satisfy ϵ_{LC} fraction of constraints.

As mentioned earlier, we need stronger properties of the Label Cover instance that we are starting with. One such property is smoothness.

► **Definition 21 (Smoothness).** *A Label Cover instance $(G = (L, R, E), \Sigma, \Pi)$ is said to be (J, ϵ) -smooth if for any vertex $u \in L$ and a set of labels $S \subseteq \Sigma, |S| \leq J$, over a uniformly random neighbor $v \in R$, $\Pr(|\bigcup_{s \in S} \Pi_{u,v}(s)| < |S|) \leq \epsilon$.*

The following is a special case of Theorem 1.17 in [33].

► **Theorem 22.** *For every $\epsilon, \epsilon_{LC} > 0$ and $J \in \mathbb{Z}_+$, there exists $n = n(\epsilon, \epsilon_{LC}, J)$ such that $(1, \epsilon_{LC})$ Gap Label Cover with $|\Sigma| = n$ that is promised to be (J, ϵ) -smooth is NP hard.*

We now prove Theorem 18.

15:14 Rainbow Coloring Hardness via Low Sensitivity Polymorphisms

Reduction. We start with $(1, \epsilon_{LC})$ Gap Label Cover instance $(G = (L, R, E), \Sigma, \Pi)$ that is promised to be (C, ϵ) -smooth, for ϵ and ϵ_{LC} to be set later, and output a PCSP instance. The reduction described here is the same as the general one from Label Cover to PCSP in e.g. [12]. Let n denote the label size $n = |\Sigma|$. For each vertex $v \in L \cup R$, we add a set of nodes K_v of size $[k-1]^n$, indexed by n length vectors. We add two types of constraints:

1. Coloring constraints: Inside every vertex of the Label Cover instance, we add the following constraints among the $[k-1]^n$ nodes. We add the constraint that the promise relation should be satisfied in the set T of k nodes $\{\mathbf{x}_1, \mathbf{x}_2, \dots, \mathbf{x}_k\}$ in $[k-1]^n$, if for every $i \in [n]$, the set $\{\bigcup_j (\mathbf{x}_j)_i\}$ has cardinality $k-1$.
2. Equality constraints: For every constraint $\Pi_e : u \rightarrow v$ of the Label Cover, we add a set of equality constraints between nodes $\mathbf{x} \in K_u, \mathbf{y} \in K_v$ if for all $i \in [n]$, $\mathbf{x}_i = \mathbf{y}_{\Pi_e(i)}$.

Note that the Coloring constraints give rise to rainbow colorings of k -uniform hypergraphs. It is yet unclear how we can justify adding equality constraints. One way to handle the equality constraints is to have a single node for all the vertices corresponding to equality constraint. However, this fails if we want to add a coloring constraint that involves two copies of the same vertex. A neater way to get around this is to argue that adding equality constraints does not change the set of polymorphisms, and thus the hardness of the predicate remains the same with or without equality constraints. This simple fact is proved in e.g. [10, 12].

Completeness. If the label cover instance is satisfiable, then PCSP instance that is being output can be satisfied by assignment from $[k-1]$. Suppose $\sigma : L \cup R \rightarrow \Sigma$ is a labeling that satisfies all the constraints of the Label Cover. For every vertex $\mathbf{x} \in K_u$ corresponding to the vertex $u \in L \cup R$, we can assign the value $\mathbf{x}_{\sigma(u)}$. In other words, in every long code, we are assigning corresponding dictator function. The coloring constraints are defined precisely such that this assignment satisfies the constraints. The equality constraints also follow since the labeling σ satisfies all the constraints of the Label Cover.

Soundness. If the Label Cover is not ϵ_{LC} satisfiable, we need to show that there is no assignment of the PCSP instance in $[q]$ that satisfies all the constraints. Taking contrapositive, if there is an assignment in $[q]$ to PCSP instance that satisfies all the constraints, then we will prove that there is an assignment to the Label Cover instance that can satisfy a c fraction of constraints, for an absolute constant c . Taking $\epsilon_{LC} < c$, we can arrive at a contradiction, thus proving that there is no assignment in $[q]$ to PCSP that satisfies all the constraints.

Let $f_v : [k-1]^n \rightarrow [q]$ denote the assignment to the PCSP instance that satisfies all the constraints for $v \in L \cup R$. From the coloring constraints, we can infer that f_v is a n -ary polymorphism of $\text{RAINBOW}(k, k-1, q)$. Thus, it is C -fixing for a constant C independent of n .

For every vertex $v \in L \cup R$ of the Label Cover instance, we will assign a set of labels $A(v) \subseteq [n]$. For vertices v in L , $A(v)$ is the C -fixing set. Since the Label Cover instance is smooth, we will only consider the constraints where all these labels go to distinct labels on the right under projections. We can set the smoothness parameter ϵ to be 0.1 for example, and we will be left with $\frac{9}{10}$ fraction of original constraints. We will prove that there is an assignment that satisfies a c fraction of these constraints, for an absolute constant c , which will prove the original soundness claim. Thus in all the remaining constraints, the set of labels in $A(v)$ go to distinct labels on the right. Thus, for a vertex $v \in R$, each constraint (u, v) gives rise to C coordinates $\Pi_{u,v}(A(u))$. Note that these C coordinates are in fact C -fixing for v for every constraint (u, v) . For a given $v \in R$, there are several such C -fixing sets. Let the set of these C -fixing sets be denoted by $B(v) = \{S_1, S_2, \dots\}$ where each $S_i \subseteq [n]$ is a C -fixing set of f_v . Now we define $A(v)$ for $v \in R$ to be the set of union of an arbitrary fixed maximal disjoint sets in $B(v)$.

In order to prove that there is a good labeling to the Label Cover, we assign a label to every vertex v from $A(v)$ uniformly at random and prove that it satisfies a constant fraction of constraints with non-zero probability. We will, in fact, show that the random assignment satisfies a constant fraction of constraints in expectation. We prove this in two steps. First, we show that for every constraint (u, v) of the Label Cover, there exists $x \in A(u), y \in A(v)$ such that $\Pi_{u,v}(x) = y$. This follows from the definitions of $A(v)$: suppose the projection of $A(u)$ is disjoint from $A(v)$. In that case, we can add the projection of $A(u)$ to $A(v)$ to get a larger set in v , which contradicts the fact that $A(v)$ is the maximal such union of disjoint projections. This implies that the uniformly random labelling satisfies each constraint (u, v) of Label Cover with probability at least $\frac{1}{|A(u)||A(v)|}$.

To complete the proof, we need to bound the sizes of $A(v)$. As we have already mentioned, for $v \in L, |A(v)| \leq C$. We bound the size of $A(v)$ for vertices v in R using the below lemma.

► **Lemma 23.** *Suppose $f : [k - 1]^n \rightarrow q$ is a polymorphism of $\text{RAINBOW}(k, k - 1, q)$. Let A_1, A_2, \dots, A_t be mutually disjoint subsets of $[n]$ such that each of them is a C -fixing set of f . Then, $t < k$.*

Proof. First note that all the A_i s should fix f to the same value in $[q]$ since otherwise, the vector $\mathbf{u} \in [k - 1]^n$ that has all the fixing sets in A_i s is forced to be equal to multiple colors in $[q]$ at the same time. Let all the A_i s be C -fixing with respect to value $b \in [q]$ i.e. for each $i \in [t]$, there exists an assignment to A_i such that if the value of \mathbf{x} in A_i is equal to the assignment, then the value of $f(\mathbf{x})$ is equal to b irrespective of values of coordinates outside A_i . If $t \geq k$, we can find $\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k$ such that all $[k - 1]$ occur in every coordinate, and \mathbf{y}_i has the fixing assignment of A_i . This implies that $f(\mathbf{y}_i) = b$ for all i . However, note that $\{\mathbf{y}_1, \mathbf{y}_2, \dots, \mathbf{y}_k\}$ is an edge of $\text{RH}_n(k, k - 1)$, and thus if f is a polymorphism of $\text{RAINBOW}(k, k - 1, q)$, all the $[q]$ elements should occur in $\{f(\mathbf{y}_1), f(\mathbf{y}_2), \dots, f(\mathbf{y}_k)\}$. This is a contradiction since for all $i, f(\mathbf{y}_i) = b$. ◀

From the lemma, we can infer that the cardinality of $A(v)$ for $v \in R$ is at most kC . Combining this with the above, we can deduce that there is an assignment that satisfies $\frac{1}{kC^2}$ fraction of constraints, which is a constant fraction of constraints, independent of n .

5 Conclusion

In this paper, we have proved that given a k -uniform hypergraph that is promised to be $(k - 1)$ -rainbow colorable, it is NP hard to rainbow color it with $\lceil \frac{k-2}{2} \rceil$ colors. As a corollary, we can deduce that for $k \leq 6$, it is NP hard to 2-color a k -uniform hypergraph that is promised to be $(k - 1)$ -rainbow colorable. An immediate question is whether $\text{RAINBOW}(7, 6, 2)$ is NP hard. It would be interesting to get an efficient algorithm though we believe it is unlikely. In Section 3.3, we have provided a polymorphism of $\text{RAINBOW}(7, 6, 2)$ that is not C -fixing. The polymorphisms for this PCSP also have other symmetries (in the form of identities) discussed in [12].

However, it should be noted the polymorphism that we have given in Section 3.3 is very far from symmetric, it seems that we should decode to the unique special coordinate. What we are missing here is a characterization of lack of symmetries that works well with Label Cover to give NP-hardness. We believe that resolving the hardness of this particular PCSP can shed light on identifying criteria for lack of symmetries that imply hardness, beyond C -fixing. Another direction to explore is whether we can further strengthen the completeness in our result. More concretely, given a k -rainbow colorable k -uniform hypergraph, can we efficiently rainbow color it with 3 colors?

Abstract

Variants of the *Exponential Time Hypothesis* (ETH) have been used to derive lower bounds on the time complexity for certain problems, so that the hardness results match long-standing algorithmic results. In this paper, we consider a syntactically defined class of problems, and give conditions for when problems in this class require strongly exponential time to approximate to within a factor of $(1 - \varepsilon)$ for some constant $\varepsilon > 0$, assuming the *Gap Exponential Time Hypothesis* (Gap-ETH), versus when they admit a PTAS. Our class includes a rich set of problems from additive combinatorics, computational geometry, and graph theory. Our hardness results also match the best known algorithmic results for these problems.

1 Introduction

Variants of the *Exponential Time Hypothesis* (ETH) [30, 31] have been used to derive lower bounds that match long-standing upper bounds for several important problems. In particular, the *Strong Exponential Time Hypothesis* (SETH) has been used to study the fine-grained complexity of problems in \mathbf{P} [46, 47, 1, 14, 8], and the *Gap Exponential Time Hypothesis* (Gap-ETH) [21, 40] was used to study inapproximability [17, 22]. In this paper, we consider a syntactically-defined class of problems, defined below, and give conditions for when problems in this class require strongly exponential time to approximate to within a factor of $(1 - \varepsilon)$ for some constant $\varepsilon > 0$, assuming Gap-ETH, versus when they admit a PTAS. Our hardness results also match the best known algorithmic results for these problems. Our class includes a rich set of problems from additive combinatorics, computational geometry, and graph theory.

16:2 Syntactic Separation of Subset Satisfiability Problems

Let $L = \{\ell_1(\mathbf{x}), \ell_2(\mathbf{x}), \dots, \ell_k(\mathbf{x})\}$ be a finite set of homogeneous linear functions in $\mathbb{Z}[\mathbf{x}]$ on the same set of variables $\mathbf{x} = (x_1, x_2, \dots, x_r)$. We define a function $\ell(\mathbf{x})$ to be TRUE at \mathbf{a} if $\ell(\mathbf{a}) \neq 0$. Otherwise, it is FALSE at \mathbf{a} . For any set S and integer r , let

$$\mathcal{D}(S, r) := \{(x_1, x_2, \dots, x_r) \in S^r : x_i \neq x_j \text{ if } i \neq j \text{ for all } i, j \in [1, r]\},$$

that is, the set of permutations over all subsets of S of size r .

SUBSET-CSAT(L). Define $L^*(\mathbf{x}) = \bigwedge_{\ell \in L} \ell(\mathbf{x})$. Given a set S of n integers, find a largest $T \subseteq S$ so that for each r -tuple $\mathbf{a} = (a_1, a_2, \dots, a_r) \in \mathcal{D}(T, r)$, L^* is TRUE at \mathbf{a} .¹

SUBSET-DSAT(L). Define $L^+(\mathbf{x}) = \bigvee_{\ell \in L} \ell(\mathbf{x})$. Given a set S of n integers, find a largest $T \subseteq S$ so that for each r -tuple $\mathbf{a} = (a_1, a_2, \dots, a_r) \in \mathcal{D}(T, r)$, L^+ is TRUE at \mathbf{a} .¹

Many problems can be encoded as one of these two problem types [35, 51, 23, 54, 20, 29, 42, 24, 2, 25], some of which are known to be **APX**-hard, some of which are known to be **NP**-hard, and some of which have no known hardness result. The best known exact algorithms for each of them take strongly exponential time, i.e. $2^{\Omega(n)}$ time. Our main results are Theorem 2 and Theorem 3, below, which can be used to show that all these problems are *strongly APX-hard*, where we define a problem X to be strongly **APX**-hard if there exists a *size-preserving PTAS* (SPTAS) reduction from MAX-3SAT to X . A SPTAS reduction is a PTAS reduction whose output has “size”² $O(n)$ for any input of size n .

Consequently, given Gap-ETH (Conjecture 1), X cannot be $(1 - \delta)$ -approximated in subexponential time for a sufficiently small constant $\delta > 0$. To simplify the reductions shown in the subsequent sections, we may restrict the instances of MAX-3SAT as was done in [22]. That is, we make use of the observation in footnote 5 of [40], so that we may assume that there is some constant Δ such that no variable of the formula appears in more than Δ clauses, and hence there are only $O(n)$ clauses, where n is the number of variables.

► **Conjecture 1** (Gap-ETH [21, 40]). *There exist constants $\varepsilon, c > 0$ so that no algorithm can distinguish a satisfiable 3SAT formula from those that cannot have more than $(1 - \varepsilon)$ -fraction of clauses being simultaneously satisfied in 2^{cn} time where n denotes the number of variables in the input instance.*

Our results are:

► **Theorem 2**. *Let L be a finite set of homogeneous linear functions whose coefficients are in \mathbb{Z} .*

- (i) *If L contains only functions with 1 or 2 variables, then SUBSET-CSAT(L) admits a PTAS and can be exactly solved in $2^{O(n^c)}$ time for some constant $c < 1$.*
- (ii) *Otherwise, SUBSET-CSAT(L) is strongly **APX**-hard.*

We observe here that it is *necessary* to limit our attention to hardness of approximation to within a *constant factor*. The problems we consider can easily be approximated to within a superconstant factor in $2^{o(n)}$ time. Thus strong APX-hardness differs from other hardness of approximation notions (which do not rely on strongly-exponential runtimes), for which it is interesting to consider larger approximation factors. We observe further that not all problems in case (i) are easy to compute exactly, nor are all problems in case (ii) hard to

¹ We assume that $|T| \geq r$ to avoid degenerate cases, which can be identified in $O(n^r)$ time.

² The size parameter is determined by problems: typically the number of variables in a formula or the number of nodes in a graph.

approximate to within a constant factor. An example problem for the former is finding a maximum independent set for *c-far unit-disk graphs*, an **NP**-hard problem [41, 56]. We defer the discussions to Appendix A. As for the latter, if all terms in L have positive sign, then a linear-time $1/2$ -approximation algorithm exists. Moreover, the constant c of case (i) depends on the coefficients of functions in L and the inapproximability constant of case (ii) depends on the number of variables of L .

We need some notions for the next result. We say an $r \times k$ matrix M is **strongly full rank** if $k \leq r$ and every $k \times k$ submatrix of M is full rank. Let $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$ be vectors of the same dimensionality, and let $\mathbf{M} = (\mathbf{v}_1 | \mathbf{v}_2 | \dots | \mathbf{v}_k)$ be the matrix where $M_{ij} = \mathbf{v}_j[i]$. We call \mathbf{M} the **aggregation** of $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_k$. We say a vector space is in **general position** if it has a set of basis vectors whose aggregation is strongly full rank.

► **Theorem 3.** *Let L be a finite set of homogeneous linear functions whose coefficients are in \mathbb{Z} . For each $\text{SUBSET-DSAT}(L)$, if the solutions to $\bigvee_{\ell \in L} \ell(\mathbf{x}) = \text{FALSE}$ form a vector space in general position and has dimension at least 2 (hence \mathbf{x} is a vector of at least 3 variables), then $\text{SUBSET-DSAT}(L)$ is strongly **APX**-hard.*

Applications. We show how to apply Theorem 2 and Theorem 3 to extend previous hardness results.

(1) **MAX-GENERAL:** Given a set S of n points in \mathbb{R}^2 , find a largest $T \subseteq S$ so that T contains no three distinct colinear points, i.e. finding a largest subset in general position. This problem is known to be **APX**-hard [25].

Here we show how to extend the **APX**-hardness result simply by encoding **MAX-GENERAL** as a $\text{SUBSET-CSAT}(L)$ problem for some L . Let $S = \{(a, a^3) : a \in Q\}$ for any set Q of integers. It is known [28] that Q has no three distinct integers that sum to 0 if and only if S has no three distinct colinear points. Therefore,

$$\text{SUBSET-CSAT}(L_{\text{GP}} := \{\ell(x, y, z) = x + y + z\})$$

can be reduced to **MAX-GENERAL** by a linear-time reduction. Together with Theorem 2, one has that **MAX-GENERAL** is strongly **APX**-hard.

Note that $\text{SUBSET-CSAT}(L_{\text{GP}})$ can be interpreted as the **MAX-3SUM** problem, and **MAX-GENERAL** is a typical example of a **MAX-3SUM**-hard problem. More examples can be found in Section 3.

(2) **MAX-GOLOMBRULER:** Given a set S of n integers in \mathbb{Z} , find a largest $T \subseteq S$ so that T has $|T|^2$ distinct pairwise sums. This problem is known to be **NP**-hard to approximate to within an additive constant $c > 0$ [42].

We show how to improve the above inapproximability by encoding **MAX-GOLOMBRULER** as a $\text{SUBSET-CSAT}(L)$ problem for some L . Observe that S has fewer than $|S|^2$ distinct pairwise sums if and only if either there exist four distinct numbers $a, b, c, d \in S$ so that $a + b = c + d$, or there exist three distinct numbers $a, b, c \in S$ so that $a + b = 2c$. To remove the fewest elements from S so that neither of the two cases hold is the same as solving

$$\text{SUBSET-CSAT}(L_{\text{GR}} := \{\ell_1(x, y, z, w) = x + y - z - w, \ell_2(x, y, z, w) = x + y - 2z\}).$$

Hence, by Theorem 2, **MAX-GOLOMBRULER** is strongly **APX**-hard.

- (3) **MAX- C_3 -FREE**: Given an undirected graph, find a largest node-induced subgraph (in terms of the number of nodes) that contains no cycle of length 3, i.e. a triangle. This problem is known to be **NP**-hard [35].

We show how to extend the **NP**-hardness result by encoding **MAX- C_3 -FREE** as a **SUBSET-CSAT(L)** problem for some L with a restricted input \bar{S} . We restrict \bar{S} to be a set such that for every six distinct integers $a_1, a_2, \dots, a_6 \in \bar{S}$, there are at most two triples summing to 0. We construct an undirected graph $G = (V, E)$ as follows. Initially, $V \leftarrow \emptyset, E \leftarrow \emptyset$. For each $a \in \bar{S}$, add v_a to V . For each triple $a, b, c \in \bar{S}$ summing to 0, add edges $\{v_a, v_b\}, \{v_b, v_c\}, \{v_a, v_c\}$ to E . Given this construction, G has a C_3 -free node-induced subgraph of k nodes if and only if

$$\text{SUBSET-CSAT}(L_{C_3} := \{\ell(x, y, z) = x + y + z\}) \text{ with input } \bar{S}$$

has output of size k , which is strongly **APX**-hard as shown in Corollary 15. Hence, **MAX- C_3 -FREE** is strongly **APX**-hard.

- (4) **MAX- k AP-FREE** for each $k \geq 3$: Given two integers n and m , decide whether there exists a subset of $S = \{1, 2, \dots, n\}$ of size at least m so that the subset contains no k distinct integers that form a k -term arithmetic progression. The tally representation of YES-instances of this problem defines a *sparse language*, which cannot be **NP**-complete unless $\mathbf{P} = \mathbf{NP}$ [45]. An analogous situation also arises in other problems, such as in lattice problems in statistical physics (survey in [57]) or in determining Ramsey numbers (survey in [49]). More generally, if we assume ETH, no optimization problem that has $2^{o(n/\log n)}$ feasible instances can be strongly **APX**-hard. We refer readers to Section 7 for more discussion.

The current best algorithms for **MAX- k AP-FREE** [29, 24, 2] rely on branch-and-bound and have to invoke many **MAX- k AP-FREE** subproblems, that is, with an arbitrary $S \subseteq \{1, 2, \dots, n\}$. A hardness result for the subproblem would suggest the limit of solving **MAX- k AP-FREE** by branch-and-bound algorithms. We show that it is strongly **APX**-hard.

We encode **MAX- k AP-FREE** as

$$\text{SUBSET-DSAT}(L_{k\text{AP}} := \{\ell_i(x_1, x_2, \dots, x_k) = x_i - 2x_{i+1} + x_{i+2} : i \in [1, k - 2]\})$$

where $|L_{k\text{AP}}| = k - 2$ and set $\mathbf{v}_1 = (1, 3, \dots, 2k - 1), \mathbf{v}_2 = (2, 4, \dots, 2k)$ as two basis vectors in the solution space of $\bigvee_{\ell \in L_{k\text{AP}}} \ell(\mathbf{x})$. Because $\mathbf{M} = (\mathbf{v}_1 | \mathbf{v}_2)$ is strongly full rank, by Theorem 3 we are done.

Our Techniques. We outline the techniques used in the proofs of Theorem 2 and Theorem 3. Both the algorithmic and the hardness results rely on Turán’s Theorem [55, 53]. As originally stated, Turán’s Theorem [55] said that for every n -node undirected simple graph G , if G has no clique of $r + 1$ nodes for an integer $r \geq 2$, then G has no more than $(1 - 1/r)n^2/2$ edges. In our proofs, when we refer to “Turán’s Theorem”, we refer to the second formulation of Turán’s Theorem [53], that is:

► **Theorem 4** (Turán’s Theorem [55, 53]). *Every n -node m -edge undirected simple graph has an independent set of size at least $\frac{n^2}{n+2m}$.*

We now describe our approach, and the role Turán’s Theorem plays in obtaining our results.

- (1) Our Algorithmic Results: Let L_{2-} be any finite set that contains only homogeneous linear functions with 1 or 2 variables, with coefficients in \mathbb{Z} . In Theorem 2, we claim that $\text{SUBSET-CSAT}(L_{2-})$ admits a PTAS and can be solved exactly in $2^{O(n^c)}$ time for some constant $c < 1$.

To obtain a PTAS or an exact algorithm for $\text{SUBSET-CSAT}(L_{2-})$, we reduce it to finding a maximum independent set for the graph class \mathcal{G} that contains all subgraphs of *c-nearest neighborhood graphs*, defined in [26, 43], for some constant c . By a generalization of Lipton and Tarjan's algorithm [36], $\text{MAX INDEPENDENT SET}$ for \mathcal{G} can be solved efficiently. Lipton and Tarjan show how to approximate the $\text{MAX INDEPENDENT SET}$ for planar graphs by exploiting the fact that every planar graph has a node separator of size $O(n^{1/2})$ whose removal partitions the graph into two balanced disconnected subgraphs. Their algorithm can be generalized to any graph class \mathcal{H} that satisfies all the following properties:

- For every graph H in \mathcal{H} , any subgraph of H is a graph in \mathcal{H} .
- Every h -node graph H in \mathcal{H} has a node separator of size $O(h^c)$ for some constant $c < 1$, whose removal partitions H into two balanced disconnected subgraphs, and the separator can be found in time polynomial in h .
- Every h -node H in \mathcal{H} has an independent set of size $\Omega(h)$.

In Section 2, we will see that \mathcal{G} satisfies all the above properties, and we generalize Lipton and Tarjan's algorithm for any graph class that fulfills all the required properties. We remark that Lipton and Tarjan [36] use the Four Color Theorem [6, 7] to prove the last property for planar graphs. However, since \mathcal{G} contains non-planar graphs, we need to replace the Four Color Theorem with Turán's Theorem to show the last property for \mathcal{G} .

- (2) Our Hardness Results: If a finite set L of homogeneous linear functions satisfies the condition for case (2) of Theorem 2 (resp. Theorem 3), then $\text{SUBSET-CSAT}(L)$ (resp. $\text{SUBSET-DSAT}(L)$) is strongly **APX**-hard.

We show the hardness results by a reduction that maps from problem instances of $\text{MAX INDEPENDENT SET}$ for sparse large-girth graphs to those of $\text{SUBSET-CSAT}(L)$ or $\text{SUBSET-DSAT}(L)$, so that if the former problem instance has an independent set of size k , then the latter problem instance has an output set of size $f(k)$ for some function f . The existence of the hardness reduction is secured by a probabilistic proof based on the Schwartz-Zippel Lemma [48, 58] as well as some tricks that prohibit the polynomials indicating the probability of desired events from vanishing, that is, that the desired events never happened.

Since all of our claims are applied to deterministic algorithms, we show how to derandomize the probabilistic construction by noting that the construction still works even when the random variables are constant-wise independent. We then use a standard technique to derandomize algorithms that use constant-wise independent random variables [37, 38]. Then, we prove that the reduction is approximation-preserving, again by Turán's Theorem.

We complete the proof by showing that $\text{MAX INDEPENDENT SET}$ is strongly **APX**-hard even for sparse large-girth graphs.

Related Work. Our strong **APX**-hardness results apply to $\text{MAX-}r\text{SUM}$ and to some similar problems, which can be viewed as replacing the sum function with more general functions. A similar generalization from $r\text{SUM}$ problems [32, 16] to a wider class of problems has also been found useful in studies of the time complexity of $r\text{SUM}$ -hard problems in \mathbf{P} , because the sum function may be not sufficient to encode an $r\text{SUM}$ -hard problem but a more general function may [10].

We present a class of optimization problems that are strongly **APX**-hard because of a simple syntactic criterion. In that respect, there is some similarity to prior work on the MAXONES problem. In [34], syntactic criteria were presented for certain MAXONES problems, that imply **APX**-hardness. Related topics were also discussed in [9, 33]. Our results are not closely related to [9, 33, 34]; the full version of our paper will compare and contrast our results in more detail.

Paper Organization. In Section 2, we show the algorithmic results. Then, in Section 3, we exhibit our main techniques by proving the strong **APX**-hardness of a simple case MAX-3SUM, implying strong **APX**-hardness for a list of MAX-3SUM-hard problems via previously-known approximation-preserving reductions from 3SUM-hardness. In Section 4 and Section 5, we generalize the techniques used in Section 3 to prove Theorem 2. We prove Theorem 3 in Section 6, and relate strong **APX**-hardness to the density of languages in Section 7. Then, in Appendix A, we reduce the maximum independent set problem for some intersection graphs to the 2-variate case of Theorem 2 part (ii). In Appendix B, we prove the strong **APX**-hardness of some problems, which are used as source problems for the hardness reductions used in Sections 3 to 6. Finally, we give an inapproximability constant for each intractable problem in our syntactically-defined class in Appendix C.

2 Algorithmic Results

In this section, we prove the algorithmic results stated in Theorem 2, that is, for any finite set L_2 that contains only functions with 1 or 2 variables, SUBSET-CSAT(L_2) admits a PTAS and can be exactly solved in $2^{O(n^c)}$ time for some constant $c < 1$. Some of these problems are known to be **NP**-hard; see Appendix A. If L_2 contains a homogeneous linear function with 1 variable, then it suffices to remove 0 from S . Thus, in what follows, we consider SUBSET-CSAT(L_2) where L_2 is a finite set of homogeneous linear functions with precisely 2 variables. Note that every $\ell(\mathbf{x}) \in L_2$ still has r input variables, but only 2 of the r variables are used.

Given a problem SUBSET-CSAT(L_2), we construct an undirected simple graph $G_{L_2} = (V, E)$ where $V = \{v_a : a \in S\}$ and

$$E = \{(v_a, v_b) : \ell(\mathbf{x}) = 0 \text{ when } x_i = a, x_j = b \text{ for some } i \neq j \in [1, r], \ell(\mathbf{x}) \in L_2\}.$$

Because L_2 contains only linear functions with 2 variables, finding a maximum independent set for G_{L_2} is equivalent to solving SUBSET-CSAT(L_2). In what follows, we show that G_{L_2} is a subgraph of some ***c*-nearest neighborhood graph** (Lemma 6), defined below, and show that MAX INDEPENDENT SET for the graph class that consists of subgraphs of *c*-nearest neighborhood graphs admits a PTAS and can be solved exactly in subexponential time (Theorem 7). We assume that the underlying point set of *c*-nearest neighborhood graphs (or subgraphs of *c*-nearest neighborhood graphs) is given. This assumption holds for our case because the *c*-nearest neighborhood graphs used in our proofs are induced by a point set, and their subgraphs are induced by a subset of the same point set.

► **Definition 5** (*c*-nearest neighborhood graphs [26]). *Given a set P of points in \mathbb{R}^d , the *c*-nearest neighborhood graph of P is a graph $G_P = (V, E)$ whose $V = \{v_a : a \in P\}$ and*

$$E = \{(v_a, v_b) \in V^2 : a \text{ is the } i\text{-th nearest neighbor of } b \text{ for some } i \leq c\},$$

where ties are broken arbitrarily.

► **Lemma 6.** G_{L_2} is a subgraph of some c_{L_2} -nearest neighborhood graph of an n -point set P_{L_2} in $\mathbb{Z}^{d_{L_2}}$ for some constants c_{L_2}, d_{L_2} .

Proof. We construct the n -point set P_{L_2} by projecting each $v_a \in V(G_{L_2})$ into a point in \mathbb{Z}^{t+2} for some constant $t \geq 0$ as follows. Define

$$\begin{aligned} D_{L_2} &= \{d : d \text{ is prime and } d \text{ divides } c, \text{ where } c \text{ is a coefficient of some } \ell(\mathbf{x}) \in L_2\} \\ &= \{d_1, d_2, \dots, d_t\} \text{ where } t := |D_{L_2}|. \end{aligned}$$

Since L_2 is a finite set and each $\ell(\mathbf{x}) \in L_2$ has constant coefficients, t is a constant. Given D_{L_2} , for each $v_a \in V(G_{L_2})$ we write a as the unique factorization

$$a = (d_1)^{a_1} \cdots (d_t)^{a_t} (-1)^{a_{t+1}} a_{t+2} \text{ where } a_{t+1} \in \{0, 1\}, a_{t+2} > 0 \text{ and } d \nmid a_{t+2} \text{ for all } d \in D_{L_2},$$

based on which we map v_a into the point $p_a := (a_1, a_2, \dots, a_{t+2})$ for each $v_a \in V(G_{L_2})$.

Since each $\ell(\mathbf{x}) \in L_2$ has constant coefficients with prime divisors in D_{L_2} , if $\ell(\mathbf{x}) = 0$ when we set $x_i = a$ and $x_j = b$ for some $i \neq j \in [1, r]$, then $a_{t+2} = b_{t+2}$ and $a_i - b_i = O(1)$ for each $i \in [1, t+1]$. This yields that for every $(v_a, v_b) \in E(G_{L_2})$ the Euclidean distance between their associated points p_a, p_b is a constant, i.e. $\|p_a - p_b\|_2$ is a constant.

Let $C = \max_{(v_a, v_b) \in E(G), i \in [1, t+2]} |a_i - b_i|$. Then, for every edge $(v_a, v_b) \in E(G_{L_2})$, p_a is the i -th nearest neighbor of p_b for some $i \leq (2C+1)^{t+2}$, and vice versa. By setting

$$c_{L_2} = (2C+1)^{t+2} \text{ and } d_{L_2} = t+2,$$

we are done. ◀

► **Theorem 7.** MAX INDEPENDENT SET for \mathcal{H} admits a PTAS and can be solved exactly in subexponential time, where \mathcal{H} is any graph class that satisfies all the following properties.

- (a) For every graph H in \mathcal{H} , any subgraph of H is a graph in \mathcal{H} .
- (b) Every h -node graph H in \mathcal{H} has a node separator of size $O(h^c)$ for some constant $c < 1$, whose removal partitions H into two balanced disconnected subgraphs, and the separator can be found in time polynomial in h .
- (c) Every h -node H in \mathcal{H} has an independent set of size $\alpha(H) = \Omega(h)$.

Proof. We show this by generalizing Lipton and Tarjan's algorithm for MAX INDEPENDENT SET on planar graphs, whose approximate version has the following pseudocode:

Input: an h -node undirected simple graph $H \in \mathcal{H}$

- 1 Find a node separator C of size $O(h/s^\varepsilon)$ whose removal partitions H into disconnected subgraphs H_1, H_2, \dots, H_t , each of which has fewer than s nodes, where $s \in (1, h)$ is a function of h and ε is some constant > 0 ;
- 2 Compute a maximum independent set I_i in H_i for each $i \in [1, t]$ by exhaustive search;

Output: $I_1 \cup I_2 \cup \dots \cup I_t$

We need to argue that such a node separator C exists, given the properties of \mathcal{H} . We initialize a computation tree \mathcal{T} as follows. Initially, \mathcal{T} has only a root node, associated with H . Then, if there exists a leaf node $a \in \mathcal{T}$ associated with a graph H_a that has more than s nodes, we find a node separator C_a to partition H_a into two balanced disconnected subgraphs H_{a_1} and H_{a_2} . Such a C_a must exist by Properties (a) and (b). Then we link a with two child nodes, a_1 and a_2 , whose associated graphs are H_{a_1} and H_{a_2} . Finally, each leaf node in \mathcal{T} has fewer than s nodes. We let the subgraphs associated with leaf nodes in \mathcal{T} be H_1, H_2, \dots, H_t , and let the union of separators found during the construction of \mathcal{T} be C .

16:8 Syntactic Separation of Subset Satisfiability Problems

By Property (b), C can be constructed in time polynomial in h . The following shows why the size of C is $O(h/s^\varepsilon)$ for some constant $\varepsilon > 0$. We label each node $a \in \mathcal{T}$ with a height $t(a)$, i.e. the maximum length among all a -to-descendant-leaf paths. Let s_i for $i \geq 1$ be the lower bound on $|H_a|$ for all $a \in \mathcal{T}$ with height i . Since the found separator C_a partitions graph H_a into two balanced subgraphs, both of which have a constant fraction of the nodes in H_a , one can set $s_1 = s$ and $s_i = \Delta s_{i-1}$ for some constant $\Delta > 1$. The total number of nodes in the separators associated with all nodes in \mathcal{T} with height i is thus

$$\sum_{a \in \mathcal{T}, t(a)=i} |C_a| \leq \delta \left(\sum_{a \in \mathcal{T}, t(a)=i} |H_a|^{1-\varepsilon} \right) \leq \delta \frac{h}{s_i^\varepsilon}$$

where δ is a constant determined in Property (b) and the last inequality holds due to Hölder's inequality. Putting it all together, we get

$$|C| = \sum_{a \in \mathcal{T}} |C_a| \leq \delta \sum_{i=1}^{\infty} \frac{h}{(\Delta^{i-1}s)^\varepsilon} = O\left(\frac{h}{s^\varepsilon}\right).$$

To devise a polynomial-time approximation algorithm, we set $s = \log h$. Thus, the exhaustive search in Step 2 can be done in polynomial time. By the maximality of I_i , we have $\alpha(H) \leq \sum_{i \in [t]} |I_i| + O(h/\log^\varepsilon h)$. Together with $\alpha(H) = \Omega(h)$ due to Property (c), $\sum_{i \in [t]} |I_i| = (1 - o(1))\alpha(H)$, yielding a $(1 - o(1))$ -approximation algorithm.

To devise a subexponential-time exact algorithm, we set $s = h^\delta$ for some constant $\delta \in (0, 1)$. Thus, the separator C has size $O(h^{1-\delta\varepsilon})$. Then we try all possible independent sets I_C of C , to be included in the output independent set, in $O(h^2 2^{h^{1-\delta\varepsilon}})$ time. For each I_C , we remove the neighbor nodes of I_C in H_1, H_2, \dots, H_t . Then, we exhaustively search for a maximum independent set in the rest of H_i for each $i \in [1, t]$. These exhaustive searches can be done in $O(h^3 2^{h^\delta})$ time. As a result, $I_C \cup I_1 \cup \dots \cup I_t$ is a maximum independent set for some I_C , and this exact algorithm takes

$$O(h^5 2^{h^\delta + h^{1-\delta\varepsilon}})$$

time, which is subexponential for any constant $\delta \in (0, 1)$. ◀

It remains to show that the graph class \mathcal{G} that consists of subgraphs of c -nearest neighborhood subgraphs for some constant c satisfies all the properties listed in Theorem 7. It is clear that Property (a) holds for \mathcal{G} . It was shown in [26] that for any h -point set P , G_P has a node separator of size $O(c^{1/d} h^{1-1/d})$ whose removal partitions G_P into two balanced disconnected subgraphs. Moreover, such a node separator can be computed deterministically in $O(ch \log c + h \log h)$ time. For any resulting subgraph H of G_P , whose nodes are associated with a point set $P' \subseteq P$, one can construct the supergraph $G_{P'}$ of H and use the node separator of $G_{P'}$ as the node separator for H . Analogously, the size of the node separator and the running time to find it match the requirement. Thus, Property (b) holds for \mathcal{G} . Since any h -node subgraph of c -nearest neighborhood graphs have $O(h)$ edges for any constant c , by Turán's Theorem, Property (c) holds.

3 Hardness of Max-3SUM

In this section, we prove the hardness of $\text{SUBSET-CSAT}(L_{3S} := \{\ell(x, y, z) = x + y + z\})$ and defer a proof for the general case in Theorem 2 to Section 4. The proof of the hardness of approximating $\text{SUBSET-CSAT}(L_{3S})$ will serve as intuition for the general case. The hardness of $\text{SUBSET-CSAT}(L_{3S})$ implies the hardness of the maximization version of numerous 3SUM-hard problems whose hardness reductions satisfy the following observation.

► **Observation 8.** There are many r SUM-hard decision problems \mathcal{P} whose hardness reductions can be directly restated as SPTAS reductions from Max- r SUM to MAX- \mathcal{P} .

Examples [28, 11, 13] include:

- MAX-GENERAL: Given $S \subset \mathbb{R}^2$, find a largest $T \subseteq S$ so that T contains no three colinear points. This is one of the applications mentioned in Section 1.
- MAX- $\delta\Delta$ -FREE: Given $S \subset \mathbb{R}^2$, find a largest $T \subseteq S$ so that T contains no three distinct points that form a triangle with area less than δ , for any fixed constant δ .
- MAX-3AP-FREE: Given $S \subset \mathbb{Z}$, find a largest $T \subseteq S$ so that T contains no three distinct integers that form an arithmetic progression. A more general case MAX- k AP-FREE for each $k > 3$ needs the hardness results shown in Section 6. We note here that a subset containing no 4-term arithmetic progressions may have 3-term arithmetic progressions, so the hardness of MAX-3AP-FREE does not immediately imply the hardness of MAX- k AP-FREE for each $k > 3$, whose proof relies on another system Subset-DSAT(L) for some L whose $|L| = k - 2$.
- MAX-3LIP: Given S , a set of lines in \mathbb{R}^2 , find a largest $T \subseteq S$ so that T contains no three distinct lines that intersect at a point.

NP-hardness. We claim the existence of a polynomial-time many-one reduction from instances of MAX INDEPENDENT SET to instances of SUBSET-CSAT(L_{3S}). Let n -node m -edge graph $G = (V, E)$ be an instance of MAX INDEPENDENT SET. We need a mapping f from $V \cup E$ to a set S of $n + m$ integers so that G has an independent set of size k iff SUBSET-CSAT(L_{3S}) with input S has output of size $k + m$. We show that such a set S exists by the probabilistic method [5] and show how to construct S deterministically in time polynomial in n , using derandomization [37, 38].

► **Lemma 9.** SUBSET-CSAT(L_{3S}) is NP-hard.

Proof. To implement a mapping $f : V \cup E \rightarrow S$, we will use an n -order superposable set w.r.t. the function $\ell(x, y, z) = x + y + z \in L_{3S}$, which we define as follows. For any set B of n integers X_1, X_2, \dots, X_n , we define the auxiliary set A_ℓ induced by B and ℓ to be

$$\{Y_{ij} : \ell(X_i, X_j, Y_{ij}) = 0, i, j \in [1, n], i < j\}.$$

We say B is an n -order superposable set if A_ℓ contains only integers, $|B \cup A_\ell| = n + \binom{n}{2}$, and for every three distinct integers $a_1, a_2, a_3 \in B \cup A_\ell$, $\ell(a_1, a_2, a_3) = 0$ only if $\{a_1, a_2, a_3\} = \{X_i, X_j, Y_{ij}\}$ for some $i, j \in [1, n], i < j$.

Given the superposable set B , one can realize a mapping $f : V \cup E \rightarrow S$, where $f(v_i) = X_i$ for each $v_i \in V$ and $f(\{v_i, v_j\}) = Y_{ij}$ for each $\{v_i, v_j\} \in E$. The following lemma will establish that the image set S and graph G preserve the relation required in the many-one reduction.

► **Lemma 10.** An n -node m -edge graph $G = (V, E)$ has an independent set of size k iff SUBSET-CSAT(L_{3S}) with input $S = f(V \cup E)$ has output of size $k + m$.

Proof.

(\Rightarrow) For each independent set I of G , $I \cup E$ corresponds to a set $T = \{f(a) : a \in I \cup E\}$, a subset of S . Since I is an independent set, for every edge $\{v_i, v_j\}$, the two integers $f(v_i)$, $f(v_j)$ are not simultaneously contained in T . By the definition of a superposable set, T is a valid output for SUBSET-CSAT(L_{3S}) with input S since it does not contain all three of $f(v_i)$, $f(v_j)$, $f(\{v_i, v_j\})$, for each pair of $i, j \in [1, n], i < j$.

16:10 Syntactic Separation of Subset Satisfiability Problems

(\Leftarrow) Let T be a valid output for $\text{SUBSET-CSAT}(L_{3S})$ with input S . For each edge $\{v_i, v_j\} \in E$, if both $f(v_i), f(v_j) \in T$, then $f(\{v_i, v_j\}) \notin T$ because T is a valid output. In that case, one can modify T by replacing $f(v_i)$ with $f(\{v_i, v_j\})$. Such a modification does not change the size of T but reduces the number of pairs of $f(v_i), f(v_j)$ in T whose corresponding nodes v_i, v_j are adjacent in G . One can repeat the change until no such $f(v_i), f(v_j)$ pair exists in T . Hence, G has an independent set of size at least k . \blacktriangleleft

Let $R_p(n)$ be a set of n integers X_1, X_2, \dots, X_n sampled uniformly at random from the universe $U = \mathbb{Z}_p$, for some prime p . In Lemma 11, we prove that, for sufficiently large p , $R_p(n)$ is a superposable set with positive probability. We choose \mathbb{Z}_p to facilitate the derandomization. However, if a set is superposable under \mathbb{Z}_p , then it is superposable under \mathbb{Z} . After the construction, we use this superposable set under \mathbb{Z} .

► **Lemma 11.** *The probability that $R_p(n)$ is an n -order superposable set is $1 - O(n^6/p)$.*

Proof. We note that for any pair of different linear polynomials, assigning an integer sampled uniformly at random from a universe U to each variable in the polynomials makes the two polynomials equal in \mathbb{Z}_p with probability $p_{eq} = 1/|U|$, by a simple version of the Schwartz-Zippel Lemma [48, 58]. Here $U = \mathbb{Z}_p$ and $1/|U| = 1/p$. In subsequent sections, we will replace U with another set and will rely more heavily on the Schwartz-Zippel Lemma.

To show $B = R_p(n)$ is superposable, we consider the two probabilities:

$$\Pr \left[|B \cup A_\ell| < n + \binom{n}{2} \right] \leq \sum_{X_i, X_j \in B} p_{eq} + \sum_{X_i \in B, Y_{ij} \in A_\ell} p_{eq} + \sum_{Y_{ij}, Y_{i'j'} \in A_\ell} p_{eq} = O(n^4/p)$$

and

$$\Pr [\ell(a_1, a_2, a_3) = 0 \text{ for some } \{a_1, a_2, a_3\} \notin \Gamma] \leq \sum_{a_1, a_2, a_3 \in B \cup A_\ell} p_{eq} = O(n^6/p),$$

where $\Gamma := \{\{X_i, X_j, Y_{ij}\} : i, j \in [n], i < j\}$. We are done by applying the Union bound to the two failure probabilities. \blacktriangleleft

Observe that a fully random assignment to the variables of the polynomials is not necessary to make the two polynomials equal with probability as small as $1/p$. Instead, since L_{3S} contains only $\ell(x, y, z) = x + y + z$, if the variables X_1, X_2, \dots, X_n are assigned 6-wise-independently, the probability p_{eq} is still $1/p$. This observation yields a polynomial-time construction of the superposable set, as follows.

► **Lemma 12.** *One can construct an n -order superposable set in time polynomial in n .*

Proof. Exhaustively explore the polynomial-size probability space of 6-wise independence to find the superposable set, which is known to exist [37, 38]. \blacktriangleleft

We complete the proof of Lemma 9 by combining Lemmas 10, 11, and 12. \blacktriangleleft

Strong APX-hardness. In the **NP**-hardness reduction, we have presented a mapping $f : V \cup E \rightarrow S$, so that every n -node m -edge graph G has an independent set of size k iff $\text{SUBSET-CSAT}(L_{3S})$ with input S has output of size $k+m$. In order to demonstrate the strong **APX**-hardness of $\text{SUBSET-CSAT}(L_{3S})$, it suffices to restrict the **MAX INDEPENDENT SET** problem to sparse graphs. Thus we will give an **SPTAS** reduction from **MAX INDEPENDENT SET** for sparse graphs, which is strongly **APX**-hard (Lemma 24), to $\text{SUBSET-CSAT}(L_{3S})$.

► **Lemma 13.** *There is an SPTAS reduction from MAX INDEPENDENT SET for sparse graphs to SUBSET-CSAT(L_{3S}).*

Proof. We use the same reduction as in the proof of Lemma 9, which has the property that independent sets of size k correspond to a solution of SUBSET-CSAT(L_{3S}) with size $\geq k + m$. But by Turán’s Theorem, we have that any sparse graph has an independent set of size $\Omega(m)$. Thus any solution that approximates SUBSET-CSAT(L_{3S}) to within a factor of $(1 - \varepsilon)$ for some constant $\varepsilon > 0$ maps to a solution that approximates MAX INDEPENDENT SET for sparse graphs to within a factor of $(1 - O(\varepsilon))$. It is easy to verify that the size of the output of the reduction is linear in the size of the input. ◀

By Lemma 13 and Lemma 24, we get:

► **Theorem 14.** *SUBSET-CSAT(L_{3S}) is strongly APX-hard.*

The above SPTAS reduction is based on the hardness of MAX INDEPENDENT SET for sparse graphs (Lemma 24), which specifies additional structure on the input set S for SUBSET-CSAT(L_{3S}). Our reduction still works if the graph class is replaced with another graph class \mathcal{G} , as long as every n -node graph in \mathcal{G} has $O(n)$ edges and has an independent set of size $\Omega(n)$, and MAX INDEPENDENT SET for \mathcal{G} is strongly APX-hard. Such a replacement is useful for proving further hardness results. For example, by Lemma 25 and Turán’s Theorem, the source problem of the reduction used in the proof of Theorem 14 can be replaced with MAX INDEPENDENT SET for triangle-free sparse graphs. This yields the following corollary.

► **Corollary 15.** *SUBSET-CSAT(L_{3S}) with input S , in which for every 6 distinct integers, there are at most two triples summing to 0, is strongly APX-hard.*

4 Hardness of Subset-CSAT(L_{S_r})

We generalize the hardness result of SUBSET-CSAT(L_{3S}) in Section 3 to SUBSET-CSAT(L_{S_r}) where $L_{S_r} := \{\ell(\mathbf{x}) = \mathbf{c} \cdot \mathbf{x}\}$, and $\ell(\mathbf{x})$ is any linear function with coefficients $\mathbf{c} \in (\mathbb{Z} \setminus \{0\})^r$, for any $r \geq 3$.

Here we extend the definition of n -order superposable set for any r -variate homogeneous linear function $\ell(\mathbf{x})$. Let $t := r - 3$. For any set

$$B = \{X_i : i \in [1, n]\} \cup \{X_{ijk} : i, j \in [1, n], i < j, k \in [1, t]\}$$

of $n + t\binom{n}{2}$ integers, we define the auxiliary set A_ℓ induced by B and ℓ to be

$$A_\ell = \{Y_{ij} : \ell(X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}) = 0, i, j \in [1, n], i < j\}.$$

Let $\Gamma = \{\mathcal{S}_{ij} := \{X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}\} : i, j \in [1, n], i < j\}$. We say B is an n -order superposable set if A_ℓ contains only integers, $|B \cup A_\ell| = n + (t + 1)\binom{n}{2}$, and for every r distinct integers $a_1, a_2, \dots, a_r \in B \cup A_\ell$, $\ell(a_1, a_2, \dots, a_r) = 0$ only if $\{a_1, a_2, \dots, a_r\} \in \Gamma$.

Let $G = (V, E)$ be a problem instance of MAX INDEPENDENT SET for sparse graphs. Given the superposable set B , we define a mapping $f : V \cup E \rightarrow 2^{B \cup A_\ell}$, where $f(v_i) = \{X_i\}$ for each $v_i \in V$ and $f(\{v_i, v_j\}) = \{X_{ij1}, \dots, X_{ijr}, Y_{ij}\}$ for each $\{v_i, v_j\} \in E$. As in the proof of Lemma 9, if an n -order superposable set B can be constructed in time polynomial in n , then SUBSET-CSAT(L_{S_r}) is NP-hard. Moreover, the hardness-reduction is approximation-preserving for $\ell(\mathbf{x})$ simply by replacing $(1 - O(\varepsilon))$ with $(1 - O(r\varepsilon))$ in the proof of Lemma 13. Hence, Lemma 16 immediately follows by constructing B in polynomial-time.

16:12 Syntactic Separation of Subset Satisfiability Problems

► **Lemma 16.** $\text{SUBSET-CSAT}(L_{S_r})$ is strongly **APX**-hard.

Proof. Recall that $\ell(\mathbf{x}) = \mathbf{c} \cdot \mathbf{x} = \sum_{i=1}^r c_i x_i$ where $c_i \in \mathbb{Z} \setminus \{0\}$ for each $i \in [1, r]$, and $t := r - 3$. Let $m = \text{lcm}(c_1, c_2, \dots, c_r)$. We construct an n -order superposable set B by sampling X_i for each $i \in [1, n]$ and X_{ijk} for $i, j \in [1, n], i < j, k \in [1, t]$ from the universe $U = \mathbb{Z}_p \cap m\mathbb{Z}$ for some prime p . We choose the universe U in this way because no matter what the sampled values of X_i 's and X_{ijk} 's are, they make all Y_{ij} 's integral. Before the sampling is performed, each X_i, X_{ijk} in B can be seen as an independent random variable and each Y_{ij} in A_ℓ can be seen as some linear combination of these independent random variables.

We show that the sampled B is an n -order superposable set with positive probability by bounding the probabilities of following bad events. Let E_1 indicate the event that $|B \cup A_\ell| < n + (t + 1)\binom{n}{2}$. We claim that $\Pr[E_1] = n^c/(p/m)$ for some constant $c > 0$. To see this, we note that every two distinct random variables $a_1, a_2 \in B \cup A_\ell$ are different linear combinations of the random variables in $\{X_1, X_2, \dots, X_n\}$. Since X_1, X_2, \dots, X_n are sampled independently from U , $\Pr[a_1 = a_2] = 1/(p/m)$. Together with the Union bound, the claimed bound for $\Pr[E_1]$ holds.

Let E_2 indicate the event that $\ell(a_1, a_2, \dots, a_r) = 0$ for some $\{a_1, \dots, a_r\} \notin \Gamma$. We claim that for every r distinct integers in $B \cup A_\ell$, $\ell(a_1, a_2, \dots, a_r)$ cannot be a zero function if $\{a_1, a_2, \dots, a_r\} \notin \Gamma$. We express a_k for each $k \in [1, r]$ as a linear combination of the random variables in B . To make $\ell(a_1, a_2, \dots, a_r)$ a zero function, each variable in B either does not appear or appear more than once in a_k 's expressions, for all $k \in [1, r]$. This observation implies that if an X_{ijk} in B for some $i, j \in [n], i < j, k \in [1, t]$ appears in the r expressions and $\ell(a_1, a_2, \dots, a_r)$ is a zero function, then $X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}$ also appear in the r expressions. Hence, in this case, $\{a_1, a_2, \dots, a_r\} \in \Gamma$.

The remaining case is that X_{ijk} does not appear in any of the r expressions. In this case, to make $\ell(a_1, a_2, \dots, a_r)$ a zero function, the only possible case happens when $r = 3$ and $\{a_1, a_2, a_3\} = \{Y_{ij}, Y_{jk}, Y_{ik}\}$ for some $i, j, k \in [n], i < j < k$. However,

$$\ell(a_1, a_2, a_3) = c_1 \left(\frac{c_1 X_i + c_2 X_j}{-c_3} \right) + c_2 \left(\frac{c_1 X_j + c_2 X_k}{-c_3} \right) + c_3 \left(\frac{c_1 X_i + c_2 X_k}{-c_3} \right)$$

cannot be a zero function because X_j 's coefficient is non-zero, or

$$\ell(a_1, a_2, a_3) = c_1 \left(\frac{c_1 X_i + c_2 X_j}{-c_3} \right) + c_2 \left(\frac{c_1 X_i + c_2 X_k}{-c_3} \right) + c_3 \left(\frac{c_1 X_j + c_2 X_k}{-c_3} \right)$$

cannot be a zero function unless $(c_1, c_2, c_3) = (\Delta, -\Delta, \Delta)$ for some $\Delta \neq 0$, which can be avoided by sorting the variables in ℓ by their coefficients. The same argument works when (a_1, a_2, a_3) equals other permutations of (Y_{ij}, Y_{jk}, Y_{ik}) . Hence, the claim is true. There are a polynomial number of non-zero linear functions $\ell(a_1, a_2, \dots, a_r)$ that cannot be zeroed by the random assigned values of X_i, X_{ijk} for $i, j \in [1, n], i < j, k \in [1, t]$. Therefore the failure rate is $n^c/(p/m)$ for some constant $c > 0$.

Given the bounds on failure probability, the randomly sampled B is an n -order superposable set with positive probability by picking p polynomially large in n . After a derandomization step similar to that in Lemma 12, we have B constructed in deterministic polynomial time. ◀

5 Hardness of Subset-CSAT(L_r)

We extend the hardness result of SUBSET-CSAT(L_{S_r}) to

$$\text{SUBSET-CSAT}(L_r := \{\ell_1(\mathbf{x}), \ell_2(\mathbf{x}), \dots, \ell_k(\mathbf{x})\}),$$

where $\ell_i(\mathbf{x}) \in \mathbb{Z}[\mathbf{x}]$ for each $i \in [1, k]$, $\mathbf{x} = (x_1, x_2, \dots, x_r)$, and at least one $\ell_i(\mathbf{x})$ uses at least 3 of the r input variables. Showing the strong **APX**-hardness of SUBSET-CSAT(L_r) proves Theorem 2.

We begin by defining a *canonical representation* for the $\ell_i(\mathbf{x})$'s. Observe that

$$\text{SUBSET-CSAT}(\{\ell_1(x, y, z, w) = x + y - z, \ell_2(x, y, z, w) = y + w - x\})$$

equals Subset-CSAT($\{\ell(x, y, z, w) = x + y - z\}$), which also equals Subset-CSAT($\{\ell(x, y, z) = \delta(x + y - z)\}$) for any constant $\delta \neq 0$, because in the definition of Subset-CSAT(L), we assume that the output has size at least r . Let $\text{Coef}(\ell_i(\mathbf{x}))$ be the multi-set of coefficients in $\ell_i(\mathbf{x})$. We say that $\ell_i(\mathbf{x})$ and $\ell_j(\mathbf{x})$ are in the same equivalence class if $\text{Coef}(\ell_i(\mathbf{x})) = \{\delta c : c \in \text{Coef}(\ell_j(\mathbf{x}))\}$ for some non-zero constant δ . Thus, we can remove redundant functions in L , if any, by removing $\ell_i(\mathbf{x})$ from L if $\ell_i(\mathbf{x})$ and $\ell_j(\mathbf{x})$ are from the same equivalence class, for some $j < i$. Given the succinct representation of L , let $\ell_*(\mathbf{x})$ be the $\ell_i(\mathbf{x})$ in L that has the largest number of variables. If there is a tie, then pick any of them.

► **Lemma 17.** *Consider an r -variate homogeneous linear function $\ell_*(\mathbf{x})$ where $r \geq 3$, and an r' -variate homogeneous linear function $\ell(\mathbf{x})$ where $r' \leq r$. Let $t := r - 3$. Then for any constant $\varepsilon > 0$ there exists a randomized algorithm that constructs with probability at least $1 - \varepsilon$ an n -order superposable set $B = \{X_i : i \in [1, n]\} \cup \{X_{ijk} : i, j \in [n], i < j, k \in [1, t]\}$ and the auxiliary set $A_{\ell_*} = \{Y_{ij} : \ell(X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}) = 0, i, j \in [1, n], i < j\}$ induced by B and ℓ_* , so that for every r distinct integers in $B \cup A_{\ell_*}$, $\ell(a_1, a_2, \dots, a_{r'}) = 0$ only if either of the following two cases applies:*

- $r' = r$ and $\{a_1, a_2, \dots, a_{r'}\} = \{X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}\}$,
- $r' = r = 3$ and $\{a_1, a_2, a_3\} = \{Y_{s_1 s_2}, Y_{s_2 s_3}, Y_{s_3 s_1}\}$ for some $1 \leq s_1 < s_2 < s_3 \leq n$.

Proof. Set each element in B to be a random variable, and therefore each element in A_{ℓ_*} is a linear combination of $r - 1$ random variables and none of them in the linear combination has coefficient 0. To make $\ell(\mathbf{x})$ a zero function by setting r' distinct variables from $(B \cup A_{\ell_*})$, it is necessary that each variable in B either does not appear among any of the r' picked variables or appears in at least two of them, noting that X_i is considered to “appear” in X_i and Y_{ij} for any $j \in [1, n]$. There are two cases. If X_{ijk} for some $i < j, i, j \in [n], k \in [1, t]$ is one of the r' picked variables, then $\ell(\mathbf{x})$ is zero only if the r' picked variables are exactly $X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}$. Otherwise, for every $i < j, i, j \in [n], k \in [1, t]$, X_{ijk} is *not* picked as one of the r' variables. In this case, to make $\ell(\mathbf{x})$ zero it is necessary that $t = 0$ (or equivalently $r = 3$), $r' = r$, and the r' picked variables are either X_i, X_j, Y_{ij} for some $i, j \in [n]$ or $Y_{s_1 s_2}, Y_{s_2 s_3}, Y_{s_3 s_1}$ for some $1 \leq s_1 < s_2 < s_3 \leq n$.

Therefore, if we let $B = R_p(n)$, then the probability that $\ell(a_1, a_2, \dots, a_{r'}) = 0$ for some $a_1, a_2, \dots, a_{r'}$ other than the two given ones (the only cases that may make $\ell(\mathbf{x})$ as a zero function) is $1/p$. By the Union bound over all possible r' distinct values from $B \cup A_{\ell_*}$ in which there are $O(n^2)$ elements, we get the success probability of our random assignment is at least $1 - n^{2r'}/p$. Picking a sufficiently large p completes the proof. ◀

We apply Lemma 17 to each $\ell(\mathbf{x})$ in the succinct representation of L , take the Union bound over the failure probabilities, by the aforementioned derandomization step, we get:

16:14 Syntactic Separation of Subset Satisfiability Problems

► **Lemma 18.** For any set $L_r(\mathbf{x})$ of r -variate homogeneous linear functions, if the function $\ell_*(\mathbf{x})$ in $L(\mathbf{x})$ that uses the largest number of variables is r' -variate for some $r' \geq 3$, let $t := r' - 3$, there exists a deterministic polynomial-time algorithm that can construct an n -order superposable set $B = \{X_i : i \in [1, n]\} \cup \{X_{ijk} : i, j \in [n], i < j, k \in [1, t]\}$ w.r.t. ℓ_* and the auxiliary set $A_{\ell_*} = \{Y_{ij} : \ell_*(X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij})\}$ induced by B and ℓ_* so that $\bigwedge_{\ell \in L} \ell(a_1, a_2, \dots, a_r)$ evaluates to FALSE only if either of the two following cases applies:

- $\{a_1, a_2, \dots, a_r\} = \{X_i, X_j, X_{ij1}, \dots, X_{ijt}, Y_{ij}\}$,
- $r = 3$ and $\{a_1, a_2, a_3\} = \{X_{ij}, X_{jk}, X_{ik}\}$.

Proof of Theorem 2. Given Lemma 18, one can reuse the many-one reduction mentioned previously, but restrict the input graph to be triangle-free (i.e. girth ≥ 3), so that a_1, a_2, a_3 in the second case of Lemma 18 cannot simultaneously appear in the set S , i.e. the input of the reduction target. By Lemma 25, the maximum independent set problem for sparse graphs of girth ≥ 3 is strongly APX-hard, implying that $\text{Subset-CSAT}(L_r)$ is strongly APX-hard. ◀

6 Hardness of Subset-DSAT(L_{\vee})

In this section, we will show the strong APX-hardness of

$$\text{SUBSET-DSAT}(L_{\vee} := \{\ell_1(\mathbf{x}), \ell_2(\mathbf{x}), \dots, \ell_k(\mathbf{x})\}),$$

where $\ell_i(\mathbf{x}) \in \mathbb{Z}[\mathbf{x}]$ for each $i \in [1, k]$, $\mathbf{x} = (x_1, x_2, \dots, x_r)$, and the solutions to $\bigvee_{\ell \in L} \ell(\mathbf{x}) = \text{FALSE}$ form a vector space in general position and has dimension d at least 2. That is, we prove Theorem 3.

To prove Theorem 3 for $d = r - 1$, one can use the proof of Theorem 2. For $d < r - 1$ in general, the number of dependent random variables induced by the superposable set B is no longer 1, thus requiring the solution set of to be in general position. We need to modify the definition of the superposable set w.r.t. such a $\chi_{L_{\vee}}(\mathbf{x})$, as described below.

Proof of Theorem 3. For any n -node, m -edge graph $G = (V, E)$ that has $m = O(n)$ and girth at least $r + 1$, we construct a set B of independent random variables and an auxiliary set $A_{\chi_{L_{\vee}}}$ so that

$$B = \{X_i : i \in V\} \cup \{X_{ijk} : (i, j) \in E, i < j, k \in [1, d - 2]\}, \text{ and}$$

$$A_{\chi_{L_{\vee}}} = \{Y_{ij1}, \dots, Y_{ij(r-d)} : \chi_{L_{\vee}}(X_i, X_j, X_{ij1}, \dots, X_{ij(d-2)}, Y_{ij1}, \dots, Y_{ij(r-d)}) = 0, \\ (i, j) \in E, i < j\},$$

where the solution space of $\chi_{L_{\vee}}(\mathbf{x}) = 0$ is in general position and has dimension $d \geq 2$. Hence, for every $(i, j) \in E, i < j$, $(Y_{ij1}, Y_{ij2}, \dots, Y_{ij(r-d)})$ is unique.

Here we define the Y_{ijk} explicitly. Let $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_d$ be a set of basis vectors (column vectors) in \mathbb{Z}^r of the solution set of $\chi_{L_{\vee}}(\mathbf{x}) = 0$. Let \mathbf{A} be the aggregation of $\mathbf{v}_1, \mathbf{v}_2, \dots, \mathbf{v}_d$ where $\mathbf{A} = (\mathbf{v}_1 | \mathbf{v}_2 | \dots | \mathbf{v}_d)$. Let \mathbf{Q} be the square matrix composed of the upper d rows of \mathbf{A} . By the definition of general position, \mathbf{A} is strongly full rank, \mathbf{Q} is full rank, and thus \mathbf{z} is uniquely defined by

$$\mathbf{Qz} = \begin{bmatrix} X_i \\ X_j \\ X_{ij1} \\ \vdots \\ X_{ij(d-2)} \end{bmatrix}, \text{ and we set } \mathbf{Az} = \mathbf{A} \left(\mathbf{Q}^{-1} \begin{bmatrix} X_i \\ X_j \\ X_{ij1} \\ \vdots \\ X_{ij(d-2)} \end{bmatrix} \right) = \begin{bmatrix} X_i \\ X_j \\ X_{ij1} \\ \vdots \\ X_{ij(d-2)} \\ Y_{ij1} \\ \vdots \\ Y_{ij(r-d)} \end{bmatrix}.$$

Thus, each of $Y_{ij1}, \dots, Y_{ij(r-d)}$ is a nontrivial linear combination of $X_i, X_j, X_{ij1}, \dots, X_{ij(d-2)}$. Note that \mathbf{AQ}^{-1} is also strongly full rank, yielding that any nontrivial linear combination of d variables from the set $\{X_i, X_j, X_{ij1}, \dots, X_{ij(d-2)}, Y_{ij1}, \dots, Y_{ij(r-d)}\}$ cannot be a zero function. We are ready to prove that B is superposable w.r.t. E , that is:

► **Lemma 19.** *For any distinct $a_1, a_2, \dots, a_r \in B \cup A_{\chi_{L_V}}$, $\chi_{L_V}(a_1, a_2, \dots, a_r)$ is a zero function only if $\{a_1, a_2, \dots, a_r\} = \{X_i, X_j, X_{ij1}, \dots, X_{ij(d-2)}, Y_{ij1}, \dots, Y_{ij(r-d)}\}$ for some $(i, j) \in E, i < j$.*

Proof. If $\{a_1, a_2, \dots, a_r\} \subseteq \{X_i : i \in [1, n]\}$, then $\chi_{L_V}(a_1, a_2, \dots, a_r)$ cannot be a zero function because the X_i 's are independent variables and each X_i appears at most once in any linear function $\ell_j(\mathbf{x})$ that comprises χ_{L_V} . Thus, to zero $\chi_{L_V}(a_1, a_2, \dots, a_r)$ we may assume that

$$a_p \in \mathcal{S}_{ij} := \{X_{ij1}, \dots, X_{ij(d-2)}, Y_{ij1}, \dots, Y_{ij(r-d)}\} \text{ for some } p \in [1, r], (i, j) \in E, i < j.$$

Say a_p appears in some homogeneous linear function $\ell_q(\mathbf{x})$ that comprises χ_{L_V} . In order to make $\chi_{L_V}(a_1, \dots, a_r)$ a zero function, one must make $\ell_q(\mathbf{x})$ a zero function. We disprove the possibility of making $\ell_q(\mathbf{x})$ zeroed as follows. If $\ell_q(\mathbf{x})$ picks $\geq d$ variables from \mathcal{S}_{ij} , then each of a_1, \dots, a_r can be represented by a linear combination of random variables in \mathcal{S}_{ij} . In other words, $\{a_1, \dots, a_r\} \subseteq (\mathcal{S}_{ij} \cup \{X_i, X_j\})$ because $d \geq 2$. If $\ell_q(\mathbf{x})$ picks $d-1$ variables from \mathcal{S}_{ij} , then to make $\ell_q(\mathbf{x})$ zeroed, $\ell_q(\mathbf{x})$ needs to pick two variables a_w and a_z where a_w is from $\mathcal{S}_{ik} \cup \{X_i\}$ and a_z is from $\mathcal{S}_{j\ell} \cup \{X_j\}$. Note that $k \neq \ell$ because G has girth $r+1 \geq d+2 \geq 4$. This would lead to a contradiction since if we solve the system by the $d-1$ variables from \mathcal{S}_{ij} as well as a_w , then a_z can be represented by linear combination of variables from $\mathcal{S}_{ij} \cup \mathcal{S}_{ik} \cup \{X_i\}$, contradicting that $a_z \in \mathcal{S}_{j\ell}$, $\ell \neq k$, and $d \geq 2$. If $\ell_q(\mathbf{x})$ picks $\leq d-2$ variables from \mathcal{S}_{ij} , since the rest of variables can be partitioned into subsets, each of which sum to a multiple of X_i , or a multiple of X_j , but not a linear combination of X_i and X_j due to G having girth at least $r+1$, therefore $\ell_q(\mathbf{x})$ cannot be zeroed since this effectively picks $\leq d$ variables from $\mathcal{S}_{ij} \cup \{X_i, X_j\}$. ◀

Lastly, the exact construction of the superposable set is similar to that in Theorems 2. By Lemma 19 and the Swartz-Zippel Lemma, we know that sampling $\{X_i : i \in [1, n]\} \cup \{X_{ijk} : (i, j) \in E, i < j, k \in [1, d-2]\}$ uniformly at random from $(\det(\mathbf{Q})\mathbb{Z})^{n+(d-2)m}$ yields a superposable set with positive probability. We pick every X_i and X_{ijk} as multiples of $\det(\mathbf{Q})$ to ensure that all dependent variables Y_{ijk} 's are in \mathbb{Z} . Then, after derandomization using techniques for constant-wise independence, the construction takes time polynomial in n . Setting $g = r+1$, we know that $\text{SUBSET-DSAT}(L_V)$ is strongly **APX**-hard by Lemma 25. ◀

16:16 Syntactic Separation of Subset Satisfiability Problems

An implication of Theorem 3 is the strong **APX**-hardness of finding the maximum-cardinality k -term AP-free subset S for any fixed $k \geq 3$, noting that S may contain elements that form an i -term arithmetic progression for $i < k$ but not $i \geq k$. This problem can be encoded as

$$\text{SUBSET-DSAT}(L_{k\text{AP}} := \{\ell_i(x_1, x_2, \dots, x_k) = x_i - 2x_{i+1} + x_{i+2} : i \in [1, k-2]\}),$$

and the solution set of $\sum_{\ell(\mathbf{x}) \in K_{k\text{AP}}} \ell^2(\mathbf{x}) = 0$ contains the plane

$$(x_1, x_2, \dots, x_k) = \alpha(1, 3, \dots, 2k-1) + \beta(2, 4, \dots, 2k) \text{ for constant } \alpha, \beta \in \mathbb{R}.$$

Therefore,

$$M = \begin{bmatrix} 1 & 2 \\ 3 & 4 \\ \vdots & \vdots \\ 2k-1 & 2k \end{bmatrix} \text{ in which every } 2 \times 2 \text{ submatrix } \begin{bmatrix} 2i-1 & 2j-1 \\ 2i & 2j \end{bmatrix}$$

is full rank. By Theorem 3, we get:

► **Corollary 20.** *Finding a maximum-cardinality k -term AP-free subset of a given integral set S for any fixed $k \geq 3$ is strongly **APX**-hard.*

Sharpness of $d \geq 2$. Not every problem in the class $\text{SUBSET-DSAT}(L)$ is hard to approximate. If the solution set of $\chi(\mathbf{x}) = \sum_{\ell(\mathbf{x}) \in L} \ell^2(\mathbf{x})$ is a point³, then it suffices to remove an integer in the set S that coincides with the coordinate of the point. If it is a line, for example $\alpha(1, 2, 4, 8)$ for $\alpha \in \mathbb{R}$, then a greedy algorithm can solve this case in P by removing the last coordinate for every tuple of 4 integers that are multiples of $(1, 2, 4, 8)$.

7 A Sparsity Bound, Assuming ETH

Define a *sparse language* as one where there are $n^{O(1)}$ length- n Yes-instances. Mahaney's theorem [39, 45] states that if $\mathbf{P} \neq \mathbf{NP}$, then there is no **NP**-hard sparse language. Buhrman and Hitchcock prove a stronger (optimal) bound from a stronger hypothesis [15]: if **PH** doesn't collapse, then there is no **NP**-hard set with $2^{n^{o(1)}}$ length- n Yes-instances. If one assumes ETH, then an even stronger bound holds for strongly **APX**-hard problems.

► **Theorem 21.** *If X is an optimization problem such that X has $2^{o(n/\log n)}$ strings of length n , then X cannot be strongly **APX**-hard unless ETH fails.*

Proof. This proof is based on the proof of Mahaney's theorem presented in [45]. Assume that X is strongly **APX**-hard, and we will present a subexponential-time algorithm to solve 3SAT. Let

$$L = \{(\varphi, a) : \varphi \text{ has a satisfying assignment } a' \text{ lexicographically smaller than } a\}.$$

L is in nondeterministic linear time, and hence by [19] there is a reduction g of L to 3SAT such that, on input (φ, a) of size n , $g(\varphi, a)$ is a 3CNF formula with $O(n \log n)$ variables, each of which appears in $O(1)$ clauses.

³ $\mathbf{0}$ must be a solution of $\chi(\mathbf{x})$ because the $\ell_i(\mathbf{x})$'s are homogeneous.

Since X is strongly **APX**-hard, there is a function f such that, for any 3CNF formula ψ of size n , $f(\psi)$ has size $O(n)$, where f yields the SPTAS reduction from MAX-3SAT to X .

Consider any satisfiable formula φ with n variables; let a_φ be its lexicographically smallest satisfying assignment. Hence, $(\varphi, a) \in L$ if and only if $a \geq a_\varphi$, lexicographically.

We now present an algorithm for finding a_φ that runs in subexponential time. (If the algorithm fails to find a satisfying assignment, then φ is not satisfiable.) We start with a search space of size 2^n . Let $C = 2^{\alpha(n)}$ be greater than the number of strings in X of length $m = O(n \log n)$, where the output of the reduction $g(\varphi, a)$ has length m . Find C assignments a_1, \dots, a_C that are evenly spaced among the current search space, and compute $z_i = f(g(\varphi, a_i))$ for $1 \leq i \leq C$.

If there are $i < j$ such that $z_i = z_j$, then $g(\varphi, a_i)$ is in 3SAT iff $g(\varphi, a_j)$ is, and thus a_φ does not lie in the segment $(a_i, a_j]$, and thus we can reduce the size of our search space by a factor of $1/C$.

Otherwise, there are C distinct elements z_i of the form $f(g(\varphi, a_i))$, which is greater than the number of relevant elements of X that can be in the range of f . Thus at least one of the formulae $g(\varphi, a_i)$ must be unsatisfiable, since f maps it to an infeasible instance of X . But if any formula $g(\varphi, a_i)$ is unsatisfiable, it follows that $g(\varphi, a_1)$ is unsatisfiable, and hence a_φ does not lie in the segment $[0^n, a_1]$, and thus again we can reduce the size of our search space by a factor of $1/C$.

We now repeat the process with a new set of C checkpoints. As in [45], the bookkeeping that is necessary to keep track of the current search space and to compute the new checkpoints does not get too complicated, and after a small number of iterations the entire search space is of size at most C , at which point we can check directly in subexponential time if any of the remaining assignments satisfies φ .

This algorithm can thus determine if φ is satisfiable or not, which is at least as hard as solving 3SAT. ◀

A Reducing Some MIS Problems to Subset-CSAT(L)

We reduce the problem of finding a maximum independent set for c -far unit-disk graphs to Subset-CSAT(L) for some 2-variable L . A unit disk graph G is an intersection graph of unit disks in the plane. We say a unit-disk graph is c -far if for each pair of disks the Euclidean distance between their centers does not fall within the interval $[0, c) \cup (2, 2 + c)$ for some constant $c > 0$. It is known that the maximum independent set problem remains NP-hard for c -far unit-disk graphs [41, 56], even when the locations of disks are given.

► **Theorem 22.** *There exists a polynomial-time many-one reduction from finding a maximum independent set for c -far unit-disk graphs to Subset-CSAT(L) for some 2-variable L .*

Proof. The reduction comes as follows. Let $D = \{d_1, d_2, \dots, d_n\}$ be the set of the n disks and let $x(d_i)$ and $y(d_i)$ denote the x - and y -coordinate of disk d_i for each $i \in [1, n]$. We discretize the locations of disks in D so that $x(d_i)$ and $y(d_i)$ for all $i \in [1, n]$ are mapped to multiples of ε where ε is set as $c/6$. Observe that, if two disks intersect before the discretization, then their distance is in the range $[4c/6, 2 + 2c/6]$; if two disks do *not* intersect before the discretization, then their distance now falls within $[2 + 4c/6, \infty)$. If we enlarge the radius of all disks from 1 to $1 + 3c/12$, then the discretization does not alter whether two disks intersect or not. In other words, if two disks intersect, then the center of one disk is located at one of the $O(1/\varepsilon^2)$ discretized coordinates surrounding the center of the other.

Consequently, if we map each disk d_i to an integer $2^{x(d_i)/\varepsilon}3^{y(d_i)/\varepsilon}$, noting that the exponents are integers for each $i \in [1, n]$, and set

$$L_{\text{udisk}} = \{\ell(a, b) = 2^{r_1}3^{r_2}a - 2^{r_3}3^{r_4}b : \varepsilon\sqrt{(r_1 - r_3)^2 + (r_2 - r_4)^2} < 2 + c/2, r_1, r_2, r_3, r_4 \in \mathbb{N}\},$$

then it is clear that Subset-CSAT(L_{udisk}) is a restatement of finding a maximum independent set for c -far unit-disk graphs. ◀

Combining Theorem 22 and Theorem 2, we get:

► **Corollary 23.** *Finding a maximum independent set for c -far unit-disk graphs admits a PTAS.*

We remark here that one can have a result analogous to Corollary 23 for c -far intersection graphs whose underlying shape is a unit symmetric convex set. This result is not as general as for ordinary intersection graphs because c -farness implies that all nodes in the intersection graph have a constant degree.

B Initial Hardness Results

Our hardness proofs are based on the strong **APX**-hardness of MAX INDEPENDENT SET for sparse large-girth graphs, which can be shown by the following chain of reductions.

Let MAX-3SAT- Δ be the subproblem of MAX-3SAT so that there exists a constant Δ such that no variables of the formula appears in more than Δ clauses. Let MAX-IS be the maximum independent set problem. In what follows, we will show that MAX-3SAT- $\Delta \leq_{\text{SPTAS}}$ MAX-IS for sparse graphs \leq_{SPTAS} MAX-IS for sparse large-girth graphs.

► **Lemma 24.** MAX INDEPENDENT SET for sparse graphs, i.e. with a linear number of edges, is strongly **APX**-hard.

Proof. Let $I_{3\text{SAT}}$ be an instance of MAX-3SAT- Δ . We assume that $I_{3\text{SAT}}$ has n variables and m clauses, and each clause in $I_{3\text{SAT}}$ has exactly 3 literals. Otherwise, one can duplicate some literal in each of the 1-literal and 2-literal clauses. Given $I_{3\text{SAT}}$, we construct a graph $G = (V, E)$ as I_{MIS} as follows. For each $i \in [1, m]$, we add three nodes $v_{i_1}, v_{i_2}, v_{i_3}$ to V , link each pair of the three nodes with an edge, and label $v_{i_1}, v_{i_2}, v_{i_3}$ with the corresponding literal in the i -th clause. Then, for every pair of nodes in V , if their labels are literals which are negations of each other, then link an edge between them. Consequently, G has $3m$ nodes and at most $3m + 9\binom{\Delta}{2}n = O(m)$ edges. It can be checked that $I_{3\text{SAT}}$ can have t clauses simultaneously satisfied if and only if I_{MIS} has an independent set of size t . Moreover, the problem instances have size linear to each other. This gives a SPTAS reduction. ◀

► **Lemma 25.** For every constant $c \geq 3$, MAX INDEPENDENT SET for sparse graphs of girth $\geq c$ is strongly **APX**-hard.

Proof. Let I_s (resp. $I_{s, g \geq c}$) be an instance of MAX INDEPENDENT SET for sparse graphs (resp. MAX INDEPENDENT SET for sparse graphs of girth $\geq c$). One can map I_s to $I_{s, g \geq c}$ by replacing each edge (v_a, v_b) with a path from v_a to v_b with $2c$ internal nodes, as shown in [44]. Hence, $I_{s, g \geq c}$ has girth $\geq 6c + 3$, and I_s has an independent set t if and only if $I_{s, g \geq c}$ has an independent set of size $t + cm$. Every $(1 - \varepsilon)$ -approximation for $I_{s, g \geq c}$ determines that $I_{s, g \geq c}$ has an independent set of size $(1 - \varepsilon)(t + cm)$, which corresponds to I_s having an independent set of size $(1 - \varepsilon)t - \varepsilon cm = (1 - O(\varepsilon))t$, where the equality holds because c is a constant and $t = \Omega(n) = \Omega(m)$ by Turán's Theorem. Moreover, the problem instances have size linear to each other. This gives a SPTAS reduction. ◀

C Inapproximability Constants

Lastly, for each problem in the syntactically-defined class that does not admit a PTAS, we determine an inapproximability constant $1 - \varepsilon$, so that it cannot be $(1 - \varepsilon)$ -approximated unless $\mathbf{P} = \mathbf{NP}$. We use the facts that MAX INDEPENDENT SET on 3-regular graphs cannot be approximated to within the constant $C_3 = 139/140 + \varepsilon$ for any constant $\varepsilon > 0$ [12], and MAX INDEPENDENT SET on 3-regular triangle-free graphs can not be approximated to within the constant $C_{3\Delta} = 1422/1432 + \varepsilon$ for any constant $\varepsilon > 0$ [18].

16:22 Syntactic Separation of Subset Satisfiability Problems

We first apply Lemma 13 to bound an inapproximability constant $1 - \delta_r$ based on C_3 and then replace the use of Turán's Theorem in Lemma 13 with the AKS Theorem [4] and Staton's result [52] to bound the claimed inapproximability constant $1 - \varepsilon_r$ based on $C_{3\Delta}$.

Since MAX INDEPENDENT SET on 3-regular graphs cannot be approximated to within C_3 , from Lemma 13 we have following theorem:

► **Lemma 26.** *For every homogeneous, r -variate ($r \geq 3$), linear function $\ell(\mathbf{x})$, SUBSET-CSAT($\{\ell(\mathbf{x})\}$) cannot be approximated to within any constant factor larger than $1 - \delta_r$ in polynomial time unless $\mathbf{P} = \mathbf{NP}$, where $\delta_r = \frac{1-C_3}{7+6(r-3)}$.*

Simply replacing C_3 with $C_{3\Delta}$ cannot increase δ_r because $C_3 < C_{3\Delta}$ and such a replacement in Lemma 26 makes δ_r smaller. Instead, we replace the use of Turán's Theorem, which applies to general graphs, with the AKS Theorem (see Theorem 27), which works for triangle-free graphs. In [3, 50], the constant in the big-Omega notation in AKS Theorem is bounded above by $1/100$ and $1/8$, respectively. Though the size of an independent set guaranteed by the AKS theorem is asymptotically larger than that of Turán theorem, it is numerically smaller when $d = 3$.

► **Theorem 27 (AKS Theorem [4]).** *Every d -regular triangle-free graph has an independent set of size $\Omega(n \log d/d)$.*

Note that the constant in the big-Omega notation is universal for every d . For a particular value of d the constant can be larger. In particular, in [52] Staton shows that every 3-regular triangle-free graph has an independent set of size $5m/21$, which is more than the $m/6$ guaranteed by Turán's theorem. The constant $5/21$ is tight due to Fajtlowicz [27]. Based on this improved guarantee of the size of an independent set, we obtain the following result.

► **Lemma 28.** *For each homogeneous, r -variate, linear function $\ell(\mathbf{x})$, SUBSET-CSAT($\{\ell(\mathbf{x})\}$) cannot be approximated to within any constant factor larger than $1 - \varepsilon_r$ in polynomial time unless $\mathbf{P} = \mathbf{NP}$, where $\varepsilon_r = 1 - \frac{1-C_{3\Delta}}{5.2+4.2(r-3)}$.*

Lemma 28 and the proof of Theorem 2 together imply that:

► **Theorem 29.** *Let L be a finite set of homogeneous linear functions whose coefficients are in \mathbb{Z} . If L contains a homogeneous r -variate linear function $\ell(\mathbf{x})$ for some $r \geq 3$, then SUBSET-CSAT(L) cannot be approximated to within any constant factor larger than $1 - \varepsilon_r$ in polynomial time unless $\mathbf{P} = \mathbf{NP}$, where $\varepsilon_r = 1 - \frac{1-C_{3\Delta}}{5.2+4.2(r-3)}$.*

To obtain the inapproximability constants for SUBSET-DSAT(L), we need Lemma 30.

► **Lemma 30.** *MAX INDEPENDENT SET for graphs whose maximum degree ≤ 3 and girth $\geq g$ cannot be approximated to within any constant factor larger than $1 - \varepsilon_g$ in polynomial time unless $\mathbf{P} = \mathbf{NP}$, where $\varepsilon_g < \frac{1}{140(6\lceil(g-3)/6\rceil+1)}$.*

Proof. We prove this by giving a PTAS reduction from MAX INDEPENDENT SET for 3-regular graphs $G_{3r} = (V_{3r}, E_{3r})$ to MAX INDEPENDENT SET for graphs $G_{g+} = (V_{g+}, E_{g+})$ of girth $\geq g$. We obtain G_{g+} from G_{3r} by replacing each edge in E_{3r} with a path of length $2t + 1$ ($t \in \mathbb{Z}$), connecting $2t$ new nodes. Hence, the smallest cycle in G_{g+} is $3 + 6t$. We pick $t = \lceil (g-3)/6 \rceil$ so that G_{g+} has no cycle of length $< g$.

It is known [44] that G_{g+} has an independent set of size $t|E_{3r}| + k$ iff G_{3r} has an independent set of size k . Every $(1 - \varepsilon)$ -approximation algorithm for MAX INDEPENDENT SET of G_{g+} can find an independent set of size $(1 - \varepsilon)(t|E_{3r}| + k)$, which corresponds to an

independent set of size $(1 - \varepsilon)k - \varepsilon t|E_{3r}| \geq (1 - (6t + 1)\varepsilon)k$ in G_{3r} , where the last inequality follows from the fact that $k \geq |E_{3r}|/6$ for every 3-regular graph, due to Turán's Theorem [53].

Based on [12], MAX INDEPENDENT SET for 3-regular graphs cannot be approximated to within $1 - \varepsilon_{3r}$ for any $\varepsilon_{3r} < 1/140$. Thus, ε cannot be less than $\frac{1}{140(6t+1)} = \frac{1}{140(6\lceil(g-3)/6\rceil+1)}$. ◀

In the proof of Theorem 3, the girth g is set as $r + 1$, where r denotes $|\mathbf{x}|$. Hence, we get:

► **Theorem 31.** *Let L be a finite set of homogeneous linear functions whose coefficients are in \mathbb{Z} . For each SUBSET-DSAT(L), if the solutions to $\bigvee_{\ell \in L} \ell(\mathbf{x}) = \text{FALSE}$ form a vector space in general position and has dimension at least 2, then SUBSET-DSAT(L) cannot be approximated to within any constant factor larger than $1 - \varepsilon_r$ in polynomial time unless $\mathbf{P} = \mathbf{NP}$, where $\varepsilon_r = \frac{1}{140(6\lceil(r-2)/6\rceil+1)}$.*

Malleable Scheduling Beyond Identical Machines

Abstract

In malleable job scheduling, jobs can be executed simultaneously on multiple machines with the processing time depending on the number of allocated machines. Jobs are required to be executed non-preemptively and in unison, in the sense that they occupy, during their execution, the same time interval over all the machines of the allocated set. In this work, we study generalizations of malleable job scheduling inspired by standard scheduling on unrelated machines. Specifically, we introduce a general model of malleable job scheduling, where each machine has a (possibly different) speed for each job, and the processing time of a job j on a set of allocated machines S depends on the total speed of S for j . For machines with unrelated speeds, we show that the optimal makespan cannot be approximated within a factor less than $\frac{e}{e-1}$, unless $P = NP$. On the positive side, we present polynomial-time algorithms with approximation ratios $\frac{2e}{e-1}$ for machines with unrelated speeds, 3 for machines with uniform speeds, and $7/3$ for restricted assignments on identical machines. Our algorithms are based on deterministic LP rounding and result in sparse schedules, in the sense that each machine shares at most one job with other machines. We also prove lower bounds on the integrality gap of $1 + \varphi$ for unrelated speeds (φ is the golden ratio) and 2 for uniform speeds and restricted assignments. To indicate the generality of our approach, we show that it also yields constant factor approximation algorithms (i) for minimizing the sum of weighted completion times; and (ii) a variant where we determine the effective speed of a set of allocated machines based on the L_p norm of their speeds.

1 Introduction

Since the late 60s, various models have been proposed by researchers [7, 8] in order to capture the real-world aspects and particularities of multiprocessor task scheduling systems, i.e., large collections of identical processors able to process tasks in parallel. High performance computing, parallel architectures, and cloud services are typical applications that motivate the study of multiprocessor scheduling, both theoretical and practical. An influential model is Rayward-Smith’s unit execution time and unit communication time (UET-UCT) model [22], where each parallel job is partitioned into a set of tasks of unit execution time and these tasks are subject to precedence constraints modeled by a task graph. The UET-UCT model and its generalizations have been widely studied and a large number of (approximation) algorithms and complexity results have been proposed [10, 20].

However, the UET-UCT model mostly focuses on task scheduling and sequencing, and does not account for the amount of resources allocated to each job, thus failing to capture an important aspect of real-world parallel systems. Specifically, in the UET-UCT model, the level of granularity of a job (that is, the number of smaller tasks that a job is partitioned into) is decided a priori and is given as part of the input. However, it is common ground in the field of parallel processing that the unconditional allocation of resources for the execution of a job may jeopardize the overall efficiency of a multiprocessor system. A theoretical explanation is provided by Amdahl’s law [1], which suggests that the speedup of a job’s execution can be estimated by the formula $\frac{1}{(1-p)+\frac{p}{s}}$, where p is the fraction of the job that can be parallelized and s is the speedup due to parallelization (i.e., s can be thought as the number of processors).

Malleable Scheduling. An interesting alternative to the UET-UCT model is that of *malleable*¹ job scheduling [5, 24]. In this setting, a set \mathcal{J} of jobs is scheduled on a set \mathcal{M} of parallel machine(-s), while every job can be processed by more than one machines at the same time (i.e., by partitioning the job into tasks). In order to quantify the effect of parallelization, the processing time of a job $j \in \mathcal{J}$ is determined by a function $f_j : \mathbb{N} \rightarrow \mathbb{R}_+^2$ depending on the number of allocated machines. Moreover, every job must be executed *non-preemptively* and in *unison*, i.e. having the same starting and completion time on each of the allocated machines. Thus, if a job j is assigned to a set of machines S starting at time τ , all machines in S are occupied with job j during the interval $[\tau, \tau + f_j(|S|)]$. It is commonly assumed that the processing time function of a job exhibits two useful and well-motivated properties:

- For every job $j \in \mathcal{J}$, the processing time $f_j(s)$ is *non-increasing* in the number of machines.³
- The total *work* of the execution of a job j on s machines, that is the product $s \cdot f_j(s)$, is *non-decreasing* in the number of machines.

The latter property, known as *monotonicity* of a malleable job, is justified by Brent’s law [3]: One cannot expect superlinear speedup by increasing the level of parallelism. A great deal of theoretical results have been published on scheduling malleable jobs according to the above model (and its variants) for the objective of minimizing the *makespan*, i.e., the completion time of the last finishing job, or other standard objectives (see, e.g., [6] and the references therein).

¹ Malleable scheduling also appears as *foldable*, while sometimes the two terms refer to slightly different models.

² We denote by \mathbb{R}_+ (resp. \mathbb{Z}_+) the set of non-negative reals (resp. integers).

³ This property holds w.l.o.g., as the system always has the choice not to use some of the allocated machines.

Although malleable job scheduling represents a valiant attempt to capture real-world aspects of massively parallel processing, the latter exhibits even more complicated characteristics. Machine heterogeneity, data locality and hardware interconnection are just a few aspects of real-life systems that make the generalization of the aforementioned model necessary. In modern multiprocessor systems, machines are not all identical and the processing time of a job not only depends on the quantity, but also on the quality of the set of allocated machines. Indeed, different physical machines may have different capabilities in terms of faster CPUs or more efficient cache hierarchies. Moreover, the above heterogeneity may be job-dependent, in the sense that a specific machine may be faster when executing a certain type of jobs than another (e.g., memory- vs arithmetic-intensive applications [21]). Finally, the execution of a job on specific combinations of machines may also yield additional benefit (e.g., machines that are local in terms of memory hierarchy).

Our Model: Malleable Scheduling on Unrelated Machines. Quite surprisingly, no results exist on scheduling malleable jobs beyond the case of identical machines, to the best of our knowledge, despite the significant theoretical and practical interest in the model. In this work, we extend the model of malleable job scheduling to capture more delicate aspects of parallel job scheduling. In this direction, while we still require our jobs to be executed non-preemptively and in unison, the processing time of a job $j \in \mathcal{J}$ becomes a set function $f_j(S)$, where $S \subseteq \mathcal{M}$ is the set of allocated machines. We require that processing times are given by a *non-increasing* function, in the set function context, while additional assumptions on the scalability of f_j are made, in order to capture the *diminishing utility* property implied by Brent's law.

These assumptions naturally lead to a generalized malleable job setting, where processing times are given by non-increasing supermodular set functions $f_j(S)$, accessed by value queries. We show that makespan minimization in this general setting is inapproximable within $\mathcal{O}(|\mathcal{J}|^{1-\varepsilon})$ factors (unless $P = NP$, see Section 4.3). The general message of the proof is that unless we make some relatively strong assumptions on processing times (in the form e.g., of a relatively smooth gradual decrease in the processing time, as more machines are allocated), malleable job scheduling (even with monotone supermodular processing times) can encode combinatorial problems as hard as graph coloring.

Thus, inspired by (standard non-malleable) scheduling models on uniformly related and unrelated machines, we introduce the notion of *speed-implementable* processing time functions. For each machine i and each job j there is a *speed* $s_{i,j} \in \mathbb{Z}_+$ that quantifies the contribution of machine i to the execution of job j , if i is included in the set allocated to j . For most of this work, we assume that the total speed of an allocated set is given by an additive function $\sigma_j(S) = \sum_{i \in S} s_{i,j}$ (but see also Section 4.1, where we discuss more general speed functions based on L_p -norms). A function is speed-implementable if we can write $f_j(S) = f_j(\sigma_j(S))$ for some function $f_j : \mathbb{R}_+ \rightarrow \mathbb{R}_+$. Again, we assume oracle access to the processing time functions.⁴

The notion of speed-implementable processing times allows us to quantify the fundamental assumptions of *monotonicity* and *diminishing utility* in a clean and natural way. More specifically, we make the following two assumptions on speed-implementable functions:

1. *Non-increasing processing time.* For every job $j \in \mathcal{J}$, the processing time $f_j(s)$ is non-increasing in the total allocated speed $s \in \mathbb{R}_+$.
2. *Non-decreasing work.* For every job $j \in \mathcal{J}$, the work $f_j(s) \cdot s$ is non-decreasing in the total allocated speed $s \in \mathbb{R}_+$.

⁴ For convenience, we use the identifier f_j for both functions. Since their arguments come from disjoint domains, it is always clear from the context which one is meant.

The first assumption ensures that allocating more speed cannot increase the processing time. The second assumption is justified by Brent's law, when the increase in speed coincides with an increase in the physical number of machines, or by similar arguments for the increase of the total speed of a single physical machine (e.g., memory access, I/O bottleneck [21] etc.). We remark that speed-implementable functions with non-increasing processing times and non-decreasing work do not need to be convex, and thus, do not belong to the class of supermodular functions.

In this work, we focus on the objective of minimizing the *makespan* $C_{max} = \max_{j \in \mathcal{J}} C_j$, where C_j the completion time of job j . We refer to this setting as the problem of *scheduling malleable jobs on unrelated machines*. To further justify this term, we present a pseudopolynomial transformation of standard scheduling on unrelated machines to malleable scheduling with speed-implementable processing times (see the full version of this reading). The reduction can be rendered polynomial by standard techniques, preserving approximation factors with a loss of $1 + \varepsilon$.

1.1 Related Work

The problem of malleable job scheduling on identical machines has been studied thoroughly for more than three decades. For the case of non-monotonic jobs, i.e., jobs that do not satisfy the monotonic work condition, Du and Leung [5] show that the problem is strongly NP-hard for more than 5 machines, while in terms of approximation, Turek, Wolf and Yu [24] provided the first 2-approximation algorithm for the same version of the problem. Jansen and Porkolab [13] devised a PTAS for instances with a constant number of machines, which was later extended by Jansen and Thöle [15] to a PTAS for the case that the number of machines is polynomial in the number of jobs.

For the case of monotonic jobs, Mounié, Rapine and Trystram [19] propose a $\frac{3}{2}$ -approximation algorithm, improving on the $\sqrt{3}$ -approximation provided by the same authors [18]. Recently, Jansen and Land [12] gave an FPTAS for the case that $|\mathcal{M}| \geq 8|\mathcal{J}|/\varepsilon$. Together with the approximation scheme for polynomial number of machines in [12], this implies a PTAS for scheduling monotonic malleable jobs on identical machines.

Several papers also consider the problem of scheduling malleable jobs with preemption and/or under precedence constraints [2, 14, 17]. An interesting alternative approach to the general problem is that of Srinivasa, Prasanna, and Musicus [23], who consider a continuous version of malleable tasks and develop an exact algorithm based on optimal control theory under certain assumptions on the processing time functions. While the problem of malleable scheduling on identical machines is very well understood, this is not true for malleable extensions of other standard scheduling models, such as unrelated machines or the restricted assignment model. We attempt to close this gap by introducing and investigating malleable scheduling with speed-implementable processing time functions.

A scheduling model similar to malleable tasks is that of *splittable jobs*. In this regime, jobs can be split arbitrarily and the resulting parts can be distributed arbitrarily on different machines. For each pair of job j and machine i , there is a setup time s_{ij} and a processing time p_{ij} . If a fraction $x_{ij} \in (0, 1]$ of job j is to be scheduled on machine i , the load that is incurred on the machine is $s_{ij} + p_{ij}x_{ij}$. Correa et al. [4] provide an $(1 + \varphi)$ -approximation algorithm for this setting (where φ is the golden ratio), which is based on an adaptation of the classic LP rounding result by Lenstra, Shmoys, and Tardos [16] for the traditional unrelated machine scheduling problem. We remark that the generalized malleable setting considered in this paper also induces a natural generalization of the splittable setting beyond setup times, when dropping the requirement that jobs need to be executed in unison. As

in [4], we provide a rounding framework based on a variant of the assignment LP from [16]. However, the fact that processing times are only given implicitly as functions in our setting makes it necessary to very carefully choose the coefficients of the assignment LP in order to ensure a constant integrality gap. Furthermore, because jobs have to be executed in unison, we employ a more sophisticated rounding scheme in order to better utilize free capacity on different machines.

1.2 Contribution and Techniques

At the conceptual level, we introduce the notion of malleable jobs with speed-implementable processing times. Hence, we generalize the standard and well-studied setting of malleable job scheduling, in a direct analogy to fundamental models in scheduling theory (e.g., scheduling on *uniformly related* and *unrelated* machines). This new and much richer model gives rise to a large family of unexplored packing problems that may be of independent interest. All omitted proofs can be found in the full version of this paper (see <https://arxiv.org/abs/1903.11016>).

From a technical viewpoint, we investigate the computational complexity and the approximability of this new setting. To the best of our understanding, standard techniques used for makespan minimization in the setting of malleable job scheduling on identical machines, such as the two-shelve approach (as used in [19, 24]) and area charging arguments, fail to yield any reasonable approximation guarantees in our more general setting. This intuition is supported by the following hardness of approximation result.

► **Theorem 1.** *For any $\epsilon > 0$, there is no $(\frac{e}{e-1} - \epsilon)$ -approximation algorithm for the problem of scheduling malleable jobs on unrelated machines, unless $P = NP$.*

Note that the lower bound of $\frac{e}{e-1}$ is strictly larger than the currently best known approximation factor of 1.5 for malleable scheduling on identical machines.

Our positive results are based on a linear programming relaxation, denoted by $[LP(C)]$ and described in Section 2. This LP resembles the assignment LP for the standard setting of non-malleable scheduling [16]. However, in order to obtain a constant integrality gap we distinguish between “small” jobs that can be processed on a single machine (within a given target makespan), and “large” jobs that have to be processed on multiple machines. For the large jobs, we carefully estimate their contribution to the load of their allocated machines. Specifically, we introduce the notion of *critical speed* and use the critical speed to define the load coefficients incurred by large jobs on machines in the LP relaxation by proportionally distributing the work volume according to machine speeds. For the rounding, we exploit the sparsity of our relaxation’s extreme points (as in [16]) and generalize the approach of [4], in order to carefully distinguish between jobs assigned to a single machine and jobs shared by multiple machines.

► **Theorem 2.** *There exists a polynomial-time $\frac{2e}{e-1}$ -approximation algorithm for the problem of scheduling malleable jobs on unrelated machines.*

An interesting corollary is that for malleable job scheduling on unrelated machines, there always exists an approximate solution where each machine shares at most one job with some other machines. We also get improved approximation guarantees for the special cases of *restricted assignment* and *uniform speeds*, respectively, by exploiting the special structure of the processing time functions.

► **Theorem 3.** *There exists a polynomial-time $\frac{7}{3}$ -approximation algorithm for the problem of scheduling malleable jobs on restricted identical machines (i.e., $s_{i,j} \in \{0, 1\}$ for all $i \in \mathcal{M}$ and $j \in \mathcal{J}$).*

► **Theorem 4.** *There exists a polynomial-time 3-approximation algorithm for the problem of scheduling malleable jobs on uniform machines (i.e., $s_{i,j} = s_i$ for all $i \in \mathcal{M}$ and $j \in \mathcal{J}$).*

All our approximation results imply corresponding upper bounds on the integrality gap of the linear programming relaxation $[\text{LP}(C)]$. Based on an adaptation of a construction in [4], we show a lower bound of $1 + \varphi \approx 2.618$ on the integrality gap of $[\text{LP}(C)]$ for malleable job scheduling on unrelated machines, where φ is the golden ratio. For the cases of restricted assignment and uniformly related machines, respectively, we obtain an integrality gap of 2.

Moreover, we extend our model and approach in two directions. First, we consider a setting where the *effective speed* according to which a set S of allocated machines processing a job j is given by the L_p -norm $\sigma_j^{(p)}(S) = (\sum_{i \in S} (s_{i,j})^p)^{1/p}$ of the corresponding speed vector. In practical settings, we tend to prefer assignments to relatively small sets of physical machines, so as to avoid delays related to communication, memory access, and I/O (see e.g., [21]). By replacing the total speed (i.e., the L_1 -norm) with the L_p -norm of the speed vector for some $p \geq 1$, we discount the contribution of additional machines (especially of smaller speeds) towards processing a job j . Thus, as p increases, we give stronger preference to *sparse* schedules, where the number of jobs shared between different machines (and the number of machines sharing a job) are kept small. Interestingly, our general approach is robust to this generalization and results in constant approximation factors for any $p \geq 1$. Asymptotically, the approximation factor is bounded by $\frac{p}{p-\ln p} + \sqrt[p]{\frac{p}{\ln p}}$ and our algorithm smoothly converges to the algorithm of [16] as p tends to infinity. For the extreme case where we use the L_∞ -norm, our setting becomes identical to standard scheduling on unrelated machines and we recover the algorithm of [16], achieving an approximation ratio of 2. These results are discussed in Section 4.1.

In another direction, we combine our approach for makespan minimization with standard techniques employed for the objective of total weighted completion time, $\sum_{j \in \mathcal{J}} w_j C_j$, and obtain a constant factor approximation for minimizing the total weighted completion time for malleable job scheduling on unrelated machines. These results are discussed in Section 4.2.

Trying to generalize malleable job scheduling beyond the simple setting of identical machines, as much as possible, we believe that our setting with speed-implementable processing times lies on the frontier of the constant-factor approximability regime. We show a strong inapproximability lower bound of $\mathcal{O}(|\mathcal{J}|^{1-\varepsilon})$ for the (far more general) setting where the processing times are given by a non-increasing supermodular set functions. These results are discussed in Section 4.3. An interesting open question is to characterize the class of processing time functions for which malleable job scheduling admits constant factor (and/or logarithmic) approximation guarantees.

2 The general rounding framework

In this section, we provide a high-level description of our algorithm. We construct a polynomial-time ρ -relaxed decision procedure for malleable job scheduling problems. This procedure takes as input an instance of the problem as well as a target makespan C and either asserts correctly that there is no feasible schedule of makespan at most C , or returns a feasible schedule of makespan at most ρC . It is well-known that a ρ -relaxed decision procedure can

be transformed into a polynomial-time ρ -approximation algorithm [11] provided that one can compute proper lower and upper bounds to the optimal value of size polynomial in the size of the input.

Given a target makespan C , let $\gamma_j(C) := \min\{q \in \mathbb{Z}_+ \mid f_j(q) \leq C\}$ be the *critical speed* of job $j \in \mathcal{J}$. Moreover, we define for every $i \in \mathcal{M}$ the sets $J_i^+(C) := \{j \mid f(s_{i,j}) \leq C\}$ and $J_i^-(C) := \mathcal{J} \setminus J_i^+(C)$ to be the set of jobs that can or cannot be processed by i alone within time C , respectively. Note that $\gamma_j(C)$ can be computed in polynomial-time given oracle access to f_j by performing binary search. When C is clear from the context, we use the short-hand notation γ_j , J_i^+ , and J_i^- instead. The following technical fact is equivalent to the non-decreasing work property and is used throughout the proofs of this paper:

► **Fact 5.** *Let f be a speed-implementable processing time function satisfying the properties of our problem. Then for every speed $q \in \mathbb{R}_+$ we have that:*

1. $f(\alpha q) \leq \frac{1}{\alpha} f(q)$ for every $\alpha \in (0, 1)$, and
2. $f(q') \leq \frac{q}{q'} f(q)$ for every $q' \leq q$.

The following feasibility LP is the starting point of the relaxed decision procedures we construct in this work:

$$[\text{LP}(C)]: \quad \sum_{i \in \mathcal{M}} x_{i,j} = 1 \quad \forall j \in \mathcal{J} \quad (1)$$

$$\sum_{j \in J_i^+} f_j(s_{i,j}) x_{i,j} + \sum_{j \in J_i^-} \frac{f_j(\gamma_j) \gamma_j}{s_{i,j}} x_{i,j} \leq C \quad \forall i \in \mathcal{M} \quad (2)$$

$$x_{i,j} \geq 0 \quad \forall j \in \mathcal{J}, i \in \mathcal{M} \quad (3)$$

In the above LP, each variable $x_{i,j}$ can be thought as the fraction of job j that is assigned to machine i . The equality constraints (1) ensure that each job is fully assigned to a subset of machines, while constraints (2) impose an upper bound to the load of every machine. As we can prove, the above formulation is feasible for any C that is greater than the optimal makespan.

► **Proposition 6.** *For every $C \geq \text{OPT}$, where OPT is the makespan of an optimal schedule, $[\text{LP}(C)]$ has a feasible solution.*

Proof. Fix a schedule of makespan OPT and let $S_j \subseteq \mathcal{M}$ be the set of machines allocated to a job j in that schedule. For every $i \in \mathcal{M}, j \in \mathcal{J}$ set $x_{i,j} = \frac{s_{i,j}}{\sigma_j(S_j)}$ if $i \in S_j$ and $x_{i,j} = 0$, otherwise. We show that x is a feasible solution to $[\text{LP}(C)]$. Indeed, constraints (1) are satisfied since $\sum_{i \in \mathcal{M}} x_{i,j} = \sum_{i \in S_j} \frac{s_{i,j}}{\sigma_j(S_j)} = 1$ for all $j \in \mathcal{J}$. For verifying that constraints (2) are fulfilled, let $j \in \mathcal{J}$ and $i \in S_j$. If $j \in J_i^+$ then $f_j(s_{i,j}) x_{i,j} = f_j(s_{i,j}) \frac{s_{i,j}}{\sigma_j(S_j)} \leq f_j(S_j)$, using Fact 5. If $j \in J_i^-$ then $\frac{f_j(\gamma_j) \gamma_j}{s_{i,j}} x_{i,j} = \frac{f_j(\gamma_j) \gamma_j}{\sigma_j(S_j)} \leq \frac{\sigma_j(S_j) f_j(S_j)}{\sigma_j(S_j)} \leq f_j(S_j)$, again using Fact 5 and the fact that $\sigma_j(S_j) \geq \gamma_j$. Therefore for any $i \in \mathcal{M}$ we obtain: $\sum_{j \in J_i^+} f_j(s_{i,j}) x_{i,j} + \sum_{j \in J_i^-} \frac{f_j(\gamma_j) \gamma_j}{s_{i,j}} x_{i,j} \leq \sum_{j \in \mathcal{J} \mid i \in S_j} f_j(S_j) \leq \text{OPT} \leq C$. ◀

Assuming that $C \geq \text{OPT}$, let x be an extreme point solution to $[\text{LP}(C)]$. We create the *assignment graph* $\mathcal{G}(x)$ with nodes $V := \mathcal{J} \cup \mathcal{M}$ and edges $E := \{\{i, j\} \in \mathcal{M} \times \mathcal{J} \mid x_{i,j} > 0\}$, i.e., one edge for each machine-job pair in the support of the LP solution. Notice that $\mathcal{G}(x)$ is bipartite by definition. Furthermore, since $[\text{LP}(C)]$ is structurally identical to the LP of unrelated machine scheduling [16], the choice of x as an extreme point guarantees the following sparsity property:

■ **Figure 1** A properly oriented pseudotree with indegree at most 1 for each node.

■ **Figure 2** Volume argument for selecting a subset of the children machines in the proof of Proposition 10.

► **Proposition 7** ([16]). *For every extreme point solution x of $[LP(C)]$, each connected component of $\mathcal{G}(x)$ contains at most one cycle.*

As a graph with at most one cycle is either a tree or a tree plus one edge, the connected components of $\mathcal{G}(x)$ are called *pseudotrees* and the whole graph is called a *pseudoforest*. It is not hard to see that the edges of an undirected pseudoforest can always be oriented in a way that every node has an *in-degree* of at most one. We call such a $\mathcal{G}(x)$ a *properly oriented pseudoforest*. Such an orientation can easily be obtained by first orienting the edges on the unique cycle (if it exists) consistently so as to obtain a directed cycle and, then, by orienting all remaining edges away from that cycle (see Figure 1).

Now fix a properly oriented $\mathcal{G}(x)$ with set of oriented edges \bar{E} . For $j \in \mathcal{J}$, we define $p(j) \in \mathcal{M}$ to be its unique *parent-machine* (if it exists) and $T(j) = \{i \in \mathcal{M} \mid (j, i) \in \bar{E}\}$ to be the set of *children-machines* of j , respectively. Notice, that for every machine i , there exists at most one $j \in \mathcal{J}$ such that $i \in T(j)$. The decision procedures we construct in this paper are based, unless otherwise stated, on the following scheme:

ALGORITHM: Given a target makespan C :

1. If $[LP(C)]$ is feasible, compute an extreme point solution x of $[LP(C)]$ and construct a properly oriented $\mathcal{G}(x)$. (Otherwise, report that $C < \text{OPT}$.)
2. A *rounding scheme* assigns every job $j \in \mathcal{J}$ either only to its parent machine $p(j)$, or to the set of its children-machines $T(j)$ (see Section 3).
3. According to the rounding, every job $j \in \mathcal{J}$ that has been assigned to $T(j)$ is placed at the beginning of the schedule (these jobs are assigned to disjoint sets of machines).
4. At any point a machine i becomes idle, it processes any unscheduled job j that has been rounded to i such that $i = p(j)$.

3 Rounding schemes

In each of the following rounding schemes, we are given as an input an extreme point solution x of $[LP(C)]$ and a properly oriented pseudoforest $\mathcal{G}(x) = (V, \bar{E})$.

3.1 A simple 4-approximation for unrelated machines

We start from the following simple rounding scheme: For each job j , assign j to its parent-machine $p(j)$ if $x_{p(j),j} \geq \frac{1}{2}$, or else, assign j to its children-machines $T(j)$. Formally, let $\mathcal{J}^{(1)} := \{j \in \mathcal{J} \mid x_{p(j),j} \geq \frac{1}{2}\}$ be the sets of jobs that are assigned to their parent-machines and $\mathcal{J}^{(2)} := \mathcal{J} \setminus \mathcal{J}^{(1)}$ the rest of the jobs. Recall that we first run the jobs

in $\mathcal{J}^{(2)}$ and then the jobs in $\mathcal{J}^{(1)}$ as described at the end of the previous section. For $i \in \mathcal{M}$, define $J_i^{(1)} := \{j \in \mathcal{J}^{(1)} \mid p(j) = i\}$ and $J_i^{(2)} := \{j \in \mathcal{J}^{(2)} \mid i \in T(j)\}$ as the sets of jobs in $\mathcal{J}^{(1)}$ and $\mathcal{J}^{(2)}$, respectively, that get assigned to i (note that $|J_i^{(2)}| \leq 1$, as each machine gets assigned at most one job as a child-machine). Furthermore, let $\ell_i := \sum_{j \in J_i^+ \cap \mathcal{J}^{(1)}} f_j(s_{i,j})x_{i,j} + \sum_{j \in J_i^- \cap \mathcal{J}^{(1)}} f_j(\gamma_j) \frac{\gamma_j}{s_{i,j}} x_{i,j}$ be the fractional load incurred by jobs in $J_i^{(1)}$ on machine i in the LP solution x .

► **Proposition 8.** *Let $i \in \mathcal{M}$. Then $\sum_{j \in \mathcal{J}^{(1)}} f_j(\{i\}) \leq 2\ell_i$.*

Proof. Let $j \in J_i^{(1)}$. Since $x_{i,j} \geq \frac{1}{2}$ by definition of $\mathcal{J}^{(1)}$, we get $f_j(s_{i,j}) \leq 2f_j(s_{i,j})x_{i,j}$. Furthermore, if $j \in J_i^-$ then $f_j(s_{i,j})x_{i,j} \leq f_j(\gamma_j) \frac{\gamma_j}{s_{i,j}} x_{i,j}$ by Fact 5 and the fact that $s_{i,j} < \gamma_j$. Thus, by summing up over all jobs in $J_i^{(1)}$ and then applying constraints (2), we get

$$\sum_{j \in J_i^{(1)}} f_j(\{i\}) \leq 2 \left(\sum_{j \in J_i^{(1)} \cap J_i^+} f_j(s_{i,j})x_{i,j} + \sum_{j \in J_i^{(1)} \cap J_i^-} \frac{f_j(\gamma_j)\gamma_j}{s_{i,j}} x_{i,j} \right) \leq 2\ell_i. \quad \blacktriangleleft$$

► **Proposition 9.** *Let $j \in \mathcal{J}^{(2)}$. Then $f_j(T(j)) \leq 2C$.*

Proof. If there is a machine $i \in T(j)$ with $j \in J_i^+$, then $f_j(T(j)) \leq f_j(\{i\}) \leq C$. So we can assume that $j \in J_i^-$ for all $i \in T(j)$. Hence constraints (2) imply $f_j(\gamma_j) \frac{\gamma_j}{s_{i,j}} x_{i,j} \leq C$ for all $i \in T(j)$. Summing these constraints yields $\sum_{i \in T(j)} \frac{f_j(\gamma_j)}{C} \gamma_j x_{i,j} \leq \sigma_j(T(j))$. Using the fact that $f_j(\gamma_j) \leq C$ by definition of γ_j and $\sum_{i \in T(j)} x_{i,j} > \frac{1}{2}$ because $j \in \mathcal{J}^{(2)}$, we get $\sigma_j(T(j)) \geq \frac{1}{2} \gamma_j \frac{f_j(\gamma_j)}{C}$. This implies $f_j(T(j)) \leq 2C$ by Fact 5. ◀

Clearly, the load of any machine $i \in \mathcal{M}$ in the final schedule is the sum of the load due to the execution of $\mathcal{J}^{(1)}$, plus the processing time of at most one job of $\mathcal{J}^{(2)}$. By Proposition 8 and 9, it follows that any feasible solution of [LP(C)] can be rounded in polynomial-time into a feasible schedule of makespan at most $4C$.

3.2 An improved $\frac{2e}{e-1} \approx 3.163$ -approximation for unrelated machines

In the simple rounding scheme described above, it can be the case that the overall makespan improves by assigning some job $j \in \mathcal{J}^{(2)}$ only to a subset of the machines in $T(j)$. This happens because some machines in $T(j)$ may have significantly higher load from jobs of $\mathcal{J}^{(1)}$ than others, but job j will incur the same additional load to all machines it is assigned to.

We can improve the approximation guarantee of the rounding scheme by taking this effect into account and filtering out children-machines with a high load. Define $\mathcal{J}^{(1)}$ and $\mathcal{J}^{(2)}$ as before. Every job in $j \in \mathcal{J}^{(1)}$ is assigned to its parent-machine $p(j)$, while every job $j \in \mathcal{J}^{(2)}$ is assigned to a subset of $T(j)$ as follows.

For $j \in \mathcal{J}^{(2)}$ and $\theta \in [0, 1]$ define $S_j(\theta) := \{i \in T(j) \mid 1 - \frac{\ell_i}{C} \geq \theta\}$. Choose θ_j so as to minimize $2(1 - \theta_j)C + f_j(\theta_j)$ (note that this minimizer can be determined by trying out at most $|T(j)|$ different values for θ_j). We then assign each job in $j \in \mathcal{J}^{(2)}$ to the machine set $S_j(\theta_j)$.

By Proposition 8, we know that the total load of each machine $i \in \mathcal{M}$ due to the execution of jobs from $\mathcal{J}^{(1)}$ is at most $2\ell_i$. Recall that there is at most one $j \in \mathcal{J}^{(2)}$ with $i \in T(j)$. If $i \notin S_j(\theta_j)$, then load of machine i bounded by $2\ell_i \leq 2C$. If $i \in S_j(\theta_j)$, then the load of machine i is bounded by

$$\max_{i' \in S_j(\theta_j)} \left\{ 2\ell_{i'} + f_j(S_j(\theta_j)) \right\} \leq 2(1 - \theta_j)C + f_j(S_j(\theta_j)), \quad (4)$$

17:10 Malleable Scheduling Beyond Identical Machines

where the inequality comes from the fact that $1 - \frac{\ell_{i'}}{C} \geq \theta_j$ for all $i' \in S_{\theta_j}$. The following proposition gives an upper bound on the RHS of (4) as a result of our filtering technique and proves Theorem 2.

► **Proposition 10.** *For each $j \in \mathcal{J}^{(2)}$, there is a $\theta \in [0, 1]$ with $2(1 - \theta)C + f_j(S_j(\theta)) \leq \frac{2e}{e-1}C$.*

Proof. Define $\alpha := \frac{2e}{e-1}$. We show that there is a $\theta \in [0, 1]$ with $\sigma_j(S_j(\theta)) \geq \frac{\gamma_j f_j(\gamma_j)}{(\alpha + 2\theta - 2)C}$. Then $f_j(S_j(\theta)) \leq (\alpha + 2\theta - 2)C$ by Fact 5, implying the lemma.

Define the function $g : [0, 1] \rightarrow \mathbb{R}_+$ by $g(\theta) := \sigma_j(S_j(\theta))$. It is easy to see g is non-increasing integrable and that

$$\int_0^1 g(\theta) d\theta = \sum_{i \in T(j)} s_{i,j} \left(1 - \frac{\ell_i}{C}\right).$$

See Figure 2 for an illustration.

Now assume by contradiction that $g(\theta) < \frac{\gamma_j f_j(\gamma_j)}{(\alpha + 2\theta - 2)C}$ for all $\theta \in [0, 1]$. Note that $\ell_i + \frac{\gamma_j f_j(\gamma_j)}{s_{i,j}} x_{i,j} \leq C$ for every $i \in T(j)$ by constraints (2) and the fact that $\frac{\gamma_j f_j(\gamma_j)}{s_{i,j}} \leq f_j(s_{i,j})$ for all i such that $j \in J_i^+$. Hence $\frac{f_j(\gamma_j) \gamma_j}{C} x_{i,j} \leq s_{i,j} \left(1 - \frac{\ell_i}{C}\right)$ for all $i \in T(j)$. Summing over all $i \in T(j)$ and using the fact that $\sum_{i \in T(j)} x_{i,j} \geq \frac{1}{2}$ because $j \in J^{(2)}$ we get

$$\frac{f_j(\gamma_j) \gamma_j}{2C} \leq \sum_{i \in T(j)} s_{i,j} \left(1 - \frac{\ell_i}{C}\right) = \int_0^1 g(\theta) d\theta < \frac{f_j(\gamma_j) \gamma_j}{C} \int_0^1 \frac{1}{\alpha + 2\theta - 2} d\theta,$$

where the last inequality uses the assumption that $g(\theta) < \frac{\gamma_j f_j(\gamma_j)}{(\alpha + 2\theta - 2)C}$ for all $\theta \in [0, 1]$. By simplifying the above inequality, we get the contradiction

$$1 < \int_{\alpha-2}^{\alpha} \frac{1}{\lambda} d\lambda = \ln\left(\frac{\alpha}{\alpha-2}\right) = 1. \quad \blacktriangleleft$$

By the above analysis, our main result for the case of unrelated machines follows.

► **Theorem 2.** *There exists a polynomial-time $\frac{2e}{e-1}$ -approximation algorithm for the problem of scheduling malleable jobs on unrelated machines.*

► **Remark 11.** We can slightly improve the above analysis by optimizing the threshold of assigning a job to the parent. This optimization gives a slightly better approximation guarantee of $\alpha = \inf_{\beta \in (0,1)} \left\{ \frac{e^{\frac{1}{\beta}-1}}{\beta(e^{\frac{1}{\beta}-1}-1)} \right\} \approx 3.14619$.

3.3 A (7/3)-approximation for restricted identical machines

We are able to provide an algorithm of improved approximation guarantee for the special case of restricted identical machines: Each job $j \in \mathcal{J}$ is associated with a set of machines $\mathcal{M}_j \subseteq \mathcal{M}$, such that $s_{i,j} = 1$ for $i \in \mathcal{M}_j$ and $s_{i,j} = 0$, otherwise.

Given a feasible solution to [LP(C)] and a properly oriented $\mathcal{G}(x)$, we define the sets $\mathcal{J}^{(1)} := \{j \in \mathcal{J} \mid x_{p(j),j} = 1\}$ and $\mathcal{J}^{(2)} := \mathcal{J} \setminus \mathcal{J}^{(1)}$. The rounding scheme for this special case can be described as follows: **(a)** Every job $j \in \mathcal{J}^{(1)}$ is assigned to $p(j)$ (which is the only machine in $\mathcal{G}(x)$ that is assigned to j). **(b.i)** Every job of $j \in \mathcal{J}^{(2)}$ such that $|T(j)| = 1$ or $|T(j)| \geq 3$ is assigned to the set $T(j)$ of its children-machines. **(b.ii)** For every job of $j \in \mathcal{J}^{(2)}$ such that $|T(j)| = 2$, the algorithm schedules the job to the subset $S \subseteq T(j)$ that results in the minimum makespan over $T(j)$. Notice that for $|T(j)| = 2$ there are exactly three such subsets. As usual, the jobs of $\mathcal{J}^{(2)}$ are placed at the beginning of the schedule, followed by the jobs of $\mathcal{J}^{(1)}$.

► **Theorem 3.** *There exists a polynomial-time $\frac{7}{3}$ -approximation algorithm for the problem of scheduling malleable jobs on restricted identical machines (i.e., $s_{i,j} \in \{0,1\}$ for all $i \in \mathcal{M}$ and $j \in \mathcal{J}$).*

3.4 A 3-approximation for uniform machines

We prove an algorithm of improved approximation guarantee for the special case of uniform machines, i.e., every machine has a unique speed s_i such that $s_{i,j} = s_i$ for all $j \in \mathcal{J}$. Given a target makespan C , we say that a machine i is j -fast for a job $j \in \mathcal{J}$ if $j \in J_i^+$, while we say that i is j -slow if $j \in J_i^-$. As opposed to the previous cases, the rounding for the uniform case starts by transforming the feasible solution of $[\text{LP}(C)]$ into another extreme point solution that satisfies a useful structural property, as described in the following proposition.

► **Proposition 12.** *There is an extreme point solution x of $[\text{LP}(C)]$ that satisfies the following property: For each $j \in \mathcal{J}$ there is at most one j -slow machine $i \in \mathcal{M}$ such that $x_{i,j} > 0$ and $x_{i,j'} > 0$ for some job $j' \neq j$. Furthermore, this machine, if it exists, is the slowest machine that j is assigned to.*

Let x be an extreme point solution of $[\text{LP}(C)]$ that satisfies the property of Proposition 12 and let $\mathcal{G}(x)$ a properly oriented pseudoforest. By the above proposition, each job j has at most three types of assignments in $\mathcal{G}(x)$: (i) j -fast machines F_j , (ii) *exclusive* j -slow machines D_j , i.e. j -slow machines that are completely assigned to j , and (iii) at most one shared j -slow machine i_j (which is the slowest machine that j is assigned to).

We now describe the rounding scheme for the special case of uniform machines. For any job $j \in \mathcal{J}$ in any order: **(a)** If $x_{p(j),j} \geq \frac{1}{2}$ then j is assigned to its parent-machine $p(j)$, otherwise **(b)** j is assigned to a subset $S \subseteq T(j)$. In the second case, the subset S is chosen according to the following rule: **(b.i)** If $F_j \neq \emptyset$, then assign j to any $i \in F_j$, else **(b.ii)** if $\sigma_j(D_j) \geq \frac{\gamma_j f_j(\gamma_j)}{3C}$, then assign j only to the machines of D_j (but not to the shared i_j). In any other case, **(b.iii)** j is assigned to $D_j \cup \{i_j\}$.

► **Theorem 4.** *There exists a polynomial-time 3-approximation algorithm for the problem of scheduling malleable jobs on uniform machines (i.e., $s_{i,j} = s_i$ for all $i \in \mathcal{M}$ and $j \in \mathcal{J}$).*

4 Model extensions and discussion

4.1 Sparse allocations via p -norm regularization

In the model of speed-implementable processing time functions that we study in the previous sections, each function $f_j(S)$ depends on the total additive speed, yet is oblivious to the actual number of allocated machines. However, the overhead incurred by the synchronization of physical machines naturally depends on their number and we therefore need to take into account both the total speed and the cardinality of the machine set allocated to a job. In this section, we model the impact of the number of machines through the notion of *effective speed*. In this setting, every job j is associated with a speed *regularizer* $p_j \geq 1$, while the total speed of a set $S \subseteq \mathcal{M}$ is given by: $\sigma_j^{(p_j)}(S) = (\sum_{i \in S} s_{i,j}^{p_j})^{\frac{1}{p_j}}$. For simplicity, we assume that every job has the same speed regularizer, $p = p_j, \forall j \in \mathcal{J}$.

Clearly, the choice of p controls the effect of the cardinality of a set to the resulting speed of an allocation, given that as p increases a sparse set has higher effective speed than a non-sparse set of the same total speed. Notice that for $p = 1$ we return to the standard case of additive speeds, while for $p \rightarrow \infty$, parallelization is no longer helpful

as $\lim_{p \rightarrow \infty} \sigma_j^{(p)}(S) = \max_{i \in S} \{s_{i,j}\}$. As before, the processing time functions satisfy the standard properties of malleable scheduling, i.e., $f_j(s)$ is non-increasing while $f_j(s) \cdot s$ is decreasing. For simplicity of presentation we assume that all jobs have the same regularizer p , but we comment on the case of job-dependent regularizers at the end of this section.

Quite surprisingly, we can easily modify the algorithms of the previous section in order to capture the above generalization. Given a target makespan C , we start from a new feasibility program $[\text{LP}^{(p)}(C)]$, which is given by constraints (1),(3) of $[\text{LP}(C)]$, combined with:

$$\sum_{j \in J_i^+} f_j(s_{i,j})x_{i,j} + \sum_{j \in J_i^-} f_j(\gamma_j) \left(\frac{\gamma_j}{s_{i,j}} \right)^p x_{i,j} \leq C \quad \forall i \in \mathcal{M} \quad (5)$$

Note that J_i^+, J_i^- , and $\gamma_j(C)$ are defined exactly as before, and that the only difference between $[\text{LP}(C)]$ and $[\text{LP}^{(p)}(C)]$ is that we replace the coefficient $\frac{\gamma_j}{s_{i,j}}$ with $\left(\frac{\gamma_j}{s_{i,j}} \right)^p$ in constraints (2) of the former. It can be shown that for every $C \geq \text{OPT}$, where OPT is the makespan of an optimal schedule, $[\text{LP}^{(p)}(C)]$ has a feasible solution.

The algorithm for this case is similar to the one of the standard case (see Section 3.1), having $[\text{LP}^{(p)}(C)]$ as a starting point. Moreover, the rounding scheme is a parameterized version of the simple rounding of Section 3.1, with the difference that the threshold parameter $\beta \in [0, 1]$ (i.e., the parameter that controls the decision of assigning a job j to either $p(j)$ or $T(j)$) is not necessarily $\frac{1}{2}$. In short, given a pseudoforest $\mathcal{G}(x)$, the rounding scheme assigns any job j to $p(j)$ if $x_{p(j),j} \geq \beta$, or to $T(j)$, otherwise.

By similar arguments as in Propositions 8,9, it can be proved that the makespan of the produced schedule is at most $\left(\frac{1}{\beta} + \frac{1}{(1-\beta)^{1/p}} \right) C$. Therefore, the algorithm can initially compute a threshold $\beta \in [0, 1]$ that minimizes the above theoretical bound. Clearly, for $p = 1$ the minimizer of the expression is $\beta = 1/2$, yielding the 4-approximation of the standard case, while for $p \rightarrow +\infty$ one can verify that $\beta \rightarrow 1$ and:

$$\lim_{p \rightarrow +\infty} \inf_{\beta \in [0,1]} \left(\frac{1}{\beta} + \frac{1}{(1-\beta)^{1/p}} \right) = 2.$$

As expected, for the limit case where $p \rightarrow +\infty$, our algorithm converges to the well-known algorithm by Lenstra et al. [16] given that our problem becomes non-malleable. By using the standard approximation $\beta = 1 - \frac{\ln p}{p}$ for $p \geq 2$, we can prove the following theorem.

► **Theorem 13.** *Any feasible solution of $[\text{LP}^{(p)}(C)]$ for $p \geq 2$ can be rounded in polynomial-time into a feasible schedule of makespan at most $\left(\frac{p}{p-\ln p} + \sqrt[p]{\frac{p}{\ln p}} \right) C$.*

Note that an analogous approach can handle the case where jobs have different regularizers, with the approximation ratio for this scenario determined by the smallest regularizer that appears in the instance (note that the approximation factor is always at most 4).

4.2 Minimizing the $\sum_{j \in \mathcal{J}} w_j C_j$ objective

The LP-based nature of our algorithms allows the design of efficient $\mathcal{O}(1)$ -approximation algorithms for the objective of minimizing the sum of weighted completion times, i.e., $\sum_{j \in \mathcal{J}} w_j C_j$, employing the standard technique of *interval-indexed formulations* [9]. In this setting, every job $j \in \mathcal{J}$ is associated with a *weight* $w_j \in \mathbb{Z}_{\geq 0}$ and the objective is to compute a feasible schedule of minimum $\sum_{j \in \mathcal{J}} w_j C_j$, where C_j the completion time of job j . In the malleable setting, the approximation guarantee of our algorithm for the $\sum_{j \in \mathcal{J}} w_j C_j$ objective depends on the approximation guarantee of the underlying makespan problem.

► **Theorem 14.** *There exists a $\mathcal{O}(\rho)$ -approximation algorithm for the problem of malleable scheduling minimizing the $\sum_{j \in \mathcal{J}} w_j C_j$ objective, where ρ the approximation ratio of the best rounding scheme of $[LP(C)]$.*

4.3 Supermodular processing time functions

In this paper we concentrated our study on speed-implementable processing time functions. However, the general definition of malleable scheduling given in Section 1 leaves room for many other possible variants of the problem with processing times given by monotone non-increasing set functions. One natural attempt of capturing the assumption of non-decreasing workload is to assume that for each job $j \in \mathcal{J}$ the corresponding processing time function f_j is supermodular, i.e.,

$$f_j(T \cup \{i\}) - f_j(T) \geq f_j(S \cup \{i\}) - f_j(S)$$

for all $S \subseteq T \subseteq \mathcal{M}$ and $i \in \mathcal{M} \setminus T$. The interpretation of this assumption is that the decrease in processing time when adding machine i diminishes the more machines are already used for job j (note that the terms on both sides of the inequality are non-positive because f_j is non-increasing). For this setting, which we refer to as *generalized malleable scheduling with supermodular processing time functions*, we derive a strong hardness of approximation result.

► **Theorem 15.** *There is no $|\mathcal{J}|^{1-\varepsilon}$ -approximation for generalized malleable scheduling with supermodular processing time functions, unless $P = NP$.*

Abstract

Clustering is a fundamental tool in data mining and machine learning. It partitions points into groups (clusters) and may be used to make decisions for each point based on its group. However, this process may harm protected (minority) classes if the clustering algorithm does not adequately represent them in desirable clusters – especially if the data is already biased.

At NIPS 2017, Chierichetti et al. [18] proposed a model for *fair clustering* requiring the representation in each cluster to (approximately) preserve the global fraction of each protected class. Restricting to two protected classes, they developed both a 4-approximation for the fair k -center problem and a $\mathcal{O}(t)$ -approximation for the fair k -median problem, where t is a parameter for the fairness model. For multiple protected classes, the best known result is a 14-approximation for fair k -center [40].

We extend and improve the known results. Firstly, we give a 5-approximation for the fair k -center problem with multiple protected classes. Secondly, we propose a relaxed fairness notion under which we can give bicriteria constant-factor approximations for all of the classical clustering objectives k -center, k -supplier, k -median, k -means and facility location. The latter approximations are achieved by a framework that takes an arbitrary existing unfair (integral) solution and a fair (fractional) LP solution and combines them into an essentially fair clustering with a weakly supervised rounding scheme. In this way, a fair clustering can be established belatedly, in a situation where the centers are already fixed.

1 Introduction

Suppose we are to reorganize school assignments in a big city. Given a long list of children starting school next year and a short list of all available teachers, the goal is to assign the students-to-be to (public) schools such that the maximum distance to the school is small. The school capacity is given by the number of its teachers: For each teacher, s students can be admitted. This challenge is in fact an instance of the capacitated (metric) k -center problem. So using a k -center algorithm, you obtain a solution. However, by chance you notice an odd occurrence: One school has a huge excess of boys, while another has a surplus of girls. From previous assignment iterations, you remember that the schools prefer more balanced classes.

Thus a new challenge arises: Assign the children such that the ratio is (approximately) 1:1 between boys and girls, and minimize the maximum distance under this condition.¹ This can be modeled by the following combinatorial optimization problem: Given a point set, half of the points are red, the other half is blue. Compute a clustering where each cluster has an equal number of red and blue points, and minimize the maximum radius.

In this form, our example is a special case of the *fair k -center* problem, as proposed by Chierichetti et al. [18] in the context of maintaining fairness in *unsupervised* machine learning tasks. Their model is based on the concept of *disparate impact* [39] (and the $p\%$ -rule). The input points are assumed to have a binary sensitive attribute modeled by two colors, and discrimination based on this attribute is to be avoided. Since preserving exact balance in each cluster may be very costly or even be impossible², the idea is to ensure that at least $1/t$ of the points of each cluster are of the minority color, where t is a parameter. A cluster with this property is called *fair*, and the fairness constraint can now be added to any clustering problem, giving rise to fair k -center, fair k -median, etc. Chierichetti et al. [18] develop a 4-approximation for a special case of fair k -center and a $(t + \sqrt{3} + \epsilon)$ -approximation for one case of fair k -median.

The fair clustering model as proposed by Chierichetti et al. [18] can also be used to incorporate other aspects into our school assignment example: For example, we might want to mitigate effects of gentrification or segregation. For these use cases, we need multiple colors. Then, in each cluster, the ratio between the number of points with one specific color and the total number of points shall be in some given range. If the allowed range is $[0.20, 0.25]$ for red points, we require that in each cluster, at least a fifth and at most a fourth of the points are red. This models well established notions of fairness (statistical parity, group fairness), which require that each cluster exhibits the same compositional makeup as the overall data with respect to a given attribute. One downside of this notion is that a malicious user could create an illusion of fairness by including proxy points: If we wanted to create a boy-heavy school in our above example, we could still achieve the desired parity by assigning only girls that are very unlikely to attend. Thus, instead of enforcing *equal representation* in the above sense, one could also ask for *equal opportunity* as proposed by Hardt et al. [24] for the case where we take binary decisions (i.e., $k = 2$) and have access to a labeled training set. This approach, however, raises the philosophical question if this equality of opportunity is a sufficient condition for the absence of discrimination. Rather than delving into this complex and much debated issue in this algorithmic paper, we refer to

¹ Or, incorporating the capacities, ensure that the teacher:boys:girls ratio is $1:\frac{s}{2}:\frac{s}{2}$.

² Imagine a point set with 49 red and 51 blue points: This cannot at all be divided into true subsets with exactly the same ratio.

the excellent surveys by Romei and Ruggieri [39] and Žliobaitė et al. [43] that systematically discuss different forms of discrimination and how they can be detected. We assume that it is the intent of the user to achieve a truly fair solution.

Finding fair clusterings turns out to be an interesting challenge from the point of view of combinatorial optimization. As other clustering problems with side constraints, it loses the property that points can be assigned locally. But while many other constraint problems at least allow polynomial algorithms that assign points to given centers optimally, we show that even this restricted problem is NP-hard in the case of fair k -center.

Chierichetti et al. [18] tackle fair clustering problems by a two-step procedure: First, they compute a micro clustering into so-called *fairlets*, which are groups of points that are fair and cannot be split further into true subsets that are also fair. Secondly, representative points of the fairlets are clustered by an approximation algorithm for the unconstrained problem. Consider the special case of a point set with 1:1 ratio of red and blue points. Then a fairlet is a pair of one red and one blue point, and a good micro clustering can be found by computing a suitable bipartite matching between the two color classes.

The problem of computing good fairlets gets increasingly difficult when considering more general variants of the problem. For multiple colors and the special case of exact ratio preservation (i.e., for all colors, the allowed range for its ratio is one specific number), the fairlet computation problem can be reduced to a capacitated clustering problem. This is used in [40] to obtain a 14 and 15-approximation for fair k -center and k -supplier with multiple colors and exact ratio preservation.

We give an extensive overview of the existing results and further the fairlet approach in order to explore its applicability for different variants of fair clustering in the Appendix of the full version [13]. Two major issues arise: Firstly, capacitated clustering is not solved for all clustering objectives; indeed, finding a constant-factor approximation for k -median is a long-standing open problem. Secondly, (even for k -center) it is unclear how fairlets even look like when we have multiple colors and want to allow ranges for the ratios. In this situation, subsets of very different size and composition may satisfy the desired ratio.

A different approach is to combine an LP relaxation of the constrained problem with a solution of the unconstrained problem. This approach is not specific for fair clustering; its general idea was for example used by Chakrabarty and Swamy [15] for the minimum latency facility location problem. Finding a reasonably good solution to the unconstrained problem is usually the easiest task with such an approach. Although finding a good formulation of the constrained problem as a linear program can be challenging, the main problem in such approaches is to combine the two solutions into a new solution whose cost can be bound using the quality of the two original solutions. We use such an approach. We start with a set of centers, i.e., a solution to the unconstrained problem. Then we build an LP to find a (fractional) fair solution, and use *weakly supervised LP rounding* to obtain the final integral fair solution. We use this method to prove the following statements.

► **Theorem 1.** *There exists a 5 and 7-approximation for the fair k -center and k -supplier problem which preserves ratios exactly.*

► **Theorem 2.** *Given any set of centers S , there exists an assignment ϕ' : which is essentially fair and incurs a cost that is linear in the cost S induces on the unconstrained problem and the cost of an optimal fractional fair clustering of P , for all objectives k -center, k -supplier, k -median, k -means, and facility location.*

► **Corollary 3.** *There exists an essentially fair $3/5/3.488/4.675/62.856$ -approximation for the fair k -center/ k -supplier/facility location/ k -median/ k -means problem.*

Here, *essentially fair* refers to our notion of bicriteria approximation: A cluster C is *essentially fair* if there exists a fractional fair cluster C' , such that for each color h the number of color h points in C differ by *at most* 1 from the mass of color h points in C' . So this is a small additive fairness violation. After the publication of our results on arXiv (Nov 2018), we have learned that in independent research, Bera et al. [12] find algorithms in a similar model as our essentially fair clustering model and achieve results similar to Corollary 3, for which they provide an almost identical analysis in their arXiv paper (Jan 2019). Theorem 1 is not affected.

We prove Theorem 2 and Corollary 3 in Section 2. Here the unconstrained starting solution can be any solution and we say our algorithm is a *black-box* approximation. We use the given integral solution to guide our rounding of a fractional solution to an LP that incorporates fairness. The proof of Theorem 1 can be found in Section 3. It is more involved as we cannot use a black-box approach, and instead need to find a suitable set of centers (a suitable integral solution) and have to adjust the weakly supervised rounding procedure.

Our results have two advantages. Firstly, we get results for a wide range of clustering problems, and these results improve previous results. For example, we get a 5-approximation for the fair k -center problem with exact ratio preservation, where the best known guarantee was 14. All our bicriteria results work for multiple colors and approximate ratio preservation, a case for which no previous algorithm was known. As for the quality of the guarantees, compare the 4.675-approximation for essentially fair k -median clusterings with the best previously known $\Theta(t)$ -approximation, which is only applicable to the case of two colors. Notice that a similar result can *not* be achieved by using bicriteria approximation algorithms for capacitated clustering. The reduction from capacitated clustering only works when the capacities are not violated.

Secondly, the black-box approach has the advantage that fairness can be established belatedly, in a situation where the centers are already given. [21, 44]. Consider our school example and notice that the location of the schools cannot be chosen. Our result says that if we are alright with essentially fair clusterings, we get a clustering which is not much more expensive than a fair clustering where the centers were chosen with the fairness constraint at hand.

Related work

Using k centers to cluster points while minimizing a certain objective function has a long history in terms of results and applications. For the k -center problem in general metric spaces, the 2-approximations developed by Gonzalez [22] and Hochbaum and Shmoys [25] were shown to be tight by Hsu and Nemhauser [26]. The k -supplier problem can be 3-approximated [25], which is also tight. Facility location can be 1.488-approximated [35], which is very close to the known APX-hardness of 1.463 for the problem [23]. For k -median, a recent breakthrough has led to a 2.675-approximation [38, 14], while the best hardness result lies below two [27]. The gap between best upper and lower bound is even larger for k -means, where a 6.357-approximation is the best known [4], and the newest hardness result is marginally above 1 [8, 32].

The k -center problem allows for constant-factor approximations for many useful constraints such as capacity constraints [11, 19, 28], lower bounds on the size of each cluster [3, 6] or allowing for outliers [16, 20]. This is also true for facility location and capacities [2, 7, 10], uniform lower bounds [5, 42], and outliers [16]. Much less is known for k -median and k -means.

True constant-factor approximations so far exist only for the outlier constraint [17, 31]. A major problem for obtaining constant factor approximations is that the natural LP has an unbounded integrality gap, which is also true for the LP with fairness constraints. Bicriteria approximations are known that either violate the capacity constraints [34, 36, 37] or the cardinality constraint [1].

A clustering problem where the points have a color was considered by Li, Yi and Zhang [33]. They provided a 2-approximation for a constraint called *diversity*, which allows at most one point per color in each cluster.

The fairness constraint has been introduced by Chierichetti et al. [18]. They show a 4-approximation for the fair k -center problem with two color classes, where one color class contains t -times as many points as the other, for some integer t . Rösner and Schmidt gave a 14-approximation algorithm for k -center in the extended case with arbitrary many color classes. For the fair k -median problem with two color classes, where one color class contains t -times as many points as the other, for some integer t , Chierichetti et al. [18] also give a $\Theta(t)$ -approximation. Backurs et al. [9] give an $O(d \cdot \log(n))$ -approximation for a more general version of the fair k -median problem with two color classes, where a problem instance consists of n points in \mathbb{R}^d . For k -means the only known approximation algorithm only works for two color classes, which each contain exactly half of the points. Schmidt et al. [41] give a 32.875-approximation for this case. In parallel to our research, Bera et al. [12] have also extended the fairness model to multiple colors and approximate fairness preservation. Their model additionally allows for an overlap of the protected classes. They achieve results similar to Corollary 3.

Recent work of Kleindessner et al. [30] considers the fairness constraints in the context of spectral clustering. Fair data summarization was considered by Kleindessner et al. [29] who imposed the fairness constraint on the cluster centers alone. Specifically, they solve k -center instances with the added constraint that the chosen centers must satisfy an input distribution on the colors (i.e. out of the chosen centers, k_i must belong to color class i , where k_i is given as part of the input). While this formulation is useful for data summarization (when only the centers are reported), it is not guaranteed to lead to fair clusters overall. They propose a 5-approximation algorithm for the case of two color classes. When there are m color classes, they obtain a $(3 \cdot 2^m - 1)$ -approximation.

Preliminaries

Points and locations

We are given a set of n points P and a set of potential locations L . We allow L to be infinite (when $L = \mathbb{R}^d$). The task is to open a subset $S \subseteq L$ of the locations and to assign each point in P to an open location via a mapping $\phi : P \rightarrow S$. We refer to the set of all points assigned to a location $i \in S$ by $P(i) := \phi^{-1}(i)$. The assignment incurs a cost governed by a semi-metric $d : (P \cup L) \times (P \cup L) \rightarrow \mathbb{R}_{\geq 0}$ that fulfills a β -relaxed triangle inequality

$$d(x, z) \leq \beta(d(x, y) + d(y, z)) \quad \text{for all } x, y, z \in P \cup L \quad (1)$$

for some $\beta \geq 1$. Additionally, we may have opening costs $f_i \geq 0$ for every potential location $i \in L$ or a maximum number of centers $k \in \mathbb{N}$.

Colors and fairness

We are also given a set of *colors* $Col := \{col_1, \dots, col_g\}$, and a coloring $col : P \rightarrow Col$ that assigns a color to each point $j \in P$. For any set of points $P' \subseteq P$ and any color $col_h \in Col$ we define $col_h(P') = \{j \in P' \mid col(j) = col_h\}$ to be the set of points colored with col_h in P' . We call $r_h(P') := \frac{|col_h(P')|}{|P'|}$ the *ratio* of col_h in P' . If an implicit assignment ϕ is clear from the context, we write $col_h(i)$ to denote the set of all points of a color $col_h \in Col$ assigned to an $i \in S$, i.e., $col_h(i) = col_h(P(i))$.

A set of points $P' \subseteq P$ is *exactly fair* if P' has the same ratio for every color as P , i.e., for each $col_h \in Col$ we have $r_h(P') = r_h(P)$. We say that P' is (ℓ, u) -*fair* or just *fair* for some $\ell = (\ell_1, \dots, \ell_g)$ and $u = (u_1, \dots, u_g)$, if we have $r_h(P') \in [\ell_h, u_h]$ for every color $col_h \in Col$.

In our fair clustering problems, we want to preserve the ratios of colors found in P in our clusters. We distinguish two cases: *exact* preservation of ratios, and *relaxed* preservation of ratios. For the exact preservation of ratios, we ask that all clusters are exactly fair, i.e., $P(i)$ is fair for all $i \in S$.

For the relaxed preservation of ratios, we are given the lower and upper bounds $\ell = (\ell_1 = p_1^1/q_1^1, \dots, \ell_g = p_1^g/q_1^g)$ and $u = (u_1 = p_2^1/q_2^1, \dots, u_g = p_2^g/q_2^g)$ on the ratio of colors in each cluster and ask that all clusters are (ℓ, u) -*fair*. The exact case is a special case of the relaxed case where we set $\ell_h = u_h = r_h(P)$ for every color $col_h \in Col$.

Essentially fair clusterings are defined below (see Definition 6).

Objectives

We consider fair versions of several classical clustering problems. An instance is given by $I := (P, L, col, d, f, k, \ell, u)$, and our goal is to choose a solution (S, ϕ) according to one of the following objectives.

- **k-center** and **k-supplier**: minimize the maximum distance between a point and its assigned location: $\min \max_{j \in P} d(j, \phi(j))$. In these problems, we have $f \equiv 0$ and d is a metric. Furthermore, in k -center, $L = P$, whereas in k -supplier, $L \neq P$ is some finite set.
- **k-median**: minimize $\sum_{j \in P} d(j, \phi(j))$, d is a metric, $f \equiv 0$ and $L \subseteq P$.
- **k-means**: minimize $\sum_{j \in P} d(j, \phi(j))$, where $P \subseteq \mathbb{R}^m$ for some $m \in \mathbb{N}$, $L = \mathbb{R}^m$ and $d(x, y) = \|y - x\|^2$ is a semi-metric for $\beta = 2$ and $f \equiv 0$.
- **facility location**: minimize $\sum_{j \in P} d(j, \phi(j)) + \sum_{i \in S} f_i$, where $k = n$, d is a metric and L is a finite set.

The fair assignment problem

For all the objectives above, we call the subproblem of computing a cost-minimal fair assignment of points to given centers the *fair assignment problem*. We show the following theorem in Section A.

► **Theorem 4.** *Finding an α -approximation for the fair assignment problem for k -center for $\alpha < 3$ is NP-hard.*

(I)LP formulations for fair clustering problems

Let $I = (P, L, col, d, f, k, \ell, u)$ be a problem instance for a fair clustering problem. We introduce a binary variable $y_i \in \{0, 1\}$ for all $i \in L$ that decides if i is opened, i.e. $y_i = 1 \Leftrightarrow i \in S$. Similarly, we introduce binary variables $x_{ij} \in \{0, 1\}$ for all $i \in L, j \in P$ with $x_{ij} = 1$ if j is assigned to i , i.e. $\phi(j) = i$. All ILP formulations have the inequalities

(2) $\sum_{i \in L} x_{ij} = 1 \forall j \in P$ saying that every point j is assigned to a center, the inequalities
(3) $x_{ij} \leq y_i \forall i \in L, j \in P$ ensuring that if we assign j to i , then i must be open, and the
integrality constraints (4) $y_i, x_{ij} \in \{0, 1\} \forall i \in L, j \in P$. We may restrict the number of open
centers to k with (5) $\sum_{i \in L} y_i \leq k$. For k -center and k -supplier, the objective is commonly
encoded in the constraints of the problem, and the (I)LP has no objective function. The
idea is to guess the optimum value τ . Since there is only a polynomial number of choices
for τ , this is easily done. Given τ , we construct a *threshold graph* $G_\tau = (P \cup L, E_\tau)$ on the
points and locations, where a connection between $i \in L$ and $j \in P$ is added iff i and j
are close, i.e., $\{i, j\} \in E_\tau \Leftrightarrow d(i, j) \leq \tau$. Then, we ensure that points are not assigned to centers
outside their range:

$$x_{ij} = 0 \quad \text{for all } i \in L, j \in P, \{i, j\} \notin E_\tau \quad (6)$$

For the remaining clustering problems, we pick the adequate objective function from the
following three (let $d_{ij} := d(i, j)$):

$$\min \sum_{i \in L, j \in P} x_{ij} d_{ij} \quad (7) \quad \min \sum_{i \in L, j \in P} x_{ij} d_{ij}^2 \quad (8) \quad \min \sum_{i \in L, j \in P} x_{ij} d_{ij} + \sum_{i \in L} y_i f_i \quad (9)$$

We now have all necessary constraints and objectives. For k -center and k -supplier, we use
inequalities (2)-(6), no objective, and define the optimum to be the smallest τ for which the
ILP has a solution. We get k -median and k -means by combining inequalities (2)-(5) with (7)
and (8), respectively, and we get facility location by combining (2)-(4) with the objective (9).
LP relaxations arise from all ILP formulations by replacing (4) by $y_i, x_{ij} \in [0, 1]$ for all
 $i \in L, j \in P$. To create the fair variants of the ILP formulations, we add fairness constraints
modeling the upper and lower bound on the balances.

$$\ell_h \sum_{j \in P} x_{ij} \leq \sum_{col(p_j)=col_h} x_{ij} \leq u_h \sum_{j \in P} x_{ij} \quad \text{for all } i \in L, h \in Col \quad (10)$$

Although very similar to the canonical clustering LPs, the resulting LPs become much
harder to round even for k -center with two colors. We show the following in Section B.

► **Lemma 5.** *There is a choice of non-trivial fairness intervals such that the integral-
ity gap of the LP-relaxation of the canonical fair clustering ILP is $\Omega(n)$ for the fair k -
center/ k -supplier/ k -median/facility location problem. The integrality gap is $\Omega(n^2)$ for the
fair k -means problem.*

Essential fairness

For a point set P' , $\text{mass}_h(P') = |col_h(P')|$ is the *mass* of color col_h in P' . For a possibly
fractional LP solution (x, y) , we extend this notion to $\text{mass}_h(x, i) := \sum_{j \in col_h(P)} x_{ij}$. We
denote the total mass assigned to i in (x, y) by $\text{mass}(x, i) = \sum_{j \in P} x_{ij}$. With this notation,
we can now formalize our notion of *essential fairness*.

► **Definition 6** (Essential fairness). *Let I be an instance of a fair clustering problem and let
 (x, y) be an integral, but not necessarily fair solution to I . We say that (x, y) is essentially
fair if there exists a fractional fair solution (x', y') for I such that $\forall i \in L$:*

$$\lfloor \text{mass}_h(x', i) \rfloor \leq \text{mass}_h(x, i) \leq \lceil \text{mass}_h(x', i) \rceil \quad \forall col_h \in Col \quad (11)$$

$$\text{and } \lfloor \text{mass}(x', i) \rfloor \leq \text{mass}(x, i) \leq \lceil \text{mass}(x', i) \rceil. \quad (12)$$

2 Essential fair clusterings via black-box approximation

For essentially fair clustering, we give a powerful framework that employs approximation algorithms for (unfair) clustering problems as a black-box and transforms their output into an essentially fair solution. In this framework, we start by computing an approximate solution for the standard variant of the clustering problem at hand. Next, we solve the LP for the fair variant of the clustering problem. Now we have an integral unfair solution, and a fractional fair solution. Our final and most important step is to combine these two solutions into an integral and essentially fair solution. It consists of two conceptual sub-steps: Firstly, we show that it is possible to find a fractional fair assignment to the centers of the integral solution that is sufficiently cheap. Secondly, we round the assignment. This last sub-step introduces the potential fairness violation of one point per color per cluster.

We show that this approach yields constant-factor approximations with fairness violation for all mentioned clustering objectives. The description will be neutral whenever the objective does not matter. Thus, descriptions like *the LP* mean the appropriate LP for the desired clustering problem. When the problem gets relevant, we will specifically discuss the distinctions. Notice that for all clustering problems defined in Section 1, P and L are finite except for k -means. However, for the k -means problem, we can assume that $L = P$ if we accept an additional factor of 2 in the approximation guarantee. Thus, we assume in the following that L and P are finite sets. Indeed, we even assume at least $L \subseteq P$ for all problems except k -supplier and facility location.

2.1 Step 1: Obtaining a fair solution with integral y

In the first step, we assume that we are given two solutions. Let (x^{LP}, y^{LP}) be an optimal solution to the LP. This solution has the property that the assignments to all centers are fair, however, the centers may be fractionally open and the points may be fractionally assigned to several centers. Let c^{LP} be the objective value of this solution. For k -supplier and k -center, it is the smallest τ for which the LP is feasible, for the other objectives, it is the value of the LP. We denote the cost of the best *integral* solution to the LP by c^* . We know that $c^{LP} \leq c^*$.

Let (\bar{x}, \bar{y}) be any integral solution to the LP that may violate fairness, i.e., inequality (10), and let \bar{c} be the objective value of this solution. We think of (\bar{x}, \bar{y}) as being a solution of an α -approximation algorithm for the standard (unfair) clustering problem for some constant α . Since the unconstrained version can only have a lower optimum cost, we then have $\bar{c} \leq \alpha \cdot c^*$.

Our goal is now to combine (x^{LP}, y^{LP}) and (\bar{x}, \bar{y}) into a third solution, (\hat{x}, \hat{y}) , such that the cost of (\hat{x}, \hat{y}) is bounded by $O(c^{LP} + \bar{c}) \subseteq O(c^*)$. Furthermore, the entries of \hat{y} shall be integral. The entries of \hat{x} may still be fractional after step 1.

Let S be the set of centers that are open in (\bar{x}, \bar{y}) . For all $j \in P$, we use $\bar{\phi}(j)$ to denote the center in S closest to j , i.e., $\bar{\phi}(j) = \arg \min_{i \in S} d(j, i)$ (ties broken arbitrarily). Notice that the objective value of using S with assignment $\bar{\phi}$ for all points in P is at most \bar{c} , since assigning to the closest center is always optimal for the standard clustering problems without fairness constraint.

Depending on the objective, L is a subset of P or not, i.e., $\bar{\phi}$ is not necessarily defined for all locations in L . We then extend $\bar{\phi}$ in the following way. Let $i \in L \setminus P$ be any center, and let j^* be the closest point to it in P . Then we set $\bar{\phi}(i) := \bar{\phi}(j^*)$, i.e., i is assigned to the center in S which is closest to the point in P which is closest to i . Finally, let $\bar{C}(i) = \bar{\phi}^{-1}(i)$ be the set of all points and centers assigned to i by $\bar{\phi}$. We show the following lemma.

► **Lemma 7.** *Let (x^{LP}, y^{LP}) and (\bar{x}, \bar{y}) be two solutions to the LP, where (\bar{x}, \bar{y}) may violate inequality (10), but is integral. Then the solution defined by $\hat{y} := \bar{y}$ and*

$$\hat{x}_{ij} := \sum_{i' \in \bar{C}(i)} x_{i'j}^{LP} \quad \text{for all } i \in S, j \in P, \quad \hat{x}_{ij} := 0 \quad \text{for all } i \notin S, j \in P.$$

satisfies inequality (10), \hat{y} is integral, and the cost \hat{c} of (\hat{x}, \hat{y}) is bounded by $c^{LP} + \bar{c}$ for k -center, by $2 \cdot c^{LP} + \bar{c}$ for k -supplier, k -median, and facility location, and by $12 \cdot c^{LP} + 8 \cdot \bar{c}$ for k -means.

Proof. Recall that for k -center and k -supplier, speaking of the cost of an LP solution is a bit sloppy; we mean that (\hat{x}, \hat{y}) is a feasible solution in the LP with threshold \hat{c} .

The definition of (\hat{x}, \hat{y}) means the following. For every (fractional) assignment from a point j to a center i' , we look at the cluster with center $i = \bar{\phi}(i')$ to which i' is assigned to by $\bar{\phi}$. We then transfer this assignment to i . So from the perspective of i , we collect all fractional assignments to centers in $\bar{C}(i)$ and consolidate them at i . Notice that the (fractional) number of points assigned to i after this process may be less than one since (\bar{x}, \bar{y}) may include centers that are very close together.

Since that \hat{y} is simply \bar{y} it is integral as well and has the same number of centers, thus \hat{y} also satisfies (5) if the problem uses it. Next, we observe that (\hat{x}, \hat{y}) satisfies fairness, i.e., respects (10). This is true because (x^{LP}, y^{LP}) satisfies them, and because we move *all* assignment from a center i' to the same center $\bar{\phi}(i')$. This transferring operation preserves the fairness. Inequality (3) is true because we only move assignments to centers that are fully open in (\bar{x}, \bar{y}) , i.e., the inequality cannot be violated as long as (2) is true (which it is for (x^{LP}, y^{LP}) since it is a feasible LP solution). Equality (2) is true for (\hat{x}, \hat{y}) since all assignment of j is moved to some fully open center. Thus (\hat{x}, \hat{y}) is a feasible solution for the LP. It remains to show that \hat{c} is small enough, which depends on the objective.

k -median and k -means. We start by showing this for k -median (where the distances are a metric, i.e., $\beta = 1$ in the β -triangle inequality (1)) and k -means (where the distances are a semi-metric with $\beta = 2$). We observe that here, the cost of (\hat{x}, \hat{y}) is

$$\hat{c} = \sum_{j \in P} \sum_{i \in L} \hat{x}_{ij} d(i, j) = \sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} x_{i'j}^{LP} d(i, j).$$

Now fix $i \in L$, $i' \in \bar{C}(i)$ and $j \in P$ arbitrarily. By the β -relaxed triangle inequality, $d(i, j) \leq \beta \cdot d(i', j) + \beta \cdot d(i', i)$. Furthermore, we know that $i' \in \bar{C}(i)$, i.e., $\bar{\phi}(i') = i$ and $d(i', i) \leq d(i', \bar{\phi}(j))$. We can use this to relate $d(i', i)$ to the cost that j pays in (\bar{x}, \bar{y}) :

$$d(i', i) \leq d(i', \bar{\phi}(j)) \leq \beta \cdot d(j, i') + \beta \cdot d(j, \bar{\phi}(j)).$$

Adding this up yields

$$\begin{aligned} & \sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} x_{i'j}^{LP} d(i, j) \\ & \leq \sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} (\beta + \beta^2) x_{i'j}^{LP} d(i', j) + \sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} \beta^2 \cdot x_{i'j}^{LP} d(j, \bar{\phi}(j)) \\ & = (\beta + \beta^2) \cdot c^{LP} + \beta^2 \cdot \bar{c}. \end{aligned}$$

For $\beta = 1$ (k -median), this is $2c^{LP} + \bar{c}$, for $\beta = 2$ (k -means), we get $12c^{LP} + 8\bar{c}$

Facility location. For facility location, we have to include the facility opening costs. We

18:10 On the Cost of Essentially Fair Clusterings

open the facilities that are open in (\bar{x}, \bar{y}) , which incurs a cost of $\sum_{i \in L} \bar{y}_i f_i$. The distance costs are the same as for k -median, so we get a total cost of

$$\sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} 2x_{i'j}^{LP} d(i', j) + \sum_{j \in P} \sum_{i \in L} \sum_{i' \in \bar{C}(i)} x_{i'j}^{LP} d(j, \bar{\phi}(j)) + \sum_{i \in L} \bar{y}_i f_i \leq 2c^{LP} + \bar{c}.$$

k -center and k -supplier. For the k -center and k -supplier proof, we again fix $i \in L$, $i' \in \bar{C}(i)$ and $j \in P$ arbitrarily and use that $d(i, j) \leq d(i, i') + d(i', j)$. Now for k -center, we know that $d(i, i') \leq \bar{c}$ since $i' \in \bar{C}(i)$, and we know that $d(i', j) \leq c^{LP}$ for all j where $x_{i'j}^{LP}$ is strictly positive. Thus, if \hat{x}_{ij} is strictly positive, then $d(i, j) \leq \bar{c} + c^{LP}$. For k -supplier, we have no guarantee that $d(i, i') \leq \bar{c}$ since i' is not necessarily an input point. Instead, $i' \in \bar{C}(i)$ means that the point j' in P which is closest to i' is assigned to i by \bar{x} . Since j' is the closest to i' in P , we have $d(i', j') \leq d(i', j)$. Furthermore, since $j' \in \bar{C}(i)$, $d(i, j') \leq \bar{c}$. Thus, we get for k -supplier that

$$d(i, j) \leq d(i, i') + d(i', j) \leq d(i, j') + d(i', j') + d(i', j) \leq \bar{c} + 2 \cdot c^{LP}. \quad \blacktriangleleft$$

2.2 Step 2: Rounding the x -variables

For rounding the x -variables, we need to distinguish between two cases of objectives. Let $j \in P$ be a point that is fractionally assigned to some centers $L_j \subseteq L$.

First, we have objectives where we can transfer mass from an assignment of j to $i' \in L_j$ to an assignment of j to $i'' \in L_j$ without modifying the objective. We say that such objectives are *reassignable* (in the sense that we can reassign j to centers in L_j without changing the cost). k -center and k -supplier have this property.

Second, we have objectives where the assignment cost is separable, i.e., where the distances influence the cost via a term of the form $\sum_{i \in L, j \in P} c_{ij} \cdot x_{ij}$ for some $c_{ij} \in \mathbb{R}_{\geq 0}$. We call such objectives *separable*. Facility location, k -median and k -means fall into this category.

► **Lemma 8.** *Let (x, y) be an α -approximate fractional solution for a fair clustering problem with the property that all $y_i, i \in L$ are integral. Then we can obtain an α -approximate integral solution (x', y') with an additive fairness violation of at most one in time $O(\text{poly}(|S| + |P|))$, with $S := \{i \in L \mid y_i \geq 1\}$ being the set of locations that are opened in (x, y) .*

Proof. We create our rounded α -approximate integral solution (x', y') by min-cost flow computations. We begin by constructing a min-cost flow instance which depends on our starting solution (x, y) as well as on the objective of the problem we are studying.

We define a min-cost flow instance $(G = (V, A), c, b)$ (also see Figure 1) with unit capacities and costs c on the edges as well as balances b on the nodes. We begin by defining a graph $G^h = (V^h, A^h)$ for every color $h \in \text{Col}$ with

$$V^h := V_S^h \cup V_P^h, \quad V_S^h := \{v_i^h \mid i \in S\}, \quad V_P^h := \{v_j^h \mid j \in \text{col}_h(P)\}, \\ A^h := \{(v_j^h, v_i^h) \mid i \in S, j \in \text{col}_h(P) : x_{ij} > 0\},$$

as well as costs c^h by $c_a^h := c_{ij}$ for $a = (v_j^h, v_i^h) \in A^h, i \in S, j \in \text{col}_h(P)$ and balances b^h by $b_v^h := 1$ if $v \in V_P^h$ and $b_v^h := -\lfloor \text{mass}_h(x, i) \rfloor$ if $v = v_i^h \in V_S^h$. We use the graphs G_h to define $G = (V, A)$ by

$$V := \{t\} \cup V_S \cup \bigcup_{h \in \text{Col}} V^h, \quad V_S := \{v_i \mid i \in S\} \\ A := \bigcup_{h \in \text{Col}} A^h \cup \{(v_i^h, v_i) \mid i \in S, h \in \text{Col} : \text{mass}_h(x, i) - \lfloor \text{mass}_h(x, i) \rfloor > 0\} \\ \cup \{(v_i, t) \mid i \in S : \text{mass}(x, i) - \lfloor \text{mass}(x, i) \rfloor > 0\},$$

together with costs c of $c_a := c_a^h$ for $a \in A^h$ and 0 otherwise, and balances b of $b_v := b_v^h$ if $v \in V^h$ for some $h \in Col$, $b_v := -B_i$ if $v = v_i \in V_S$ and $b_t := -B$ with $B_i = \lfloor \text{mass}(x, i) \rfloor - \sum_{h \in Col} \lfloor \text{mass}_h(x, i) \rfloor$ and $B := |P| - \sum_{i \in S} \lfloor \text{mass}(x, i) \rfloor$.

Separable objectives – k -median and k -means

We observe that:

1. B and B_i are integers for all $i \in S$, and so are all capacities, costs and balances. Consequently, there are integral optimal solutions for the min-cost flow instance (G, c, b) ,
2. (x, y) induces a feasible solution for (G, c, b) , by defining a flow x in G as follows:

$$x_a := \begin{cases} x_{ij} & \text{if } a = (v_j^h, v_i^h) \in A^h, j \in P, i \in S, \\ \text{mass}_h(x, i) - \lfloor \text{mass}_h(x, i) \rfloor & \text{if } a = (v_i^h, v_i) \in A, h \in Col, i \in S, \\ \text{mass}(x, i) - \lfloor \text{mass}(x, i) \rfloor & \text{if } a = (v_i, t) \in A, i \in S. \end{cases}$$

Since (x, y) is a fractional solution, x satisfies capacity and non-negativity constraints because $x_{ij} \in [0, 1]$ for all $i \in L, j \in P$ and $\text{mass}_h(x, i) - \lfloor \text{mass}_h(x, i) \rfloor, \text{mass}(x, i) - \lfloor \text{mass}(x, i) \rfloor \in [0, 1]$ for all $i \in S$ and $col_h \in Col$ as well. We have flow conservation since the fractional solution needs to assign all points, and the flow of the edges (v_i^h, v_i) and (v_i, t) as well as the demand of v_i and t are chosen in such a way that we have flow conservation for all the other nodes as well.

3. Integral solutions x to the min-cost flow instance (G, c, b) induce an integral solution (\bar{x}, y) to the original clustering problem by setting $\bar{x}_{ij} := x_a$ for $a = (v_j^h, v_i^h) \in A^h$ if $j \in col_h(P), i \in S$. Since the flow x is integral, this gives us an integral assignment of all points to centers which have been opened, since y was already integral before this step. This incurs the additive fairness violation of at most one, since every $i \in S$ is guaranteed by our balances to have at least $\lfloor \text{mass}_h(x, i) \rfloor$ points of color $h \in Col$ and at least $\lfloor \text{mass}(x, i) \rfloor$ points in total assigned to it. Since there is at most one outgoing arc of unit capacity (v_i^h, v_i) and (v_i, t) for an $i \in S$ if $\text{mass}_h(x, i) - \lfloor \text{mass}_h(x, i) \rfloor > 0$, we have at most $\lceil \text{mass}_h(x, i) \rceil$ points of color col_h and $\lceil \text{mass}(x, i) \rceil$ total points assigned to i .

Together, this yields that computing a min-cost flow \hat{x} for (G, c, b) followed by applying the third observation to \hat{x} yields a solution (\hat{x}, y) to the clustering with an additive fairness violation of at most one.

Since (x, y) was inducing the fractional solution x with $\text{cost}(x) = \text{cost}(x, y)$ to the min-cost flow instances, and $\text{cost}(x) \geq \text{cost}(\hat{x})$ by construction we have $\text{cost}(\hat{x}, y) \leq \text{cost}(x, y)$.

Reassignable objectives – k -center and k -supplier

In the case of reassignable objectives, we do not have to care about costs, as long as the reassignments happen to centers in L_j for all points $j \in P$. We essentially use the same strategy as before, but instead of a min cost flow problem we solve the transshipment problem $(G = (V, A), b)$ with unit capacities on the edges and balances b on the nodes. Notice that the three observations from the previous case apply here as well, and reassignability guarantees that the cost does not increase. ◀

Lemmas 7 and 8 then lead directly to Theorem 2, or, in more detail, to:

▶ **Theorem 9.** *Black-box approximation for fair clustering gives essentially fair solutions with a cost of $c^{LP} + \bar{c}$ for k -center, $2c^{LP} + \bar{c}$ for k -supplier, k -median and facility location, and $12c^{LP} + 8\bar{c}$ for k -means where c^{LP} is the cost of an optimal solution to the fair LP relaxation and \bar{c} is the cost of the given solution.*

We know that c^{LP} is not more expensive than an optimal solution to the fair clustering problem. If we use an α -approximation to obtain the unfair clustering solution, we have that \bar{c} is at most α times the cost of an optimal solution to the fair clustering problem. Currently, the best known approximation factors are 2 for k -center [22, 25], 3 for k -supplier [25], 1.488 for facility location [35], 2.675 for k -median [14, 38] and 6.357 for k -means [4], which yields Corollary 3.

■ **Figure 1** Example for the graph G used in the rounding of the x -variables. $B_i = \lfloor \text{mass}(x, i) \rfloor - \sum_{h \in \text{Col}} \lfloor \text{mass}_h(x, i) \rfloor$ and $B = |P| - \sum_{i \in S} \lfloor \text{mass}(x, i) \rfloor$.

3 True approximations for fair k -center and k -supplier

We now extend our weakly supervised rounding technique for k -center and k -supplier in the case of the exact fairness model. We replace the black-box algorithm with a specific approximation algorithm, and then achieve true approximations for the fair clustering problems by informed rounding of the LP solution.

3.1 5-Approximation Algorithm for k -center

In this section, we consider the fair k -center problem with exact preservation of ratios and without any additive fairness violation.

We give a 5-approximation for this variant. The algorithm begins by choosing a set of centers. In contrast to Section 2 we do not use an arbitrary algorithm for the standard k -center problem but specifically look for nodes in the threshold graph $G_\tau = (P, E_\tau)$ where $E_\tau = \{(i, j) \mid i \neq j \in P, d(i, j) \leq \tau\}$ that form a maximal independent set S in G_τ^2 . Here G_τ^t denotes the graph on P that connects all pairs of nodes which are connected by a path of length at most t in G_τ and we denote the edge set of G_τ^t by E_τ^t . As we use the following procedure independent for each connected component of G_τ , we will in the description and the following proofs of the procedure assume that G_τ is a connected graph. The procedure uses the approach by Khuller and Sussmann [28] (procedure ASSIGNMONARCHS) to find S which ensures the following property: There exists a tree T spanning all the nodes in S and two adjacent nodes in T are exactly distance 3 apart in G_τ . The procedure begins by choosing an arbitrary vertex $r \in P$, called *root*, into S and marking every node within distance 2 of r (including itself). Until all the nodes in P are marked, it chooses an unmarked node u that is adjacent to a marked node v and marks all nodes in the distance two neighborhood of u . Observe that u is exactly at distance 3 from a node $u' \in S$ chosen earlier that caused v to get marked. Thus the run of the procedure implicitly defines the tree T over the nodes of

S . In case G_τ is not a connected graph this procedure is run on each connected component and the set S has the following property: There exists a forest F such that F reduced to a connected component of G_τ is a tree T spanning all the nodes of S inside of that connected component and two adjacent nodes in T are exactly distance 3 apart in G_τ .

In the next phase, we make use of some structure that feasible solutions with exact preservation of the ratios must have.

► **Observation 10.** *Let $m \in \mathbb{N}$ be the smallest integer such that for each color $h \in \text{Col}$ we have $r_h(P) = \frac{q_h}{m}$ for some $q_h \in \mathbb{N}$. Then for each cluster $P(i)$ in a fair clustering \mathcal{C} of P with exact preservation of ratios, there exists a positive integer $i' \in \mathbb{N}_{\geq 1}$ such that $P(i)$ contains exactly $i' \cdot q_h$ points with color h for each color $h \in \text{Col}$ and $i' \cdot m$ total points. Thus every cluster must have at least q_h points of color h for each color $h \in \text{Col}$.*

We use Observation 10 and the fixed set of centers S to obtain the following adjusted LP for the fractional fair k -center problem.

$$\sum_{i \in S} x_{ij} = 1, \quad \forall j \in P \quad (13)$$

$$\sum_{j \in \text{col}_h(P)} x_{ij} = r_h(P) \sum_{j \in P} x_{ij} \quad \forall i \in S \quad (14)$$

$$\sum_{\substack{j \in \text{col}_h(P) \\ (i,j) \in E_\tau^2}} x_{ij} \geq q_h \quad \forall i \in S, \forall h \in \text{Col} \quad (15)$$

$$x_{ij} = 0 \quad \forall i \in S, j \in P \text{ with } (i,j) \notin E_\tau^3 \quad (16)$$

$$0 \leq x_{ij} \leq 1 \quad \forall i \in S, j \in P \quad (17)$$

Here inequality (15) ensures that each cluster contains at least q_h points of color h . Let S_{opt} be the set of centers in the optimal solution and let $\phi_{opt} : P \rightarrow S_{opt}$ be the optimal fair assignment. For the correct guess τ , every center $i \in S$ has a distinct center in S_{opt} which is at most distance one away from i in G_τ . Therefore, there exists q_h points of each color h within distance two of i . This ensures that inequality (15) is satisfiable for the right guess τ . And since, every center in S_{opt} is within distance two of some $i \in S$, there exists a fair assignment of points in P to centers in S within distance three. Thus the above LP is feasible for the right τ .

Now for the final phase, the algorithm rounds a fractional solution for the above assignment LP to an integral solution of cost at most 5τ in a procedure motivated by the LP rounding approach used by Cygan et al. in [19] for the capacitated k -center problem. Let $\beta(i)$ denote the children of node $i \in S$ in the tree T . Starting from the leaf nodes we recursively define quantities $\Gamma(i)$ and $\delta(i)$, $\forall i \in S$ as follows:

$$\Gamma(i) = \left\lfloor \frac{\sum_{j \in \text{col}_1(P)} x_{ij} + \sum_{i' \in \beta(i)} \delta(i')}{q_1} \right\rfloor q_1$$

$$\delta(i) = \sum_{j \in \text{col}_1(P)} x_{ij} + \sum_{i' \in \beta(i)} \delta(i') - \Gamma(i)$$

For a leaf node i in the tree T we have $\beta(i) = \emptyset$, then $\Gamma(i)$ denotes the amount of color 1 points assigned to i rounded down to the nearest multiple of q_1 , while $\delta(i)$ denotes the remaining amount. The idea is to reassign the remainder to the parent of i . Then for a non leaf i' $\Gamma(i')$ denotes the amount of color 1 points assigned to i' plus the remainder that all children of i' want to reassign to i' rounded down to the nearest multiple of q_1 , while

18:14 On the Cost of Essentially Fair Clusterings

$\delta(i')$ again denotes the remainder. Since by definition of q_1 the total number of points in $col_1(P)$ must be an integer multiple of q_1 , $\Gamma(r)$ also denotes the the amount of color 1 points assigned to r plus the remainder that all children of r want to reassign to r and $\delta(r) = 0$.

Also note that $\Gamma(i)$ is always a positive integer multiple of q_1 for any i , and $\delta(i)$ is always non-negative and less than q_1 .

One can think of the x_{ij} variables as encoding flow from a vertex j to a node $i \in S$. We call it a color h flow if j has color h . We will re-route these flows (maintaining the ratio constraints) such that $\forall i \in S, j \in col_1(P) x_{ij}$ is equal to $\Gamma(i)$ which is an integral multiple of q_1 .

► **Lemma 11.** *There exists an integral assignment of all vertices with color 1 to centers in S in G_τ^5 that assigns $\Gamma(i)$ vertices with color 1 to each center $i \in S$.*

Proof. Construct the following flow network: Take sets $col_1(P)$ and S to form a bipartite graph with an edge of capacity one between a vertex $j \in col_1(P)$ and a center $i \in S$ if and only if $(i, j) \in E_\tau^5$. Connect a source s with unit capacity edges to all vertices in $col_1(P)$ and each center $i \in S$ with capacity $\Gamma(i)$ to a sink t . We now show a feasible fractional flow of value $|col_1(P)|$ in this network. For each leaf node i in T which is not the root, assign $\Gamma(i)$ amount of color 1 flow from the total incoming color 1 flow $\sum_{j \in col_1(P)} x_{ij}$ from vertices that are at most distance three away from i in G_τ and propagate the remaining $\delta(i)$ amount of color 1 flow, coming from distance two vertices, upwards to be assigned to the parent of node i . This is always possible because by definition $\delta(i) < q_1$ and constraint (15) ensures that every center has at least q_1 amount of color 1 flow coming from distance two vertices. For every non-leaf node i , assign $\Gamma(i)$ amount of incoming color 1 flow from distance five vertices (including the color 1 flows propagated upwards by its children) and propagate $\delta(i)$ amount of color 1 flow from distance two vertices (possible due to constraint (15)). Thus every center has $\Gamma(i)$ amount of color 1 flow passing through it and it is easy to verify that the value of the total flow in the network is $|col_1(P)|$. Since the network only has integral capacities, there exists an integral max-flow of value $|col_1(P)|$. ◀

► **Lemma 12.** *For any reassignment of a color 1 flow, there exists a reassignment of color h -flow between the same centers for all $h \in Col \setminus \{1\}$, such that the resulting fractional assignment of the vertices satisfies the fairness constraints at each center.*

Proof. Say f_1 amount of color 1 flow is reassigned from center i_1 to another center i_2 . Reassign $f_h = r_h \cdot f_1 / r_1$ amount of color h flow from i_1 to i_2 for each color $h \in Col \setminus \{1\}$. This is possible as constraint (14) implies that the amount of color h points assigned to i_1 must be equal to $\frac{r_h}{r_1}$ times the amount of color 1 points assigned to i_1 and f_1 must be less than the amount of color 1 points assigned to i_1 . It is easy to verify that the ratios at i_1 and i_2 remain unchanged as by construction the ratio of the reassigned flows is equal to the original ratio. ◀

From Lemmas 11 and 12 we can say that there is a fair fractional assignment within distance 5τ such that all the color 1 assignments are integral and every center i has $\Gamma(i)$ color 1 vertices assigned to it. Since this assignment is fair the total incoming color h flow at each center must be $\Gamma(i) \frac{q_h}{q_1}$ which are integers for every center $i \in S$ and every color $h \in Col$.

► **Lemma 13.** *There exists an integral fair assignment in G_τ^5 .*

Proof. Construct a flow network for color h vertices similar to the one in lemma 11: Take sets $col_h(P)$ and S to form a bipartite graph with an edge of capacity one between a vertex $j \in col_h(P)$ and a center $i \in S$ if and only if $(i, j) \in E_\tau^5$. Connect a source s with unit

capacity edges to all vertices in $col_h(P)$ and each center $i \in S$ with capacity $\Gamma(i) \frac{r_h}{r_1}$ to a sink t . The above fractional assignment in G_τ^5 gives a flow for the above network. Since the network only consists of integral demands and capacities, there is an integral max-flow which gives the assignment for the color h vertices. ◀

► **Theorem 14.** *There exists a 5-approximation for the fair k -center problem with exact preservation of ratios.*

Proof. Follows from Lemmas 11, 12 and 13 ◀

3.2 7-approximation for k -suppliers

We adapt the algorithm in Section 3.1 to work for the k -suppliers model to give a 7-approximation for the variant with exact preservation of ratios. In the k -suppliers model, we are not allowed to open centers anywhere in P . Instead, we are provided a set L of potential locations to open centers. The procedure closely resembles the k -center algorithm: construct a bipartite threshold graph $G_\tau = (P \cup L, E_\tau)$ where $E_\tau = \{(i, j) \mid i \in L, j \in P, d(i, j) \leq \tau\}$. Choose a *root* vertex $r \in P$ into S and mark all vertices in P that are within distance two. Until all vertices in P are marked, choose an unmarked vertex $u \in P$ that is distance two away from a marked vertex and mark all vertices in the distance two neighborhood of u . Note that, since G_τ is bipartite, no two vertices in P are adjacent. The vertex u is exactly at distance four from a vertex $u' \in S$ chosen earlier. This process of selecting vertices in S defines a tree T over them with the property that adjacent vertices in T are exactly at distance four of each other in G_τ . Since we apply the procedure separately for each of the connected components of the threshold graph, we may safely assume that G_τ is connected.

Let us now temporarily open one center at each vertex in S and make the following observations for the k -suppliers case:

1. Observation 10 still holds.
2. The corresponding LP is the same as the k -center LP, except it has E_τ^4 in place of E_τ^3 in constraint (16). This ensures the feasibility of the LP since every location in L is at most distance three away from some vertex in S . (Note that in case G_τ is not connected, it can happen that some locations in L are not connected to any point and therefore more than distance three away from some vertex in S , but since they are not connected to any point we can safely ignore them, as they cannot be part of the optimal solution.)
3. Lemma 11 with G_τ^6 instead of G_τ^5 holds. The extra distance of one is introduced because the distance between a child vertex and its parent vertex in T is four instead of three.
4. Lemma 12 holds as it is and Lemma 13 holds when G_τ^5 is replaced with G_τ^6 .

Thus we have a distance six fair assignment to centers in S . However, this is not a valid solution for k -suppliers as $S \subseteq P$ and we are allowed to open centers only in L . So, we move each of these temporary centers to a neighboring location in L to obtain a distance seven assignment.

A NP-hardness of the fair assignment problem for k -center

In this section, we reduce the Exact Cover by 3-sets to the fair assignment problem for k -center. The input to the Exact Cover by 3-sets problem is a ground set \mathcal{U} of elements and a family \mathcal{F} of subsets such that each set has exactly three elements from \mathcal{U} . The objective is to find a set cover such that each element is included in exactly one set. For example, let $\mathcal{U} = \{a, b, c, d, e, f\}$, $\mathcal{F} = \{A = \{a, b, c\}, B = \{b, c, d\}, C = \{d, e, f\}\}$ be an instance. The set $\{A, C\}$ is an exact cover. We call the problem of computing a cost-minimal fair assignment of points to given centers the *fair assignment problem*. It exists once for every objective listed above. Even for k -center, the fair assignment problem is NP-hard. This can be shown by a reduction from Exact Cover by 3-sets, a variant of set cover. The input is a ground set \mathcal{U} of elements and a family \mathcal{F} of subsets such that each set has exactly three elements from \mathcal{U} . The objective is to find a set cover such that each element is included in exactly one set. For example, let $\mathcal{U} = \{a, b, c, d, e, f\}$, $\mathcal{F} = \{A = \{a, b, c\}, B = \{b, c, d\}, C = \{d, e, f\}\}$ be an instance. The set $\{A, C\}$ is an exact cover.

■ **Figure 2** Example for the reduction from Exact Cover with 3-sets to the fair assignment problem for k -center, with $\mathcal{U} = \{a, b, c, d, e, f\}$ and $\mathcal{F} = \{A = \{a, b, c\}, B = \{b, c, d\}, C = \{d, e, f\}\}$.

For an instance \mathcal{U}, \mathcal{F} of the exact cover problem, we construct an unweighted graph, which then translates to an input for the fair assignment problem for k -center by assigning distance 1 to each edge and using the resulting graph metric. The vertices consist of \mathcal{U} , \mathcal{F} and two sets defined below, \mathcal{A} and \mathcal{T} . We start by adding an edge between all $e \in \mathcal{U}$ and any $A \in \mathcal{F}$ iff $e \in A$. We assign color red to the vertices from \mathcal{F} and blue to those from \mathcal{U} . Then we construct a set \mathcal{A} which contains three auxiliary blue vertices for each vertex in \mathcal{F} . These are exclusively connected to their corresponding vertex in \mathcal{F} . Then we construct a set \mathcal{T} of $|\mathcal{U}|/3$ red vertices,³ and connect each vertex in \mathcal{T} to every vertex in \mathcal{F} . Finally, we open a center at each vertex in \mathcal{F} . The construction is shown in Figure 2. Observe that the distance between an element $e \in \mathcal{U}$ and an open center at $A \in \mathcal{F}$ in this construction is 1 iff $e \in A$, and otherwise, it is 3: If $e \notin A$, then there is no edge between e and A , and since there are no direct connections between the centers, the minimum distance between e and another open center is 3.

► **Lemma 15.** *If there exists an exact cover, there exists a fair assignment of cost 1 where the red:blue ratio is 1:3 for each cluster.*

Proof. Assign each red vertex $A \in \mathcal{F}$ and the three auxiliary blue vertices connected to it to the center at A . If A is in the exact cover, assign the three blue vertices representing its elements and one red vertex from \mathcal{T} to the center at A . It is straightforward to verify that this assignment is fair and assigns every vertex to some center to which it is connected via a direct edge. ◀

► **Lemma 16.** *If there exists a fair assignment where red:blue = 1:3 for all clusters of cost less than 3, there exists an exact cover.*

Proof. For $A \in \mathcal{F}$, the red vertex at A and the three auxiliary blue vertices attached to it must be assigned to the center at A as this is the only center within distance less than 3. Also, no center can have more than two red vertices assigned to it because there are only six blue vertices in distance less than 3 of any center. Therefore, each red vertex in \mathcal{T} must be assigned to a distinct center and each such center A will have exactly three blue vertices from \mathcal{U} assigned to it which correspond to the elements in the set that A represents. Thus, the sets corresponding to the centers that have two red vertices assigned to them form an exact cover for \mathcal{U} . ◀

³ Note that if $|\mathcal{U}|$ is not a multiple of three, it cannot have an exact cover, so we can assume that $|\mathcal{U}|$ is a multiple of three.

B

 Integrality gap of the canonical clustering LP

We show that any integral fair solution needs large clusters to implement awkward ratios of the input points. This allows us to derive a non-constant integrality gap for the canonical clustering LP.

► **Lemma 17.** *Let P be a point set with r red and $r - 1$ blue points and let $k \geq 1$. If the ratio of red points $r_{red}(C_i)$ is at most $\frac{r-k+1}{2r-2k+1}$ for each cluster C_i , then any fair solution can have at most k clusters.*

Proof. Consider a solution with $k' > k$ clusters. Since we have more red points there must be at least one cluster C_i that contains more red points than blue points. The ratio of red points $r_{red}(C_i)$ of this cluster is minimized if the solution contains $k' - 1$ clusters with one blue and one red point, and one cluster with the remaining $r - k'$ blue and $r - k' + 1$ red points. However,

$$\frac{r - k' + 1}{2r - 2k' + 1} > \frac{r - k + 1}{2r - 2k + 1}$$

Since the highest ratio of red points in any other solution can only be higher, the claim follows. ◀

We remark that Lemma 17 is not true for essentially fair solutions.

The canonical fair clustering ILP consists of (2)–(6) and (10). In the k -median/facility location case and in the k -means case, let write OPT_F for the optimum value of its LP relaxation and let us call the value of an optimum integral solution OPT_I . We then define the integrality gap of the ILP as $\text{OPT}_I/\text{OPT}_F$. In the k -center case, the ILP does not have an objective function, but we can define its integrality gap in the following sense: If τ_I, τ_F is the smallest τ such that the LP-relaxation has a feasible *integral* or *fractional* solution, respectively, then we define the integrality gap as τ_I/τ_F .

► **Lemma 5.** *There is a choice of non-trivial fairness intervals such that the integrality gap of the LP-relaxation of the canonical fair clustering ILP is $\Omega(n)$ for the fair k -center/ k -supplier/ k -median/facility location problem. The integrality gap is $\Omega(n^2)$ for the fair k -means problem.*

■ **Figure 3** Integrality gap example.

Proof. Consider the input points P lying on a line, as shown in Figure 3. Specifically, we have r red points $\{r_1, r_2, \dots, r_r\}$ that alternate with $r - 1$ blue points $\{b_1, b_2, \dots, b_{r-1}\}$. The distance between consecutive points is 1.

We require that the ratio of the red points of each cluster is between 0 and $(r - 1)/(2r - 3)$ and set $k = r - 1$. The input ratio $r/(2r - 1)$ of the red points lies in the interior of this interval as

$$\frac{r}{2r - 1} < \frac{r - 1}{2r - 3} \iff 2r^2 - 3r < 2r^2 - 3r + 1,$$

and thus our input is well-defined and the fairness relaxation is non-trivial. We then ask for a clustering of P with at most k centers that respects the fairness constraints.

Consider the following feasible solution for the LP-relaxation. The solution opens a center at each of the $r - 1 = k$ blue points and assigns the blue point to itself and the red points on each side in the following way: for each $1 \leq i \leq r - 1$, assign r_i to b_i by a fraction of $\frac{r-i}{r-1}$ and for each $2 \leq i \leq r$ assign r_i to b_{i-1} a fraction of $\frac{i-1}{r-1}$. Each red point is fully assigned in this way. We also get that in a cluster around some fixed b_i , the total assignment coming from red points is $\frac{r}{r-1}$ and the assignment coming from blue points is 1; thus, each cluster has a ratio of red points of

$$\frac{\frac{r}{r-1}}{1 + \frac{r}{r-1}} = \frac{\frac{r}{r-1}}{\frac{2r-1}{r-1}} = \frac{r}{2r-1}.$$

We therefore respect the balance requirements.

However, as $(r-1)/(2r-3) = (r-k'+1)/(2r-2k'+1)$ for $k' = 2$, by Lemma 17 any integral solution satisfying the ratio requirement can at most open two centers.

- In the k -center case, the fractional solution has a radius of 1 and the integral solution has a radius of at least $\lfloor (r-1)/2 \rfloor = \Omega(n)$. The k -center problem is a special case of the k -supplier problem; thus, the integrality gap for the k -supplier problem can only be larger.
- In the k -median case, the fractional solution has a cost of $O(n)$: The blue points incur no cost and each red point r_i contributes $(r-i)/(r-1) \cdot 1 + (i-1)/(r-1) \cdot 1 = 1$ to the objective function. Since the optimum integral solution can have at most two centers, it has to contain one cluster spanning at least $\lfloor r/2 \rfloor$ consecutive points. This incurs a cost of at least $2 \cdot \sum_{j=1}^{\lfloor r/4 \rfloor - 1} j = \Omega(n^2)$.
- In the facility location case, we observe that we can open at most two facilities in a fair integral solution. Hence, the analysis for the k -median case carries over (even if we set all opening costs to zero).
- In the k -means case, each red point r_i incurs a cost of $(r-i)/(r-1) \cdot 1^2 + (i-1)/(r-1) \cdot 1^2 = 1$ in the fractional solution; the blue points again incur no cost as they are chosen as centers. However, the integral solution now has a cost of at least $2 \cdot \sum_{j=1}^{\lfloor r/4 \rfloor - 1} j^2 = \Omega(n^3)$. ◀

This integrality gap yields a lower bound on the quality guarantee of any LP-rounding approach for this ILP. Thus, Lemma 5 implies that no fair constant factor approximation can be achieved by rounding the canonical fair clustering ILP. The counterexample in 5 breaks down in the essential fairness model.

C Facts about the k -means cost function

We use some well-known facts about the k -means function when extending our results for k -median to k -means. The first one is that squared distances satisfy a relaxed triangle inequality:

► **Lemma 18.** *It holds for all $x, y, z \in \mathbb{R}^d$ that*

$$\|x - z\|^2 \leq 2\|x - y\|^2 + 2\|y - z\|^2.$$

The next lemma is also a folklore statement which can be extremely useful. It implies that the best 1-means is always the centroid of a point set, and has further consequences, like Lemma 20 which we state below, a fact which is also commonly used in approximation algorithms for the k -means problem.

18:22 On the Cost of Essentially Fair Clusterings

► **Lemma 19.** For any $P \subset \mathbb{R}^d$, and $z \in \mathbb{R}^d$,

$$\sum_{x \in P} \|x - z\|^2 = \sum_{x \in P} \|x - \mu(P)\|^2 + |P| \cdot \|\mu(P) - z\|^2,$$

where $\mu(P) = \frac{1}{|P|} \sum_{x \in P} x$ is the centroid of P .

One corollary of Lemma 19 is that the optimum cost of the best discrete solution is not much more expensive than the best choice of centers from \mathbb{R}^d .

► **Lemma 20.** Let $P \subset \mathbb{R}^d$ be a set of point in the Euclidean space, and let $S^* \subset \mathbb{R}^d$ be a set of k points that minimizes the k -means objective, i.e., it minimizes

$$\sum_{x \in P} \min_{c \in S} \|x - c\|^2$$

over all choices of $S \subset \mathbb{R}^d$ with $|S| = k$. Furthermore, let \hat{S} be the set of centers that minimizes the k -means objective over all choices of $S \subset P$ with $|S| = k$, i.e., the best choice of centers from P itself. Then it holds that

$$\sum_{x \in P} \min_{c \in \hat{S}} \|x - c\|^2 \leq \sum_{x \in P} \min_{c \in S^*} \|x - c\|^2.$$

Thus, restricting the set of centers to the input point set increases the cost of an optimal solution by a factor of at most 2.

The Maximum Exposure Problem

Abstract

Given a set of points P and axis-aligned rectangles \mathcal{R} in the plane, a point $p \in P$ is called *exposed* if it lies outside all rectangles in \mathcal{R} . In the *max-exposure problem*, given an integer parameter k , we want to delete k rectangles from \mathcal{R} so as to maximize the number of exposed points. We show that the problem is NP-hard and assuming plausible complexity conjectures is also hard to approximate even when rectangles in \mathcal{R} are translates of two fixed rectangles. However, if \mathcal{R} only consists of translates of a single rectangle, we present a polynomial-time approximation scheme. For general rectangle range space, we present a simple $O(k)$ bicriteria approximation algorithm; that is by deleting $O(k^2)$ rectangles, we can expose at least $\Omega(1/k)$ of the optimal number of points.

1 Introduction

Let $S = (P, \mathcal{R})$ be a geometric set system, also called a *range space*, where P is a set of points and each $R \in \mathcal{R}$ is a collection of subsets of P , also called a range. We are primarily interested in range spaces defined by a set of points in two dimensions and ranges defined by axis-aligned rectangles. We say that a point $p \in P$ is *exposed* if no range in \mathcal{R} contains p . The *max-exposure problem* is defined as follows: given a range space (P, \mathcal{R}) and an integer parameter $k \geq 1$, remove k ranges from \mathcal{R} so that a maximum number of points are exposed. That is, we want to find a subfamily $\mathcal{R}^* \subseteq \mathcal{R}$ with $|\mathcal{R}^*| = k$, so that the number of exposed points in the (reduced) range space $(P, \mathcal{R} \setminus \mathcal{R}^*)$ is maximized.

The max-exposure problem arises naturally in many geometric coverage settings. For instance, if points are the location of clients, and ranges are coverage of some facilities in the plane, then exposed points are those not covered by any facility. The max-exposure problem in this case gives a worst-case bound on the number of clients that can be exposed if an adversary disables k facilities. Similarly, in distributed sensor networks, ranges correspond to *sensing zones*, points correspond to physical assets being monitored by the network, and the max-exposure problem computes the number of assets exposed when k sensors are compromised.

More broadly, the max-exposure problem is related to the densest k -subgraph problem in *hypergraphs*. In the *densest k -subhypergraph* problem, we are given a hypergraph $H = (X, E)$, and we want to find a set of k vertices with a maximum number of induced hyperedges. In general hypergraphs, finding k -densest subgraphs is known to be (conditionally) hard to approximate within a factor of $n^{1-\epsilon}$, where n is the number of vertices. The max-exposure problem is equivalent to the densest k -subhypergraph problem on a *dual* hypergraph, the vertex set X corresponds to the ranges \mathcal{R} , and set of edges E of the dual hypergraph correspond to the set of points P . In the rest of the paper, we will use $n = |\mathcal{R}|$ for the number of ranges in \mathcal{R} and $m = |P|$ to be the number of points. We show that if the range space is defined by *convex polygons*, then the max-exposure problem is just as hard as the densest k -subhypergraph problem. However, for ranges defined by *axis-aligned rectangles*, one can achieve much better approximation. In particular, we obtain the following results.

- We show that the max-exposure problem is NP-hard and assuming the *dense vs random* conjecture to be true, it is also hard to approximate better than a factor of $O(n^{1/4})$ even if the range space is defined by *only two types of rectangles* in the plane. (For range space defined by convex polygons, we show that max-exposure is equivalent to densest k -subhypergraph problem, which is hard to approximate within $O(n^{1-\epsilon})$).
- When ranges are defined by translates of a *single* rectangle, we give a polynomial-time approximation scheme (PTAS) for max-exposure. The PTAS stands in sharp contrast to the inapproximability of ranges defined by *two* types of rectangles. Moreover, as an easy consequence of this result, we obtain a constant approximation when the ratio of longest and smallest side of rectangles in \mathcal{R} is bounded by a constant. However, we do not know if max-exposure with translates of a single rectangle can be solved in polynomial time or is NP-hard.
- For ranges defined by arbitrary rectangles, we present a simple greedy algorithm that achieves a bicriteria $O(k)$ -approximation. No such approximation is possible for general hypergraphs. If rectangles in \mathcal{R} have a bounded aspect ratio, the approximation improves to $O(\sqrt{k})$.

Related Work. Coverage and exposure problems have been widely studied in geometry and graphs. In the classical *set cover* problem, we want to select a subfamily of k sets that cover the maximum number of items (points) [14, 17]. For the set cover problem, the classical greedy algorithm achieves a factor $\log n$ approximation on the number of sets needed to cover all the items, or factor $(1 - 1/e)$ approximation on the number of items covered by using exactly k sets. Similarly, in geometry, the art gallery problems explore coverage of polygons using a minimum number of guards. Unlike coverage problems where greedy algorithms deliver reasonably good approximation, the exposure problems turn out to be much harder. Specifically, choosing k sets whose union is of *minimum size* is much harder to approximate with a conditional inapproximability of $O(n^{1-\epsilon})$ where n is the number of elements and $O(m^{1/4-\epsilon})$ where m is the number of sets [10]. This so-called *min-union* problem is essentially the densest k -subgraph problem on hypergraphs [9]. The densest k -subgraph problem for graphs has a long history [15, 3, 2, 6]. The classical coverage problems have been extensively studied for geometric set systems and significantly better approximation bounds have been achieved for them [1, 7, 20]. Several other variations such as the set multi-cover problem [8, 12] where each input point needs to be covered by more than one set have also been studied. Also closely related to max-exposure is the geometric constraint removal problem [4, 13], where given a set of ranges, the goal is to *expose* a path

between two given points by deleting at most k ranges (a path is exposed if it lies in the exterior of all ranges). Even for simple shapes such as unit disks (or unit squares) [5, 19], no PTAS is known for this problem.

The remainder of the paper is organized as follows. In Section 2, we discuss our hardness results followed by the bicriteria $O(k)$ -approximation in Section 3. In Section 4, we study the case when \mathcal{R} consists of translates of a fixed rectangle and describe a PTAS for it. Finally, in Section 5, we use these ideas to obtain a bicriteria $O(\sqrt{k})$ -approximation when aspect ratio of rectangles in \mathcal{R} is bounded by a constant.

2 Hardness of Max-Exposure

We show that max-exposure problem for geometric ranges is both NP-hard and inapproximable within a polynomial factor, under some well known hardness conjectures. In particular, we first show that the densest k -subgraph on bipartite graphs (*bipartite-DkS*) can be easily reduced to the max-exposure problem. In the *bipartite-DkS* problem, we are given a bipartite graph $G = (A, B, E)$, an integer k , and we want to compute a set of k vertices such that the induced subgraph on those k vertices has the maximum number of edges. Given an instance $G = (A, B, E)$ of bipartite-DkS, we will construct a max-exposure instance as follows.

Let $R_1 = [0, \epsilon] \times [0, n]$ be a thin vertical rectangle and $R_2 = [0, n] \times [0, \epsilon]$ be a thin horizontal rectangle. For each vertex $v_i \in A$, we create a copy R_i of R_1 , and place it such that its lower-left corner is at $(i, 0)$. Similarly, for each vertex $v_j \in B$, we create a copy R_j of R_2 , and place it such that its lower-left corner is at $(0, j)$. These $|A| + |B|$ rectangles create a checkerboard arrangement, with $|A| \times |B|$ cells of intersection. For each edge $(v_i, v_j) \in E$, we place a single point in the cell corresponding to intersection of R_i and R_j . It is now easy to see that G has a k -subgraph with m^* edges if and only if we can expose m^* points in this instance by removing k -rectangles: the removed rectangles are exactly the k vertices chosen in the graph, and each exposed point corresponds to the edge included in the output subgraph. (See also Figure 1.)

► **Lemma 1.** *The max-exposure problem is at least as hard as bipartite-DkS.*

Since bipartite-DkS is known to be NP-hard [16], we have the following.

► **Theorem 2.** *Max-exposure problem with axis-aligned rectangles is NP-hard.*

2.1 Hardness of Approximation

The construction in the preceding proof shows that max-exposure with rectangles is at least as hard as bipartite-DkS problem. Moreover, the geometric construction uses translates of *only two rectangles* R_1, R_2 . In the following, we show that even with such a restricted range space, the problem is also hard to approximate. To that end we prove that bipartite-DkS cannot be approximated better than a factor $O(n^{1/4})$, where n is the number of vertices in this graph. More precisely, if the densest subgraph over k vertices has m^* edges, it is hard to find a subgraph over k vertices that contains at least $\Omega(m^*/n^{1/4-\epsilon})$ edges in polynomial time. This hardness of approximation is conditioned on the so-called *dense vs random* conjecture [10] being true. Roughly speaking, we are given a graph G , constants $0 < \alpha, \beta < 1$, and a parameter k , and we want to distinguish between the following two cases.

1. (RANDOM) $G = G(n, p)$ where $p = n^{\alpha-1}$, that is, G has average degree approximately n^α .
2. (DENSE) G is adversarially chosen so that the densest k -subgraph of G has average degree k^β .

■ **Figure 1** Reducing bipartite-DkS to max-exposure with axis-aligned rectangles.

■ **Figure 2** Reducing densest k -subhypergraph problem to max-exposure. Hypergraph vertices A, B shown as convex ranges.

The conjecture states that for all $0 < \alpha < 1$, sufficiently small $\epsilon > 0$, and for all $k \leq \sqrt{n}$, one cannot distinguish between the *dense* and *random* cases in polynomial time (w.h.p), when $\beta \leq \alpha - \epsilon$.

In order to obtain hardness guarantees using the above conjecture, one needs to find the “distinguishing ratio” r , that is the least multiplicative gap between the optimum solution for the problem on the dense and random instances. If there exists an algorithm with an approximation factor significantly smaller than r , then we would be able to use it to distinguish between the dense and random instances, thereby refuting the conjecture. We obtain the following result for densest k -subgraph problem on bipartite graphs. (See Appendix A.1 for a proof.)

► **Lemma 3.** *Assuming that dense vs random conjecture is true, the densest k -subgraph problem on bipartite graphs is hard to approximate better than a factor $O(n^{1/4})$ of optimum.*

Using the same construction as in Lemma 1, we obtain the following.

► **Corollary 4.** *Assuming the dense vs random conjecture, max-exposure with axis-aligned rectangles is hard to approximate better than a factor $O(n^{1/4})$ of optimum.*

Hardness of Max-exposure with Convex Polygons

If the range space (P, \mathcal{R}) consists of convex polygons, the max-exposure problem is *equivalent* to the densest k -subhypergraph problem for general hypergraphs. A max-exposure instance (P, \mathcal{R}) naturally corresponds to a hypergraph $H = (\mathcal{R}, P)$ whose vertices are the ranges and the edges correspond to points and are defined by the containment relationship. Clearly, the densest k -subhypergraph corresponds to the set of k ranges deleting which exposes maximum number of points. For the other direction, we have the following lemma. (See also Figure 2.)

► **Lemma 5.** *Given a hypergraph $H = (X, E)$, one can construct a max-exposure instance with convex ranges \mathcal{R} and points P such that the densest k -subhypergraph of H corresponds to a solution of max-exposure.*

Proof. For each edge $e \in E$ of the hypergraph, add a point $p_e \in P$. We place all the points of P in convex position. Let $v \in X$ be a vertex and E_v be the set of hyperedges adjacent to v . Then for every $v \in X$, we add a convex polygon $R_v \in \mathcal{R}$ such that the corners of R_v is precisely the point set E_v . Note that this is possible since points of P are in convex position. It is easy to see that in order to include an edge e (expose p_e), we must include all vertices in E_v , which corresponds to removing all polygons corresponding to vertices in E_v . ◀

3 A Bicriteria $O(k)$ -approximation Algorithm

In this section, we present a simple approximation algorithm for the max-exposure problem that achieves bicriteria $O(k)$ -approximation for range spaces defined by arbitrary axis-aligned rectangles. Specifically, if the optimal number of points exposed is m^* , the algorithm picks a subset of k^2 rectangles such that the number of points exposed is at least m^*/ck , for some constant c . In fact, the results hold for any polygonal range with $O(1)$ complexity.

This bicriteria approximation should be contrasted with the fact that no such approximation is possible for the densest k -subhypergraph problem: that is, one cannot compute a set of $O(k^b)$ vertices for any constant b such that the number of edges in the induced subhypergraph is at least optimal. Thus the geometric properties of the range space have a significant impact on the problem complexity. In particular, if \mathcal{R} consists of rectangle ranges, we show that the following strategy picks a subset of αk ranges such that the number of points exposed is at least $\alpha m^*/ck^2$, for a parameter $1 \leq \alpha \leq k$ and constant c that will be fixed later. Choosing $\alpha = k$ gives us the claimed bound.

Our algorithm is essentially greedy. We divide the points into maximal equivalence classes, where each class is the maximal subset of points belonging to the same subset of ranges. We define $\mathcal{R}(p)$ as the set of ranges that contain a point $p \in P$, and remove all points that are contained in more than k ranges, since they can be never exposed in the optimal solution. Therefore, without loss of generality, we can assume that $|\mathcal{R}(p)| \leq k$ for all points $p \in P$.

■ **Algorithm 1** Greedy-Bicriteria.

-
1. Partition P into a set \mathcal{G} of groups where each group $G_i \in \mathcal{G}$ is an equivalence class of points that are contained in the same set of ranges. That is, for any $p \in G_i, p' \in G_j$, we have $\mathcal{R}(p) = \mathcal{R}(p')$ if $i = j$ and $\mathcal{R}(p) \neq \mathcal{R}(p')$, otherwise.
 2. Sort the groups in \mathcal{G} by decreasing order of their size $|G_i|$ and select the first α groups. Return $m' = \sum_{1 \leq i \leq \alpha} |G_i|$ as the number of points exposed.
-

Observe that every point $p \in G_i$ is contained in the same set of ranges $\mathcal{R}_i = \mathcal{R}(p)$ and $|\mathcal{R}_i| \leq k$. Therefore, the total number of ranges that we remove is at most αk . It remains to show that the number of points exposed m' is at least $\alpha m^*/ck^2$.

► **Lemma 6.** *Let m' be the number of points exposed by the algorithm Greedy-Bicriteria, and let m^* be the optimal number of exposed points, Then, $m' \geq \alpha m^*/ck^2$.*

Proof. Consider the optimal set \mathcal{R}^* of k ranges that are deleted, and let P^* be the set of exposed points. We partition the set of points P^* into groups \mathcal{G}^* as before, such that each group $G_i^* \in \mathcal{G}^*$ is identified by the range set $\mathcal{R}_i^* = \mathcal{R}(p)$, for any $p \in G_i^*$. Since $P^* \subseteq P$, we must have that $\mathcal{G}^* \subseteq \mathcal{G}$. This holds because for every group $G_i^* \in \mathcal{G}^*$ there must be a group $G_i \in \mathcal{G}$ such that $\mathcal{R}_i^* = \mathcal{R}_i$. Moreover since P^* is the maximum set of points that can be exposed, we must have that $G_i^* = G_i$. Finally, we note that the number of groups $|\mathcal{G}^*|$ is bounded by the number of cells in the arrangement of ranges in \mathcal{R}^* which is at most ck^2 for some fixed constant c , for all $O(1)$ -complexity ranges.

If the groups in \mathcal{G} are arranged by decreasing order of their sizes, we have that

$$m^* = \sum_{1 \leq i \leq |\mathcal{G}^*|} |G_i^*| \leq \sum_{1 \leq i \leq |\mathcal{G}^*|} |G_i| \leq \sum_{1 \leq i \leq ck^2} |G_i| \leq \frac{ck^2}{\alpha} \sum_{1 \leq i \leq \alpha} |G_i| = \frac{ck^2}{\alpha} \cdot m' \quad \blacktriangleleft$$

The parameter α can be tuned to improve the approximation guarantee with respect to one criterion (say the number of exposed points) at the cost of other. With $\alpha = k$, the algorithm exposes at least $\Omega(m^*/k)$ by removing k^2 ranges. If the range space \mathcal{R} consists of pseudodisk of *bounded-ply* (no point in the plane is incident to more than a constant number ρ of pseudodisks), then the algorithm Greedy-Bicriteria achieves an $O(\rho)$ approximation. This holds because the number of cells in an arrangement of k pseudodisks with depth at most ρ is $O(\rho k)$ [11].

4 A PTAS for Unit Square Ranges

We have seen that max-exposure is hard to approximate even if the ranges are translates of two types of rectangles. We now describe an approximation scheme when the ranges are translates of a *single* rectangle. In this case, we can scale the axes so that the rectangle becomes a *unit square* without changing any point-rectangle containment. Therefore, we can assume that our ranges are all unit squares. The problem is non-trivial even for unit square ranges, and as a warmup we first solve the following special case: *all the points lie inside a unit square*. We develop a dynamic programming algorithm to solve this case exactly, and then use it to design an approximation for the general set of points.

4.1 Exact Solution in a Unit Square

We are given a max-exposure instance consisting of unit square ranges \mathcal{R} and a set of points P in a unit square C . Without loss of generality, we can assume that the lower left corner of C lies at origin $(0, 0)$ and all ranges in \mathcal{R} intersect C . We classify the ranges in \mathcal{R} to be one of the two types: (See also Figure 3).

- Type-0** : Unit square ranges that intersect $x = 0$.
- Type-1** : Unit square ranges that intersect $x = 1$.

(A unit square range coincident with both $x = 0$ and $x = 1$ is assumed to be Type-0). We draw two parallel horizontal lines $\ell_0 : y = 0$ and $\ell_1 : y = 1$ coincident with bottom and top horizontal sides of C respectively. We say that a range $R \in \mathcal{R}$ is *anchored* to a line ℓ if it intersects ℓ . Note that every $R \in \mathcal{R}$ is anchored to exactly one of ℓ_0 or ℓ_1 . (When R is coincident with both ℓ_0 and ℓ_1 , we say that it is anchored to ℓ_0). Moreover, for the rest of our discussion, let $x = x_i$ be a vertical line and define $P_i \subseteq P$ to be the set of points that have x -coordinate at least x_i . Similarly, define $\mathcal{R}_i \subseteq \mathcal{R}$ to be the set of ranges that have at least one corner to the right of $x = x_i$. That is a range $R \in \mathcal{R}_i$ either intersects $x = x_i$ or lies completely to the right of it.

■ **Figure 3** Max-exposure in a unit square C . Type 0 ranges are drawn with solid lines, Type 1 ranges are dash-dotted.

■ **Figure 4** An example of *closer* relationship. Point p is *closer* to ℓ_1 than p' . R is *closer* to ℓ_0 than R' .

In order to gain some intuition, we will first consider the following two natural dynamic programming formulations for the problem.

DP-template-0. Suppose that the points in P are ordered by their increasing x -coordinates and let x_i be the x -coordinate of the i th point p_i . We define a subproblem as $S(i, k', \mathcal{R}_d)$ which represents the maximum number of points in P_i that can be exposed by removing k' ranges from the set $\mathcal{R}_i \setminus \mathcal{R}_d$. If we define $x_0 = 0$, then $S(0, k, \emptyset)$ gives the optimal number of exposed points for our problem.

Let $k_i = |\mathcal{R}(p_i) \setminus \mathcal{R}_d|$ be the number of ranges of $\mathcal{R}_i \setminus \mathcal{R}_d$ that contain p_i . Then, we can express the subproblems at i in terms of subproblems at $i + 1$ as follows.

$$S(i, k', \mathcal{R}_d) = \max \begin{cases} S(i + 1, k' - k_i, \mathcal{R}_d \cup \mathcal{R}(p_i)) + 1 & \text{expose } p_i \\ S(i + 1, k', \mathcal{R}_d) & \text{otherwise} \end{cases}$$

Roughly speaking, at $x = x_i$ which is the *event* corresponding to a point $p_i \in P$, we have two choices : *expose* p_i or *do not expose* p_i . If we expose p_i , we pay for deleting the ranges in $\mathcal{R}_i \setminus \mathcal{R}_d$ that contain p_i and mark them as deleted by adding to the *deleted range set* \mathcal{R}_d . Moreover, since we only delete ranges from $\mathcal{R}_i \setminus \mathcal{R}_d$, we can assume that $\mathcal{R}_d = \mathcal{R}_d \cap \mathcal{R}_i$ at each x_i . It is easy to see that this correctly computes the optimal number of exposed points. However, there is one complication: a priori it is not clear how to bound the number of range subset \mathcal{R}_d used by this dynamic program. We later argue that the geometry of range space for Type-0 ranges allows us to use only a polynomial number of choices.

DP-template-1. An alternative approach is to consider both *point* and *begin-range* events. That is, $x = x_i$ is either incident to a point $p_i \in P$ or to the left vertical side of a range $R_i \in \mathcal{R}$. Then, we can define a subproblem by the tuple $S(i, k', P_f)$ which represents the maximum number of points in $(P_i \setminus P_f)$ that can be exposed by removing k' ranges in \mathcal{R}_i . If we define $x_0 = 0$, then $S(0, k, \emptyset)$ gives the optimal number of exposed points. Let $P(R_i) \subseteq P$ be the set of points contained in the range R_i , then we have the following recurrence.

$$\begin{aligned} S(i, k', P_f) &= \max \begin{cases} S(i + 1, k' - 1, P_f) & \text{delete range } R_i \\ S(i + 1, k', P_f \cup P(R_i)) & \text{otherwise} \end{cases} \\ &\quad (\text{event } x = x_i \text{ was beginning of a range } R_i \in \mathcal{R}_i) \\ &= \max \begin{cases} S(i + 1, k', P_f) & \text{if } p_i \in P_f, \text{ cannot expose } p_i \\ S(i + 1, k', P_f) + 1 & \text{otherwise, expose } p_i \end{cases} \\ &\quad (\text{otherwise, event } x = x_i \text{ was a point } p_i \in P_i) \end{aligned}$$

In the above formulation, at each *begin-range* event for some $R_i \in \mathcal{R}_i$, we have two choices: *delete* R_i or *do not delete* R_i . If R_i was deleted, we reduce the budget k' by one. Otherwise, if R_i was not deleted, we can never expose the points in $P(R_i)$, and therefore we add $P(R_i)$ to the *forbidden point set* P_f . The correctness of the dynamic program follows from the fact that for every point p_i , all the ranges containing it must begin before $x = x_i$, and we expose p_i only if those ranges were *deleted*. Finally, since we only expose points in $P_i \setminus P_f$, we can assume that $P_f = P_f \cap P_i$ at each x_i . Again, it is not obvious how many different subsets P_f are needed by the dynamic program. However, we will later show that by keeping track of polynomial number of sets P_f , we can solve max-exposure with Type-1 ranges.

We note that the Type-0 and Type-1 ranges may superficially seem symmetric but once we fix the order of computing subproblems, they become structurally different. Therefore, we would need slightly different techniques to handle each type. For the ease of exposition, we present dynamic programs for Type-0 and Type-1 ranges separately and finally combine them.

We first define the following ordering relations that will be useful. Let ℓ be a horizontal line, and let $d(p, \ell)$ denote the orthogonal distance of $p \in P$ from ℓ . If $p, p' \in P$ are two points, we say that p is *closer* to ℓ than p' if $d(p, \ell) < d(p', \ell)$. Similarly, for a range $R \in \mathcal{R}$ that is anchored to ℓ , let $d(R, \ell)$ be the vertical distance *inside the unit square C* between ℓ and the side of R parallel to ℓ . If $R, R' \in \mathcal{R}$ are two ranges, we say that R is *closer* (or equivalently R' is *farther*) from ℓ if both R, R' are anchored to ℓ and $d(R, \ell) < d(R', \ell)$. (See Figure 4.)

4.1.1 Max-exposure with Type-0 Ranges

Recall that Type-0 ranges intersect the vertical lines $x = 0$ and are anchored to either ℓ_0 or ℓ_1 . We will apply the formulation discussed in *DP-template-0*. The key challenge here is to bound the number of possible deleted range sets \mathcal{R}_d . Towards that end, we make the following claim.

► **Lemma 7.** *Let q_0, q_1 be the two exposed points strictly to the left of $x = x_i$ that are closest to ℓ_0 and ℓ_1 respectively. Then our dynamic program only needs to consider the set of deleted ranges $\mathcal{R}_d = \mathcal{R}(q_0) \cup \mathcal{R}(q_1)$ at $x = x_i$ conditioned on q_0, q_1 .*

Proof. Observe that since \mathcal{R} consists of Type-0 ranges, every range in \mathcal{R}_i must intersect the vertical line $x = x_i$. Suppose we partition \mathcal{R}_i into ranges \mathcal{R}_i^0 that are anchored to ℓ_0 and \mathcal{R}_i^1 that are anchored to ℓ_1 . Let $P' \subseteq P$ be the set of all *exposed points* strictly to the left of $x = x_i$. Observe that for all $p \in P'$, any range $R \in \mathcal{R}_i^0$ that contains p must also contain q_0 . Therefore, we must have $\mathcal{R}_i^0 \cap \mathcal{R}(p) \subseteq \mathcal{R}_i^0 \cap \mathcal{R}(q_0)$, for all $p \in P'$. Similarly, $\mathcal{R}_i^1 \cap \mathcal{R}(p) \subseteq \mathcal{R}_i^1 \cap \mathcal{R}(q_1)$, for all $p \in P'$. Hence, $\bigcup_{p \in P'} \mathcal{R}_i \cap \mathcal{R}(p) = \mathcal{R}(q_0) \cup \mathcal{R}(q_1)$. Recall that \mathcal{R}_d is precisely the set of ranges at $x = x_i$ that contain any exposed point to the left of $x = x_i$, so we have $\mathcal{R}_d = \mathcal{R}(q_0) \cup \mathcal{R}(q_1)$. ◀

Therefore, if our dynamic program remembers the exposed points q_0, q_1 , then we can compute the deleted range set $\mathcal{R}_d = \mathcal{R}(q_0) \cup \mathcal{R}(q_1)$ at $x = x_i$. There are $O(m^2)$ choices for the pair q_0, q_1 , so the number of possible sets \mathcal{R}_d is also $O(m^2)$. We can therefore identify our subproblems by the tuple $S(i, k', q_0, q_1)$ which represents the maximum number of exposed points with x -coordinates x_i or higher using k' rectangles from the set $\mathcal{R}_i \setminus \mathcal{R}_d$. With $k_i = |\mathcal{R}(p_i) \setminus \mathcal{R}_d|$, we obtain the following recurrence:

$$S(i, k', q_0, q_1) = \max \begin{cases} S(i+1, k' - k_i, \text{closer}(p_i, q_0), \text{closer}(p_i, q_1)) + 1 & \text{expose } p_i \\ S(i+1, k', q_0, q_1) & \text{otherwise} \end{cases}$$

where the function $\text{closer}(p_i, q_0)$ returns whichever of p_i, q_0 is closer to ℓ_0 , and $\text{closer}(p_i, q_1)$ returns whichever of p_i, q_1 is closer to ℓ_1 . The optimal solution is given by $S(0, k, q_0^*, q_1^*)$, where $q_0^* = (0, 1)$ and $q_1^* = (0, 0)$ are two artificial points with $\mathcal{R}(q_0^*) = \mathcal{R}(q_1^*) = \emptyset$ (not contained in any range). The base case is defined by the vertical line $x = 1$ and is initialized with zeroes for all q_0, q_1 and $k' \geq 0$. Any subproblem with $k' < 0$ has value $-\infty$.

4.1.2 Max-exposure with Type-1 Ranges

Next we consider the case when we only have Type-1 ranges in \mathcal{R} . Unfortunately in this case, our previous dynamic program does not work and we need to remember a different set of parameters. More precisely, we will apply the formulation discussed in *DP-template-1*, and bound the number of possible forbidden point sets P_f .

► **Lemma 8.** *Let Q_0, Q_1 be two ranges that begin to the left of $x = x_i$ and were not deleted. Moreover, Q_0 is anchored to and is farthest from ℓ_0 . Similarly Q_1 is anchored to and is farthest from ℓ_1 (Figure 5). Then the forbidden point set at $x = x_i$ is given by $P_f = P(Q_0) \cup P(Q_1)$, where $P(Q)$ is the set of points contained in range Q .*

Proof. Recall that the set \mathcal{R}_i consists of ranges that have at least one corner to the right of the vertical line $x = x_i$. Since we are dealing with Type-1 ranges, every range that begins to the left of $x = x_i$ lies in \mathcal{R}_i . Now let $\mathcal{R}' \subseteq \mathcal{R}_i$ be the set of ranges that begin to the left of $x = x_i$ and were *not deleted*. Recall that P_i is the set of points in P that have x -coordinate x_i or higher. Now consider any range $R \in \mathcal{R}'$. Observe that if R was anchored to ℓ_0 , then every point of P_i that lies in R also lies in Q_0 . Otherwise, if R was anchored to ℓ_1 , every point of P_i that lies in R also lies in Q_1 . Therefore, we must have $\bigcup_{R \in \mathcal{R}'} (P_i \cap P(R)) = P(Q_0) \cup P(Q_1)$. Recall that P_f was precisely the set of points in P_i contained in ranges that begin to the left of $x = x_i$ and were not deleted. Therefore, we have that $P_f = P(Q_0) \cup P(Q_1)$. ◀

■ **Figure 5** Undeleted ranges Q_0 and Q_1 farthest from ℓ_0 and ℓ_1 respectively.

■ **Figure 6** Remembering one of R_1, R_2 in (a) or one of p_1, p_2 in (b) is not sufficient.

Therefore, if our dynamic program remembers the ranges Q_0 and Q_1 , we can compute the forbidden point set $P_f = P(Q_0) \cup P(Q_1)$ at $x = x_i$. Since there are $O(n^2)$ choices for the pair Q_0, Q_1 , the number of possible sets P_f is also $O(n^2)$. We can now identify the subproblems by the tuple $S(i, k', Q_0, Q_1)$ which represents the maximum number of points in $P_i \setminus P_f$ that are exposed by deleting k' ranges that begin on or after $x = x_i$. This gives us the following recurrence.

$$\begin{aligned}
 & S(i, k', Q_0, Q_1) = \\
 & \max \begin{cases} S(i+1, k'-1, Q_0, Q_1) & \text{delete range } R_i \\ S(i+1, k', \text{farther}(R_i, Q_0), Q_1) & \text{otherwise, } R_i \text{ is not deleted and anchored to } \ell_0 \\ S(i+1, k', Q_0, \text{farther}(R_i, Q_1)) & \text{otherwise, } R_i \text{ is not deleted and anchored to } \ell_1 \end{cases} \\
 & \quad (\text{event } x = x_i \text{ was beginning of a range } R_i \in \mathcal{R}) \\
 & \max \begin{cases} S(i+1, k', Q_0, Q_1) & \text{if } p_i \in P_f, \text{ cannot expose } p_i \\ S(i+1, k', Q_0, Q_1) + 1 & \text{otherwise, expose } p_i \end{cases} \\
 & \quad (\text{otherwise, event } x = x_i \text{ was a point } p_i \in P)
 \end{aligned}$$

19:10 The Maximum Exposure Problem

Here, $\text{farther}(R_i, Q_0)$ returns whichever of R_i, Q_0 is farther from ℓ_0 ; and $\text{farther}(R_i, Q_1)$ returns whichever of R_i, Q_1 is farther from ℓ_1 . The optimal solution is given by $P(0, k, Q_0^*, Q_1^*)$, where Q_0^*, Q_1^* are two artificial ranges of zero-width : Q_0^* is anchored to ℓ_0 and is defined by corners $(0, 0)$ and $(0, 1)$; similarly, Q_1^* is anchored to ℓ_1 and is defined by corners $(0, 1)$ and $(1, 1)$.

► **Remark 9.** We note that remembering constant number of exposed points q_0, q_1 or a constant number of undeleted ranges Q_1, Q_2 by themselves cannot solve *both* Type-0 and Type-1 ranges. For instance, in Figure 6(a) with Type-0 ranges, if R_1, R_2 were both *not deleted* but we remembered one of them, then we will incorrectly expose one of p, p' . Similarly in Figure 6(b) with Type-1 ranges, if p_1, p_2 were both exposed but we only remembered one of them, we will pay for one of the ranges R, R' again when we expose p_3 . However, since the previous dynamic programs for Type-0 and Type-1 ranges express subproblems at event i in terms of subproblems at event $i + 1$, we can easily combine them with minor adjustments.

4.1.3 Combining them together

In the following, we combine the dynamic programs for Type-0 and Type-1 ranges to obtain a dynamic program for max-exposure in a unit square C . We will need a couple of changes. First, the events at $x = x_i$ are now defined by either a point $p_i \in P$ or beginning of a Type-1 range R_i . Next, the *deleted range set* \mathcal{R}_d at $x = x_i$ will only consist of Type-0 ranges and is defined as $\mathcal{R}_d = \mathcal{R}_{i0} \cap (\mathcal{R}(q_0) \cup \mathcal{R}(q_1))$ where $\mathcal{R}_{i0} \subseteq \mathcal{R}_i$ is the set of Type-0 ranges that intersect the vertical line $x = x_i$, The *forbidden point set* $P_f = P(Q_0) \cup P(Q_1)$ stays the same. Here q_0, q_1, Q_0, Q_1 are same as defined before. The subproblems represent the maximum number of points in $P_i \setminus P_f$ that can be exposed by deleting k' ranges from $\mathcal{R}_i \setminus \mathcal{R}_d$. If $k_i = |\mathcal{R}(p_i) \setminus \mathcal{R}_d|$, then we obtain the following combined recurrence.

$$\begin{aligned}
 S(i, k', q_0, q_1, Q_0, Q_1) = & \\
 \max \begin{cases} S(i+1, k', q_0, q_1, Q_0, Q_1) & \text{if } p_i \in P_f, \text{ cannot expose } p_i \\ S(i+1, k', q_0, q_1, Q_0, Q_1) & \text{choose to not expose } p_i \\ S(i+1, k' - k_i, q_0, q_1, Q_0, Q_1) + 1 & \text{otherwise, expose } p_i \end{cases} & \\
 (\text{event } x = x_i \text{ was a point } p_i \in P_i) & \\
 \max \begin{cases} S(i+1, k' - 1, q_0, q_1, Q_0, Q_1) & \text{delete Type-1 range } R_i \\ S(i+1, k', q_0, q_1, \text{farther}(R_i, Q_0), Q_1) & R_i \text{ not deleted and anchored to } \ell_0 \\ S(i+1, k', q_0, q_1, Q_0, \text{farther}(R_i, Q_1)) & R_i \text{ not deleted and anchored to } \ell_1 \end{cases} & \\
 (\text{event } x = x_i \text{ was beginning of a Type-1 range } R_i \in \mathcal{R}_i) &
 \end{aligned}$$

The optimal solution is given by $S(0, k, q_0^*, q_1^*, Q_0^*, Q_1^*)$. The correctness of the above formulation follows from the fact that when we choose to expose p_i , we are guaranteed that all Type-1 ranges in $\mathcal{R}(p_i)$ have already been deleted, and the expression k_i only charges for Type-0 ranges containing p_i . As for the running time, for each event $x = x_i$, we compute $O(kn^2m^2)$ entries and computing each entry takes constant time. Since there are $O(n + m)$ events, we obtain the following.

► **Lemma 10.** *Given a set P of m points in a unit square C and a set of n unit square ranges \mathcal{R} , we can compute their max-exposure in $O(k(n + m)n^2m^2)$ time.*

4.2 A Constant Factor Approximation

We now use the preceding algorithm to solve the max-exposure problem for general set of points and unit square ranges within a factor 4 of optimum. In particular, we compute a set of $4k$ ranges in \mathcal{R} such that the number of points exposed in P by deleting them is at least the optimal number of points. Suppose we embed the ranges \mathcal{R} on a uniform unit-sized grid G , and define \mathcal{C} as the collection of all cells in G that contain at least one point of P . We have the following approximation algorithm.

■ **Algorithm 2** DP-Approx.

1. Apply Lemma 10 to solve max-exposure locally in every cell $C_i \in \mathcal{C}$ for all $0 \leq k_i \leq k$. Call this a *local* solution denoted by $local(P(C_i), \mathcal{R}(C_i), k_i)$, where $P(C_i) \subseteq P$ is the set of points contained in cell C_i and $\mathcal{R}(C_i)$ is the set of ranges intersecting C_i .
2. Process cells in \mathcal{C} in any order C_1, C_2, \dots, C_g , and define $global(i, k')$ as the maximum number of points exposed in the cells C_i through C_g using k' ranges. Combine local solutions to obtain $global(i, k')$ as follows.

$$global(i, k') = \max_{0 \leq k_i \leq k'} global(i + 1, k' - k_i) + local(P(C_i), \mathcal{R}(C_i), k_i)$$

3. Return $global(1, 4k)$ as the number of exposed points.

We have the following lemma. (See Section A.2 in the Appendix for a proof.)

► **Lemma 11.** *If $P^* \subseteq P$ is the optimal set of exposed points, then $global(1, 4k) \geq |P^*|$, that is, the algorithm DP-Approx achieves a 4-approximation and runs in $O(k(n + m)n^2m^2)$ time.*

4.3 Towards a PTAS

We now consider the max-exposure instance in a horizontal strip of unit width. That is, all points in P lie in a horizontal strip bounded by lines ℓ_0, ℓ_1 and \mathcal{R} consists of unit square ranges. Suppose, we subdivide the strip into unit square cells $C_1, C_2, \dots, C_r \in \mathcal{C}$ ordered from left to right. We make the following simple observation.

■ **Figure 7** Max-exposure instance in a strip. $C_{j-1}, C_j \in \mathcal{C}$ are two consecutive cells.

► **Lemma 12.** *Let $R \in \mathcal{R}$ be a unit square range and C_{j-1} be the first cell from left which it intersects. Then the only other cell that R can intersect is C_j . Moreover, R is Type-1 with respect to C_{j-1} and Type-0 with respect to C_j . (See Figure 7.)*

Observe that the set of points exposed in cell C_j will also depend on the set of Type-0 objects of C_j that were already deleted in C_{j-1} . So we need to ensure that we do not double count the set of ranges that were already deleted in C_{j-1} . To do this, we again use a dynamic

19:12 The Maximum Exposure Problem

program similar to that for max-exposure within a cell where we express the subproblems at $x = x_i$ in terms of subproblems to the right of $x = x_i$. However, there are some important differences in how we define our subproblems. First, events at a vertical line $x = x_i$ are one of three types:

1. *cell-boundary*: $x = x_i$ is coincident with left-boundary of a cell $C_j \in \mathcal{C}$,
2. *begin-range*: $x = x_i$ is coincident with left-vertical side of a range $R_i \in \mathcal{R}$
3. *point*: $x = x_i$ is incident to an input $p_i \in P$

Moreover for a given cell C_j , in addition to the points q_0, q_1 , and ranges Q_0, Q_1 , we will also need to remember two additional ranges : L_0 (anchored to ℓ_0) and L_1 (anchored to ℓ_1) that begin in C_{j-1} , were *not deleted* and are farthest from ℓ_0, ℓ_1 respectively. For the sake of clarity, we will use $Z_0 = (q_0, Q_0, L_0)$ to denote the triplets corresponding to ℓ_0 and $Z_1 = (q_1, Q_1, L_1)$ to denote the triplets corresponding to ℓ_1 .

Suppose $x = x_i$ lies in the cell C_j . Then we show that the set of deleted ranges \mathcal{R}_d consisting of Type-0 ranges in C_j , and the set of forbidden points P_f can be uniquely identified using the triples Z_0, Z_1 .

- *Deleted Type-0 range-set \mathcal{R}_d* Let \mathcal{R}_{j-1} be the set of ranges that begin in cell C_{j-1} , and therefore are Type-1 with respect to C_{j-1} . Suppose we define $\mathcal{L}_{>0} \subseteq \mathcal{R}_{j-1}$ to be the set consisting of ranges anchored to ℓ_0 and farther from ℓ_0 than L_0 . Similarly, $\mathcal{L}_{>1} \subseteq \mathcal{R}_{j-1}$ consists of ranges anchored to ℓ_1 and farther from ℓ_1 than L_1 . Then, we define $\mathcal{R}_d = (\mathcal{R}(q_0) \cup \mathcal{R}(q_1) \cup \mathcal{L}_{>0} \cup \mathcal{L}_{>1})$.
- *Forbidden point-set P_f* We define $P_f = (P(L_0) \cup P(L_1) \cup P(Q_0) \cup P(Q_1))$.

Finally, we say that a range R *dominates* another range R' , if both R, R' begin in the same cell C_j and $R' \cap C_j \subseteq R \cap C_j$. That is, R completely contains the part of R' that lies in cell C_j . Note that the key difference from earlier formulations is that at a begin-range event for a Type-1 range R_i in cell C_j , we choose to *ignore* R_i if it is dominated by ranges Q_0 or Q_1 , because the points of R_i contained in C_j already lie in the forbidden set P_f . With $k_i = |\mathcal{R}(p_i) \setminus \mathcal{R}_d|$, we obtain the following recurrence.

$$\begin{aligned}
 S(i, k', Z_0, Z_1) &= S(i+1, k, \mathcal{U}(Z_0, C_j), \mathcal{U}(Z_1, C_j)) \\
 &\quad (\text{event } x = x_i \text{ is left-boundary of cell } C_j) \\
 \max \begin{cases} S(i+1, k', Z_1, Z_2) & \text{if } p_i \in P_f, \text{ cannot expose } p_i \\ S(i+1, k', Z_1, Z_2) & \text{otherwise, choose to not expose } p_i \\ S(i+1, k' - k_i, Z_1, Z_2) + 1 & \text{otherwise, expose } p_i \end{cases} \\
 &\quad (\text{otherwise, event } x = x_i \text{ was a point } p_i \text{ in cell } C_j) \\
 \max \begin{cases} S(i+1, k', Z_0, Z_1) & \text{if either } Q_0 \text{ or } Q_1 \text{ dominates } R_i, \text{ ignore } R_i \\ S(i+1, k' - 1, Z_0, Z_1) & \text{otherwise, delete Type-1 range } R_i \\ S(i+1, k', \mathcal{U}(Z_0, R_i), Z_1) & \text{otherwise if } R_i \text{ is not deleted and anchored to } \ell_0 \\ S(i+1, k', Z_0, \mathcal{U}(Z_1, R_i)) & \text{otherwise, } R_i \text{ is not deleted and anchored to } \ell_1 \end{cases} \\
 &\quad (\text{otherwise, event } x = x_i \text{ was beginning of a Type-1 range } R_i \text{ in cell } C_j.)
 \end{aligned}$$

The function $\mathcal{U}(Z, E)$ used above is defined as follows. Roughly speaking, it updates the triplets $Z \in \{Z_0, Z_1\}$ based on the event E and returns an updated triplet. We have the following three cases.

- For a cell-boundary event C_j , if we have $Z_0 = (q_0, Q_0, L_0)$, the function $\mathcal{U}(Z_0, C_j) = (q_0^*, Q_0^*, L_0)$. Similarly, $\mathcal{U}(Z_1, C_j) = (q_1^*, Q_1^*, L_1)$. This corresponds to resetting the points q_0, q_1 , rectangles Q_0, Q_1 for the current cell C_j , and remembering the rectangles L_0, L_1 from the previous cell C_{j-1} .

- For a point event p_i , we have $\mathcal{U}(Z_0, p_i) = (\text{closer}(p_i, q_0), Q_0, L_0)$ and similarly $\mathcal{U}(Z_1, p_i) = (\text{closer}(p_i, q_1), Q_1, L_1)$. Recall that the function $\text{closer}(p_i, q_0)$ returns whichever of p_i, q_0 is closer to ℓ_0 , and $\text{closer}(p_i, q_1)$ returns whichever of p_i, q_1 is closer to ℓ_1 .
- Finally for a begin-rectangle event R_i , we have $\mathcal{U}(Z_0, R_i) = (q_0, \text{farther}(R_i, Q_0), L_0)$ and $\mathcal{U}(Z_1, R_i) = (q_1, \text{farther}(R_i, Q_1), L_1)$. Recall that the function $\text{farther}(R_i, Q_0)$ returns whichever of R_i, Q_0 is farther from ℓ_0 , and $\text{farther}(R_i, Q_1)$ returns whichever of R_i, Q_1 is farther from ℓ_1 .

The optimal solution is given by $W(0, k, Z_0^\theta, Z_1^\theta)$ where $Z_0^\theta = (q_0^*, Q_0^*, L_0^*)$ and $Z_1^\theta = (q_1^*, Q_1^*, L_1^*)$. In order to establish the correctness of the above formulation, we make the following claim.

► **Lemma 13.** *Let $P^* \subseteq P$ be the optimal set of exposed points. Then, for every point $p_i \in P^*$, we count the range $R \in \mathcal{R}(p_i)$ towards the total number of deleted ranges exactly once.*

Proof. We begin by noting that R intersects at most two cells : C_{j-1} as a Type-0 range and C_j as a Type-1 range. It suffices to show that we count R towards the total number of deleted ranges in exactly one of these two cells. Alternatively, it suffices to show that we count R in cell C_j if and only if we have not already counted R in C_{j-1} . Recall that we can only count for R in C_{j-1} by deleting it at a begin-range event. Moreover, we can only count for R in C_j when a point $p_i \notin P_f$ that lies in cell C_j is exposed. Without loss of generality, assume that R is anchored to ℓ_0 . The case when R is anchored to ℓ_1 is symmetric.

We first consider the easy case when R was not deleted in C_{j-1} . Observe that since R is Type-0 with respect to C_j , similar to the earlier cases, the terms $\mathcal{R}(q_0) \cup \mathcal{R}(q_1)$ in the expression for \mathcal{R}_d will correctly charge for R in cell C_j .

■ **Figure 8** Three cases for the proof: $R_1 \in \mathcal{L}_{>0}$, and $R_2, R_3 \notin \mathcal{L}_{>0}$. R_2 begins before L_0 and R_3 begins after L_0 .

Now, we move to the second case where we are currently in cell C_j and we have already counted R by deleting it at a begin-range event in cell C_{j-1} . In this case, we show that we will not count R again in C_j . More precisely, we show that if R contains a point p that lies in cell C_j but is not contained in the forbidden point set P_f , then the deleted range set \mathcal{R}_d contains R , and therefore the expression $k_i = \mathcal{R}(p) \setminus \mathcal{R}_d$ will not charge for R again. We have three cases.

1. $R \in \mathcal{L}_{>0}$. This case is straightforward as \mathcal{R}_d contains all ranges in $\mathcal{L}_{>0}$.
2. $R \notin \mathcal{L}_{>0}$ and R begins before L_0 . This case is not possible because any point that is contained in $(R \cap C_j)$ is also contained in L_0 . This holds because R and L_0 have the same width, so if R begins before L_0 in C_{j-1} , it must end before L_0 in C_j . Since every point contained in L_0 is contained in the forbidden set P_f , we must have $p \in P_f$ which is a contradiction. (See Figure 8 with $R = R_2$.)
3. $R \notin \mathcal{L}_{>0}$ and R begins after L_0 . This case is also not possible because if this were true L_0 would have dominated R . Therefore, we would have ignored R in C_{j-1} and would not have deleted it. (See Figure 8 with $R = R_3$.) ◀

19:14 The Maximum Exposure Problem

► **Lemma 14.** *The restricted max-exposure instance such that all points in P lie within a unit-width horizontal strip bounded by lines ℓ_0, ℓ_1 and \mathcal{R} consists of unit squares can be solved in $O(k(n+m)n^4m^2)$ time, where $m = |P|$ and $n = |\mathcal{R}|$.*

Using similar ideas as Lemma 11, the above lemma readily gives a 2-approximation for max-exposure. More precisely, we can embed the input instance on to a unit-sized grid as before, but instead of solving max-exposure in a cell, we use the above algorithm to solve max-exposure locally in a row of the grid. Since each range $R \in \mathcal{R}$ can intersect at most two rows, R is split into two sub-ranges R_1, R_2 contained in at most two rows. Since these new sub-ranges in two different rows are disjoint, there exists an optimal solution with $2k$ sub-ranges. Therefore, if we have already computed the local solutions for each row i , using the algorithm *DP-Approx* we can compute $global(1, 2k)$ which exposes at least optimal number of points using at most $2k$ ranges.

► **Corollary 15.** *There exists a 2-approximation algorithm for max-exposure with unit square ranges running in $O(k(n+m)n^4m^2)$ time.*

Generalizing to h anchor lines. The dynamic program for max-exposure in a horizontal strip bounded by two anchor lines ℓ_0, ℓ_1 can be generalized to the case when we have h anchor lines $\ell_1, \ell_2, \dots, \ell_h$. However, there is a minor technical change required. Observe that for a given anchor line ℓ_i , there can be points and anchored ranges on either side of ℓ_i . Therefore, we will need to remember the closest exposed points and the farthest undeleted ranges on both sides of ℓ_i . So for each anchor line ℓ_i , we will need the triplet $Z_i^+ = (q_i^+, Q_i^+, L_i^+)$ for points and ranges above ℓ_i and the triplet $Z_i^- = (q_i^-, Q_i^-, L_i^-)$ for points and ranges below ℓ_i . The dynamic program will now need to remember at most $4h$ ranges and $2h$ points which gives a running time of $O(k(n+m)n^{4h}m^{2h})$. If we denote a collection of h consecutive anchor lines by a *bundle* of width h , then we have the following.

► **Lemma 16.** *Max-exposure in a bundle of width h can be solved in $O(k(n+m)n^{4h}m^{2h})$ time.*

4.4 An $(1 + \epsilon)$ -Approximation Algorithm

We are now ready to describe our PTAS for the problem. Suppose the anchor lines correspond to the horizontal lines of the uniform unit-sized grid G . Since we have already solved max-exposure exactly for h consecutive rows in G , we can now apply standard shifting techniques [18] to obtain an $(1 + \epsilon)$ -approximation. If P^* is the optimal set of exposed points, then we show how to compute a set of $(1 + \epsilon)k$ ranges deleting which will expose at least $|P^*|$ points. Note that using similar ideas, it is also possible to expose at least $(1 - \epsilon)|P^*|$ points by deleting exactly k ranges (See Appendix B).

Suppose that anchor lines $\ell_1, \ell_2, \dots, \ell_z$ are ordered by increasing y -coordinates. We define a *bundle* B_j to be a set of h consecutive anchor lines, identified by the lowest index anchor ℓ_j . We also define *bundle-set* to be a sequence of consecutive bundles, identified by the index of the lowest bundle. For instance the bundle B_1 comprises of anchor lines ℓ_1 through ℓ_h (inclusive). And the bundle-set \mathcal{B}_1 comprises of bundles $B_1, B_h, B_{2h}, \dots, B_{\lceil z/h \rceil}$. The lines $\ell_1, \ell_h, \dots, \ell_{\lceil z/h \rceil}$ form the *bundle boundaries* $\partial\mathcal{B}_1$ of bundle-set \mathcal{B}_1 .

For each bundle $B_j \in \mathcal{B}_1$, we can use the dynamic program from Lemma 16 to solve max-exposure locally. Using the exact solution for each bundle as local solution, we can use the algorithm *DP-Approx* (from Section 4.2) to combine them into a global solution for the

bundle-set \mathcal{B}_1 given by $P(\mathcal{B}_1) = \text{global}(1, (k + k/h))$. We repeat this for each bundle-set \mathcal{B}_i for all $i \in \{1, 2, \dots, h\}$, and return the point set $P(\mathcal{B}_i)$ that has maximum cardinality over all $i \in \{1, 2, \dots, h\}$.

It remains to show that this achieves a good approximation. To see this, we observe that the only ranges that may be double counted are the ones that are anchored to bundle boundaries of $\partial\mathcal{B}_i$. In the following, we show that this number is a small fraction of the optimum solution. (Proof in Appendix A.3.)

► **Lemma 17.** *The bundle boundaries $\partial\mathcal{B}_i, \partial\mathcal{B}_j$ for any two bundle-set $\mathcal{B}_i, \mathcal{B}_j$ are disjoint, and therefore the set of ranges anchored to lines in $\partial\mathcal{B}_i$ are also disjoint. Then, there exists a bundle-set \mathcal{B}_{\min} such that the number of ranges of the optimal solution anchored to lines in $\partial\mathcal{B}_{\min}$ is at most k/h .*

Choosing $\epsilon = 1/h$ gives us a set of $(1 + \epsilon)k$ objects such that the number of points exposed by selecting these objects is at least the optimum number of points.

► **Theorem 18.** *There exists an $(1 + \epsilon)$ -approximation algorithm for max-exposure with unit square ranges running in $O(k(n + m)n^{4/\epsilon}m^{2/\epsilon})$ time.*

5 Extensions and Applications

In this section, we discuss some extensions and applications of our the results from previous section. We say that the range family \mathcal{R} consists of *fat rectangles* if every range $R \in \mathcal{R}$ is a rectangle of bounded *aspect ratio*. Moreover, we say that \mathcal{R} consists of *similar and fat rectangles*, if ranges in \mathcal{R} are rectangles and the ratio of the largest to the smallest side in \mathcal{R} is constant. We show that if \mathcal{R} consists of *similar and fat* rectangles, one can achieve a constant approximation. Moreover, if \mathcal{R} consists of *fat rectangles* one can achieve a bicriteria $O(\sqrt{k})$ -approximation.

5.1 Approximation for Similar and Fat Rectangles

Let a, b be the length of smallest and largest sides of rectangles in \mathcal{R} such that $b/a = c$ is constant. Then we can modify the input instance as follows. Replace each range $R \in \mathcal{R}$ by tiling it with at most c^2 squares of sidelength a such that the area occupied by R and its replacements are the same. Now, we have a modified set of ranges \mathcal{R}' consisting of squares that have the same sidelength. Consider the optimal solution with k ranges \mathcal{R}^* that exposes m^* points. It is easy to see that the set \mathcal{R}^* corresponds to at most c^2k ranges in the modified instance, and therefore deleting c^2k ranges from \mathcal{R}' exposes at least m^* points. Therefore, we can run the polynomial-time 2-approximation algorithm (Corollary 15) to obtain a set of at most $2c^2k$ ranges that expose at least m^* points.

► **Theorem 19.** *Given a set of points P , a set of rectangle ranges \mathcal{R} such that the ratio of largest to smallest side in \mathcal{R} is bounded by a constant, then there exists a polynomial time $O(1)$ -approximation algorithm for max-exposure.*

5.2 Approximation for Fat Rectangles

We now consider the case when rectangles in \mathcal{R} have bounded aspect ratio. That is for all rectangles $R \in \mathcal{R}$, the ratio of its two sides is bounded by a constant c . We transform the input ranges \mathcal{R} to obtain a modified set of ranges \mathcal{R}' as follows. For each rectangle $R \in \mathcal{R}$, let x be the length of the smaller side of R . Then we replace R by at most $\lceil c \rceil$ squares each of sidelength x . If m^* is the optimal number of points exposed by deleting k ranges from \mathcal{R} ,

then there exists a set of $O(k)$ ranges in \mathcal{R}' deleting which will expose at least m^* points. Observe that the set \mathcal{R}' consists of *square* ranges, of possibly different sizes. Therefore, if we can obtain an f -approximation for square ranges, we can easily obtain $O(f)$ -approximation with fat rectangles.

5.2.1 A Bicriteria $O(\sqrt{k})$ -approximation for Squares

We will describe an approximation algorithm for the case when the set of ranges \mathcal{R} consists of axis-aligned squares. We achieve an approximation algorithm in three steps. First, we partition the point set by assigning them to one of the input squares. Next, we solve the problem exactly for a fixed square. Finally, we combine these solutions to achieve a good approximation to the optimal solution.

We define $\mathcal{A} : P \rightarrow \mathcal{R}$ to be a function that assigns a point in P to exactly one range in \mathcal{R} . If $\mathcal{R}(p_i)$ is the set of squares that contain p_i , then $\mathcal{A}(p_i)$ is the smallest square in $\mathcal{R}(p_i)$. This assignment scheme ensures the following property.

► **Lemma 20.** *Let $R \in \mathcal{R}$ be a square and let $P(R) = \mathcal{A}^{-1}(R)$ be the set of points assigned to it. Moreover, let $\mathcal{R}' \subseteq \mathcal{R}$ be the set of squares that intersect R and contain at least one point in $P(R)$. Then, every square $R' \in \mathcal{R}'$ must have sidelength bigger than that of R , and therefore contains at least one corner of R .*

Now suppose we fix a square R , and consider a restricted max-exposure instance with the set of its assigned points $P(R)$. Since, ranges that contain a point in $P(R)$ are all bigger than R , this case is essentially the same as points inside a unit square, and therefore Lemma 10 can be easily extended to solve it exactly. This gives us the following algorithm. Here $1 \leq \alpha \leq k$ is a parameter.

■ **Algorithm 3** Greedy-Squares.

-
1. For every square $R \in \mathcal{R}$, apply Lemma 10 over the point set $P(R)$ to expose the maximum set of points $P(R, k) \subseteq P(R)$ by deleting k ranges.
 2. Order squares in \mathcal{R} by decreasing $|P(R, k)|$ values, and pick the set $\mathcal{S} \subseteq \mathcal{R}$ of first α squares. Return $\bigcup_{R \in \mathcal{S}} P(R, k)$ as the set of exposed points.
-

► **Lemma 21.** *Let m^* be the optimal number of points exposed using k squares, then algorithm Greedy-Squares computes a set of at most αk squares that expose at least $\alpha m^*/k$ points.*

For $\alpha = \sqrt{k}$, the above algorithm achieves a bicriteria $O(\sqrt{k})$ -approximation. Since an f -approximation for square ranges gives an $O(f)$ -approximation for fat rectangles, we obtain the following.

► **Theorem 22.** *Given a set of points P and a set of ranges \mathcal{R} consisting of rectangles of bounded aspect ratio, then one can obtain a bicriteria $O(\sqrt{k})$ -approximation for max-exposure in polynomial time.*

6 Conclusion

In this paper, we introduced the max-exposure problem over the range space (P, \mathcal{R}) and presented approximation algorithms for rectangle range spaces. We showed that the problem is hard to approximate even when \mathcal{R} consists of two types of rectangles, and therefore focused

on the complexity of the problem for the case when \mathcal{R} consists of translates of a single rectangle. We show that in this case, the geometry of ranges can be exploited to obtain a PTAS. A natural question to consider is how does the complexity of the problem change with more general shapes. In particular, does there exist a constant approximation when \mathcal{R} consists of axis-aligned squares?

A Missing Proofs

A.1 Proof of Lemma 3

Given a graph $G' = (V', E')$ sampled from one of the dense or random instances, we first construct a bipartite graph $G = (A, B, E)$ as follows. For every vertex $v \in V'$, we add a vertex v_a to A and v_b to B . Now for every edge $e = (u, v) \in E'$, we add the pair of edges $e_1 = (u_a, v_b)$ and $e_2 = (v_a, u_b)$ to E . That is, every edge $e \in E'$ is mapped to two copies $e_1, e_2 \in E$ and we can define $\text{par}(e_1) = \text{par}(e_2) = e$. Similarly, we define $\text{par}(u_a) = \text{par}(u_b) = u$. We say that G is dense if the underlying graph G' was sampled from the dense case, otherwise we say that G is random.

Consider a set of $k^* = 2k$ vertices in G . If G came from the dense case, there must be a set of $2k$ vertices that have $2k^{\beta+1}$ edges between them. So the number of edges in dense case $m_d^* \geq 2k^{\beta+1}$. Otherwise, we are in the random case. Consider the optimal set of $2k$ vertices V^* and let E^* be the set of edges in the induced subgraph $G[V^*]$. Now consider the corresponding set of vertices $V_p = \{\text{par}(v) \mid v \in V^*\}$ of the original graph G' and the set of edges E_p in the induced subgraph $G'[V_p]$. We have that $|V_p| \leq |V^*| = 2k$ and $|E_p| \geq |E^*|/2$ because for each edge $e = (u, v) \in E^*$, we will have the edge $\text{par}(e) = (\text{par}(u), \text{par}(v)) \in E_p$. We can now bound the number of edges E_p over $2k$ vertices in the random case to be $\tilde{O}(\max(2k, 4k^2n^{\alpha-1}))$ w.h.p, and therefore the optimum number of edges in the random case is $m_r^* = |E^*| \leq 2|E_p| = \tilde{O}(\max(k, k^2n^{\alpha-1}))$ w.h.p.

Choosing $k = n^{1/2}$, $\alpha = \frac{1}{2}$, $\beta = \frac{1}{2} - \epsilon$, gives us $m_r^* = \tilde{O}(n^{1/2})$ w.h.p. and $m_d^* = \tilde{\Omega}(n^{\frac{3-2\epsilon}{4}})$. Suppose, we could approximate this problem within a factor $O(n^{1/4-\epsilon})$, then in the dense case, the number of edges computed by this approximation algorithm is $\tilde{\Omega}(n^{\frac{1+\epsilon}{2}})$ which is strictly more than the maximum possible edges in the random case. Therefore, we would be able to distinguish between dense and random cases, and thereby refuting the conjecture for these values of α, β and k .

A.2 Proof of Lemma 11

■ **Figure 9** Embedding a max-exposure instance with unit square ranges on a unit-sized grid. Optimal solution in each grid cell can be computed exactly using Lemma 10.

Consider the optimal set of ranges $\mathcal{R}^* \subseteq \mathcal{R}$. Observe that each range $R \in \mathcal{R}^*$ intersects at most four grid cells. Let $R_i = R \cap C_i$ be the rectangular region defined by intersection of R and C_i . Clearly, there are at most four regions R_i for each $R \in \mathcal{R}^*$ and therefore $4k$ in total. At this point, the regions in cell C_i are disjoint from regions in some other cell $C_j \in \mathcal{C}$. Therefore, optimal solution exposes $|P^*|$ points over a set of cells \mathcal{C}^* such that the set \mathcal{R}^* has at most $4k$ disjoint components in the cells \mathcal{C}^* . Since we can solve the problem exactly for each cell and can combine them using the above dynamic program, we have that $\text{global}(1, 4k) \geq |P^*|$ and we achieve a 4-approximation.

For the running time, we observe that solving max-exposure locally in a cell C_i takes $O(k(n_i + m_i)n_i^2m_i^2)$ time, where n_i is the number of ranges that intersect C_i and m_i is the number of points in P that lie in C_i . Summed over all cells, we get the following bound.

$$\begin{aligned} \sum_i k(n_i + m_i)n_i^2m_i^2 &\leq k \sum_i (n_i + m_i) \sum_i n_i^2 \sum_i m_i^2 \\ &\leq k(n + m) \left(\sum_i n_i\right)^2 \left(\sum_i m_i\right)^2 = O(k(n + m)n^2m^2) \end{aligned}$$

Once the local solutions are computed, the dynamic program that merges them into a global solution has $O(k|\mathcal{C}|)$ subproblems and computing each subproblem takes $O(k)$ time. Recall that every cell in \mathcal{C} contains at least one point, so $|\mathcal{C}| \leq n$ and the merge step takes an additional $O(k^2n)$ time.

A.3 Proof of Lemma 17

Let $\mathcal{R}^* \subseteq \mathcal{R}$ be the optimal set of ranges, and let $\mathcal{R}_i^* \subseteq \mathcal{R}^*$ be the set of ranges anchored to lines in $\partial\mathcal{B}_i$. Since $\bigcup_{i \in \{1, \dots, h\}} \partial\mathcal{B}_i$ is the set of all anchor lines, we have

$$\begin{aligned} \bigcup_{i \in \{1, \dots, h\}} \mathcal{R}_i^* = \mathcal{R}^* &\implies \sum_{i \in \{1, \dots, h\}} |\mathcal{R}_i^*| = k \\ \implies \sum_{i \in \{1, \dots, h\}} |\mathcal{R}_{\min}^*| \leq k &\implies |\mathcal{R}_{\min}^*| \leq k/h \end{aligned}$$

A.4 Proof of Lemma 21

It is easy to see that the number of squares is at most αk . To show the bound on number of points exposed, consider the optimal solution \mathcal{R}^* and let the optimal set of points exposed by \mathcal{R}^* to be P^* . We will now use the same assignment procedure $\mathcal{A}^* : P^* \rightarrow \mathcal{R}^*$ to assign points in P^* to a square in \mathcal{R}^* . That is, $\mathcal{A}^*(p_i)$ is the smallest square in \mathcal{R}^* that contains p_i . We claim that $\mathcal{A}^*(p_i) = \mathcal{A}(p_i)$ for all $p_i \in P^*$ since every square that contains p_i lies in \mathcal{R}^* . Moreover, let $P^*(R)$ denote the set of points of P^* assigned to R .

Let m^* be the optimal number of points that are exposed, and m' be the number of points exposed by the algorithm. Now assume that the squares in \mathcal{R} are ordered such that $|P(R_i, k)| \geq |P(R_j, k)|$ for all $i < j$. Then, we have the following.

$$\begin{aligned} m^* &= \left| \bigcup_{R \in \mathcal{R}^*} P^*(R) \right| = \sum_{R \in \mathcal{R}^*} |P^*(R)| \\ &\leq \sum_{1 \leq i \leq k} |P(R_i, k)| \leq \frac{k}{\alpha} \sum_{1 \leq i \leq \alpha} |P(R_i, k)| \\ &= \frac{k}{\alpha} m' \end{aligned}$$

B PTAS for Unit Square Ranges on Number of Exposed Points

Given a set of points P , unit square ranges \mathcal{R} , we will now show that the PTAS for unit square ranges can be modified so that we can compute a set of k ranges that expose at least $(1 - \epsilon)$ fraction of the maximum possible number of points. For simplicity we assume that h is odd. The basic setup is the same: we have the anchor lines $\ell_1, \ell_2, \dots, \ell_z$ that

19:20 The Maximum Exposure Problem

are unit distance apart. However, there is one important change, we will only use the odd-numbered lines $\ell_1, \ell_3, \dots, \ell_h, \ell_{h+2}, \dots, \ell_z$ to define bundles. For instance, the bundle B_1 now consists of the anchor lines $\ell_1, \ell_3, \dots, \ell_h$, while the bundle-set \mathcal{B}_1 now comprises of bundles $B_1, B_h, B_{2h}, \dots, B_{z/h}$. Same as before, the lines $\ell_1, \ell_h, \dots, \ell_{z/h}$ form the boundary $\partial\mathcal{B}_1$. We have the following algorithm.

■ **Algorithm 4** PTAS-Exposed-Points.

1. Assign each point $p \in P$ to the closest line among $\ell_1, \ell_3, \dots, \ell_z$.
2. For each $i \in \{1, 3, \dots, h\}$, process bundle set \mathcal{B}_i as follows.
 - Let P_i be the set of points assigned to anchor lines $\ell_j \in \partial\mathcal{B}_i$, boundaries of \mathcal{B}_i .
 - Using the exact algorithm for each bundle $B \in \mathcal{B}_i$ as local solutions, we run the algorithm DP-Approx (from Section 4.2) over the point set $P \setminus P_i$ to obtain global solutions given by $global(1, k)$. Let $P(\mathcal{B}_i)$ be the set of exposed points returned by DP-Approx.
3. Return the set $P(\mathcal{B}_i)$ that has maximum cardinality over all $i \in \{1, 3, \dots, h\}$.

Clearly, the number of ranges used by the above algorithm is k . It remains to show that the number of points m' exposed by the algorithm is also close to m^* , the optimal number of exposed points. Let $P^* \subseteq P$ be the optimal set of exposed points.

► **Lemma 23.** *The bundle boundaries $\partial\mathcal{B}_i, \partial\mathcal{B}_j$ for any two bundle-set $\mathcal{B}_i, \mathcal{B}_j$ are disjoint, and therefore the set of points assigned to lines in $\partial\mathcal{B}_i$ are also disjoint. Then, there exists a bundle-set \mathcal{B}_{\min} such that the number of points of P^* assigned to its boundaries $\partial\mathcal{B}_{\min}$ is at most $\frac{2m^*}{h-1}$.*

Proof. let $P_i^* \subseteq P^*$ be the set of points in P^* that are assigned to lines in boundaries $\partial\mathcal{B}_i$ of some bundle \mathcal{B}_i . Since $\bigcup_{i \in \{1, 3, \dots, h\}} \partial\mathcal{B}_i$ is the set of all anchor lines to which we assign points, we have

$$\begin{aligned} \bigcup_{i \in \{1, 3, \dots, h\}} P_i^* &= P^* & \implies & \sum_{i \in \{1, 3, \dots, h\}} |P_i^*| = m^* \\ \implies \sum_{i \in \{1, 3, \dots, h\}} |P_{\min}^*| &\leq m^* & \implies & \left(\frac{h-1}{2}\right) |P_{\min}^*| \leq m^* \\ \implies |P_{\min}^*| &\leq \frac{2m^*}{h-1} & & \blacktriangleleft \end{aligned}$$

Observe that for the bundle-set \mathcal{B}_{\min} , we may have removed P_{\min} points, but the remaining set $P \setminus P_{\min}$ consists at least $m^* - \frac{2m^*}{h-1} = (1 - \frac{2}{h-1})m^*$ points of the optimal set P^* . Moreover, observe that we have removed points that are within a unit distance on either side of anchor line $\ell_j \in \partial\mathcal{B}_{\min}$, the set of ranges deleted in each bundle are disjoint from another. Therefore, the value $P(\mathcal{B}_{\min})$ returned by the algorithm DP-Approx exposes at least $P \setminus P_{\min} = (1 - \frac{2}{h-1})m^*$ points by deleting k ranges. If we set $h = 2/\epsilon + 1$ we have the following result.

► **Theorem 24.** *There exists an $(1 - \epsilon)$ -approximation on the number of exposed points for max-exposure with unit-square ranges running in $k(nm)^{O(1/\epsilon)}$ time.*

Small Space Stream Summary for Matroid Center

Sagar Kale

EPFL, Lausanne, Switzerland
sagar.kale@epfl.ch

Abstract

In the matroid center problem, which generalizes the k -center problem, we need to pick a set of centers that is an independent set of a matroid with rank r . We study this problem in streaming, where elements of the ground set arrive in the stream. We first show that any randomized one-pass streaming algorithm that computes a better than Δ -approximation for partition-matroid center must use $\Omega(r^2)$ bits of space, where Δ is the aspect ratio of the metric and can be arbitrarily large. This shows a quadratic separation between matroid center and k -center, for which the Doubling algorithm [7] gives an 8-approximation using $O(k)$ -space and one pass. To complement this, we give a one-pass algorithm for matroid center that stores at most $O(r^2 \log(1/\varepsilon)/\varepsilon)$ points (viz., stream summary) among which a $(7 + \varepsilon)$ -approximate solution exists, which can be found by brute force, or a $(17 + \varepsilon)$ -approximation can be found with an efficient algorithm. If we are allowed a second pass, we can compute a $(3 + \varepsilon)$ -approximation efficiently.

We also consider the problem of matroid center with z outliers and give a one-pass algorithm that outputs a set of $O((r^2 + rz) \log(1/\varepsilon)/\varepsilon)$ points that contains a $(15 + \varepsilon)$ -approximate solution. Our techniques extend to knapsack center and knapsack center with z outliers in a straightforward way, and we get algorithms that use space linear in the size of a largest feasible set (as opposed to quadratic space for matroid center).

1 Introduction

In the k -center problem, the input is a metric, and we need to select a set of k centers that minimizes the maximum distance between a point and its nearest center. Matroid center is a natural generalization of k -center, where, along with a metric over a set, the input also contains a matroid of rank r over the same set. We then need to choose a set of centers that is an independent set of the matroid that minimizes the maximum distance between a point and its nearest center. Then k -center is rank- k -uniform-matroid center. Examples of clustering problems where the set of centers needs to form an independent set of a partition matroid arise in content distribution networks (see Hajiaghayi et al. [16] and references therein). A partition matroid constraint can also be used to enforce fairness conditions such as having k_M centers of type M and k_W centers of type W. As another example, say the input points lie in a euclidean space, and we are required to output linearly independent centers, then

this is the linear-matroid center problem. Studying a combinatorial optimization problem in the streaming model is worthwhile not only in its own right, but also because it can lead to discovery of much faster algorithms¹.

In the streaming model, the input points arrive in the stream, and we are interested in designing algorithms that use space sublinear in the input size. We study the matroid center problem in the streaming model. By a clean reduction from the INDEX problem, we first show that any randomized one-pass streaming algorithm that computes a better than Δ -approximation for matroid center must use $\Omega(r^2)$ bits of space, where Δ is the aspect ratio of the metric (ratio of the largest distance to the smallest distance between two points), which can be arbitrarily large. Since the Doubling algorithm [7] gives an 8-approximation for k -center in one pass over the stream by storing at most k points, we get a quadratic separation between matroid center and k -center. We then give a one-pass algorithm that computes a $(7 + \varepsilon)$ -approximation using a *stream summary* of $O(r^2 \log(1/\varepsilon)/\varepsilon)$ points. The algorithm maintains an efficiently-updatable summary, and runs a brute-force step when the end of the stream is reached. We can replace the brute-force step by an efficient algorithm to get a $(17 + \varepsilon)$ -approximation. Alternatively, using a second pass, we can (efficiently) compute a $(3 + \varepsilon)$ -approximation. Our algorithms assume only oracle accesses to the metric and to the matroid.

In k -center or matroid center, even very few rogue points can wreck up the solution, which motivates the outlier versions where we can choose up to z points that our solution will not serve. McCutchen and Khuller [28] give a one-pass $(4 + \varepsilon)$ -approximation algorithm for k -center with z outliers that uses space $O(kz \log(1/\varepsilon)/\varepsilon)$. Building on their ideas, we give a $(15 + \varepsilon)$ -approximation one-pass algorithm for matroid center with z outliers, using a brute-force search through the summary as the last step, and a $(51 + \varepsilon)$ -approximation algorithm if we want an efficient implementation in the last step.

To the best of our knowledge, matroid center problems have not been considered in streaming. Chen, Li, Liang, and Wang [11] give an offline 3-approximation algorithm for matroid center and a 7-approximation algorithm for the outlier version; this approximation ratio is improved to 3 by Harris et al. [19]. These algorithms are not easily adaptable to the streaming setting if we are allowed only one pass, though, our two-pass algorithm for matroid center may be thought of as running multiple copies of Chen et al.’s 3-approximation algorithm. We mention that optimization problems over matroid or related constraints have been studied before in streaming [2, 3, 10].

The Doubling algorithm [7] gives an 8-approximation for k -center. Guha [15], using his technique of “stream-strapping”, improves this to $2 + \varepsilon$. We use the stream-strapping technique in this paper to reduce space-usage of our algorithms as well. Known streaming algorithms for k -center problems do not extend to the matroid center problems. Indeed, the gap between the space complexities of k -center and matroid center, exhibited by our lower bound, warrants the need for new ideas.

¹ This is demonstrated by Chakrabarti and Kale [3] who give streaming algorithms for submodular maximization problems that make *only* $2|E|$ total submodular-oracle calls ($\tilde{O}(|E|)$ total time) and achieve constant-factor approximations, where E is the ground set. On the other hand earlier fastest algorithms were greedy and potentially could make $\Omega(|E|^2)$ oracle calls. Trivially, $|E|$ oracle calls are needed for any non-trivial approximation.

1.1 Techniques

At the heart of many algorithms for k -center is Gonzalez's [13] furthest point heuristic that gives a 2-approximation. It first chooses an arbitrary point and adds it to the current set C of centers. Then it chooses a point that is farthest from C and adds it to C . This is repeated until C has k centers. Let C_E be the set of centers returned by this algorithm, and let p be the point that is farthest from C_E . Then $d(p, C_E)$ is the cost of the solution, whereas the set $C_E \cup \{p\}$ of size $k + 1$ acts as a certificate that an optimum solution must have cost at least $d(p, C_E)/2$. This can be easily implemented in streaming if we are given a "guess" τ of OPT, i.e., the cost of an optimum solution. When we see a new point e in the stream, we add it to C if $d(e, C) > 2\tau$. Assuming that we know the aspect ratio Δ , we can do this for $2 \log_{1+\varepsilon} \Delta$ guesses of OPT to get a $(2 + \varepsilon)$ -approximation as follows. Let R be the distance between first two points in the stream. Then maintain the set C as described above for guesses $\tau \in \{R/\Delta, (1 + \varepsilon)R/\Delta, (1 + \varepsilon)^2 R/\Delta, \dots, R\Delta\}$. The stream-strapping technique reduces the number of active guesses to $O(\log(1/\varepsilon)/\varepsilon)$.

In extending this to matroid center, the biggest challenge is deciding which point to make a center. In a solution to k -center, if we replace a point by another point that is very close to it, then the cost can change only slightly, whereas if we do the same in a solution to matroid center, the solution might just become infeasible. Therefore, if we maintain a set C as earlier, it might quickly lose its independence in the matroid. The idea is to store, for each of the at most r points $c \in C$, a maximal independent set I_c of points close to c ; here, by close we mean close in terms of the guess τ . This way, we store at most $r^2 + r$ points. Storing a maximal independent set for each point in C may seem wasteful, but our lower bound shows that it is necessary. Our first algorithmic insight is to show that this idea works for a correct guess. We show that if each optimum center s is in the span of an independent set I_c for a c that is close to s , then we can recover an independent set of small cost from the *summary* $\bigcup_{c \in C_E} I_c$. And as our second insight, we show how to extend the stream-strapping approach to reduce the number of active guesses, which helps us reduce the space usage. These ideas naturally combine with those of McCutchen and Khuller [28] and help us design an algorithm for matroid center with z outliers, but it is nontrivial to prove that the combination of these ideas works.

Knapsack center

In the knapsack center problem, each point e has a non-negative weight $w(e)$, and the goal is to select a set C of centers that minimizes the maximum distance between a point and its nearest center subject to the constraint that $\sum_{c \in C} w(c) \leq B$, where B is the *budget*. The k -center problem is a special case with unit weights and $B = k$. In the streaming setting, our algorithms for matroid center and matroid center with outliers can be extended to get constant approximations using space proportional to the size of a largest feasible set, i.e., $\max\{|S| : \sum_{e \in S} w(e) \leq B\}$. As described earlier, we maintain a set C of potential centers using the guess τ , and for each potential center c , we also maintain a smallest weight point, say s_c , in its vicinity. Then, in the end, the summary $\{s_c : c \in C\}$ contains a good solution. This idea works because replacing a center by a nearby point with a smaller weight does not affect the feasibility in the knapsack setting (which could destroy independence in the matroid setting).

1.2 Related Work

The k -center problem was considered in the '60s [17, 18]. It is NP-hard to achieve a factor of better than 2 [23], and polynomial-time 2-approximation algorithms exist [13, 21]. As mentioned earlier, Chen et al. [11] give a 3-approximation algorithm for matroid center

and a 7-approximation algorithm for the outlier version, and this approximation ratio is improved to 3 by Harris et al. [19]. Motivated by applications in content distribution networks, the matroid median problem is considered as well [16, 25]. The problem of k -center with outliers was first studied by Charikar et al. [8] who gave a 3-approximation algorithm. The approximation ratio was recently improved to 2 by Chakrabarty et al. [4]. We mention the work of Lattanzi et al. [26] that considers hierarchical k -center with outliers.

For knapsack center, a 3-approximation was given by Hochbaum and Shmoys [22]. For the outlier version of knapsack center, very recently, Chakrabarty and Negahbani [5] gave the first non-trivial approximation (a 3-approximation).

Streaming

Charikar et al. [9] and Guha et al. [14] consider k -median with and without outliers in streaming. Guha [15] gives a $(2 + \varepsilon)$ -approximation one-pass algorithm for k -center that uses $O(k \log(1/\varepsilon)/\varepsilon)$ space, and McCutchen and Khuller [28] give a $(4 + \varepsilon)$ -approximation one-pass algorithm for k -center with z outliers that uses $O(kz \log(1/\varepsilon)/\varepsilon)$ space. The special cases of 1-center (or, the minimum enclosing ball problem) and 2-center in euclidean spaces have been considered [29, 24, 20] and better approximation ratios than the general k -center problem are known in streaming. Correlation clustering is studied in streaming by Ahn et al. [1]. Cohen-Addad et al. [12] give streaming algorithms for k -center in the sliding windows model, where we want to maintain a solution for only some number of the most recent points in the stream. Guha [15] also gives a space lower bound of $\Omega(n)$ for one-pass algorithms that give a better than 2 approximation for (even the special case of) 1-center by a simple reduction from INDEX, where n is the number of points.

k -center in different models

Chan et al. [6] consider k -center in the fully dynamic adversarial setting, where points can be added or deleted from the input, and the goal is to always maintain a solution by processing the input updates quickly. Malkomes et al. [27] study distributed k -center with outliers.

1.3 Organization of the Paper

We define the model and the problems in Section 2. Section 3 is on the lower bound. In Section 4, we give our important algorithmic ideas and discuss our algorithm for matroid center, and then in Section 5, we discuss the outlier version. In Appendix A, we give the improved space bounds.

2 Preliminaries

A matroid \mathcal{M} is a pair (E, \mathcal{I}) , where E is a finite set and is called the ground set of the matroid, and \mathcal{I} is a collection of subsets of E that satisfies the following *axioms*:

1. $\emptyset \in \mathcal{I}$,
2. if $J \in \mathcal{I}$ and $I \subseteq J$, then $I \in \mathcal{I}$, and
3. if $I, J \in \mathcal{I}$ and $|I| < |J|$, then there exists $e \in J \setminus I$ such that $I \cup \{e\} \in \mathcal{I}$.

If a set $A \subseteq E$ is in \mathcal{I} , then it is called an *independent* set of the matroid \mathcal{M} , otherwise it is called a *dependent set*. A singleton dependent set is called a *loop*. *Rank* of a set A , denoted by $\text{rank}(A)$, is the size of a maximal independent set within A ; note that rank is a well-defined function because of the third axiom, which is called the *exchange* axiom. Clearly,

for $A \subseteq B$, $\text{rank}(A) \leq \text{rank}(B)$. Rank of a matroid is the size of a maximal independent set within E . *Span* of a set A , denoted by $\text{span}(A)$, is the largest set that contains A and has the same rank as A (it can be shown that such a set is unique). We will also use *submodularity* of the rank function, i.e., for $A, B \subseteq E$,

$$\text{rank}(A \cup B) + \text{rank}(A \cap B) \leq \text{rank}(A) + \text{rank}(B). \quad (1)$$

A matroid (E, \mathcal{I}) is a *partition* matroid if there exists a partition $\{E_1, E_2, \dots, E_p\}$ of E and nonnegative integers $\ell_1, \ell_2, \dots, \ell_p$, such that $\mathcal{I} = \{A \subseteq E : \forall i \in [p], |A \cap E_i| \leq \ell_i\}$. We say that ℓ_i is the *capacity* of part E_i . Observe that the rank of the matroid is $\sum_{i=1}^p \ell_i$.

A metric d over E is a (distance) function $d : E \times E \rightarrow \mathbb{R}_+$ that satisfies the following properties for all $e_1, e_2, e_3 \in E$:

1. $d(e_1, e_2) = 0$ if and only if $e_1 = e_2$,
2. $d(e_1, e_2) = d(e_2, e_1)$, and
3. $d(e_1, e_3) \leq d(e_1, e_2) + d(e_2, e_3)$; this property is called the *triangle inequality*.

We sometimes call elements in E points. For a point e and a positive number α , the closed ball of radius α around e , denoted by $\mathfrak{B}(e, \alpha)$, is the set $\{x \in E : d(e, x) \leq \alpha\}$. We overload d by defining $d(e, A) := \min_{x \in A} d(e, x)$ for $e \in E$ and $A \subseteq E$. The aspect ratio Δ of a metric is the ratio of the largest distance to the smallest in the metric, i.e., $\max_{x,y} d(x, y) / \min_{x,y} d(x, y)$.

The input for the matroid center problem is a matroid $\mathcal{M} = (E, \mathcal{I})$ of rank r and a metric d over E . The goal is to output an independent set S such that its cost $\max_{e \in E} d(e, S)$ is minimized. We are interested in algorithms that assume oracle (or black-box) accesses to the matroid and the metric. The algorithm can ask the matroid oracle whether a set is independent or not, and it can ask the metric oracle (or distance oracle) what the distance between given two points is. In the streaming model, elements of E arrive one by one, and we want to design an algorithm that uses small (sublinear in the input) space. The algorithm can query the oracles only with the elements of E . If the algorithm queries an oracle with an element not in E , then we say that it *fails*. A streaming algorithm can only remember a small part of the input, and the aforementioned restriction disallows plausible learning about forgotten elements indirectly from oracle calls. Also, an algorithm cannot just enumerate elements of E on the fly without looking at the stream, because it does not know the names of the elements in advance.

The input for matroid center with z outliers is also a matroid $\mathcal{M} = (E, \mathcal{I})$ and a metric d over E , but the goal is to output an independent set whose cost is computed with respect to $|E| - z$ closest points. Formally, cost of a set S is $\min\{\alpha \in \mathbb{R}_+ : |E \setminus (\bigcup_{s \in S} \mathfrak{B}(s, \alpha))| \leq z\}$.

We denote by OPT the cost of an optimum solution of the instance in the context.

3 Space Lower Bound for One Pass Matroid Center

We show that $\Omega(r^2)$ space is required to achieve better than Δ -approximation for a one-pass algorithm for matroid center. We reduce from the communication problem of INDEX. This reduction is based on the simple reduction for the maximum-matching-size problem: see Figure 1. In INDEX_N , Alice holds an N -bit string and Bob holds an index $I \in [N]$; Alice sends a message to Bob, who has to determine the bit at position I . It is known that Alice has to send a message of size at least $(1 - H_2(3/4))N \geq 2N/11$ for Bob to output correctly with a success probability of $3/4$, where H_2 is the binary entropy function.

■ **Figure 1** If we have a one-pass streaming algorithm that computes the size of a maximum matching of a k vertex bipartite graph using $o(k^2)$ space, then we can solve INDEX_N using $o(N)$ communication, which would be a contradiction. Alice and Bob agree on a bijection from $[N]$ to the edges of a complete bipartite graph $K_{k,k}$ and construct a graph G as follows. If ℓ th bit is 1, Alice adds the corresponding edge (shown in solid red). If the index corresponds to the edge $\{u, v\}$ (shown as a dotted orange edge), Bob adds a new perfect matching between all but vertices u and v and $2k - 2$ new vertices (shown as dashed black edges). Alice runs the matching-size estimation algorithm and sends the memory contents to Bob, who continues running it and computes the output. By design, if the index is 1, then maximum-matching-size is $2k - 1$, otherwise it is $2k - 2$, and an exact algorithm can distinguish between the two cases.

3.1 Reduction from Index to Partition-Matroid Center

We prove the following theorem.

► **Theorem 1.** *Any one-pass algorithm for partition-matroid center that outputs a better than Δ -approximation with probability at least $3/4$ must use at least $r^2/24$ bits of space.*

Proof. Assume, towards a contradiction, that there exists a one-pass algorithm for partition-matroid center that outputs a better than Δ -approximation using at most $r^2/24$ bits of space. Then we use it to solve the INDEX problem. Given an input for INDEX , Alice and Bob first construct a bipartite graph G just as described in Figure 1. Then they construct a partition-matroid center instance based on G . Before formalizing the construction, we emphasize that the metric does not correspond to the graph metric given by G , but each edge in G will become a point in the metric. The vertex set they use is union of four sets C_A, V_A , each of size q , and C_B, V_B , each of size $q - 1$. Alice constructs a subset of edges between C_A and V_A based on her N -bit string, so we use $N = q^2$. We say that these edges are owned by Alice. If the index that Bob holds corresponds to an edge $\{u, v\}$ with $u \in C_A$ and $v \in V_A$, he adds a perfect matching M between $C_A \setminus \{u\}$ and V_B and a perfect matching M' between $V_A \setminus \{v\}$ and C_B . The edges in $M \cup M'$ are owned by Bob.

To each $u \in C_A \cup C_B$, we associate a cluster $C(u)$ of at most q points in the metric that we will construct, and to each $v \in V_A \cup V_B$, we associate a part $P(v)$ in the partition matroid with capacity 1. Thus, rank of the matroid $r = 2q - 1$ because $|V_A \cup V_B| = 2q - 1$. By our design, no two clusters will intersect and no two parts will intersect, i.e., $C(u) \cap C(u') = \emptyset$ for $u \neq u'$, and $P(v) \cap P(v') = \emptyset$ for $v \neq v'$. The metric is as follows. Any two points in the same cluster are a unit distance apart and any two points in two different clusters are distance Δ apart. This trivially forms a metric, because the clusters are disjoint. For each $u \in C_A$, Bob adds a point $p(u)$ in the cluster $C(u)$, so that it is nonempty. Add $P' := \{p(u) : u \in C_A\}$ as a part in the partition matroid with capacity 0, so no $p(u)$ can be a center. For each edge $\{u, v\}$ in G with $u \in C_A \cup C_B$ and $v \in V_A \cup V_B$, whoever owns that edge adds a point $p(\{u, v\})$ that goes in cluster $C(u)$ and part $P(v)$. Now, Alice runs the partition-matroid

center algorithm on the points she constructed. She can do this because she knows the metric and the part identity of each point, so she can simulate the distance and matroid oracles. Note that if the algorithm expects an explicit description of the partition matroid, Alice can also send along with each point the identity of the part to which it belongs and the capacity of the part (which is always 1 for her points). She then sends the memory contents to Bob, who continues running the algorithm on his points and computes the cost of the output. We note that Bob can also simulate the distance and matroid oracles. Any point he does not own corresponds to a red edge, and using the identity of that edge, he can figure out the part and cluster to which the point belongs.

Now we prove the correctness of the reduction. Say Bob holds the index corresponding to the edge $\{u, v\}$, where $u \in C_A$ and $v \in V_A$. If the index is 1, then $\{u, v\}$ exists in the graph, then opening centers at points corresponding to edges in $M \cup M' \cup \{u, v\}$ satisfies the partition matroid constraint and also for each $u \in C_A \cup C_B$, we have a center opened in $C(u)$, so the cost is 1. Let the index be 0. We want to show that there is no independent set of cost less than Δ . For a contradiction, assume there is such an independent set. Now, recall that $p(u)$ cannot be a center, so it has to be served by some center in $C(u)$, otherwise the cost will be Δ . Let $p(u)$ be served by some $p(\{u, v'\})$ for $v' \neq v$. Then $p(\{v', w\})$, where $\{v', w\} \in M'$, cannot be a center, because both $p(\{u, v'\})$ and $p(\{v', w\})$ belong to the part $P(v')$ with capacity 1. The point $p(\{v', w\})$ is the lone point in its cluster, and since it cannot be a center, the cost is Δ . If the algorithm is better than Δ -approximation, then Bob can distinguish between these two cases, and thus, solve INDEX_N using communication at most $r^2/24 \leq 4q^2/24 = N/6$ bits, which is a contradiction. \blacktriangleleft

After seeing the lower bound, a remark is in order. The difficulty in designing an algorithm is as follows. Even if we know that one center must lie in a ball of small radius centered at a known point, we do not know which points in that ball to store so as to recover an independent set of the matroid.

4 Matroid Center

Our algorithm for matroid center can be seen as a generalization of the algorithm by Hochbaum and Shmoys for k -center [21] adapted to the streaming setting. We first quickly describe the algorithm for k -center. Given an upper bound τ on the optimum cost, the algorithm stores a set C of up to k pivots such that distance between any two pivots is more than 2τ . When the algorithm sees a new point e in the stream such that distance between e and any pivot is more than 2τ , it makes e a pivot. The size of C cannot exceed k in this way, because τ is an upper bound on the optimum cost, so no two pivots are served by a single optimum center. Also, any other point is within distance 2τ of some pivot. In the end, the algorithm designates all pivots as centers. In generalizing this to matroid center, one obvious issue is that the set C of pivots constructed as above may not be an independent set for the given general matroid². What we do know is that there has to be an optimum center within distance τ of each pivot. Formally, for $c \in C$, there exists s_c such that $d(c, s_c) \leq \tau$ and $\{s_c : c \in C\}$ is an independent set. For each pivot c , we maintain an independent set I_c of nearby points. We prove that it is enough to have each s_c be spanned by some I_c to get a good solution within $\bigcup_{c \in C} I_c$. Algorithm 1 gives a formal description.

² This is precisely why we call points in C “pivots” rather than “centers” in this paper.

20:8 Small Space Stream Summary for Matroid Center

Note that in Algorithm 1 if we try to add e to I_c under the condition that $d(e, c) \leq \tau$, then we may miss spanning some s_c . This will happen if $d(s_c, C) \in (\tau, 2\tau]$, where C is the set of pivots when s_c arrived. Using the condition $d(e, c) \leq \tau$ works if each s_c arrives after c though (we use it in the second pass of our two-pass algorithm).

■ **Algorithm 1** One pass algorithm for matroid center.

```

1: function MATROIDCENTER( $\tau, \text{flag}$ )
2:   Initialize pivot-set  $C \leftarrow \emptyset$ .
3:   for each point  $e$  in the stream do
4:     if there is a pivot  $c \in C$  such that  $d(e, c) \leq 2\tau$  (pick arbitrary such  $c$ ) then
5:       if  $I_c \cup \{e\}$  is independent then
6:          $I_c \leftarrow I_c \cup \{e\}$ .
7:       else if  $|C| = r$  then                                ▷ We cannot have more pivots than the rank.
8:         Abort.                                             ▷ Because  $C \cup \{e\}$  acts as a certificate that the guess is incorrect.
9:       else
10:         $C \leftarrow C \cup \{e\}$ .                               ▷ Make  $e$  a pivot.
11:        If  $\{e\}$  is not a loop,  $I_e \leftarrow \{e\}$ , else  $I_e \leftarrow \emptyset$ .
12:      if  $\text{flag} = \text{"brute force"}$  then
13:        Find an independent set  $C'_B$  in  $\bigcup_{c \in C} I_c$  such that  $d(c, C'_B) \leq 5\tau$  for  $c \in C$ .
14:        If such  $C'_B$  does not exist, then abort, else return  $C'_B$ .
15:   return EFFICIENTMATROIDCENTER( $5\tau, C, (I_c)_{c \in C}, \mathcal{M}$ ) (given in Algorithm 6
    in Appendix B).

```

First, we quickly bound the space usage.

► **Lemma 2.** *In any call to MATROIDCENTER, we store at most $r^2 + r$ points.*

Proof. The check on Line 7 ensures that $|C| \leq r$. For each pivot c , the size of its independent set I_c is at most r , hence the total number of points stored is at most $r^2 + r$. ◀

Consider a call to MATROIDCENTER with $\tau \geq \text{OPT}$. Let C_E be the set of pivots at the end of the stream. As alluded to earlier, for an optimum independent set I^* , the following holds: for each $c \in C_E$, there exists $s_c \in I^*$ such that $d(c, s_c) \leq \tau$, and also $s_c \neq s_{c'}$ for $c \neq c'$, because $d(c, c') > 2\tau$. Now, we prove the following structural lemma that we need later.

► **Lemma 3.** *Let I_1, \dots, I_t and $S = \{s_1, \dots, s_u\}$ be independent sets of a matroid such that there is an onto function $f : [u] \rightarrow [t]$ with the property that s_i is in the span of $I_{f(i)}$ for $i \in [u]$. Then there exists an independent set B such that $|B \cap I_j| \geq 1$ for $j \in [t]$.*

Proof. For each $\ell \in \{0, 1, \dots, u\}$, we construct an independent set S_ℓ such that $|S_\ell| = u$, $|S_\ell \cap I_{f(j)}| \geq 1$ for $j \leq \ell$, and $s_{\ell+1}, \dots, s_u \in S_\ell$, then S_u is our desired set B . Start with $S_0 = S$, and assume that we have constructed $S_0, S_1, \dots, S_{\ell-1}$. If $s_\ell \in I_{f(\ell)}$, we are done, so let $s_\ell \notin I_{f(\ell)}$, then we claim that $\text{rank}((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)}) \geq u$. To see this, observe that $\text{rank}(S_{\ell-1}) = u$, so by monotonicity of the rank function, $\text{rank}(S_{\ell-1} \cup I_{f(\ell)}) \geq u$, but $s_\ell \in \text{span}(I_{f(\ell)})$, so removing s_ℓ from $S_{\ell-1} \cup I_{f(\ell)}$ would not reduce its rank. We now give a formal argument for completeness. We have $(I_{f(\ell)} \cup \{s_\ell\}) \cup ((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)}) = S_{\ell-1} \cup I_{f(\ell)}$, and $(I_{f(\ell)} \cup \{s_\ell\}) \cap ((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)}) = I_{f(\ell)}$. By submodularity of the rank function (see (1) in Section 2), we have

$$\text{rank}(S_{\ell-1} \cup I_{f(\ell)}) + \text{rank}(I_{f(\ell)}) \leq \text{rank}(I_{f(\ell)} \cup \{s_\ell\}) + \text{rank}((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)}).$$

Let $q = \text{rank}(I_{f(\ell)})$. Since $s_\ell \in \text{span}(I_{f(\ell)})$, we have $\text{rank}(I_{f(\ell)} \cup \{s_\ell\}) = q$ and the above inequality gives

$$u + q \leq q + \text{rank}((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)}),$$

which proves the claim. Now, $\text{rank}(S_{\ell-1} \setminus \{s_\ell\}) = u - 1 < \text{rank}((S_{\ell-1} \setminus \{s_\ell\}) \cup I_{f(\ell)})$, therefore there exists $a \in I_{f(\ell)}$ such that $S_\ell := (S_{\ell-1} \setminus \{s_\ell\}) \cup \{a\}$ is independent by the exchange axiom. \blacktriangleleft

► **Lemma 4** (Small stream summary for matroid center). *Consider a call to MATROIDCENTER with $\tau \geq \text{OPT}$. Then there exists an independent set $B \subseteq \bigcup_{c \in C_E} I_c$ such that $d(e, B) \leq 7\tau$ for any point e and $d(c, B) \leq 5\tau$ for any pivot $c \in C_E$.*

Proof. For $c \in C_E$, denote by s_c the optimum center that serves it, so $d(c, s_c) \leq \tau$. Let $c' \in C_E$ be such that we tried to add s_c to $I_{c'}$ either on Line 6 or on Line 11; note that c' may not be the same as c if we added it on Line 6. For an $x \in I^*$, let $a(x) \in C_E$ denote the pivot whose independent set $I_{a(x)}$ we tried to add x to. Either we succeeded, in which case $x \in I_{a(x)}$, or we failed, in which case $x \in \text{span}(I_{a(x)})$. In any case, by Lemma 3, for $\mathcal{A} := \{I_{a(x)} : x \in I^*\}$ there exists an independent set B such that $|I \cap B| \geq 1$ for all $I \in \mathcal{A}$.

Now, we will bound the cost of B . See Figure 2. Consider any point e in the stream. Let

- $c(e) \in C_E$ be such that $d(e, c(e)) \leq 2\tau$,
 - $s_{c(e)}$ be the optimum center that serves $c(e)$, so $d(c(e), s_{c(e)}) \leq \tau$,
 - $a(s_{c(e)}) \in C_E$ be the pivot whose independent set we tried to add $s_{c(e)}$, so $d(s_{c(e)}, a(s_{c(e)}))$ is at most 2τ ,
 - $c'(e)$ be an arbitrary point in $I_{a(s_{c(e)})} \cap B$, so $d(a(s_{c(e)}), c'(e)) \leq 2\tau$ because $c'(e) \in I_{a(s_{c(e)})}$.
- Then by triangle inequality, $d(e, B)$ is at most

$$d(e, c'(e)) \leq d(e, c(e)) + d(c(e), s_{c(e)}) + d(s_{c(e)}, a(s_{c(e)})) + d(a(s_{c(e)}), c'(e)) \leq 2\tau + \tau + 2\tau + 2\tau,$$

which is 7τ ; this proves the first part of the lemma.

For any $c \in C_E$, we can bound $d(c, B)$ in a similar way. Let s_c be the optimum center that serves c , and similarly define $a(s_c)$ to be the pivot such that $d(s_c, a(s_c)) \leq 2\tau$. Also, let c' be the point in B such that $d(a(s_c), c') \leq 2\tau$. This gives that $d(c, B) \leq d(c, c') \leq 5\tau$. \blacktriangleleft

■ **Figure 2** To see how to bound the cost of the independent set B , let e be any point in the stream, $c(e) \in C_E$ be the pivot close to e , $s_{c(e)}$ be the optimum center that covers $c(e)$, $a(s_{c(e)}) \in C_E$ be the pivot close to $s_{c(e)}$, and $c'(e)$ be a point in B that covers $a(s_{c(e)})$.

Before proving our main theorem, we need the following guarantee on the efficient offline 3-approximation algorithm denoted by EFFICIENTMATROIDCENTER. This algorithm is based on the offline algorithm for matroid center by Chen et al. [11]. We give it as input $\alpha = 5\tau$,

20:10 Small Space Stream Summary for Matroid Center

the set C_E of pivots, their independent sets $(I_c)_{c \in C_E}$, and the underlying matroid \mathcal{M} with the promise on the input that there is an independent set $B \subseteq \bigcup_{c \in C_E} I_c$ such that for $c \in C_E$, it holds that $d(c, B) \leq 5\tau = \alpha$.

► **Theorem 5.** *If EFFICIENTMATROIDCENTER does not fail, then it outputs a set C' such that $d(c, C') \leq 3\alpha$ for each $c \in C_E$. If the input promise holds, then EFFICIENTMATROIDCENTER does not fail.*

Proof. This theorem is proved as Theorem 22 in the appendix. See Appendix B. ◀

Now we prove the main result.

► **Theorem 6.** *There is an efficient $(17 + \varepsilon)$ -approximation one-pass algorithm for matroid center that stores at most $2(r^2 + r) \log_{(1+\varepsilon/17)} \Delta$ points. With a brute force algorithm, one can get a $(7 + \varepsilon)$ -approximation.*

Proof. The algorithm is as follows. Let δ be the distance between the first two points. Then for $2 \log_{1+\varepsilon/17} \Delta$ guesses τ of OPT starting from δ/Δ to $\delta\Delta$, we run MATROIDCENTER(τ , flag). We return the set of centers returned by the instance corresponding to the smallest guess τ . Lemma 2 gives the desired space bound.

Case 1. flag = “brute force”.

Suppose the algorithm returned C'_B . Lemma 4 guarantees that for $\tau \in [\text{OPT}, (1 + \varepsilon/17) \text{OPT}]$, the algorithm will not abort. Then, by the check on Line 14, cost of C'_B is at most $7\tau \leq (7 + \varepsilon) \text{OPT}$.

Case 2. flag = “efficient algorithm”.

Let the algorithm returned C' . Theorem 5 guarantees that for $\tau \in [\text{OPT}, (1 + \varepsilon/17) \text{OPT}]$, the algorithm will not abort. By Theorem 5 for any $c \in C_E$, we have $d(c, C') \leq 15\tau$. Since we forget only the points within distance 2τ of C_E , we get that for any point e in the stream, $d(e, C') \leq 17\tau \leq (17 + \varepsilon) \text{OPT}$. ◀

We make some remarks.

► **Remark 7.** We do need to know the rank of the matroid (or an upper bound), otherwise we cannot control the space usage. The instances run using a very small guess may store a very large number of pivots without the check on Line 7.

► **Remark 8.** We can decrease the space usage to $O(r^2 \log(1/\varepsilon)/\varepsilon)$ points using the parallelization ideas of Guha [15]. To make the ideas work, we do need some properties of matroids. We give the details in Appendix A.

► **Remark 9.** By running $\binom{|E|}{2}$ guesses, EFFICIENTMATROIDCENTER can be used to get an offline 3-approximation algorithm for a more general version of matroid center, where the cost is computed with respect to a subset C_E of E and any point in E can be a center.

4.1 Extension to Knapsack Center

Recall that in the knapsack center problem, each point e has a non-negative weight $w(e)$, and the goal is to select a set C of centers that minimizes the maximum distance between a point and its nearest center subject to the constraint that $\sum_{c \in C} w(c) \leq B$, where B is the *budget*. We modify Algorithm 1 slightly to give an algorithm for knapsack center using space r factor smaller than the matroid case, where, in this case, r is the size of a largest feasible set. We make sure that all I_c variables are singletons, so the algorithm stores at most $2r$ points. Instead of the if condition on Line 5, we replace the point x in I_c by e if $w(x) > w(e)$.

This idea works because replacing a point by a nearby point with a smaller weight does not affect the feasibility in the knapsack setting (which could destroy independence in the matroid setting). Let C_E be the set of pivots at the end of the stream. By almost the same argument as in the proof of Lemma 4, we get the following.

► **Lemma 10.** *Let $\tau \geq \text{OPT}$. Then there exists a feasible set $K \subseteq \bigcup_{c \in C_E} I_c$ such that $d(e, K) \leq 7\tau$ for any point e and $d(c, K) \leq 5\tau$ for any pivot $c \in C_E$.*

For the efficient version, we then use the 3-approximation algorithm by Hochbaum and Shmoys [22].

► **Theorem 11.** *There is an efficient $(17 + \varepsilon)$ -approximation one-pass algorithm for knapsack center that stores at most $4r \log_{(1+\varepsilon/17)} \Delta$ points, where r is the size of a largest feasible set. With a brute force algorithm, one can get a $(7 + \varepsilon)$ -approximation.*

4.2 An Efficient Two Pass Algorithm

This algorithm is a streaming two-pass simulation of the offline 3-approximation algorithm of Chen et al. [11] for matroid center. We describe the algorithm and give the analysis below.

In our one-pass algorithm, i.e. Algorithm 1, say we are promised that for any pivot c , the optimum center that serves it appears after c . Then it is enough to try to add e to I_c whenever $d(e, c) \leq \tau$; we call this a modified check. Let C_E be the set of pivots in the end, then $(I_c)_{c \in C_E}$ form a partition such that if we pick one point from each I_c to get set B , we can serve each point in C_E using B with cost at most τ . With the modified check, for $c, c' \in C_E$ such that $c \neq c'$, the optimum points s_c and $s_{c'}$ that serve them are also different because $d(c, c') > 2\tau$. Now, $s_c \in \text{span}(I_c)$ due to the promise that s_c arrived after c , and Lemma 3 gives us the required independent set B . We then define a partition matroid \mathcal{M}_C with partition $(I_c)_{c \in C_E}$ and capacities 1 and solve the matroid intersection problem on \mathcal{M}_C and \mathcal{M} restricted to $\bigcup_{c \in C_E} I_c$ and get the output C' . Existence of B guarantees that $|C'| = |C_E|$, thus we are able to serve all points in C_E at a cost of τ . Since the points we forget are within distance 2τ of C_E , our total cost is at most 3τ by triangle inequality. We can get rid of the assumption that s_c arrives after c by having a second pass through the stream. We give a formal description in Algorithm 2.

As in the one-pass algorithm, we run $2 \log_{1+\varepsilon/3} \Delta$ guesses τ of OPT . We return the set of centers returned by the instance corresponding to the smallest guess. For $\tau \in [\text{OPT}, (1 + \varepsilon/3) \text{OPT}]$, the algorithm will not abort due to existence of the independent set B (which we argued earlier). This gives us the following theorem.

► **Theorem 12.** *There is an efficient $(3 + \varepsilon)$ -approximation two-pass algorithm for matroid center that stores at most $2(r^2 + r) \log_{(1+\varepsilon/3)} \Delta$ points.*

5 Matroid Center with Outliers

We first present a simplified analysis of McCutchen and Khuller's algorithm [28] for k -center with z outliers. This abstracts their ideas and sets the stage for the matroid version that we will see later.

5.1 McCutchen and Khuller's Algorithm

As usual, we start with a guess τ for the optimum cost. The algorithm maintains a set C of pivots such that $|\mathfrak{B}(c, 2\tau)| \geq z + 1$ for any $c \in C$, so the optimum has to serve at least one of these nearby points. (Recall that $\mathfrak{B}(e, \alpha) = \{x \in E : d(e, x) \leq \alpha\}$.) When a new point

16:   Return  $C'$ .

```

arrives, it is ignored if it is within distance 4τ of C . Otherwise it is added to the set F of “free” points. As soon as the size of F reaches $(k - |C| + 1)z + 1$, we know for sure that, for a correct guess, the optimum will have to serve the free points with at most $k - |C|$ clusters, and one of those clusters will have more than z points by the generalized pigeonhole principle. Hence, there *must* exist a free point that has at least z other points within distance 2τ in F , because its cluster diameter is at most 2τ . This gives us a new pivot $c \in F$ with its support points. We remove those points in F that are within distance 4τ of c and continue to the next element in the stream. In the end, we will be left with at most $(k - |C| + 1)z$ free points, and they are served by at most $k - |C|$ optimum centers. On these remaining free points, we run an offline 2-approximation algorithm for $(k - |C|)$ -center with z outliers, e.g., that of Chakrabarty et al.[4]. Algorithm 3 gives a formal description. We note that we do not need the sets A_c for $c \in C$ in the algorithm, but we need them in the analysis.

Let us bound the space usage first. The variable C contains at most k pivots, otherwise we abort on Section 5.1, and Section 5.1 make sure that the variable F contains at most $(k + 1)z + 1$ points. In total, we store at most $(k + 1)z + 1$ points at any moment.

► **Lemma 13.** *For $\tau \geq \text{OPT}$, $\text{K-CENTER-Z-OUTLIERS}(\tau)$ stores at most $(k + 1)z + 1$ points, and the cost of C' returned by $\text{K-CENTER-Z-OUTLIERS}(\tau)$ is at most 4τ .*

Proof. Let C_E be the set of pivots and F_E be the set of free points when the stream ended, and let $|C_E| = \ell_E$. We claim that for any $c \neq c'$, where $c, c' \in C_E$, $e \in A_c$, and $e' \in A_{c'}$, we have $d(e, e') > 2\tau$. We now prove this claim. Assume without loss of generality that c was made a pivot before c' by the algorithm. So points within distance 4τ of c were removed from F . Any point that existed in F after this removal, in particular e' , must be farther than 4τ from c . This implies that

$$4\tau < d(c, e') \leq d(c, e) + d(e, e'), \quad \text{and} \quad d(e, e') > 2\tau,$$

because $d(c, e) \leq 2\tau$. Now, we know that for $c \in C_E$, there exists $x_c \in A_c$ that has to be served by an optimum center, say s_c , because $|A_c| > z$, so not all of the points in A_c can be outliers. By the earlier claim, for $c \neq c'$, we have $d(x_c, x_{c'}) > 2\tau$ implying that $s_c \neq s_{c'}$ and

■ **Algorithm 3** McCutchen and Khuller’s algorithm [28] for k -center with z outliers.

```

1: function K-CENTER-Z-OUTLIERS( $\tau$ )
2:   Pivot-set  $C \leftarrow \emptyset$ , free-point set  $F \leftarrow \emptyset$ , and  $\ell \leftarrow 0$ .
3:   for each point  $e$  in the stream do
4:     if  $d(e, C) > 4\tau$  then
5:        $F \leftarrow F \cup \{e\}$ .
6:     if  $|F| = (k - \ell + 1)z + 1$  then      ▷ there is a new pivot among the free points;
7:       Let  $c \in F$  be s.t.  $|\mathfrak{B}(c, 2\tau) \cap F| \geq z + 1$     ▷ such  $c$  exists for a correct guess.
8:       If such  $c$  does not exist, then abort.
9:        $C \leftarrow C \cup \{c\}$ .
10:       $F \leftarrow F \setminus \mathfrak{B}(c, 4\tau)$ .
11:       $A_c \leftarrow \{c\} \cup$  arbitrary subset of  $\mathfrak{B}(c, 2\tau) \setminus \{c\}$  of size  $z$ .
12:       $\ell \leftarrow \ell + 1$ .
13:      If  $\ell = k + 1$ , then abort.                                ▷ guess is wrong.
14:       $C_F \leftarrow$  2-approx for  $(k - \ell)$ -center with  $z$  outliers on  $F$  by an efficient offline algorithm.
15:   return  $C' \leftarrow C \cup C_F$ .

```

$\ell_E \leq k$. Also note that none of these optimum centers can serve a point in F_E , because by triangle inequality

$$d(s_c, F_E) \geq d(c, F_E) - d(c, x_c) - d(x_c, s_c) > 4\tau - 2\tau - \tau = \tau$$

for $c \in C_E$. This shows that all but z points in F_E have to be served by at most $k - \ell_E$ optimum centers with cost at most τ . For each of these optimum centers, there exists a free point in F_E within distance τ . So there exists a set B_F of $k - \ell_E$ points in F_E , such that B_F covers all but at most z points of F_E with cost 2τ . So a 2-approximation algorithm recovers $k - \ell_E$ centers with cost at most 4τ . Observing that we only forget points in the stream that are within distance 4τ of some pivot in C_E finishes the proof. ◀

By running K-CENTER-Z-OUTLIERS(τ) for at most $O(\log(1/\varepsilon)/\varepsilon)$ geometrically-increasing active guesses, we get the $(4 + \varepsilon)$ -approximation algorithm for k -center with z outliers. This analysis is based on that of McCutchen and Khuller [28].

5.2 Matroid Center with Outliers

It is now possible to naturally combine the ideas used for matroid center and those used for k -center with z outliers to develop an algorithm for matroid center with z outliers.

Whenever the free-point set becomes large enough, we create a pivot c and an independent set I_c to which we try to add all free points within distance 4τ of c . We do the same for a new point e in the stream that is within distance 4τ of some pivot $c \in C$, i.e., we try to add it to I_c keeping I_c independent in the matroid. Otherwise $d(e, C) > 4\tau$, so we make it a free point. The structural property of matroids that we proved as Lemma 3 then enables us to show that $\bigcup_{c \in C} I_c$ and the set of free points make a good summary of the stream. See Algorithm 4 for a formal description. Here, we note that we do not need the sets A_c for $c \in C$ in the algorithm if flag is set to “brute force”, but we need them in the analysis in any case.

Let C_E be the set of pivots and F_E be the set of free points when the stream ended, and let $\ell_E = |C_E|$.

■ **Algorithm 4** One-pass algorithm for matroid center with outliers.

```

1: function MATROID-CENTER-Z-OUTLIERS( $\tau$ , flag)
2:   Pivot-set  $C \leftarrow \emptyset$ , free-point set  $F \leftarrow \emptyset$ , and  $\ell \leftarrow 0$ .
3:   for each point  $e$  in the stream do
4:     if  $\exists c \in C$  such that  $d(e, c) \leq 4\tau$  then
5:       If  $I_c \cup \{e\}$  is independent, then  $I_c \leftarrow I_c \cup \{e\}$ .
6:     else
7:        $F \leftarrow F \cup \{e\}$ .
8:     if  $|F| = (r - \ell + 1)z + 1$  then
9:       Let  $c \in F$  be s. t.  $|\mathfrak{B}(c, 2\tau) \cap F| \geq z + 1$  (if not, we guessed wrong, so abort).
10:       $C \leftarrow C \cup \{c\}$ .
11:       $A_c \leftarrow \{c\}$  and if  $\{c\}$  is not a loop,  $I_c \leftarrow \{c\}$ , else  $I_c \leftarrow \emptyset$ .
12:       $\ell \leftarrow \ell + 1$  (if  $\ell$  becomes  $r + 1$  here, we guessed wrong, so abort).
13:      for each  $x \in F \cap \mathfrak{B}(c, 4\tau)$  do
14:         $F \leftarrow F \setminus \{x\}$ .
15:        If  $I_c \cup \{x\}$  is independent, then  $I_c \leftarrow I_c \cup \{x\}$ .
16:        If  $|A_c| \leq z$ , then  $A_c \leftarrow A_c \cup \{x\}$ .
17:      if flag = “brute force” then
18:        Find an independent set  $C'_B$  in  $F \cup \bigcup_{c \in C} I_c$  by brute force such that cost of  $C'_B$ 
        is  $\leq 11\tau$  with respect to  $C$  and  $\leq 9\tau$  with respect to all but at most  $z$  points of  $F$ .
19:        If such  $C'_B$  does not exist, abort, else return  $C'_B$ .
20:      if flag = “efficient” then
21:        Run the offline 3-approximation algorithm by Harris et al. [19] for matroid center
        with  $z$  outliers to get an independent set  $C'$  of centers in  $F \cup \bigcup_{c \in C} (A_c \cup I_c)$  such that
        cost of  $C'$  is  $\leq 47\tau$  with respect to  $C$  and  $\leq 45\tau$  with respect to all but  $z$  points of  $F$ .
22:        If such  $C'$  does not exist, abort, else return  $C'$ .

```

► **Lemma 14** (Small summary for matroid center with outliers). *For $\tau \geq \text{OPT}$, Algorithm 4 stores at most $O(r^2 + rz)$ points, and there exists an independent set $B \subseteq F_E \cup \bigcup_{c \in C_E} I_c$ such that cost of B is at most 15τ ; also $d(c, B) \leq 11\tau$ for any pivot $c \in C_E$, and B covers all but at most z points of F_E with cost at most 9τ .*

Proof. Let I^* be an optimum independent set of centers. By the same argument as in the proof of Lemma 13, the following claim is true. For any $c \neq c'$, where $c, c' \in C_E$, $e \in A_c$, and $e' \in A_{c'}$, we have $d(e, e') > 2\tau$. Now, we know that for $c \in C_E$, there exists $x_c \in A_c$ that has to be served by an optimum center, say s_c , because $|A_c| > z$. By the earlier claim, for $c \neq c'$, we have $d(x_c, x_{c'}) > 2\tau$ implying that $s_c \neq s_{c'}$ and $\ell_E \leq r$. Let $I_{C_E}^* = \{s_c : c \in C_E\}$ be the set of optimum centers that serve some $x_c \in A_c$ for $c \in C_E$. None of the optimum centers in $I_{C_E}^*$ can serve a point in F_E , because $d(s_c, F_E) > \tau$ for $c \in C_E$. This shows that all but z points in F_E have to be served by at most $r - \ell_E$ optimum centers with cost at most τ . Since $|I_c| \leq r$ for any c in the variable C , size of $\bigcup_{c \in C} I_c$ is always bounded by r^2 . Also, the check on the size of F ensures that $|F| \leq (r + 1)z + 1$, so total number of points stored is at most $O(r^2 + rz)$ at any moment.

When we first process a new point e in the stream, we either try to add it to some I_c or to F . If e is never removed from F , then $e \in F_E$, otherwise, we try to add it to some I_c . The same argument applies to any $x \in I^*$, so if $x \notin F_E$, then we did try to add it to some I_c . For an $x \in I^* \setminus F_E$, let $a(x) \in C_E$ denote the pivot whose independent set $I_{a(x)}$ we tried to add x to.

By Lemma 3, for $\mathcal{A} := \{I_{a(x)} : x \in I^* \setminus F_E\} \cup \{\{x\} : x \in I^* \cap F_E\}$, there exists an independent set B such that $|I \cap B| \geq 1$ for all $I \in \mathcal{A}$. Since for $x \in I^* \cap F_E$ the singleton $\{x\} \in \mathcal{A}$, the set B must contain $\{x\}$. For a free point e served by an optimum center s such that we tried to add s to some I_c , we have that $d(e, B) \leq d(e, s) + d(s, c) + d(c, B) \leq \tau + 4\tau + 4\tau = 9\tau$, which means that B serves all but z points of F_E with cost at most 9τ . Now, we claim that for any point e in the stream, $d(e, B) \leq 15\tau$. We just saw that if $e \in F_E$ is served by an optimum center, then $d(e, B) \leq 9\tau$, so assume that $e \notin F_E$, that means there is a $c \in C_E$ such that $d(e, c) \leq 4\tau$; denote this c by $c(e)$. See Figure 3. Let $s_{c(e)}$ be the optimum center that serves an $x_{c(e)} \in A_{c(e)}$ (recall that such a point exists because $|A_{c(e)}| > z$). So $d(c(e), s_{c(e)}) \leq 3\tau$, and $a(s_{c(e)}) \in C_E$ was the pivot such that $d(s_{c(e)}, a(s_{c(e)})) \leq 4\tau$. Let $c'(e)$ be an arbitrary point in $I_{a(s_{c(e)})} \cap B$, whose existence is guaranteed by the property of B . We have $d(a(s_{c(e)}), c'(e)) \leq 4\tau$, because $c'(e) \in I_{a(s_{c(e)})}$. Then by triangle inequality,

$$\begin{aligned} d(e, B) &\leq d(e, c'(e)) \\ &\leq d(e, c(e)) + d(c(e), x_{c(e)}) + d(x_{c(e)}, s_{c(e)}) + d(s_{c(e)}, a(s_{c(e)})) + d(a(s_{c(e)}), c'(e)) \\ &\leq 4\tau + 2\tau + \tau + 4\tau + 4\tau = 15\tau, \end{aligned}$$

hence, cost of B is at most 15τ .

For any $c \in C_E$, we can bound $d(c, B)$ in a similar way. Let s_c be the optimum center that serves an $x_c \in A_c$. Define $a(s_c)$ to be the pivot such that $d(s_c, a(s_c)) \leq 4\tau$. Also, let c' be the point in B such that $d(a(s_c), c') \leq 4\tau$. This gives that $d(c, B) \leq d(c, c') \leq 11\tau$. We already established that B covers all but at most z points of F_E with cost at most 9τ . The proof is now complete. \blacktriangleleft

■ **Figure 3** To see how to bound the cost of the independent set B , let e be any point in the stream, $c(e) \in C_E$ be the pivot close to e , $x_{c(e)}$ be the point in the support $A_{c(e)}$ of $c(e)$ that an optimum center serves, $s_{c(e)}$ be the optimum center that serves $x_{c(e)}$, $a(s_{c(e)}) \in C_E$ be the pivot close to $s_{c(e)}$, and $c'(e)$ be a point in B that covers $a(s_{c(e)})$.

► **Theorem 15.** *There is an efficient $(51 + \varepsilon)$ -approximation one-pass algorithm for matroid center with z outliers that stores at most $O((r^2 + rz) \log \Delta/\varepsilon)$ points. With a brute force algorithm, one can get a $(15 + \varepsilon)$ -approximation.*

Proof. We run $O(\log \Delta/\varepsilon)$ parallel copies of `MATROID-CENTER-Z-OUTLIERS`(τ , flag) and return the output of the copy for the smallest un-aborted guess. We claim that the copy corresponding to guess $\tau' \in [\text{OPT}, (1 + \varepsilon/50)\text{OPT})$, call it $\mathbb{I}(\tau')$, will not abort. Denote by C_E , F_E , and $(I_c)_{c \in C_E}$ contents of the corresponding variables in $\mathbb{I}(\tau')$ at the end of the stream (we will not abort mid-stream because $\tau' \geq \text{OPT}$).

By Lemma 14, $F_E \cup \bigcup_{c \in C_E} I_c$ contains a solution that has cost $11\tau'$ with respect C_E and $9\tau'$ with respect to all but at most z of F_E . These checks can be performed by the brute force algorithm. Since any instance for guess τ forgets only those points within distance 4τ of its pivots, the brute force algorithm outputs a $(15 + \varepsilon)$ -approximation.

By Lemma 14, there exists a solution of cost $\leq 15\tau'$, and the efficient 3-approximation algorithm for matroid center with z outliers will return a solution C' with cost at most $45\tau'$. Note that C' has to cover at least one point from A_c for each $c \in C_E$, hence $d(c, C') \leq 47\tau'$. Since we forget points only within distance $4\tau'$ of C_E , we get the desired approximation ratio. \blacktriangleleft

A Handling the Guesses

We extend the ideas of Guha [15] and McCutchen and Khuller [28] to run $O(\log(1/\varepsilon)/\varepsilon)$ active guesses. Although, to make this idea work for matroids, we do need a property of matroids (see Lemma 16). The way to do this is to start with a lower bound R on the optimum and spawn instances, which we call *original* instances, $\mathbb{I}(\tau)$ for guesses $\tau = R, R(1 + \varepsilon), \dots, R(1 + \varepsilon)^\beta = R\alpha/\varepsilon$, for some α that depends on the basic algorithm that we use, e.g., for matroid center, we will use $\alpha = 2 + \varepsilon$. When a guess τ' fails, we replace an instance $\mathbb{I} = \mathbb{I}(\tau)$ for $\tau \leq \tau'$ with a new instance, which we call its *child* instance, $\mathbb{I}_N = \mathbb{I}(\tau(1 + \varepsilon)^\beta)$. In the new instance \mathbb{I}_N , we treat the summary that we maintained for $\mathbb{I}(\tau)$ as the initial stream. Since the new guess in \mathbb{I}_N is about $1/\varepsilon$ times larger than the old guess in \mathbb{I} , the distance between a point that we forgot and the summary stored by \mathbb{I} is about ε times the new guess. Therefore, the cost analysis does not get much affected for a correct guess. If we forgot an optimum center, a nearby point in the summary can act as its replacement. This statement is obvious for a uniform matroid, because all points are treated the same way within the matroid, but it is not true for general matroids; in fact, as exhibited by our lower bound, it is not true even for partition matroids. So with each point in the summary, we pass to the new instance an independent set I_o . The following simple lemma shows that if an optimum center x is in the span of I_o , and if we construct I_c for a new pivot c such that $I_o \subseteq \text{span}(I_c)$, then I_c also spans the optimum center.

► **Lemma 16.** *Let I and J be independent sets of a matroid such that $J \subseteq \text{span}(I)$. If $e \in \text{span}(J)$, then $e \in \text{span}(I)$.*

Proof. Let $\text{rank}(I) = q$. Towards a contradiction, let $\text{rank}(I \cup \{e\}) = q+1$. Since $J \subseteq \text{span}(I)$, $\text{rank}(I \cup J) = q$. Now, $e \in \text{span}(J)$, so $\text{rank}(I \cup J \cup \{e\}) = q$, i.e., $\text{rank}(I \cup \{e\}) \leq q$, which gives us the desired contradiction. ◀

A.1 A Smaller Space Algorithm for Matroid Center

We modify the function $\text{MATROIDCENTER}(\tau, \text{flag})$ from earlier to accept a starting stream and an independent set for each point in the starting stream: $\text{MATROIDCENTER}(\tau, C_o, (J_{c_o})_{c_o \in C_o}, \text{flag})$. Before processing any new points in the stream we process the points in C_o as follows. When processing a $c_o \in C_o$, if $d(c_o, C) \leq 2\tau$, try to add points in J_{c_o} to I_c . Otherwise create a new pivot c in C and initialize $I_c = J_{c_o}$. Once C_o is processed, we continue with the stream and work exactly as in $\text{MATROIDCENTER}(\tau)$. We give complete pseudocode in Algorithm 5.

For an instance $\mathbb{I}(\tau)$ let $C_o(\tau)$ be the initial summary and $\mathcal{J}(\tau)$ be the collection of independent sets that we passed to it, and let $E(\tau)$ be the part of the actual stream that it processed. Also, let $\mathbb{I}(\tau_o)$ be the instance for $\tau_o = \varepsilon\tau/(2 + \varepsilon)$ from which $\mathbb{I}(\tau)$ was spawned.

► **Lemma 17.** *Let e be a point that arrived before the substream $E(\tau)$. Then e has a nearby representative $\rho_e \in C_o(\tau)$ such that $d(e, \rho_e) \leq \varepsilon\tau$ and also the independent set J_{ρ_e} corresponding to ρ_e spans e .*

Proof. We prove this claim by induction on the number of ancestors. For an original instance, the claim holds trivially, because no point arrived before. Otherwise, there are two cases: either $e \in E(\tau_o)$ or e arrived before $E(\tau_o)$. If $e \in E(\tau_o)$, then by the logic of the algorithm, there exists $a(e) \in C_o(\tau)$ such that $d(e, a(e)) \leq 2\tau_o = 2\varepsilon\tau/(2 + \varepsilon) \leq \varepsilon\tau$, and also we tried

■ **Algorithm 5** One pass algorithm for matroid center with smaller space.

```

1: Let  $R$  be the minimum distance for some two points in the first  $r + 1$  points in the stream.
2: for  $\tau \in \{R, R(1 + \varepsilon), \dots, R(1 + \varepsilon)^\beta = (2 + \varepsilon)R/\varepsilon\}$  in parallel do
3:   MATROIDCENTER( $\tau, \emptyset, \emptyset$ ).
4:   if an instance with guess  $\tau$  is aborted then
5:     for all active  $\mathbb{I}(\tau')$  with guess  $\tau' \leq \tau$ , current pivots  $C_o$ , and independent sets
        $(J_{c_o})_{c_o \in C_o}$  do
6:       Replace it with the child instance MATROIDCENTER( $\tau'(1 + \varepsilon)^\beta, C_o, (J_{c_o})_{c_o \in C_o},$ 
       flag).
7: Return the set  $C'$  of centers returned by the active instance with the smallest guess.
8:
9: function MATROIDCENTER( $\tau, C_o, (J_{c_o})_{c_o \in C_o}, \text{flag}$ )
10:   $C \leftarrow \emptyset$ .
11:  for each point  $c_o$  in  $C_o$  do
12:    if  $\exists c \in C$  such that  $d(c_o, c) \leq 2\tau$  (pick arbitrary such  $c$  if there are several) then
13:      for  $e_o \in J_{c_o}$  do
14:        if  $I_c \cup \{e_o\}$  is independent then
15:           $I_c \leftarrow I_c \cup \{e_o\}$ .
16:        else
17:           $C \leftarrow C \cup \{c_o\}$ .
18:           $I_{c_o} \leftarrow J_{c_o}$ .
19:  # Processing of the old pivots finished, continue with the actual stream.
20:  for each point  $e$  in the stream do
21:    if there is a pivot  $c \in C$  such that  $d(e, c) \leq 2\tau$  (pick arbitrary such  $c$ ) then
22:      if  $I_c \cup \{e\}$  is independent then
23:         $I_c \leftarrow I_c \cup \{e\}$ .
24:      else if  $|C| = r$  then ▷ We cannot have more pivots than the rank.
25:        Abort. ▷ Because  $C \cup \{e\}$  acts as a certificate that the guess is incorrect.
26:      else
27:         $C \leftarrow C \cup \{e\}$ . ▷ Make  $e$  a pivot.
28:        If  $\{e\}$  is not a loop,  $I_e \leftarrow \{e\}$ , else  $I_e \leftarrow \emptyset$ .
29:  if flag = “brute force” then
30:    Find an independent set  $C'_B$  in  $\bigcup_{c \in C} I_c$  such that  $d(c, C'_B) \leq (5 + 2\varepsilon)\tau$  for  $c \in C$ .
31:    If such  $C'_B$  does not exist, then abort, else return  $C'_B$ .
32:  return EFFICIENTMATROIDCENTER( $(5 + 2\varepsilon)\tau, C, (I_c)_{c \in C}, \mathcal{M}$ ).

```

to add e to $I_{a(e)}$ (that became $J_{a(e)}$ for the next instance $\mathbb{I}(\tau)$). Otherwise, by induction hypothesis, there is a point $e' \in C_o(\tau_o)$ such that $d(e, e') \leq \varepsilon\tau_o$ and $J_{e'}$ spans e . Now, let $\rho_{e'} \in C_o(\tau)$ be such that $d(e', \rho_{e'}) \leq 2\tau_o$ (such $\rho_{e'}$ must exist by logic of the algorithm). Using triangle inequality and the above inequality that $d(e, e') \leq \varepsilon\tau_o$, we get

$$d(e, \rho_{e'}) \leq d(e, e') + d(e', \rho_{e'}) \leq \varepsilon\tau_o + 2\tau_o = (2 + \varepsilon)\tau_o = (2 + \varepsilon) \frac{\varepsilon\tau}{(2 + \varepsilon)} = \varepsilon\tau.$$

Moreover, in the instance $\mathbb{I}(\tau_o)$, we tried to add all points in $J_{e'}$ to $I_{\rho_{e'}}$, so by Lemma 16, $e \in \text{span}(I_{\rho_{e'}})$ (see that $I_{\rho_{e'}}$ became $J_{\rho_{e'}}$ for the next instance $\mathbb{I}(\tau)$), which proves the claim. ◀

20:20 Small Space Stream Summary for Matroid Center

► **Theorem 18.** *There is an efficient $((17 + 7\varepsilon)(1 + \varepsilon))$ -approximation one-pass algorithm for matroid center that stores at most $O(r^2 \log(1/\varepsilon)/\varepsilon)$ points. With a brute force algorithm, one can get a $((7 + 3\varepsilon)(1 + \varepsilon))$ -approximation.*

Proof. Space usage is easy to analyze. At any time, we have at most $O(\log_{1+\varepsilon}(1/\varepsilon)) = O(\log(1/\varepsilon)/\varepsilon)$ active instances and each instance stores at most $O(r^2)$ points.

Consider the instance $\mathbb{I}(\tau')$ for which we returned on Line 7 in Algorithm 5, and suppose the outputs were C' or C'_B (depending on “flag”). We note that some active copy *will* return, because τ cannot keep on increasing indefinitely. E.g., consider τ larger than the maximum distance between any two points. Let C_E be the contents of the variable C in $\mathbb{I}(\tau')$ at the end of the stream. Then we know that costs of C'_B and C' are at most $(5 + 2\varepsilon)\tau'$ and $(15 + 6\varepsilon)\tau'$ with respect to C_E due to the check that we do on Line 31 and by Theorem 5 for EFFICIENTMATROIDCENTER. By Lemma 17, any point that arrived before $E(\tau')$ is within distance $\varepsilon\tau'$ of $C_o(\tau')$, and each point in $C_o(\tau')$ is within distance $2\tau'$ of C_E , which shows that costs of C'_B and C' are at most $(7 + 3\varepsilon)\tau'$ and $(17 + 7\varepsilon)\tau'$ with respect to the whole stream (by triangle inequality). Next, we show that $\tau' \leq (1 + \varepsilon) \text{OPT}$, and that will finish the proof.

Consider the guess $\tau \in (\text{OPT}, (1 + \varepsilon) \text{OPT}]$. If τ was never active, that means $\tau' \leq \text{OPT}$, and we are done. Otherwise, τ was active, and we will prove that it was not aborted. Since $\tau \leq \text{OPT}$, we will not abort mid-stream in $\mathbb{I}(\tau)$, so let C_E be the set of pivots at the end of the stream in $\mathbb{I}(\tau)$. We will show that there is an independent set B such that cost of B with respect to C_E is at most $(5 + 2\varepsilon)\tau$. By Line 31 and by Theorem 5 for EFFICIENTMATROIDCENTER, this would imply that $\mathbb{I}(\tau)$ cannot abort.

From here on, the proof follows that of Lemma 4. Let $c \in C_E$. Denote by s_c the optimum center that serves it, so $d(c, s_c) \leq \tau$. If $s_c \in E(\tau)$, then $s_c \in \text{span}(I_{c'})$ for some $c' \in C_E$ and $d(s_c, c') \leq 2\tau$. Otherwise, s_c arrived before $E(\tau)$. Let ρ_{s_c} be the representative of s_c whose existence is guaranteed by Lemma 17, so $d(s_c, \rho_{s_c}) \leq \varepsilon\tau$. Then let $c' \in C_E$ be such that $d(\rho_{s_c}, c') \leq 2\tau$ and $J_{\rho_{s_c}}$ is spanned by $I_{c'}$. Thus, by triangle inequality

$$d(s_c, c') \leq d(s_c, \rho_{s_c}) + d(\rho_{s_c}, c') \leq \varepsilon\tau + 2\tau = (2 + \varepsilon)\tau, \quad (2)$$

and by Lemma 16, s_c is spanned by $I_{c'}$. Denote by \mathcal{A} the collection of such $I_{c'}$'s. Now, by Lemma 3, there exists an independent set B such that $|I \cap B| \geq 1$ for all $I \in \mathcal{A}$. Pick c_p from $I_{c'} \cap B$. Either $c_p \in E(\tau)$ or it arrived before. In any case, again using Lemma 17, we have $d(c_p, c') \leq (2 + \varepsilon)\tau$ (we use this below), and

- $d(c, s_c) \leq \tau$, because s_c is the optimum center that covers c ,
- $d(s_c, c') \leq (2 + \varepsilon)\tau$, by Inequality (2), and
- $d(c', c_p) \leq (2 + \varepsilon)\tau$.

Thus, by triangle inequality, $d(c, B) \leq (5 + 2\varepsilon)\tau$. So $\mathbb{I}(\tau)$ will not abort. This finishes the proof. ◀

Reducing the space usage for matroid center with z outliers can be done by naturally combining the techniques above and those in Section 5.2. We define a similar overloading MATROID-CENTER-Z-OUTLIERS($\tau, C_o, (J_{c_o})_{c_o \in C_o}, F_o, \text{flag}$), where F_o contains the set of free points in $\mathbb{I}(\tau_o)$ when it aborted and this function was called with the updated guess τ . We skip the details and state the following theorem without proof.

► **Theorem 19.** *There is an efficient $(51 + \varepsilon)$ -approximation one-pass algorithm for matroid center with z outliers that stores at most $O((r^2 + rz) \log(1/\varepsilon)/\varepsilon)$ points. With a brute force algorithm, one can get a $(15 + \varepsilon)$ -approximation.*

A.2 Extension to Knapsack Center

In Section 4.1, we saw how to modify Algorithm 1 to get an algorithm for knapsack center that stores at most $2r$ points, where r is the size of a largest feasible set. Using the same idea, algorithms for two-pass matroid center, matroid center with outliers, and smaller space matroid center, which are Algorithms 2, 4 and 6, can be extended to the knapsack center without losing the approximation ratio and with a space r factor smaller than the matroid case. For the outlier version of knapsack center, to get an efficient algorithm, we use the 3-approximation algorithm by Chakrabarty and Negahbani [5]. So we get the following theorems, where r is the size of a largest feasible set.

► **Theorem 20.** *There is an efficient $(17 + \varepsilon)$ -approximation one-pass algorithm for knapsack center that stores at most $O(r \log(1/\varepsilon)/\varepsilon)$ points. With a brute force algorithm, one can get a $(7 + \varepsilon)$ -approximation.*

► **Theorem 21.** *There is an efficient $(51 + \varepsilon)$ -approximation one-pass algorithm for knapsack center with z outliers that stores at most $O(rz \log(1/\varepsilon)/\varepsilon)$ points. With a brute force algorithm, one can get a $(15 + \varepsilon)$ -approximation.*

B An Implementation of Efficient Matroid Center

We now give an implementation of EFFICIENTMATROIDCENTER. The input consists of α , C_E , X , such that $C_E \subseteq X$, and the underlying matroid \mathcal{M} defined over X . Furthermore, the promise is that there is an independent set $B \subseteq X$ such that for each $c \in C_E$, we have $d(c, B) \leq \alpha$. Our implementation is based on the algorithm of Chen et al. [11] for matroid center. We show that it outputs a set C' such that, assuming the promise, $d(c, C') \leq 3\alpha$ for $c \in C_E$.

■ **Algorithm 6** Efficient algorithm for matroid center based on the algorithm by [11].

```

1: function EFFICIENTMATROIDCENTER( $\alpha, C_E, X, \mathcal{M}$ )
2:   Initialize:  $C \leftarrow \emptyset$ .
3:   while there is an unmarked point  $e$  in  $C_E$  do
4:      $C \leftarrow C \cup \{e\}$ ,  $B_e \leftarrow \mathfrak{B}(e, \alpha) \cap X$ , and mark all points in  $\mathfrak{B}(e, 2\alpha) \cap C_E$ .
5:   Let  $\mathcal{M}_C = (\cup_{c \in C} B_c, \mathcal{I}_C)$  be a partition matroid with partition  $\{B_c : c \in C\}$  and
   capacities 1.
6:   Let  $\mathcal{M}'$  be the matroid  $\mathcal{M}$  restricted to  $\cup_{c \in C} B_c$ .
7:    $C' \leftarrow \text{MATROID-INTERSECTION}(\mathcal{M}_C, \mathcal{M}')$ 
8:   if  $|C'| < |C|$  then
9:     Return fail.
10:  Return  $C'$ .

```

► **Theorem 22.** *If EFFICIENTMATROIDCENTER does not fail, then it outputs a set C' such that $d(c, C') \leq 3\alpha$ for each $c \in C_E$. If the input promise holds, then EFFICIENTMATROIDCENTER does not fail.*

Proof. In this proof, we refer by C the contents of the variable C after the while loop ended, and let c_E be any arbitrary point in C_E . Define the function $\text{Marker} : C_E \rightarrow C$ such that $\text{Marker}(c_E) \in C$ is the “marker” of c_E , i.e., we marked c_E when processing $\text{Marker}(c_E)$. In the end, all c_E ’s are marked, so Marker is a valid function. By the logic on Line 4, we have that

$$d(c_E, \text{Marker}(c_E)) \leq 2\alpha. \quad (3)$$

20:22 Small Space Stream Summary for Matroid Center

Let `EFFICIENTMATROIDCENTER` does not fail, then $|C'| \geq |C|$ and C' satisfies the partition matroid constraint of \mathcal{M}_C . By definition of \mathcal{M}_C , $\text{rank}(\mathcal{M}_C) = |C|$, hence $|C'| \leq |C|$, which implies that $|C'| = |C|$. Therefore, for each $c \in C$, the set C' must contain exactly one element in $\mathfrak{B}(c, \alpha)$ and $d(c, C') \leq \alpha$, in particular, $d(\text{Marker}(c_E), C') \leq \alpha$. This, triangle inequality, and Inequality (3) gives

$$d(c_E, C') \leq d(c_E, \text{Marker}(c_E)) + d(\text{Marker}(c_E), C') \leq 2\alpha + \alpha = 3\alpha,$$

which proves the first part of the statement of the lemma. We prove the second part next.

Assume that the promise holds. Then let B be the set such that cost of B is at most α with respect to C_E , in particular, with respect to C . For $c \in C$, define $\text{Coverer}(c) \in B$ to be an arbitrarily chosen “coverer” of c , i.e.,

$$d(c, \text{Coverer}(c)) \leq \alpha. \tag{4}$$

Then the set $B' := \{\text{Coverer}(c) : c \in C\}$ is a subset of B , so it is independent in \mathcal{M} . Now, for $c, c' \in C$, such that $c \neq c'$, we have $\text{Coverer}(c) \neq \text{Coverer}(c')$ by Inequality (4) because $d(c, c') > 2\alpha$. This implies that $|B'| = |C|$. Next, $\text{Coverer}(c) \in B' \cap B_c$ for each $c \in C$, hence the set B' is also independent in \mathcal{M}_C . Therefore $B' \in \mathcal{M}_C \cap \mathcal{M}'$, and `MATROID-INTERSECTION` returns an independent set of size $|C|$, i.e., it does not fail. ◀

► **Remark 23.** By running $\binom{|X|}{2}$ guesses, `EFFICIENTMATROIDCENTER` can be used to get an offline 3-approximation algorithm for a more general version of matroid center, where the cost is computed with respect to a subset C_E of X and any point in X can be a center.

Improved Bounds for Open Online Dial-a-Ride on the Line

Abstract

We consider the open, non-preemptive online DIAL-A-RIDE problem on the real line, where transportation requests appear over time and need to be served by a single server. We give a lower bound of 2.0585 on the competitive ratio, which is the first bound that strictly separates online DIAL-A-RIDE on the line from online TSP on the line in terms of competitive analysis, and is the best currently known lower bound even for general metric spaces. On the other hand, we present an algorithm that improves the best known upper bound from 2.9377 to 2.6662. The analysis of our algorithm is tight.

1 Introduction

We consider the online DIAL-A-RIDE problem on the line, where transportation requests appear over time and need to be transported to their respective destinations by a single server. More precisely, each request is of the form $\sigma_i = (a_i, b_i; r_i)$ and appears in position $a_i \in \mathbb{R}$ along the real line at time $r_i \geq 0$ and needs to be transported to position $b_i \in \mathbb{R}$. The server starts at the origin, can move at unit speed, and has a capacity $c \in \mathbb{N} \cup \{\infty\}$ that bounds the number of requests it can carry simultaneously. The objective is to minimize the completion time, i.e., the time until all requests have been served. In this paper, we focus on the *non-preemptive* and *open* setting, where the former means that requests can only be unloaded at their destinations, and the latter means that we do not require the server to return to the origin after serving all requests.

We aim to bound the *competitive ratio* of the problem, i.e., the smallest ratio any online algorithm can guarantee between the completion time of its solution compared to an (offline) optimum solution that knows all requests ahead of time. To date, the best known lower bound of 2.0346 on this ratio was shown by Bjelde et al. [5], already for online TSP, where $a_i = b_i$ for all requests (i.e., requests only need to be visited). The best known upper bound of 2.9377 was achieved by the SMARTSTART algorithm [4].

Our results. Our first result is an improved lower bound for online DIAL-A-RIDE on the line. Importantly, since the bound of roughly 2.0346 was shown to be tight for online TSP [5], our new bound is the first time that DIAL-A-RIDE on the line can be strictly separated from online TSP in terms of competitive analysis. In addition, our bound is the currently best known lower bound even for general metric spaces. Specifically, we show the following.

► **Theorem 1.1.** *Let $\rho \approx 2.0585$ be the second largest root of the polynomial $4\rho^3 - 26\rho^2 + 39\rho - 5$. There is no $(\rho - \varepsilon)$ -competitive algorithm for open, non-preemptive ($c < \infty$) online DIAL-A-RIDE on the line for any $\varepsilon > 0$.*

Our construction is a non-trivial variation of the construction achieving roughly 2.0346 for online TSP [5]. This construction is comprised of an initial request, a first stage consisting in turn of different iterations, and a second stage. We show that, by using a proper transportation requests as initial requests, we can adapt a single iteration of the first stage as well as the second stage to achieve the bound of roughly 2.0585 in the DIAL-A-RIDE setting.

Our second result is an improved algorithm SMARTERSTART for online DIAL-A-RIDE on the line. This algorithm improves the waiting strategy of the SMARTSTART algorithm, which was identified as a weakness in [4]. We show that this modification improves the competitive ratio of the algorithm and give a tight analysis. Specifically, we show the following.

► **Theorem 1.2.** *The competitive ratio of SMARTERSTART is (roughly) 2.6662.*

The general idea of SMARTERSTART is to improve the tradeoff between the case when the algorithm waits before starting its final schedule and the case when it starts the final schedule immediately. Our modification of SMARTSTART significantly improves the performance in the former case, while only moderately degrading the performance in the latter case. Overall, this results in an improved worst-case performance.

Related Work. The online DIAL-A-RIDE problem has received considerable attention in the past (e.g. [1, 4, 5, 6, 9, 13]). Table 1 gives an overview of the currently best known bounds on the line for open online DIAL-A-RIDE and its special case open online TSP.

The following results are known for *closed* online DIAL-A-RIDE: For general metric spaces, the competitive ratio is exactly 2, both for online DIAL-A-RIDE as well as online TSP [1, 3, 9]. On the line, a better upper bound is known only for online TSP, where the competitive ratio is exactly $(9 + \sqrt{17})/8 \approx 1.6404$ [3, 5]. The best known lower bound for closed, non-preemptive DIAL-A-RIDE on the line is 1.75 [5].

When the objective is to minimize the maximum flow time, on many metric spaces no online algorithm can be competitive [15, 16]. Hauptmeier et al. [12] showed that a competitive algorithm is possible if we restrict ourselves to instances with “reasonable” load. Yi and Tian [18] considered online DIAL-A-RIDE with deadlines, where the objective is to maximize the number of requests that are served in time. Other interesting variants of online DIAL-A-RIDE where destinations of requests are only revealed upon their collection were studied by Lipmann et al. [17] as well as Yi and Tian [19].

■ **Table 1** Overview of the best known bounds for online DIAL-A-RIDE on the line (top), and online DIAL-A-RIDE on general metric spaces (bottom). Results are split into the non-preemptive case (with $c < \infty$), the preemptive case, and the TSP-case, where source and destination of each request coincide. Bold results are original, all other results follow immediately.

		open		closed	
		lower bound	upper bound	lower bound	upper bound
line	non-preemptive	2.0585 (Thm 1.1)	2.6662 (Thm 1.2)	1.75 [5]	2
	preemptive	2.04	2.41 [5]	1.64	2
	TSP	2.04 [5]	2.04 [5]	1.64 [3]	1.64 [5]
general	non-preemptive	2.0585 (Thm 1.1)	3.41 [14]	2	2 [1, 9]
	preemptive	2.04	3.41	2	2
	TSP	2.04	2.5 [3]	2 [3]	2 [3]

For an overview of results for the offline version of DIAL-A-RIDE on the line, see [8]. Without release times, Gilmore and Gomory [10] and Atallah and Kosaraju [2] gave a polynomial time algorithm for closed, non-preemptive DIAL-A-RIDE on the line with capacity $c = 1$. Guan [11] showed that the closed, non-preemptive problem is hard for $c = 2$, and Bjelde et al. [5] extended this result for any finite capacity $c \geq 2$ in both the open and the closed variant. Bjelde et al. [5] also showed that the problem with release times is already hard for finite $c \geq 1$ in both variants, and Krumke [14] gave a 3-approximation algorithm for the closed variant. The complexity for the case $c = \infty$ remains open. For closed, preemptive DIAL-A-RIDE on the line without release times, Atallah and Kosaraju [2] gave a polynomial time algorithm for $c = 1$ and Guan [11] for $c \geq 2$. Charikar and Raghavachari [7] presented approximation algorithms for the closed case without release times on general metric spaces.

2 General Lower Bound

In this section, we prove Theorem 1.1. Let $c < \infty$ and ALG be a deterministic online algorithm for open online DIAL-A-RIDE. Let $\rho \approx 2.0585$, be the second largest root of the polynomial $4\rho^3 - 26\rho^2 + 39\rho - 5$. We describe a request sequence σ_ρ such that $\text{ALG}(\sigma_\rho) \geq \rho \text{OPT}(\sigma_\rho)$.

We first give a high-level description of our construction disregarding many technical details. Our construction is based on that in [5] for the TSP version of the problem. That construction consists of two *stages*: After an initial request $(1, 1; 1)$ (assuming w.l.o.g. ALG's position at time 1 is at most 0), the first stage starts. This stage consists of a loop, which ends as soon as two so-called critical requests are established. The second stage consists of augmenting the critical requests by suitable additional ones to show the desired competitive ratio. A single iteration of the loop only yields a lower bound of roughly 2.0298, but as the number of iterations approaches infinity one can show the tight bound of roughly 2.0346 in the limit.

In the DIAL-A-RIDE setting, we show a lower bound of roughly 2.0585 using the same general structure but only a single iteration. Our additional leeway stems from replacing the initial request $(1, 1; 1)$ with c initial requests of the form $(1, \delta; 1)$ where $\delta > 1$: At the time when an initial request is loaded, we show that w.l.o.g. all c requests are loaded and then proceed as we did when $(1, 1; 1)$ was served. In the new situation, the algorithm has to first deliver the c initial requests to be able to serve additional requests. For the optimum, the two situations however do not differ, because in the new situation there will be an additional

request to the right of δ later anyway. Interestingly, this leeway turns out to be sufficient not only to create critical requests (w.r.t. a slightly varied notion of criticality) for a competitive ratio of larger than 2.0298 but even strictly larger than 2.0346. The second stage has to be slightly adapted to match the new notion of criticality. It remains unclear how to use multiple iterations in our setting.

We start by making observations that will simplify the exposition. Consider a situation in which the server is fully loaded. First note that it is essentially irrelevant whether we assume that the server, without delivering any of the loaded requests, can still serve requests $(a_i, b_i; t_i)$ for which $a_i = b_i$: If it can, we simply move a_i and b_i by $\varepsilon > 0$ apart, forbidding the server to serve it before delivering one of the loaded requests first. Therefore, we assume for simplicity that, when fully loaded, the server has to first deliver a request before it can serve any other one. We note that, in our construction, the above idea can be implemented without loss, not even in terms of ε .

The latter discussion also motivates restricting the space of considered algorithms: We call ALG *eager* if it, when fully loaded with requests with identical destinations, immediately delivers these requests without detour. It is clear that we can transform every algorithm ALG' into an eager algorithm $\text{ALG}'_{\text{eager}}$ by letting it deliver the requests right away, waiting until ALG' would have delivered them, and then letting it continue like ALG' . Since ALG' cannot collect or serve other requests while being fully loaded, we have $\text{ALG}'_{\text{eager}}(\sigma) \leq \text{ALG}'(\sigma)$ for every request sequence σ .

► **Observation 2.1.** *Every algorithm for online DIAL-A-RIDE can be turned into an eager algorithm with the same competitive ratio.*

Thus, we may assume that ALG is eager. We now consider the second stage and then design a first stage to match the second stage. Suppose we have two requests $\sigma^R = (t^R, t^R; t^R)$ and $\sigma^L = (-t^L, -t^L; t^L)$ with $t^L \leq t^R$ to the right and to the left of the origin, respectively. We assume that ALG serves σ^R first at some time $t^* \geq (2\rho - 2)t^L + (\rho - 2)t^R$. Now suppose we could force ALG to serve σ^L directly after σ^R , even if additional requests are released. Then we could just release the request $\sigma_*^R = (t^R, t^R, 2t^L + t^R)$ and we would have

$$\text{ALG}(\sigma_\rho) = t^* + 2t^L + 2t^R \geq 2\rho t^L + \rho t^R = \rho \text{OPT}(\sigma_\rho),$$

since OPT can serve the three requests in time $2t^L + t^R$ by serving σ^L first. In fact, we will show that we can force ALG into this situation (or a worse situation) if the requests $\sigma^R = (t^R, t^R; t^R)$ and $\sigma^L = (-t^L, -t^L; t^L)$ satisfy the following properties. To describe the trajectory of a server, we use the notation “move(a)” for the tour that moves the server from its current position with unit speed to the point $a \in \mathbb{R}$.

► **Definition 2.2.** *We call the last two requests $\sigma^R = (t^R, t^R; t^R)$ and $\sigma^L = (-t^L, -t^L; t^L)$ of a request sequence with $0 < t^L \leq t^R$ critical for ALG if the following conditions hold:*

- (i) *Both tours $\text{move}(-t^L) \oplus \text{move}(t^R)$ and $\text{move}(t^R) \oplus \text{move}(-t^L)$ serve all requests presented until time t^R .*
- (ii) *ALG serves both σ^R and σ^L after time t^R and ALG’s position at time t^R lies between t^R and $-t^L$.*
- (iii) *If ALG serves σ^R before σ^L , it does so no earlier than $t_*^R := (2\rho - 2)t^L + (\rho - 2)t^R$.*
- (iv) *If ALG serves σ^L before σ^R , it does so no earlier than $t_*^L := (2\rho - 2)t^R + (\rho - 2)t^L$.*
- (v) *It holds that $\frac{t^R}{t^L} \leq \frac{4\rho^2 - 30\rho + 50}{-8\rho^2 + 50\rho - 66}$.*

► **Lemma 2.3.** *If there is a request sequence with two critical requests for ALG, we can release additional requests such that ALG is not $(\rho - \varepsilon)$ -competitive on the resulting instance for any $\varepsilon > 0$.*

Definition 2.2 differs from [5, Definition 5] only in property (v), which is $\frac{t^R}{t^L} \leq 2$ in the original paper. Lemma 2.3 has been proved in [5, Lemma 6] for request sequences that satisfy the properties of [5, Definition 5], however, a careful inspection of the proof of [5, Lemma 6] shows that the statement of Lemma 2.3 also holds for request sequences that only satisfy (v) instead of $\frac{t^R}{t^L} \leq 2$. For a detailed proof, see Appendix A. Thus, our goal is to construct a request sequence σ_ρ that satisfies all properties of Definition 2.2.

The remaining part of this section focusses on establishing critical requests. There are no requests released until time 1. Without loss of generality, we assume that ALG's position at time 1 is $\text{pos}(1) \leq 0$ (the other case is symmetric). Here and throughout, we let $\text{pos}(t)$ denote the position of ALG's server at time t . Now, let

$$\delta := \frac{3\rho^2 - 11}{-3\rho^3 + 15\rho - 4}$$

and let c initial requests $\sigma_{(j)}^R = (1, \delta; 1)$ with $j \in \{1, \dots, c\}$ appear. These are the only requests appearing in the entire construction with a starting point differing from the destination. We make a basic observation on how ALG has to serve these requests.¹

► **Lemma 2.4.** *ALG cannot collect any of the requests $\sigma_{(j)}^R$ before time 2. If ALG collects the requests after time $\rho\delta - (\delta - 1)$ or serves $c' < c$ requests before loading the remaining $c - c'$, it is not $(\rho - \varepsilon)$ -competitive.*

We hence may assume that ALG loads all c requests $\sigma_{(j)}^R$ at the same time. Let $t^L \in [2, \rho\delta - (\delta - 1))$ be the time ALG loads the c requests $\sigma_{(j)}^R$. We start the first stage and present a variant of a single iteration of the construction in [5]: We let the request $\sigma^L = (-t^L, -t^L; t^L)$ appear and define the function

$$\ell(t) = (4 - \rho) \cdot t - (2\rho - 2) \cdot t^L,$$

which can be viewed as a line in the path-time diagram. Because of $\rho > 2$, we have $\ell(t^L) = (6 - 3\rho)t^L < 0 < \text{pos}(t^L)$, i.e., ALG's position at time t^L is to the right of the line ℓ . Thus, ALG crosses the line ℓ before it serves σ^L . Let t^R be the time ALG crosses ℓ for the first time and let the request $\sigma^R = (t^R, t^R; t^R)$ appear. Assume ALG crosses the line ℓ and serves σ^R before σ^L . Then it does not serve σ^R before time

$$t^R + |\ell(t^R) - t^R| = (2\rho - 2)t^L + (\rho - 2)t^R = t_*^R. \quad (1)$$

Now assume ALG crosses ℓ at time $t^R \geq \frac{3\rho - 5}{7 - 3\rho}t^L$ and serves σ^L before σ^R . Then it does not serve σ^L before time

$$\begin{aligned} t^R + |\ell(t^R) - (-t^L)| &= (5 - \rho)t^R - (2\rho - 3)t^L \\ &\geq (2\rho - 2)t^R + (7 - 3\rho)\frac{3\rho - 5}{7 - 3\rho}t^L - (2\rho - 3)t^L \\ &= (2\rho - 2)t^R + (\rho - 2)t^L = t_*^L. \end{aligned} \quad (2)$$

The following lemma shows that the two requests cannot be served before these respective times by establishing that indeed $t^R \geq \frac{3\rho - 5}{7 - 3\rho}t^L$.

¹ The full proof and other omitted proofs can be found at <http://arxiv.org/abs/1907.02858>.

21:6 Improved Bounds for Open Online Dial-a-Ride on the Line

► **Lemma 2.5.** *ALG can neither serve σ^L before time t_*^L nor can it serve σ^R before time t_*^R .*

Proof. Since ALG is eager, it delivers the c requests $\sigma_{(j)}^R$ without waiting or detour, i.e., we have $\text{pos}(t^L + (\delta - 1)) = \delta$. Furthermore, we have

$$\begin{aligned} \ell(t^L + (\delta - 1)) &= (4 - \rho)(t^L + (\delta - 1)) - (2\rho - 2)t^L \\ &= (6 - 3\rho)t^L + (4 - \rho)(\delta - 1) \\ &\leq (6 - 3\rho)(\rho\delta - (\delta - 1)) + (4 - \rho)(\delta - 1) \\ &= \frac{3\rho^4 - 18\rho^3 + 3\rho^2 + 50\rho - 14}{3\rho^3 - 15\rho + 4} \\ &\stackrel{\rho < 2.06}{<} \delta = \text{pos}(t^L + (\delta - 1)), \end{aligned}$$

i.e., ALG's position at time $t^L + (\delta - 1)$ is to the right of ℓ . The earliest possible time ALG crosses ℓ is the solution of

$$\ell(t^R) = (4 - \rho)t^R - (2\rho - 2)t^L = \text{pos}(t^L + (\delta - 1)) + t^L + (\delta - 1) - t^R,$$

which is $t^R = \frac{2\rho-1}{5-\rho}t^L + \frac{2\delta-1}{5-\rho}$. The inequality

$$\begin{aligned} \left(\frac{3\rho-5}{7-3\rho} - \frac{2\rho-1}{5-\rho}\right)t^L &= \frac{3\rho^2 + 3\rho - 18}{3\rho^2 - 22\rho + 35}t^L \\ &\leq \frac{3\rho^2 + 3\rho - 18}{3\rho^2 - 22\rho + 35}(\rho\delta - (\delta - 1)) \\ &= \frac{3\rho^3 + 6\rho^2 - 15\rho - 18}{3\rho^4 - 15\rho^3 - 15\rho^2 + 79\rho - 20} \\ &= \frac{2\delta - 1}{5 - \rho}, \end{aligned}$$

implies that we have

$$t^R \geq \frac{3\rho-5}{7-3\rho}t^L. \quad (3)$$

Because of inequality (1) ALG does not serve σ^R before t_*^R and because of the inequalities (3) and (2) it does not serve σ^L before time t_*^L . ◀

In fact, also the other properties of critical requests are satisfied.

► **Lemma 2.6.** *The requests σ^R and σ^L of the request sequence σ_ρ are critical.*

Proof. We have to show that the requests σ^R and σ^L of the request sequence σ_ρ satisfy the properties (i) to (v) of Definition 2.2. The release time of every request is equal to its starting position, thus every request can be served/loaded immediately once its starting position is visited and (i) of Definition 2.2 is satisfied. At time t^R ALG has not served σ^R , because for that it would have needed to go right from time 0 on; it has not served σ^L either, because during the period of time $[t_L, t_R]$ ALG and σ^L were on different sides of ℓ . This establishes the first part of (ii) of Definition 2.2. Furthermore at time t^R ALG is at position $\text{pos}(t^R) = (4 - \rho)t^R - (2\rho - 2)t^L$ with

$$-t^L \leq (4 - \rho)t^R - (2\rho - 2)t^L \leq t^R$$

Therefore, the second part of (ii) of Definition 2.2 is satisfied as well.

Lemma 2.5 shows that (iii) and (iv) of Definition 2.2 are satisfied. It remains to show that property (v) is satisfied. For this we need to examine the release time t^R of σ^R . The time t^R is largest if ALG tries to avoid crossing the line ℓ for as long as possible, i.e., it continues to move right after serving the requests $\sigma_{(j)}^R$. Then, we have $\text{pos}(t) = 1 - t^L + t$ for $t \in [t^L, t^R]$ and t^R is the solution of

$$1 - t^L + t^R = (4 - \rho)t^R - (2\rho - 2)t^L.$$

Thus, in general, we have $t^R \leq \frac{2\rho-3}{3-\rho}t^L + \frac{1}{3-\rho}$, i.e.,

$$\frac{t^R}{t^L} \leq \frac{2\rho - 3}{3 - \rho} + \frac{1}{(3 - \rho)t^L} \stackrel{t^L \geq 2}{\leq} \frac{4\rho - 5}{6 - 2\rho}. \quad (4)$$

For property (v), we need $\frac{t^R}{t^L} \leq \frac{4\rho^2 - 30\rho + 50}{-8\rho^2 + 50\rho - 66}$. This is satisfied if

$$\frac{4\rho - 5}{6 - 2\rho} \leq \frac{4\rho^2 - 30\rho + 50}{-8\rho^2 + 50\rho - 66},$$

which is equivalent to

$$4\rho^3 - 26\rho^2 + 39\rho - 5 \geq 0,$$

which is true by definition of ρ . ◀

Together with Lemma 2.3, this completes the proof of Theorem 1.1.

3 An Improved Algorithm

One of the simplest approaches for an online algorithm to solve DIAL-A-RIDE is the following: Always serve the set of currently unserved requests in an optimum offline schedule and ignore all new incoming request while doing so. Afterwards, repeat this procedure with all ignored unserved requests until no new requests arrive. This simple algorithm that is often called IGNORE [1] has a competitive ratio of exactly 4 [4, 14]. The main weakness of IGNORE is that it always starts its schedule immediately. Ascheuer et al. showed that it is beneficial if the server waits sometimes before starting a schedule and introduced the SMARTSTART algorithm [1], which has a competitive ratio of roughly 2.94 [4].

We define $L(t, p, R)$ to be the smallest makespan of a schedule that starts at position p at time t and serves all requests in $R \subseteq \sigma$ after they appeared (i.e., the schedule must respect release times). For the description of online algorithms, we denote by t the current time and by R_t the set of requests that have appeared until time t but have not been served yet.

The algorithm SMARTSTART is given in Algorithm 1. Essentially, at time t , SMARTSTART waits before starting an optimal schedule to serve all available requests at time

$$\min_{t' \geq t} \left\{ t' \geq \frac{L(t', p, R_{t'})}{\Theta - 1} \right\}, \quad (5)$$

where p is the current position of the server and $\Theta > 1$ is a parameter of the algorithm that scales the waiting time. Importantly, like IGNORE, SMARTSTART ignores incoming requests while executing a schedule.

Birx and Disser identified that SMARTSTART's waiting routine defined by inequality (5) has a critical weakness [4, Lemma 4.1]. It is possible to lure the server to any position q in time $q + \varepsilon$ for every $\varepsilon > 0$. Roughly speaking, a request $\sigma_1 = ((\Theta - 1)\varepsilon, (\Theta - 1)\varepsilon; (\Theta - 1)\varepsilon)$ is

Algorithm 1 SMARTSTART.

```

 $p_1 \leftarrow 0$ 
for  $j = 1, 2, \dots$  do
    while current time  $t < L(t, p_j, R_t)/(\Theta - 1)$  do
         $\lfloor$  wait
         $t_j \leftarrow t$ 
         $S_j \leftarrow$  optimal offline schedule serving  $R_t$  starting from  $p_j$ 
        execute  $S_j$ 
     $p_{j+1} \leftarrow$  current position
    
```

released first and then for every $i \in \{2, \dots, \frac{q}{\varepsilon}\}$ a request $\sigma_i = (i\varepsilon, i\varepsilon; i\varepsilon)$ follows. The schedule to serve the request σ_1 is started at time ε and finished at time 2ε . The schedule to serve the request at position $i\varepsilon$ is not started earlier than time

$$\frac{L(i\varepsilon, (i-1)\varepsilon, \{\sigma_i\})}{\Theta - 1} = \frac{|(i-1)\varepsilon - i\varepsilon|}{\Theta - 1} = \frac{\varepsilon}{\Theta - 1}. \quad (6)$$

This time is (depending on the choice of Θ) later than the current time $i\varepsilon$ for every $i \geq 2$. Thus there is no waiting time for any schedule except the first one and the server reaches position q at time $q + \varepsilon$. We see that the request sequence to lure the server away heavily uses that inequality (5) relies on SMARTSTART's current position p , when computing the waiting time. Thus, we modify the waiting routine of SMARTSTART to avoid luring accordingly. Denote by $\sigma_{\leq t}$ the set of requests that have been released until time t .

Algorithm 2 SMARTERSTART.

```

 $p_1 \leftarrow 0$ 
for  $j = 1, 2, \dots$  do
    while current time  $t < L(t, 0, \sigma_{\leq t})/(\Theta - 1)$  do
         $\lfloor$  wait
         $t_j \leftarrow t$ 
         $S_j \leftarrow$  optimal offline schedule serving  $R_t$  starting from  $p_j$ 
        execute  $S_j$ 
     $p_{j+1} \leftarrow$  current position
    
```

The improved algorithm SMARTERSTART is given in Algorithm 2. At time t , it waits before starting an optimal schedule to serve all available requests at time

$$\min_{t' \geq t} \left\{ t' \geq \frac{L(t', 0, \sigma_{\leq t'})}{\Theta - 1} \right\}. \quad (7)$$

Again, $\Theta > 1$ is a parameter of the algorithm that scales the waiting time. In contrast to SMARTSTART, the waiting time is dependent on the length of the optimum offline schedule serving all requests appeared until the current time and starting from the origin. This guarantees that the server cannot be forced to reach any position q before time $q/(\Theta - 1)$ since we always have $L(t, 0, \sigma_{\leq t}) > q$ if $\sigma_{\leq t}$ contains a request with destination in position q .

Whenever we need to distinguish the behavior of SMARTERSTART for different values of $\Theta > 1$, we write SMARTERSTART $_{\Theta}$ to make the choice of Θ explicit. The length of SMARTERSTART's trajectory is denoted by SMARTERSTART(σ). Note that the schedules used by IGNORE, SMARTSTART and SMARTERSTART are NP-hard to compute for $1 < c < \infty$, see [5].

We let $N \in \mathbb{N}$ be the number of schedules needed by SMARTERSTART to serve σ . The j -th schedule is denoted by S_j , its starting time by t_j , its starting point by p_j , its ending point by p_{j+1} , and the set of requests served in S_j by σ_{S_j} . For convenience, we set $t_0 = p_0 = 0$.

3.1 Upper Bound for SMARTERSTART

We show the upper bound of Theorem 1.2. The completion time of SMARTERSTART is

$$\text{SMARTERSTART}(\sigma) = t_N + L(t_N, p_N, \sigma_{S_N}). \quad (8)$$

First, observe that, for all $0 \leq t \leq t'$, $p, p' \in \mathbb{R}$, and $R \subseteq \sigma$, we have

$$L(t, p, R) \geq L(t', p, R), \quad (9)$$

$$L(t, p, R) \leq |p - p'| + L(t, p', R), \quad (10)$$

$$L(t, 0, \sigma_{\leq t}) \leq L(t, 0, \sigma) \leq L(0, 0, \sigma) \leq \text{OPT}(\sigma). \quad (11)$$

Similar to [4], we distinguish between two cases, depending on whether or not SMARTERSTART waits after finishing schedule S_{N-1} and before starting the final schedule S_N . If the algorithm SMARTERSTART waits, the starting time of schedule S_N is given by

$$t_N = \frac{1}{\Theta - 1} L(t_N, 0, \sigma_{\leq t_N}), \quad (12)$$

otherwise, we have

$$t_N = t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}). \quad (13)$$

We start by giving a lower bound on the starting time of a schedule. It was shown in [4] that the schedule S_j of SMARTSTART is never started earlier than time $\frac{|p_{j+1}|}{\Theta}$. This changes slightly for SMARTERSTART.¹

► **Lemma 3.1.** *Algorithm SMARTERSTART does not start schedule S_j earlier than time $\frac{|p_{j+1}|}{\Theta - 1}$, i.e., we have $t_j \geq \frac{|p_{j+1}|}{\Theta - 1}$.*

Using Lemma 3.1, we can give an upper bound on the length of SMARTERSTART's schedules, which is an essential ingredient in our upper bounds. The following lemma is proved similarly to [4, Lemma 3.2], which yields an upper bound of $(1 + \frac{\Theta}{\Theta + 2})\text{OPT}(\sigma)$ for the length of every schedule S_j of SMARTSTART.¹

► **Lemma 3.2.** *For every schedule S_j of SMARTERSTART, we have*

$$L(t_j, p_j, \sigma_{S_j}) \leq \left(1 + \frac{\Theta - 1}{\Theta + 1}\right) \text{OPT}(\sigma).$$

Proof sketch. To prove the claim we have to show the two inequalities

$$L(t_j, p_j, \sigma_{S_j}) \leq \text{OPT}(\sigma) + |p_j| \quad \text{and} \quad L(t_j, p_j, \sigma_{S_j}) \leq 2\text{OPT}(\sigma) - 2\frac{|p_j|}{\Theta - 1}. \quad (14)$$

This implies

$$\begin{aligned} L(t_j, p_j, \sigma_{S_j}) &\stackrel{(14)}{\leq} \min \left\{ \text{OPT}(\sigma) + |p_j|, 2\text{OPT}(\sigma) - \frac{2}{\Theta - 1}|p_j| \right\} \\ &\leq \left(1 + \frac{\Theta - 1}{\Theta + 1}\right) \text{OPT}(\sigma), \end{aligned}$$

since the minimum above is largest for $|p_j| = \frac{\Theta - 1}{\Theta + 1} \text{OPT}(\sigma)$. ◀

21:10 Improved Bounds for Open Online Dial-a-Ride on the Line

The following proposition uses Lemma 3.2 to provide an upper bound for the competitive ratio of SMARTERSTART, in the case that SMARTERSTART does have a waiting period before starting the final schedule.

► **Proposition 3.3.** *In case SMARTERSTART waits before executing S_N , we have*

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \leq f_1(\Theta) := \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1}.$$

Proof. Assume SMARTERSTART waits before starting the final schedule. Lemma 3.2 yields the claimed bound:

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(8)}{=} t_N + L(t_N, p_N, \sigma_{S_N}) \\ &\stackrel{(12)}{=} \frac{1}{\Theta - 1} L(t_N, 0, \sigma_{\leq t_N}) + L(t_N, p_N, \sigma_{S_N}) \\ &\stackrel{(11)}{\leq} \frac{1}{\Theta - 1} \text{OPT}(\sigma) + L(t_N, p_N, \sigma_{S_N}) \\ &\stackrel{\text{Lem. 3.2}}{\leq} \left(\frac{1}{\Theta - 1} + 1 + \frac{\Theta - 1}{\Theta + 1} \right) \text{OPT}(\sigma) \\ &= \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1} \text{OPT}(\sigma). \quad \blacktriangleleft \end{aligned}$$

In comparison, the upper bound for the competitive ratio of SMARTSTART, in case SMARTSTART has a waiting period before starting the final schedule is $\frac{2\Theta^2 + 2\Theta}{\Theta^2 + \Theta - 2} \text{OPT}(\sigma)$ [4, Proposition 3.2]. Note that SMARTERSTART's bound is better than SMARTSTART's bound for $\Theta > 1$.

It remains to examine the case that the algorithm SMARTERSTART has no waiting period before starting the final schedule. For this we use two lemmas from [4] originally proved for SMARTSTART, which are still valid for SMARTERSTART since they give bounds on the optimum offline schedules independently of the waiting routine.

By $x_- := \min\{0, \min_{i=1, \dots, n}\{a_i\}, \min_{i=1, \dots, n}\{b_i\}\}$ we denote the leftmost position that needs to be visited by the server and by $x_+ := \max\{0, \max_{i=1, \dots, n}\{a_i\}, \max_{i=1, \dots, n}\{b_i\}\}$ the rightmost. We denote by $y_-^{S_j}$ the leftmost and by $y_+^{S_j}$ the rightmost position that occurs in the requests σ_{S_j} . Note that $y_-^{S_j}$ and $y_+^{S_j}$ need not lie on different sides of the origin, in contrast to $x_-/+$.

► **Lemma 3.4** (Lemma 3.4, Full Version of [4]). *Let S_j with $j \in \{1, \dots, N\}$ be a schedule of SMARTERSTART. Moreover, let $\text{OPT}(\sigma) = |x_-| + x_+ + y$ for some $y \geq 0$. Then, we have*

$$L(t_j, 0, \sigma_{S_j}) \leq |\min\{0, y_-^{S_j}\}| + \max\{0, y_+^{S_j}\} + y.$$

► **Lemma 3.5** (Lemma 3.6, Full Version of [4]). *Let S_j with $j \in \{1, \dots, N\}$ be a schedule of SMARTERSTART. Moreover, let $|x_-| \leq x_+$ and $\text{OPT}(\sigma) = |x_-| + x_+ + y$ for some $y \geq 0$. Then, for every point p that is visited by S_j we have*

$$p \leq |p_j| + |p_j - p_{j+1}| + y - |\min\{0, y_-^{S_j}\}|.$$

Using the bounds established by Lemma 3.4 and Lemma 3.5, we can give an upper bound for the competitive ratio of SMARTERSTART if the server is not waiting before starting the final schedule.

► **Proposition 3.6.** *If SMARTERSTART does not wait before executing S_N , we have*

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \leq f_2(\Theta) := \frac{3\Theta^2 + 3}{2\Theta + 1}.$$

Proof. Assume algorithm SMARTERSTART does not have a waiting period before the last schedule, i.e., SMARTERSTART starts the final schedule S_N immediately after finishing S_{N-1} . Without loss of generality, we assume $|x_-| \leq x_+$ throughout the entire proof by symmetry.

First of all, we notice that we may assume that SMARTERSTART executes at least two schedules in this case. Otherwise either the only schedule has length 0, which would imply $\text{OPT}(\sigma) = \text{SMARTERSTART}(\sigma) = 0$, or the only schedule would have a positive length, implying a waiting period. Let $\sigma_{S_N}^{\text{OPT}}$ be the first request of σ_{S_N} that is served by OPT and let a_N^{OPT} be its starting point and r_N^{OPT} be its release time. We have

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(8)}{=} t_N + L(t_N, p_N, \sigma_{S_N}) \\ &\stackrel{(13)}{=} t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + L(t_N, p_N, \sigma_{S_N}) \\ &\stackrel{t_N \geq r_N^{\text{OPT}}}{\leq} t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + L(r_N^{\text{OPT}}, p_N, \sigma_{S_N}). \end{aligned} \quad (15)$$

Since OPT serves all requests of σ_{S_N} after time r_N^{OPT} , starting with a request with starting point a_N^{OPT} , we also have

$$\text{OPT}(\sigma) \geq r_N^{\text{OPT}} + L(r_N^{\text{OPT}}, a_N^{\text{OPT}}, \sigma_{S_N}). \quad (16)$$

Furthermore, we have

$$r_N^{\text{OPT}} > t_{N-1} \quad (17)$$

since otherwise $\sigma_{S_N}^{\text{OPT}} \in \sigma_{S_{N-1}}$ would hold. This gives us

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(15)}{\leq} t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + L(r_N^{\text{OPT}}, p_N, \sigma_{S_N}) \\ &\stackrel{(10)}{\leq} t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| \\ &\quad + L(r_N^{\text{OPT}}, a_N^{\text{OPT}}, \sigma_{S_N}) \\ &\stackrel{(16)}{\leq} t_{N-1} + L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| \\ &\quad + \text{OPT}(\sigma) - r_N^{\text{OPT}} \\ &\stackrel{(17)}{<} L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| + \text{OPT}(\sigma) \\ &\stackrel{(10)}{\leq} |p_{N-1}| + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| + \text{OPT}(\sigma) \\ &\stackrel{\text{Lem. 3.1}}{\leq} (\Theta - 1)t_{N-2} + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| + \text{OPT}(\sigma). \end{aligned} \quad (18)$$

(19)

We have

$$\text{OPT}(\sigma) \geq t_{N-2} + |a_N^{\text{OPT}} - p_N|, \quad (20)$$

because OPT has to visit both a_N^{OPT} and p_N after time t_{N-2} : It has to visit a_N^{OPT} to collect $\sigma_{S_N}^{\text{OPT}}$ and it has to visit p_N to deliver some request of $\sigma_{S_{N-1}}$. Using the above inequality, we get

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(19)}{<} (\Theta - 1)t_{N-2} + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| + \text{OPT}(\sigma) \\ &\stackrel{(20)}{\leq} 2\text{OPT}(\sigma) + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + (\Theta - 2)t_{N-2}. \end{aligned} \quad (21)$$

21:12 Improved Bounds for Open Online Dial-a-Ride on the Line

In the case $\Theta \geq 2$, we have

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(21)}{<} 2\text{OPT}(\sigma) + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + (\Theta - 2)t_{N-2} \\ &\stackrel{(11)}{\leq} (\Theta + 1)\text{OPT}(\sigma) \\ &\stackrel{\Theta \geq 2}{\leq} \frac{3\Theta^2 + 3}{2\Theta + 1}\text{OPT}(\sigma). \end{aligned}$$

Thus, we may assume $\Theta < 2$. Similarly as in inequality (21), we get

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(19)}{<} (\Theta - 1)t_{N-2} + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + |a_N^{\text{OPT}} - p_N| + \text{OPT}(\sigma) \\ &\stackrel{(20)}{\leq} \Theta\text{OPT}(\sigma) + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + (2 - \Theta)|a_N^{\text{OPT}} - p_N| \\ &\stackrel{(7)}{\leq} \Theta\text{OPT}(\sigma) + (\Theta - 1)t_{N-1} + (2 - \Theta)|a_N^{\text{OPT}} - p_N| \\ &\leq (2\Theta - 1)\text{OPT}(\sigma) + (2 - \Theta)|a_N^{\text{OPT}} - p_N|, \end{aligned} \tag{22}$$

where the last inequality follows, because there exists a request in σ with release date later than t_{N-1} . This means the claim is shown if we have

$$|p_N - a_N^{\text{OPT}}| \leq \text{OPT}(\sigma) - \frac{\Theta - 1}{2\Theta + 1}\text{OPT}(\sigma) \tag{23}$$

since then we have

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(22)}{<} (2\Theta - 1)\text{OPT}(\sigma) + (2 - \Theta)|a_N^{\text{OPT}} - p_N| \\ &\stackrel{(23)}{\leq} (2\Theta - 1)\text{OPT}(\sigma) + (2 - \Theta) \left(1 - \frac{\Theta - 1}{2\Theta + 1}\right) \text{OPT}(\sigma) \\ &= \frac{3\Theta^2 + 3}{2\Theta + 1}\text{OPT}(\sigma). \end{aligned}$$

Therefore, we may assume in the following that

$$|p_N - a_N^{\text{OPT}}| > \text{OPT}(\sigma) - \frac{\Theta - 1}{2\Theta + 1}\text{OPT}(\sigma). \tag{24}$$

Let $\text{OPT}(\sigma) = |x_-| + x_+ + y$ for some $y \geq 0$. By definition of x_- and x_+ we have

$$|p_N - a_N^{\text{OPT}}| + y \leq \text{OPT}(\sigma). \tag{25}$$

In the case that OPT visits position p_N before it collects $\sigma_{S_N}^{\text{OPT}}$, we have

$$|a_N^{\text{OPT}} - p_N| + |p_N| \leq \text{OPT}(\sigma). \tag{26}$$

Similarly, if OPT collects $\sigma_{S_N}^{\text{OPT}}$ before it visits position p_N for the first time, we have

$$\begin{aligned} \text{OPT}(\sigma) &\geq r_N^{\text{OPT}} + |a_N^{\text{OPT}} - p_N| \\ &\stackrel{(17)}{>} t_{N-1} + |a_N^{\text{OPT}} - p_N| \\ &\stackrel{\text{Lem. 3.1}}{\geq} \frac{|p_N|}{\Theta - 1} + |a_N^{\text{OPT}} - p_N| \\ &\stackrel{\Theta < 2}{\geq} |p_N| + |a_N^{\text{OPT}} - p_N|. \end{aligned}$$

Thus, inequality (26) holds in general. To sum it up, we may assume that

$$\max\{y, |p_N|, t_{N-2}\} \stackrel{(24),(25),(26),(20)}{<} \frac{\Theta - 1}{2\Theta + 1} \text{OPT}(\sigma) \quad (27)$$

holds. In the following, denote by $y_-^{S_{N-1}}$ the leftmost starting or ending point and by $y_+^{S_{N-1}}$ the rightmost starting or ending point of the requests in $\sigma_{S_{N-1}}$. We compute

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(18)}{<} L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + |p_N - a_N^{\text{OPT}}| + \text{OPT}(\sigma) \\ &\stackrel{(26)}{<} L(t_{N-1}, p_{N-1}, \sigma_{S_{N-1}}) + 2\text{OPT}(\sigma) - |p_N| \\ &\stackrel{(9)}{\leq} |p_{N-1}| + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + 2\text{OPT}(\sigma) - |p_N| \\ &\stackrel{\text{Lem. 3.1}}{\leq} (\Theta - 1)t_{N-2} + L(t_{N-1}, 0, \sigma_{S_{N-1}}) + 2\text{OPT}(\sigma) - |p_N| \\ &\stackrel{\text{Lem. 3.4}}{\leq} (\Theta - 1)t_{N-2} + \max\{0, |y_-^{S_{N-1}}|\} + \max\{0, y_+^{S_{N-1}}\} + y \\ &\quad + 2\text{OPT}(\sigma) - |p_N|. \end{aligned} \quad (28)$$

Obviously, position $y_+^{S_{N-1}}$ is visited by SMARTERSTART in schedule S_{N-1} . Therefore, $y_+^{S_{N-1}}$ is smaller than or equal to the rightmost point that is visited by SMARTERSTART during schedule S_{N-1} , which gives us

$$y_+^{S_{N-1}} \stackrel{\text{Lem. 3.5}}{\leq} |p_{N-1}| + |p_{N-1} - p_N| + y - \max\{0, |y_-^{S_{N-1}}|\}. \quad (29)$$

On the other hand, because of $|x_-| \leq x_+$, we have $\text{OPT}(\sigma) \geq 2|x_-| + x_+$, which implies $y \geq |x_-|$. By definition of x_- and $y_-^{S_{N-1}}$, we have $|x_-| \geq \max\{0, |y_-^{S_{N-1}}|\}$. This gives us $y \geq \max\{0, |y_-^{S_{N-1}}|\}$ and

$$0 \leq |p_{N-1}| + |p_{N-1} - p_N| + y - \max\{0, |y_-^{S_{N-1}}|\}. \quad (30)$$

To sum it up, we have

$$\max\{0, y_+^{S_{N-1}}\} \stackrel{(29),(30)}{\leq} |p_{N-1}| + |p_{N-1} - p_N| + y - \max\{0, |y_-^{S_{N-1}}|\}. \quad (31)$$

The inequality above gives us

$$\begin{aligned} \text{SMARTERSTART}(\sigma) &\stackrel{(28)}{<} (\Theta - 1)t_{N-2} + \max\{0, |y_-^{S_{N-1}}|\} + \max\{0, y_+^{S_{N-1}}\} \\ &\quad + y + 2\text{OPT}(\sigma) - |p_N| \\ &\stackrel{(31)}{\leq} (\Theta - 1)t_{N-2} + |p_{N-1}| + |p_{N-1} - p_N| + 2y + 2\text{OPT}(\sigma) - |p_N| \\ &\leq (\Theta - 1)t_{N-2} + |p_{N-1}| + |p_{N-1}| + |p_N| + 2y + 2\text{OPT}(\sigma) - |p_N| \\ &\stackrel{\text{Lem. 3.1}}{\leq} (\Theta - 1)t_{N-2} + 2(\Theta - 1)t_{N-2} + 2y + 2\text{OPT}(\sigma) \\ &\stackrel{(27)}{\leq} (3\Theta - 3) \frac{\Theta - 1}{2\Theta + 1} \text{OPT}(\sigma) + 2 \frac{\Theta - 1}{2\Theta + 1} \text{OPT}(\sigma) + 2\text{OPT}(\sigma) \\ &= \frac{3\Theta^2 + 3}{2\Theta + 1} \text{OPT}(\sigma). \end{aligned} \quad \blacktriangleleft$$

In comparison, the upper bound for the competitive ratio of SMARTSTART in case it does not have a waiting period before starting the final schedule is $\Theta + 1 - \frac{\Theta - 1}{3\Theta + 3} \text{OPT}(\sigma)$ [4, Proposition 3.4]. Note that SMARTERSTART's bound is slightly worse than SMARTSTART's bound for $\Theta > 1.47$. However, in combination with the bound of Proposition 3.3, SMARTERSTART has a better worst-case than SMARTSTART.

21:14 Improved Bounds for Open Online Dial-a-Ride on the Line

► **Theorem 3.7.** *Let Θ^* be the largest solution of $f_1(\Theta) = f_2(\Theta)$, i.e.,*

$$\frac{3\Theta^{*2} + 3}{2\Theta^* + 1} = \frac{2\Theta^{*2} - \Theta^* + 1}{\Theta^{*2} - 1}.$$

Then, $\text{SMARTERSTART}_{\Theta^}$ is ρ^* -competitive with $\rho^* := f_1(\Theta^*) = f_2(\Theta^*) \approx 2.6662$.*

Proof. According to Proposition 3.3 and Proposition 3.6, if it exists,

$$\Theta^* = \operatorname{argmin}_{\Theta > 1} \{\max\{f_1(\Theta), f_2(\Theta)\}\}$$

is the parameter for SMARTERSTART with the smallest upper bound. We note that f_1 is strictly decreasing for $\Theta > 1$ and that f_2 is strictly increasing for $\Theta > 1$. Therefore, if an intersection point of f_1 and f_2 that is larger than 1 exists, then this is at Θ^* . Indeed, the intersection point exists, which is the largest solution of

$$\frac{3\Theta^2 + 3}{2\Theta + 1} = \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1}.$$

The resulting upper bound for the competitive ratio is

$$\rho^* = f_1(\Theta^*) = f_2(\Theta^*) \approx 2.6662. \quad \blacktriangleleft$$

3.2 Lower Bound for SMARTERSTART

We show the lower bound of Theorem 1.2. In this section, we explicitly construct instances that demonstrate that the upper bounds given in the previous section are tight for certain ranges of $\Theta > 1$, in particular for $\Theta = \Theta^*$ (as in Theorem 3.7). Further, we show that choices of $\Theta > 1$ different from Θ^* yield competitive ratios worse than $\rho^* \approx 2.67$. Together, this implies that ρ^* is exactly the best possible competitive ratio for SMARTERSTART .¹

► **Proposition 3.8.** *Let $1 < \Theta < 2$. For every sufficiently small $\varepsilon > 0$, there is a set of requests σ such that SMARTERSTART waits before starting the final schedule and such that the inequality*

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \geq \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1} - \varepsilon$$

holds, i.e., the upper bound established in Proposition 3.3 is tight for $\Theta \in (1, 2)$.

Proof sketch. Let $\varepsilon > 0$ with $\varepsilon < \frac{\Theta}{\Theta+1}$ and $\varepsilon' = \frac{\Theta+1}{2\Theta}\varepsilon$. The request sequence $\sigma = \{\sigma_1, \sigma_2\}$ with

$$\sigma_1 = (1, 1; 0) \quad \text{and} \quad \sigma_2 = \left(-\frac{1}{\Theta-1} + \varepsilon', 1; \frac{1}{\Theta-1} + \varepsilon'\right)$$

achieves the desired result. ◀

► **Proposition 3.9.** *Let $\frac{1}{2}(1 + \sqrt{5}) \leq \Theta \leq 2$. For every sufficiently small $\varepsilon > 0$ there is a set of requests σ such that SMARTERSTART immediately starts S_N after S_{N-1} and such that*

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \geq \frac{3\Theta^2 + 3}{2\Theta + 1} - \varepsilon,$$

i.e., the upper bound established in Proposition 3.6 is tight for $\Theta \in [\frac{1}{2}(1 + \sqrt{5}), 2] \approx [1.6180, 2]$.

Proof sketch. Let $\varepsilon > 0$ with $\varepsilon < \frac{1}{4}(\frac{5\Theta^2-9\Theta+4}{2\Theta+1})$ and $\varepsilon' = \frac{2\Theta+1}{5\Theta^2-9\Theta+4}\varepsilon$. The request sequence $\sigma = \{\sigma_1, \sigma_2\}$ with

$$\begin{aligned} \sigma_1 &= (1, 1; 0), \\ \sigma_2^{(1)} &= \left(2 + \frac{1}{\Theta-1} - 2\varepsilon', 2 + \frac{1}{\Theta-1} - 2\varepsilon'; \frac{1}{\Theta-1} + \varepsilon'\right), \\ \sigma_2^{(2)} &= \left(-\frac{1}{\Theta-1}, -\frac{1}{\Theta-1}; \frac{1}{\Theta-1} + \varepsilon'\right), \\ \sigma_3 &= \left(\frac{3}{(\Theta-1)^2} - \varepsilon', \frac{3}{(\Theta-1)^2} - \varepsilon'; \frac{3}{(\Theta-1)^2} + \frac{2}{\Theta-1}\right) \end{aligned}$$

achieves the desired result. ◀

Recall that the optimal parameter Θ^* established in Theorem 3.7 is the only positive, real solution of the equation

$$\frac{3\Theta^2 + 3}{2\Theta + 1} = \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1},$$

which is $\Theta^* \approx 1.7125$. Therefore, according to Proposition 3.8 and Proposition 3.9 the parameter Θ^* lies in the range where the upper bounds of Propositions 3.3 and 3.6 are both tight. It remains to make sure that for all Θ that lie outside of this range the competitive ratio of $\text{SMARTERSTART}_\Theta$ is larger than $\rho^* \approx 2.6662$.¹

► **Lemma 3.10.** *Let $\Theta > 2$. There is a set of requests $\sigma_{\Theta>2}$ such that*

$$\frac{\text{SMARTERSTART}(\sigma_{\Theta>2})}{\text{OPT}(\sigma_{\Theta>2})} > \rho^* \approx 2.6662.$$

Figure 1 shows the upper and lower bounds that we have established. Theorem 1.2 now follows from Theorem 3.7 combined with Propositions 3.8 and 3.9, as well as Lemma 3.10.

Proof of Theorem 1.2. We have shown in Proposition 3.8 that the upper bound

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \leq f_1(\Theta) = \frac{2\Theta^2 - \Theta + 1}{\Theta^2 - 1}$$

established in Proposition 3.3 for the case, where SMARTERSTART waits before starting the final schedule, is tight for all $\Theta \in (1, 2)$. Furthermore, we have shown in Proposition 3.9 that the upper bound

$$\frac{\text{SMARTERSTART}(\sigma)}{\text{OPT}(\sigma)} \leq f_2(\Theta) = \frac{3\Theta^2 + 3}{2\Theta + 1}$$

established in Proposition 3.6 for the case, where SMARTERSTART does not wait before starting the final schedule, is tight for all $\Theta \in (\frac{1}{2}(1 + \sqrt{5}), 2]$. Since $\Theta^* \approx 1.71249$ lies in those ranges, the competitive ratio of $\text{SMARTERSTART}_{\Theta^*}$ is indeed exactly ρ^* .

It remains to show that for every $\Theta > 1$ with $\Theta \neq \Theta^*$ the competitive ratio is larger. First, according to Lemma 3.10, the competitive ratio of SMARTERSTART with parameter $\Theta \in (2, \infty)$ is larger than ρ^* . By monotonicity of f_1 , every function value in $(1, \Theta^*)$ is larger than $f_1(\Theta^*) = \rho^*$. Thus, the competitive ratio of SMARTERSTART with parameter $\Theta \in (1, \Theta^*)$ is larger than ρ^* , since f_1 is tight on $(1, \Theta^*)$ by Proposition 3.8. Similarly, by monotonicity of f_2 , every function value in $(\Theta^*, 2]$ is larger than $f_2(\Theta^*) = \rho^*$. Thus, the competitive ratio of SMARTERSTART with parameter $\Theta \in (\Theta^*, 2]$ is larger than ρ^* , since f_2 is tight on $(\Theta^*, 2]$ by Proposition 3.9. ◀

■ **Figure 1** Overview of our bounds for SMARTERSTART. The functions f_1 (green) / f_2 (red) are upper bounds for the cases where SMARTERSTART waits / does not wait before starting the final schedule, respectively. The upper bounds are drawn solid in the domains where they are tight for their corresponding case. The functions g_1 and g_2 (blue) are general lower bounds.

A Proof of Lemma 2.3

In this section we prove Lemma 2.3. The proof is almost identical to the proof of [5, Lemma 6]. Since there are however several parts where inequalities change slightly, we decided to present the full proof here.

► **Lemma 2.3.** *If there is a request sequence with two critical requests for ALG, we can release additional requests such that ALG is not $(\rho - \varepsilon)$ -competitive on the resulting instance for any $\varepsilon > 0$.*

Let the requests σ^L and σ^R be critical. Furthermore, let $p_0 \in \{t^L, t^R\}$ be the starting position of the request $\sigma_0 \in \{\sigma^L, \sigma^R\}$ that is served first by ALG and let $p_1 \in \{t^L, t^R\}$ be the starting position of the request $\sigma_1 \in \{\sigma^L, \sigma^R\}$ that is not served first by ALG. By properties (iii) and (iv) of Definition 2.2, ALG cannot serve σ_0 before time $(2\rho - 2)|p_1| + (\rho - 2)|p_0|$. Thus, we have

$$\text{ALG}(\sigma_\rho) \geq (2\rho - 2)p_1 + (\rho - 2)p_0 + |p_0 - p_1| = (2\rho - 1)|p_1| + (\rho - 1)|p_0|. \quad (32)$$

We have equality in inequality (32) if ALG serves σ_0 the earliest possible time and then moves directly to position p_1 . However, in general ALG does not need to do this and instead can wait. At time $t \geq \max\{|p_0|, |p_1|\}$, we have $\text{ALG}(\sigma_\rho) \geq t + |\text{pos}(t) - p_0| + |p_0 - p_1|$ if ALG still has to serve σ_0 and $\text{ALG}(\sigma_\rho) \geq t + |\text{pos}(t) - p_1|$ if σ_0 is served and only σ_1 is left

21:18 Improved Bounds for Open Online Dial-a-Ride on the Line

to be served. We want to measure the delay of ALG at a time $t \geq \max\{|p_0|, |p_1|\}$, i.e. the difference between the time ALG needs at least to serve both requests σ_0 and σ_1 and the time $(2\rho - 1)|p_1| + (\rho - 1)|p_0|$. We define for $t \geq \max\{|p_0|, |p_1|\}$ the function

$$\text{delay}(t) := \begin{cases} t + |\text{pos}(t) - p_0| - (\rho - 2)|p_0| - (2\rho - 2)|p_1| & \text{if } \sigma_0 \text{ is not served at } t, \\ t + |\text{pos}(t) - p_1| - (\rho - 1)|p_0| - (2\rho - 1)|p_1| & \text{if } \sigma_0 \text{ is served at } t, \text{ but } \sigma_1 \text{ not,} \\ \text{undefined} & \text{otherwise.} \end{cases}$$

We make the following observation about delay.

► **Observation A.1.** *Let $t \geq \max\{|p_0|, |p_1|\}$ be a time at which σ_1 is not served yet. The earliest time ALG can serve σ_1 is $(2\rho - 1)|p_1| + (\rho - 1)|p_0| + \text{delay}(t)$.*

► **Lemma A.2.** *There is a $W \geq 0$ with*

$$\text{delay}\left(2|p_1| + |p_0| + \frac{W}{\rho - 1}\right) = W$$

Proof. Because of property (ii) of Definition 2.2, at time $\max\{|p_0|, |p_1|\}$ neither σ_0 nor σ_1 has been served by ALG yet. Since ALG serves σ_1 after σ_0 , the request σ_1 is not served before time $\max\{|p_0|, |p_1|\} + |p_0| + |p_1| \geq 2|p_1| + |p_0|$, i.e. $\text{delay}(2p_1 + p_0)$ is defined. Because of properties (iii) and (iv) of Definition 2.2, σ_0 is not served before time $(2\rho - 2)|p_1| + (\rho - 2)|p_0|$. Thus, for $t \geq (2\rho - 2)p_1 + (\rho - 2)p_0$, we have $\text{delay}(t) \geq 0$. We have

$$\begin{aligned} 2p_1 + p_0 &\stackrel{\text{Def 2.2 (v)}}{\geq} 2p_1 + (3 - \rho) \frac{-8\rho^2 + 50\rho - 66}{4\rho^2 - 30\rho + 50} |p_1| + (\rho - 2)|p_0| \\ &\stackrel{2 < \rho < 2.5}{>} (2\rho - 2)|p_1| + (\rho - 2)|p_0|, \end{aligned} \quad (33)$$

i.e. $\text{delay}(2p_1 + p_0) \geq 0$. If $\text{delay}(2p_1 + p_0) = 0$, we have $W = 0$ and are done. Otherwise, by inequality (33), we have $\text{delay}(2p_1 + p_0) > 0$. Note that ALG needs to serve σ_1 at some point to be $(\rho - \varepsilon)$ -competitive. Let W^* be chosen such that ALG serves σ_1 at time $2|p_1| + |p_0| + \frac{W^*}{\rho - 1}$. Therefore $\text{delay}(2|p_1| + |p_0| + \frac{W^*}{\rho - 1} - \varepsilon')$ is defined for some sufficiently small $\varepsilon' \leq |p_1|$. We define the function

$$f(W) := \text{delay}\left(2|p_1| + |p_0| + \frac{W}{\rho - 1}\right) - W.$$

Note that f is continuous and we have $f(0) > 0$. If

$$\text{delay}\left(2|p_1| + |p_0| + \frac{W^*}{\rho - 1} - \varepsilon'\right) \leq \frac{W^*}{\rho - 1} - \varepsilon' \stackrel{\rho > 1}{<} W^* - (\rho - 1)\varepsilon',$$

we have $f(W^* - (\rho - 1)\varepsilon') < 0$ and we find W in the interval $(0, W^* - (\rho - 1)\varepsilon']$. Otherwise, we have

$$\text{delay}\left(2|p_1| + |p_0| + \frac{W^*}{\rho - 1} - \varepsilon'\right) > \frac{W^*}{\rho - 1} - \varepsilon'.$$

By Observation A.1 ALG has not served σ_1 at time

$$(2\rho - 1)|p_1| + (\rho - 1)|p_0| + \frac{W^*}{\rho - 1} - \varepsilon' \stackrel{\rho > 2, \varepsilon' \leq |p_1|}{>} 2|p_1| + |p_0| + \frac{W^*}{\rho - 1}.$$

This is a contradiction to the fact, that W^* was chosen such that ALG serves σ_1 at time $2|p_1| + |p_0| + \frac{W^*}{\rho - 1}$. ◀

► **Lemma A.3.** *Let $W \geq 0$ with*

$$\text{delay}\left(2|p_1| + |p_0| + \frac{W}{\rho-1}\right) = W.$$

ALG serves σ_0 no later than time $2|p_1| + |p_0| + \frac{W}{\rho-1}$.

Proof. Assume we have

$$2|p_1| + |p_0| + \frac{W}{\rho-1} \geq (2\rho-2)|p_1| + (\rho-2)|p_0| + W. \quad (34)$$

Then, by definition of W and Observation A.1, ALG can serve σ_1 at time

$$(2\rho-1)|p_1| + (\rho-1)|p_0| + \text{delay}\left(2|p_1| + |p_0| + \frac{W}{\rho-1}\right) = (2\rho-1)|p_1| + (\rho-1)|p_0| + W. \quad (35)$$

Because of inequality (34), this can only be the case if ALG serves σ_0 no later than time

$$(2\rho-1)|p_1| + (\rho-1)|p_0| + W - |p_1| - |p_0| = (2\rho-2)|p_1| + (\rho-2)|p_0| + W \stackrel{(34)}{\leq} 2|p_1| + |p_0| + \frac{W}{\rho-1}.$$

Thus, it remains to show inequality (34). Because of property (i) of Definition 2.2 all requests can be served the tours $\text{move}(p_0) \oplus \text{move}(p_1)$ and $\text{move}(p_1) \oplus \text{move}(p_0)$. By inequality 35, we have $\text{ALG}(\sigma_\rho) \geq (2\rho-1)|p_1| + (\rho-1)|p_0| + W$. Thus, if we have

$$\text{ALG}(\sigma_\rho) \geq (2\rho-1)|p_1| + (\rho-1)|p_0| + W > (\rho-\varepsilon)(2|p_1| + |p_0|) \geq (\rho-\varepsilon)\text{OPT}(\sigma_\rho),$$

ALG is not $(\rho-\varepsilon)$ -competitive. Therefore, we may assume

$$(2\rho-1)|p_1| + (\rho-1)|p_0| + W \leq (\rho-\varepsilon)(2|p_1| + |p_0|),$$

and thus

$$\begin{aligned} W &\leq (\rho-\varepsilon)(2|p_1| + |p_0|) - (2\rho-1)|p_1| - (\rho-1)|p_0| \\ &= (1-2\varepsilon)|p_1| + (1-\varepsilon)|p_0| \\ &< |p_1| + |p_0|. \end{aligned} \quad (36)$$

Inequality (34) now is equivalent to the inequality

$$\begin{aligned} \frac{2|p_1| + |p_0| - ((2\rho-2)|p_1| + (\rho-2)|p_0|)}{1 - \frac{1}{\rho-1}} &= \frac{(\rho-1)(4-2\rho)}{\rho-2}|p_1| + \frac{(\rho-1)(3-\rho)}{\rho-2}|p_0| \\ &\stackrel{\text{Def 2.2 (v)}}{\geq} |p_0| + (2-2\rho)|p_1| \\ &\quad + \frac{(-\rho^2 + 3\rho - 1)(-8\rho^2 + 50\rho - 66)}{(\rho-2)(4\rho^2 - 30\rho + 50)}|p_1| \\ &\geq |p_0| + \frac{5\rho^3 - 36\rho^2 + 86\rho - 67}{2\rho^3 - 19\rho^2 + 55\rho - 50}|p_1| \\ &\stackrel{2 < \rho < 2.5}{>} |p_0| + |p_1| \\ &\stackrel{(36)}{>} W \end{aligned}$$

if we solve inequality (34) for W . ◀

21:20 Improved Bounds for Open Online Dial-a-Ride on the Line

Now we have all ingredients to proof Lemma 2.3.

Proof of Lemma 2.3. Let $W \geq 0$ with $\text{delay}(2|p_1| + |p_0| + \frac{W}{\rho-1}) = W$. We present the request

$$\sigma_0^+ = (p_0^+, p_0^+; t_0^+) := \left(p_0 + \text{sgn}(p_0) \frac{W}{\rho-1}, p_0 + \text{sgn}(p_0) \frac{W}{\rho-1}; 2|p_1| + |p_0| + \frac{W}{\rho-1} \right)$$

and distinguish two cases.

Case 1: At time t_0^+ , ALG is at least as close to p_1 as to p_0^+ or it serves σ_1 before σ_0^+ . In this case, we do not present additional requests. By Lemma A.3, ALG has served σ_0 at time t_0^+ or before and by Observation A.1 it does not serve σ_1 earlier than time $(2\rho-1)|p_1| + (\rho-1)|p_0| + W$. Thus, we have

$$\begin{aligned} \text{ALG}(\sigma_\rho) &\geq (2\rho-1)|p_1| + (\rho-1)|p_0| + W + |p_1| + |p_0| + \frac{W}{\rho-1} \\ &\geq \rho \left(2|p_1| + |p_0| + \frac{W}{\rho-1} \right) \\ &= \rho \text{OPT}(\sigma_\rho). \end{aligned}$$

Case 2: At time t_0^+ , ALG is closer to p_0^+ than to p_1 and it serves σ_0^+ first. We assume that the offline server continues moving away from the origin after serving σ_0^+ at time p_0^+ . Then, the position of the offline server at time $t \geq |p_1|$ is $\text{sgn}(p_0)t + 2p_1$. We denote by

$$M(t) := \frac{\text{sgn}(p_0)t + 3p_1}{2}$$

the midpoint between the current position of the offline server and the position p_1 . Note that the time $M^{-1}(p)$, when the midpoint is at position p is given by

$$M^{-1}(p) := |2p - 3p_1|.$$

We again distinguish two cases

Case 2.1: ALG does not serve σ_0^+ until time $M^{-1}(p_0^+)$. In this case, we do not present additional requests. Since we are in Case 2, neither σ_0^+ nor σ_1 is served at time $M^{-1}(p_0^+)$. Thus, we have

$$\begin{aligned} \text{ALG}(\sigma_\rho) &\geq M^{-1}(p_0^+) + |p_0^+| + |p_1| \\ &= |2p_0^+ - 3p_1| + |p_0^+| + |p_1| \\ &= |2p_0 + 2\text{sgn}(p_0) \frac{W}{\rho-1} - 3p_1| + |p_0| + \frac{W}{\rho-1} + |p_1| \\ &= 3|p_0| + 4|p_1| + 3 \frac{W}{\rho-1} \\ &\stackrel{2 < \rho < 2.5}{>} \rho|p_0| + 2\rho|p_1| + 3 \frac{W}{\rho-1} \\ &> \rho \left(|p_0| + 2|p_1| + \frac{W}{\rho-1} \right) \\ &= \rho \text{OPT}(\sigma_\rho). \end{aligned}$$

Case 2.2: ALG serves σ_0^+ before time $M^{-1}(p_0^+)$. By definition of W , the delay function is defined for time p_0^+ , hence ALG has not served σ_1 before time p_0^+ . Since ALG is to the right of the midpoint $M(p_0^+)$ at time p_0^+ , there is a first time t_{mid} at which $M(t_{\text{mid}}) = \text{pos}(t_{\text{mid}})$. We present the request

$$\sigma_0^{++} = (p_0^{++}, p_0^{++}; t_0^{++}) := (\text{sgn}(p_0)t_{\text{mid}} + 2p_1, \text{sgn}(p_0)t_{\text{mid}} + 2p_1; t_{\text{mid}}).$$

Note that ALG is at the midpoint between p_0^{++} and p_1 and thus, both tours $\text{move}(p_0^{++}) \oplus \text{move}(p_1)$ and $\text{move}(p_1) \oplus \text{move}(p_0^{++})$ incur identical costs for ALG. We have

$$\text{ALG}(\sigma_\rho) \geq t_{\text{mid}} + 3 \left(\frac{|\text{sgn}(p_0)t_{\text{mid}} + 2p_1 - p_1|}{2} \right) = \frac{5t_{\text{mid}} + 3|p_1|}{2}$$

We have $\text{OPT}(\sigma_\rho) = t_{\text{mid}}$, i.e., if we want to show

$$\text{ALG}(\sigma_\rho) \geq \frac{5t_{\text{mid}} + 3|p_1|}{2} \geq \rho t_{\text{mid}} = \rho \text{OPT}(\sigma_\rho) \quad (37)$$

Inequality (37) is equivalent to

$$(5 - 2\rho)t_{\text{mid}} \geq 3|p_1|. \quad (38)$$

Since $2\rho < 2.5$, the coefficient $(5 - 2\rho)$ of t_{mid} is positive. Thus we may assume t_{mid} is minimal to show the inequality (38). By assumption, σ_0^+ is already served at time t_{mid} . Hence, t_{mid} is minimum if, starting at time t_0^+ at position $\text{pos}(t_0^+)$, ALG serves σ_0^+ and then moves towards the origin. Then, t_{mid} is the solution of the equation

$$\text{sgn}(p_0)t_0^+ + |\text{pos}(t_0^+) - p_0^+| + p_0^+ - \text{sgn}(p_0)t_{\text{mid}} = \frac{\text{sgn}(p_0)t_{\text{mid}} + 3p_1}{2}. \quad (39)$$

Because of Lemma A.3, the request σ_0 is already served at time t_0^+ . Furthermore, since the position of σ_1 has not been visited yet at time t_0^+ , we have $\text{sgn}(p_0)\text{pos}(t_0^+) > \text{sgn}(p_0)p_1$, i.e.,

$$|\text{pos}(t_0^+) - p_1| = \text{sgn}(p_0)(\text{pos}(t_0^+) - p_1) > 0$$

and thus, because of $-\text{sgn}(p_0)p_1 = |p_1|$, we get

$$\begin{aligned} \text{delay}(t_0^+) &= t_0^+ + |\text{pos}(t_0^+) - p_1| - (\rho - 1)|p_0| - (2\rho - 1)|p_1| \\ &= t_0^+ + \text{sgn}(p_0)\text{pos}(t_0^+) - \text{sgn}(p_0)p_1 - (\rho - 1)|p_0| - (2\rho - 1)|p_1| \\ &= t_0^+ + \text{sgn}(p_0)\text{pos}(t_0^+) + |p_1| - (\rho - 1)|p_0| - (2\rho - 1)|p_1|. \end{aligned} \quad (40)$$

Solving equation (40) for $\text{sgn}(p_0)\text{pos}(t_0^+)$ gives

$$\begin{aligned} \text{sgn}(p_0)\text{pos}(t_0^+) &= \text{delay} \left(2|p_1| + |p_0| + \frac{W}{\rho - 1} \right) - \frac{W}{\rho - 1} \\ &\quad + (\rho - 2)|p_0| + (2\rho - 4)|p_1| \\ &= W - \frac{W}{\rho - 1} + (\rho - 2)|p_0| + (2\rho - 4)|p_1| \\ &= \frac{\rho - 2}{\rho - 1}W + (\rho - 2)|p_0| + (2\rho - 4)|p_1| \\ &\stackrel{\rho \leq 3}{\leq} \frac{W}{\rho - 1} + (\rho - 2)|p_0| + (2\rho - 4)|p_1| \\ &\stackrel{\text{Def 2.2 (v)}}{\leq} \frac{W}{\rho - 1} + \left((\rho - 2) + (2\rho - 4) \frac{4\rho^2 - 30\rho + 50}{-8\rho^2 + 50\rho - 66} \right) |p_0| \\ &\stackrel{1.9 < \rho < 4.3}{\leq} \frac{W}{\rho - 1} + |p_0| \\ &\stackrel{\text{sgn}(p_0) = \text{sgn}(p_0^+)}{=} \text{sgn}(p_0)p_0^+. \end{aligned} \quad (41)$$

21:22 Improved Bounds for Open Online Dial-a-Ride on the Line

Thus, we have

$$|\text{pos}(t_0^+) - p_0^+| = \text{sgn}(p_0)(p_0^+ - \text{pos}(t_0^+)) > 0 \quad (42)$$

Using inequality (42) and plugging inequality (41) into inequality (39) gives us

$$\begin{aligned} \text{sgn}(p_0)t_{\text{mid}} &= \frac{1}{3}(2\text{sgn}(p_0)t_0^+ + 2|\text{pos}(t_0^+) - 2p_0^+| + 2p_0^+ - 3p_1) \\ &\stackrel{(42)}{=} \frac{1}{3}(2\text{sgn}(p_0)t_0^+ + 2\text{sgn}(p_0)p_0^+ - 2\text{sgn}(p_0)\text{pos}(t_0^+) + 2p_0^+ - 3p_1) \\ &= \frac{1}{3}\left(-7p_1 + 6p_0 + \frac{(6\text{sgn}(p_0))W}{\rho - 1} - 2\text{sgn}(p_0)\text{pos}(t_0^+)\right) \\ &\stackrel{(41)}{=} \frac{1}{3}\left(-(15 - 4\rho)p_1 + (10 - 2\rho)p_0 + \frac{(10 - 2\rho)\text{sgn}(p_0)W}{\rho - 1}\right) \end{aligned} \quad (43)$$

Note that we also used $\text{sgn}(p_0) = \text{sgn}(p_0^+) = -\text{sgn}(p_1)$. Multiplying equality (43) with $\text{sgn}(p_0)$ gives us

$$t_{\text{mid}} = \frac{1}{3}\left((15 - 4\rho)|p_1| + (10 - 2\rho)|p_0| + \frac{(10 - 2\rho)W}{\rho - 1}\right). \quad (44)$$

By substituting (44) into (38) and noting that it is hardest to satisfy, when $W = 0$, we get

$$\frac{|p_0|}{|p_1|} \leq \frac{4\rho^2 - 30\rho + 50}{-8\rho^2 + 50\rho - 66},$$

which is true due to Definition 2.2 (v). ◀

Improved Online Algorithms for Knapsack and GAP in the Random Order Model

Abstract

The *knapsack problem* is one of the classical problems in combinatorial optimization: Given a set of items, each specified by its size and profit, the goal is to find a maximum profit packing into a knapsack of bounded capacity. In the online setting, items are revealed one by one and the decision, if the current item is packed or discarded forever, must be done immediately and irrevocably upon arrival. We study the online variant in the random order model where the input sequence is a uniform random permutation of the item set.

We develop a randomized $(1/6.65)$ -competitive algorithm for this problem, outperforming the current best algorithm of competitive ratio $1/8.06$ [Kesselheim et al. SIAM J. Comp. 47(5)]. Our algorithm is based on two new insights: We introduce a novel algorithmic approach that employs two given algorithms, optimized for restricted item classes, sequentially on the input sequence. In addition, we study and exploit the relationship of the knapsack problem to the 2-secretary problem.

The *generalized assignment problem* (GAP) includes, besides the knapsack problem, several important problems related to scheduling and matching. We show that in the same online setting, applying the proposed sequential approach yields a $(1/6.99)$ -competitive randomized algorithm for GAP. Again, our proposed algorithm outperforms the current best result of competitive ratio $1/8.06$ [Kesselheim et al. SIAM J. Comp. 47(5)].

1 Introduction

Many real-world problems can be considered resource allocation problems. For example, consider the loading of cargo planes with (potential) goods of different weights. Each item raises a certain profit for the airline if it is transported; however, not all goods can be loaded due to airplane weight restrictions. Clearly, the dispatcher seeks for a maximum profit packing fulfilling the capacity constraint. This example from [24] illustrates the *knapsack problem*: Given a set of n items, specified by a size and a profit value, and a resource (called knapsack) of fixed capacity, the goal is to find a subset of items (called packing) with maximum total

¹ A part of this work was done when the author was at Technical University of Munich.

profit and whose total size does not exceed the capacity. Besides being a fundamental and extensively studied problem in combinatorial optimization, knapsack problems arise in many and various practical settings. We refer the readers to textbooks [24, 35] and to the surveys of previous work in [14, 19] for further references.

In the *generalized assignment problem* (GAP) [35], resources of different capacities are given, and the size and the profit of an item depend on the resource to which it is assigned. The GAP includes many prominent problems, such as the (multiple) knapsack problem [13], weighted bipartite matching [28], AdWords [36], and the display ads problem [17]. Further applications of GAP are outlined in the survey articles [11, 41].

We study online variants of the knapsack and GAP problems. Here, n items are presented sequentially, and the decision for each item must be made immediately upon arrival. In fact, many real-world optimization problems occur as online problems, as often decisions must be made under uncertain conditions. For example, consider the introducing logistics example, if the airline needs to answer customer requests immediately without knowing future requests. The online knapsack problem has been studied in particular in the context of online auctions [9, 45].

Typically, the performance measure for online algorithms is the *competitive ratio*, which is defined as the ratio between the values of the algorithmic solution and an optimal offline solution for a worst-case input. It can be shown that, even for the knapsack problem, the general online setting admits no algorithms with bounded competitive ratio [34, 45]. However, most hardness results are based on a worst-case input presented in adversarial order. In the *random order model*, the performance of an algorithm is evaluated for a worst-case input, but the adversary has no control over the input order; the input sequence is drawn uniformly at random among all permutations. This model is known from the secretary problem [15, 31] and its generalizations [7, 12, 18]; it has been successfully applied to other online problems, for example, scheduling and packing [1, 16, 20, 25, 27, 39], graph problems [8, 26, 33], facility location [37], budgeted allocation [38], and submodular welfare maximization [30].

1.1 Related Work

Online knapsack problem. The problem was first studied by Marchetti-Spaccamela and Vercellis [34], who showed that no deterministic online algorithm for this problem can obtain a constant competitive ratio. Moreover, Chakrabarty et al. [45] demonstrated that this fact cannot be overcome by randomization.

Given such hardness results, several relaxations have been introduced and investigated. Most relevant to our work are results in the random order model. Introduced as the *secretary knapsack problem* [6], Babai et al. developed a randomized algorithm of competitive ratio $1/(10e) < 1/27$. Kesselheim et al. [27] achieved a significant improvement by developing a $(1/8.06)$ -competitive randomized algorithm for the generalized assignment problem. Finally, Vaze [43] showed that there exists a deterministic algorithm of competitive ratio $1/(2e) < 1/5.44$, assuming that the maximum profit of a single item is small compared to the profit of the optimal solution.

Apart from the random order model, different further relaxations have been considered. Marchetti-Spaccamela and Vercellis [34] studied a stochastic model wherein item sizes and profits are drawn from a fixed distribution. Lueker [32] obtained improved bounds in this model. Chakrabarty et al. [45] studied the problem when the density (profit-size ratio) of each item is in a fixed range $[L, U]$. Under the further assumption that item sizes are small compared to the knapsack capacity, Chakrabarty et al. proposed an algorithm of competitive ratio $\ln(U/L) + 1$ and provided a lower bound of $\ln(U/L)$. Another branch of

research considers removable models, where the algorithm can remove previously packed items. Removing such items can incur no cost [22, 23] or a cancellation cost (*buyback model*, [4, 5, 21]). Recently, Vaze [44] considered the problem under a (weaker) expected capacity constraint. This variant admits a competitive ratio of $1/4e$.

Online GAP. Since all hardness results for online knapsack also hold for online GAP, research focuses on stochastic variants or modified online settings. Currently, the only result for the random order model is the previously mentioned $(1/8.06)$ -competitive randomized algorithm proposed by Kesselheim et al. [27]. To the best of our knowledge, the earliest paper considering online GAP is due to Feldman et al. [17]. They obtained an algorithm of competitive ratio tending to $1 - 1/e$ in the *free disposal model*. In this model, the total size of items assigned to a resource might exceed its capacity; in addition, no item consumes more than a small fraction of any resource. A stochastic variant of online GAP was studied by Alaei et al. [2]. Here, the size of an item is drawn from an individual distribution that is revealed upon arrival of the item, together with its profit. However, the algorithm learns the actual item size only after the assignment. If no item consumes more than a $(1/k)$ -fraction of any resource, the algorithm proposed by Alaei et al. has competitive ratio $1 - 1/\sqrt{k}$.

Online packing LPs. In contrast to GAP, general packing LPs describe problems where requests can consume more than one resource. The study of online packing LPs was initiated by Buchbinder and Naor [10] in the adversarial model. In several papers [1, 16, 27, 39] it has been shown that the random order model admits $(1 - \varepsilon)$ -competitive algorithms assuming large capacity ratios, i.e., when the capacity of any resource is large compared to the maximum demand for it. Most recently, Kesselheim et al. [27] showed that there is a $(1 - \varepsilon)$ -competitive algorithm if $B = \Omega((\log d)/\varepsilon^2)$, where B is the capacity ratio and d is the column sparsity (the maximum number of resources occurring in a single column).

1.2 Our Contributions

As outlined above, for online knapsack and GAP in the adversarial input model, nearly all previous works attain constant competitive ratios at the cost of either (a) imposing structural constraints on the input or (b) significantly relaxing the original online model. Therefore, we study both problems in the random order model, which is less pessimistic than the adversarial model but still considers worst-case instances without further constraints on the item properties. For the knapsack problem, our main result is the following.

► **Theorem 1.1.** *There exists a $(1/6.65)$ -competitive randomized algorithm for the online knapsack problem in the random order model assuming $n \rightarrow \infty$.*

One challenge in the design of knapsack algorithms is that the optimal packing can have, on a high level, at least two different structures. Either there are few large items, constituting the majority of the packing's profit, or there are many small such items. Previous work [6, 27] is based on splitting the input according to item sizes and then employing algorithms tailored for these restricted instances. However, the algorithms from [6, 27] choose a single item type via an initial random choice, and then pack items of that type exclusively. In contrast, our approach considers different item types in distinct time intervals, rather than discarding items of a specific type in advance. More precisely, we develop algorithms \mathcal{A}_L and \mathcal{A}_S which are combined in a novel *sequential approach*: While large items appearing in early rounds are packed using \mathcal{A}_L , algorithm \mathcal{A}_S is applied to pack small items revealed in later rounds. We think that this approach may be helpful for other problems in similar online settings as well.

The proposed algorithm \mathcal{A}_L deals with the knapsack problem where all items consume more than $1/3$ of the capacity (we call this problem 2-KS). The 2-KS problem is closely related to the k -secretary problem [29] for $k = 2$. We also develop a general framework that allows to employ any algorithm for the 2-secretary problem to obtain an algorithm for 2-KS. As a side product, we obtain a simple $(1/3.08)$ -competitive deterministic algorithm for 2-KS in the random order model. For items whose size is at most $1/3$ of the resource capacity, we give a simple and efficient algorithm \mathcal{A}_S . Here, a challenging constraint is that \mathcal{A}_L and \mathcal{A}_S share the same resource, so we need to argue carefully that the decisions of \mathcal{A}_S are feasible, given the packing of \mathcal{A}_L from previous rounds.

Finally, we show that the proposed sequential approach also improves the current best result for GAP [27] from competitive ratio $1/8.06$ to $1/6.99$.

► **Theorem 1.2.** *There exists a $(1/6.99)$ -competitive randomized algorithm for the online generalized assignment problem in the random order model assuming $n \rightarrow \infty$.*

For this problem we use the algorithmic building blocks \mathcal{A}_L , \mathcal{A}_S developed in [26,27]. However, we need to verify that \mathcal{A}_L , an algorithm for edge-weighted bipartite matching [26], satisfies the desired properties for the sequential approach. We point out that the assignments of our algorithm differ structurally from the assignments of the algorithm proposed in [27]. In the assignments of the latter algorithm, all items are either large or small compared to the capacity of the assigned resource. In our approach, both situations can occur, because resources are managed independently.

Roadmap. We focus on the result on the knapsack problem (Theorem 1.1) in the first chapters of this paper. For this purpose, we provide elementary definitions in Section 2. Our main technical contribution is formally introduced in Section 3: Here, we describe an algorithmic framework performing two algorithms \mathcal{A}_L , \mathcal{A}_S sequentially. In Sections 4 and 5, we design and analyze the algorithms \mathcal{A}_L and \mathcal{A}_S for the knapsack problem. Finally, in Section 6 we describe how the sequential approach can be applied to GAP. Due to space constraints, some proofs are deferred to Appendix A (knapsack) and to Appendix B (GAP).

2 Preliminaries

Let $[n] := \{1, \dots, n\}$. Further, let $\mathbb{Q}_{\geq 0}$ and $\mathbb{Q}_{> 0}$ denote the set of non-negative and positive rational numbers, respectively.

Knapsack problem. We are given a set of items $I = [n]$, each item $i \in I$ has size $s_i \in \mathbb{Q}_{> 0}$ and a profit (value) $v_i \in \mathbb{Q}_{\geq 0}$. The goal is to find a maximum profit packing into a knapsack of size $W \in \mathbb{Q}_{> 0}$, i.e., a subset $M \subseteq I$ such that $\sum_{i \in M} s_i \leq W$ and $\sum_{i \in M} v_i$ is maximized. W.l.o.g. we can assume $s_i \leq W$ for all $i \in I$. In the online variant of the problem, in each round $\ell \in [n]$ a single item i is revealed together with its size and profit. The online algorithm must decide immediately and irrevocably whether to pack i . We call an item *visible in round* ℓ if it arrived in round ℓ or earlier.

Random order performance. We analyze the performance of algorithms in the *random order model*. Given a worst case input \mathcal{I} , the order in which \mathcal{I} is presented is drawn uniformly at random from the set of all permutations. For an algorithm \mathcal{A} , its *competitive ratio* is defined as $\mathbf{E}[\mathcal{A}(\mathcal{I})] / \text{OPT}(\mathcal{I})$, where $\mathcal{A}(\mathcal{I})$ and $\text{OPT}(\mathcal{I})$ denote the profits of the solutions of \mathcal{A} and an optimal offline algorithm, respectively. Here, the expectation is taken over

■ **Algorithm 1** Sequential approach.

Input : Random permutation π of n items in I , a knapsack of capacity W ,
parameters $c, d \in (0, 1)$ with $c < d$, algorithms $\mathcal{A}_L, \mathcal{A}_S$.

Output : A feasible (integral) knapsack packing.

Let ℓ be the current round.

if $\ell \leq cn$ **then**
| Sampling phase – discard all items;

if $cn + 1 \leq \ell \leq dn$ **then**
| Pack $\pi(\ell)$ iff \mathcal{A}_L packs $\pi_L(\ell)$;

if $dn + 1 \leq \ell \leq n$ **then**
| Pack $\pi(\ell)$ iff \mathcal{A}_S packs $\pi_S(\ell)$ and the remaining capacity is sufficiently large.

all permutations and random choices of the algorithm. As above, we slightly overload the notation and also use \mathcal{A} as a random variable for the profit of the solution returned by an algorithm \mathcal{A} .

We classify items as large or small, depending on their size compared to W and a parameter $\delta \in (0, 1)$ to be determined later.

► **Definition 2.1.** We say an item i is δ -large if $s_i > \delta W$ and δ -small if $s_i \leq \delta W$. Whenever δ is clear from the context, we say an item is large or small for short. Based on the given item set I , we define two modified item sets I_L and I_S , which are obtained as follows:

- I_L : Replace each small item by a large item of profit 0
- I_S : Replace each large item by a small item of profit 0.

Therefore, I_L only contains large items and I_S only contains small items. We can assume that no algorithm packs a zero-profit item, thus any algorithmic packing of I_L or I_S can be turned into a packing of I having the same profit. Let OPT , OPT_L , and OPT_S be the total profits of optimal packings for I , I_L , and I_S , respectively. A useful upper bound for OPT is

$$\text{OPT} \leq \text{OPT}_L + \text{OPT}_S. \quad (1)$$

3 Sequential Approach

A common approach in the design of algorithms for secretary problems is to set two phases: a *sampling phase*, where all items are rejected, followed by a *decision phase*, where some items are accepted according to a decision rule. Typically, this rule is based on the information gathered in the sampling phase. We take this concept a step further: The key idea of our sequential approach is to use a part of the sampling phase of one algorithm as decision phase of another algorithm, which itself can have a sampling phase. This way, two algorithms are performed in a sequential way, which makes better use of the entire instance. We combine this idea with using different strategies for small and large items.

Formally, let \mathcal{A}_L and \mathcal{A}_S be two online knapsack algorithms and I_L and I_S be the item sets constructed according to Definition 2.1. Further, let $0 < c < d < 1$ be two parameters to be specified later. Our proposed algorithm samples the first cn rounds; during this time no item is packed. From round $cn + 1$ to dn , the algorithm considers large items exclusively. In this interval we follow the decisions of \mathcal{A}_L . After round dn , the algorithm processes only small items and follows the decisions of \mathcal{A}_S . However, it might be the case that an item accepted by \mathcal{A}_S cannot be packed because the knapsack capacity is exhausted due to the packing of \mathcal{A}_L in earlier rounds. Note that all rounds $1, \dots, dn$ can be considered as the

■ **Algorithm 2** Algorithm \mathcal{A}_L for large items.

Input : Random permutation of n ($1/3$)-large items, a knapsack of capacity W , parameters $c, d \in (0, 1)$ with $c < d$.

Output : A feasible (integral) packing of the knapsack.

Let ℓ be the current round.

if $\ell \leq cn$ **then**
 | Sampling phase – discard all items.

Let v^* be the maximum profit seen up to round cn .

if $cn + 1 \leq \ell \leq dn$ **then**
 | Pack the first two items of profit higher than v^* , if feasible.

if $\ell > dn$ **then**
 | Discard all items.

sampling phase for \mathcal{A}_S . A formal description is given in Algorithm 1. Here, for a given input sequence π of I , let π_L and π_S denote the corresponding sequences from I_L and I_S , respectively. Note that π is revealed sequentially and π_L, π_S can be constructed online. For any input sequence π , let $\pi(\ell)$ denote the item at position $\ell \in [n]$.

In the final algorithm we set the threshold for small items to $\delta = 1/3$ and use Algorithm 1 with parameters $c = 0.42291$ and $d = 0.64570$. Under the assumption $n \rightarrow \infty$ we can assume $cn, dn \in \mathbb{N}$. We next give a high-level description of the proof of Theorem 1.1.

Proof of Theorem 1.1. Let \mathcal{A} be Algorithm 1 and $\mathcal{A}_L, \mathcal{A}_S$ be the algorithms developed in Sections 4 and 5. In the next sections we prove the following results (see Lemmas 4.7 and 5.5): The expected profit from \mathcal{A}_L in rounds $cn + 1, \dots, dn$ is at least $\frac{1}{6.65} \text{OPT}_L$, and the expected profit from \mathcal{A}_S in rounds $dn + 1, \dots, n$ is at least $\frac{1}{6.65} \text{OPT}_S$. Together with inequality (1), we obtain

$$\mathbf{E}[\mathcal{A}] \geq \mathbf{E}[\mathcal{A}_L] + \mathbf{E}[\mathcal{A}_S] \geq \frac{1}{6.65} \text{OPT}_L + \frac{1}{6.65} \text{OPT}_S \geq \frac{1}{6.65} \text{OPT} . \quad \blacktriangleleft$$

The order in which \mathcal{A}_L and \mathcal{A}_S are arranged in Algorithm 1 follows from two observations. Algorithm \mathcal{A}_S is powerful if it samples roughly $(2/3)n$ rounds; a part of this long sampling phase can be used as the decision phase of \mathcal{A}_L , for which a shorter sampling phase is sufficient. Moreover, the first algorithm should either pack high-profit items, or should leave the knapsack empty for the following algorithm with high probability. The algorithm \mathcal{A}_L we propose in Section 4 has this property (see Lemma 4.8). In contrast, if \mathcal{A}_S would precede \mathcal{A}_L , the knapsack would be empty at the beginning of \mathcal{A}_L with very small probability, in which case we would not benefit from \mathcal{A}_L .

Finally, note that better algorithms and parameterizations for the respective sub-problems exist (see Lemma 4.6 and [27]). However, for the overall performance we need algorithms \mathcal{A}_L and \mathcal{A}_S that perform well evaluated in the sequential framework.

4 Large Items

The approach presented in this section is based on the connection between the online knapsack problem under random arrival order and the k -secretary problem [29]. In the latter problem, the algorithm can accept up to k items and the goal is to maximize the sum of their profits. The k -secretary problem generalizes the classical secretary problem [15, 31] and is itself a special case of the online knapsack problem under random arrival order (if all knapsack items have size W/k).

■ **Table 1** Definition of packing types A-M. We use set notation $\{i, j\}$ if i and j can be packed in any order, and tuple notation (i, j) if the packing order must be as given.

type	content	constraint on j	probability p_X
A	$\{1, 2\}$	-	$p_{12} + p_{21}$
B	$\{1, 3\}$	-	$p_{13} + p_{31}$
C	$\{2, 3\}$	-	$p_{23} + p_{32}$
D	$(1, j)$	-	p_1
E	$(2, j)$	-	p_2
F	$(3, j)$	-	p_3
G	$(4, j)$	-	p_4
H	$(1, j)$	$j \neq 2$	$p_1 - p_{12}$
I	$(1, j)$	$j \neq 3$	$p_1 - p_{13}$
J	$(2, j)$	$j \neq 1$	$p_2 - p_{21}$
K	$(2, j)$	$j \neq 3$	$p_2 - p_{23}$
L	$(3, j)$	$j \neq 1$	$p_3 - p_{31}$
M	$(3, j)$	$j \neq 2$	$p_3 - p_{32}$

In our setting, each large item consumes more than $\delta = 1/3$ of the knapsack capacity. We call this problem 2-KS, since at most two items can be packed completely. Therefore, any 2-secretary algorithm can be employed to identify high-profit items and pack them if feasible. Although this idea applies to any δ and corresponding k , the approach seems stronger for small k : Intuitively, the characteristics of k -KS and k -secretary deviate with growing k , while 1-KS is exactly 1-secretary. Furthermore, the k -secretary problem is for $k = 2$ rather well studied [3, 12], while the exact optimal competitive ratios for $k \geq 3$ are still unknown.

In the following, let \mathcal{A}_L be Algorithm 2. This is an adaptation of the algorithm SINGLE-REF developed for the k -secretary problem in [3]. As discussed above, 2-secretary and 2-KS are similar, but different problems. Therefore, in our setting it is not possible to apply the existing analysis from [3] or from any other k -secretary algorithm directly.

Assumption. For this section we assume that all profits are distinct. This is without loss of generality, as ties can be broken by adjusting the profits slightly, using the items' identifiers. Further, we assume $v_1 > v_2 > \dots > v_n$ and say that i is the *rank* of item i .

4.1 Packing Types

As outlined above, in contrast to the 2-secretary problem, not all combinations of two knapsack items can be packed completely. Therefore, we analyze the probability that \mathcal{A}_L selects a feasible set of items whose profit can be bounded from below. We restrict our analysis to packings where an item $i \in \{1, 2, 3, 4\}$ is packed as the first item and group such packings into several packing types A-M defined in the following. Although covering more packings might lead to further insights into the problem and to a stronger result, we expect the improvement to be marginal.

Let p_X be the probability that \mathcal{A}_L returns a packing of type $X \in \{A, \dots, M\}$. In addition, let p_i for $i \in [n]$ be the probability that \mathcal{A}_L packs i as the first item. Finally, let p_{ij} for $i, j \in [n]$ be the probability that \mathcal{A}_L packs i as the first item and j as the second item.

In a packing of type A, the items 1 and 2 are packed in any order. Therefore, $p_A = p_{12} + p_{21}$. The types B and C are defined analogously using the items $\{1, 3\}$ and $\{2, 3\}$, respectively. In a packing of type D, the item 1 is accepted as the first item, together with no or any second

■ **Figure 1** Input sequence considered in Lemma 4.2. The gray dashed slots represent items of rank greater than a .

item j . This happens with probability $p_D = p_1$. Accordingly, we define types E, F, and G using the items 2, 3, and 4, respectively. Finally, for each item $i \in \{1, 2, 3\}$, we introduce two further packing types. For $i = 1$, types H and I characterize packings where the first accepted item is 1, the second accepted item j is not 2 (type H) and not 3 (type I), respectively. Therefore, we get $p_H = p_1 - p_{12}$ and $p_I = p_1 - p_{13}$. Packing types J-K and L-M describe analogous packings for $i = 2$ and $i = 3$, respectively. Table 1 shows all packing types A-M and their probabilities expressed by p_i and p_{ij} .

The packing types defined above allow to describe all packings where a specific item $i \in \{1, 2, 3, 4\}$ is packed as the first item, without covering the same packing multiple times. For example, packing types A and D (with $j = 2$) both include the packing $(1, 2)$; however, we can consider the disjoint packing types A and H.

4.2 Acceptance Probabilities of Algorithm 2

In the following we compute the probabilities p_i and p_{ij} from Table 1 as functions of c and d . Throughout the following proofs, we denote the position of an item i in a given permutation with $\text{pos}(i) \in [n]$. Further, let a be the maximum profit item from sampling.

We think of the random permutation as being sequentially constructed. The fact given below follows from the hypergeometric distribution and becomes helpful in the proofs of Lemmas 4.2 and 4.3.

► **Fact 4.1.** *Suppose there are N balls in an urn from which M are blue and $N - M$ red. The probability of drawing K blue balls without replacement in a sequence of length K is $h(N, M, K) := \binom{M}{K} / \binom{N}{K}$.*

In the first lemma, we provide the probabilities p_i for $i \in [4]$ assuming $n \rightarrow \infty$.

► **Lemma 4.2.** *Assuming $n \rightarrow \infty$, it holds that*

$$p_i = \begin{cases} c \ln \frac{d}{c} & i = 1 \\ c \left(\ln \frac{d}{c} - d + c \right) & i = 2 \\ c \left(\ln \frac{d}{c} - 2(d - c) + \frac{1}{2}(d^2 - c^2) \right) & i = 3 \\ c \left(\ln \frac{d}{c} - 3(d - c) + \frac{3}{2}(d^2 - c^2) - \frac{1}{3}(d^3 - c^3) \right) & i = 4. \end{cases}$$

Proof. We construct the random permutation by drawing the positions for items sequentially, starting with the items i and a . For any position $k \geq cn + 1$, the permutation fulfills $\text{pos}(i) = k$ and $\text{pos}(a) \leq cn$ with probability $\frac{1}{n} \frac{cn}{n-1} = \frac{c}{n-1}$. Next, we draw the remaining $k - 2$ items for the slots up to position k . Since i is packed as the first item, all previous items (except for a) must have rank greater than a (see Figure 1). As these items are drawn from the remaining $n - 2$ items (of which $n - a$ have rank greater than a), the probability for this step is $h(n - 2, n - a, k - 2)$ according to Fact 4.1. Using the law of total probability for $k \in \{cn + 1, \dots, dn\}$ and $a \in \{i + 1, \dots, n\}$ we obtain

$$p_i = \frac{c}{n-1} \sum_{k=cn+1}^{dn} \sum_{a=i+1}^n h(n-2, n-a, k-2) = \frac{c}{n-1} \sum_{k=cn+1}^{dn} \frac{1}{\binom{n-2}{k-2}} \sum_{a=i+1}^n \binom{n-a}{k-2}.$$

We can simplify this term further by observing

$$\sum_{a=i+1}^n \binom{n-a}{k-2} = \sum_{a=0}^{n-i-1} \binom{a}{k-2} = \binom{n-i}{k-1}.$$

Therefore, $p_i = \frac{c}{n-1} \sum_{k=cn+1}^{dn} \binom{n-i}{k-1} / \binom{n-2}{k-2}$.

Asymptotics. It holds that

$$\lim_{n \rightarrow \infty} \frac{\binom{n-i}{k-1}}{\binom{n-2}{k-2}} = \lim_{n \rightarrow \infty} \frac{(n-i)!}{(n-2)!} \frac{(n-k)!}{(n-i-k+1)!} \frac{1}{k-1} = \frac{(n-k)^{i-1}}{n^{i-2}} \frac{1}{k}.$$

Hence, $\lim_{n \rightarrow \infty} p_i = (c/n^{i-1}) \sum_{k=cn+1}^{dn} f(k)$ where $f(k) := (n-k)^{i-1}/k$. Since f is monotonically decreasing in k , we have $\int_{cn+1}^{dn+1} f(k) dk \leq \sum_{k=cn+1}^{dn} f(k) \leq \int_{cn}^{dn} f(k) dk$. Let F be a function such that $\int_a^b f(k) dk = F(b) - F(a)$ for $0 < a < b$. As it holds that $\lim_{n \rightarrow \infty} F(dn+1) - F(dn) = \lim_{n \rightarrow \infty} F(cn+1) - F(cn) = 0$, the above bounds are asymptotically tight, i.e., $\lim_{n \rightarrow \infty} \sum_{k=cn+1}^{dn} f(k) = F(dn) - F(cn)$. Below we give functions F for $i \in [4]$.

i	$f(k)$	$F(k)$	$F(dn) - F(cn)$
1	$\frac{1}{k}$	$\ln k$	$\ln \frac{d}{c}$
2	$\frac{n-k}{k}$	$n \ln k - k$	$n \ln \frac{d}{c} - dn + cn$
3	$\frac{(n-k)^2}{k}$	$n^2 \ln k - 2nk + \frac{k^2}{2}$	$n^2 \ln \frac{d}{c} - 2n(dn - cn) + \frac{d^2 n^2 - c^2 n^2}{2}$
4	$\frac{(n-k)^3}{k}$	$n^3 \ln k - 3n^2 k + \frac{3}{2} n k^2 - \frac{k^3}{3}$	$n^3 \ln \frac{d}{c} - 3n^3(d - c) + \frac{3}{2} n^3(d^2 - c^2) - \frac{1}{3} n^3(d^3 - c^3)$

The claims follow by multiplying the respective terms with c/n^{i-1} . ◀

Next, we analyze the probabilities p_{ij} for $i \neq j$ and $i, j \in [3]$. The next lemma deals with the cases where $j = i + 1$.

► **Lemma 4.3.** *For $n \rightarrow \infty$ it holds that*

$$p_{12} = c \left(d - c \ln \frac{d}{c} - c \right),$$

$$p_{23} = c \left(d - c \ln \frac{d}{c} - c - \frac{d^2}{2} + cd - \frac{c^2}{2} \right).$$

The proof of Lemma 4.3 is technically similar to the proof of Lemma 4.2 and thus deferred to Appendix A. It remains to analyze the probabilities p_{13} , p_{31} , p_{21} , and p_{32} . Interestingly, they all reduce to the two probabilities considered in Lemma 4.3. The following two lemmas should be intuitively clear from the description of Algorithm 2. For completeness, we give formal proofs in Appendix A.

► **Lemma 4.4.** *For any two items i and j it holds that $p_{ij} = p_{ji}$.*

► **Lemma 4.5.** *For any three items $i < k < j$ it holds that $p_{ij} = p_{kj}$.*

Therefore, we have $p_{13} = p_{23}$ by Lemma 4.5 and $p_{31} = p_{13}$, $p_{21} = p_{12}$, and $p_{32} = p_{23}$ by Lemma 4.4.

4.3 Analysis

Let T be the set of items in the optimal packing of I_L . This set may contain a single item, may be a two-item subset of $\{1, 2, 3\}$, or may be a two-item subset containing an item $j \geq 4$. In the following we analyze the performance of Algorithm 2 for each case.

Single-item case. Let case 1 be the case where $T = \{1\}$. In case 1, $\mathbf{E}[\mathcal{A}_L] \geq p_D \text{OPT}_L$.

Two-item cases. In cases 2–4, we consider packings of the form $T = \{i, j\}$ with $1 \leq i < j \leq 3$. We define cases 2, 3, and 4 as $T = \{1, 2\}$, $T = \{1, 3\}$, and $T = \{2, 3\}$, respectively. We want to consider all algorithmic packings whose profit can be bounded in terms of $\text{OPT}_L = v_i + v_j$. For this purpose, for each case 2–4 we build three groups of feasible packing types, according to whether the profit of a packing is OPT_L , at least v_i , or in the interval $(v_i, v_j]$. We ensure that no packing is counted multiple times by (a) choosing appropriate packing types and (b) grouping these packing types in a disjoint way, according to their profit. Let α_w be the probability that the algorithm returns the optimal packing in case $w \in \{2, 3, 4\}$. It holds that $\alpha_2 = p_A$, $\alpha_3 = p_B$, and $\alpha_4 = p_C$. In addition, let β_w be the probability that an item $k \leq i$ is packed as the first item in case $w \in \{2, 3, 4\}$. We have $\beta_2 = p_H$, $\beta_3 = p_I$, and $\beta_4 = p_D + p_K$. Finally, let γ_w be the probability that an item k with $i < k \leq j$ is packed as the first item in case $w \in \{2, 3, 4\}$. It holds that $\gamma_2 = p_J$, $\gamma_3 = p_E + p_L$, and $\gamma_4 = p_M$.

Finally, we define case 5 as $T = \{i, j\}$ with $i \geq 1$, $j \geq 4$, and $i < j$. In this case, note that packings of type D contain an item of value at least v_i , and packings of type E, F, and G contain an item of value at least v_j . Hence, we can slightly abuse the notation and set $\alpha_5 = 0$, $\beta_5 = p_D$, and $\gamma_5 = p_E + p_F + p_G$, such that it holds that

$$\mathbf{E}[\mathcal{A}_L] \geq \alpha_w(v_i + v_j) + \beta_w v_i + \gamma_w v_j \quad \text{in case } w \in \{2, 3, 4, 5\}.$$

To bound this term against $\text{OPT}_L = v_i + v_j$, consider the following two cases: If $\beta_w \geq \gamma_w$, we obtain from Chebyshev's sum inequality $\beta_w v_i + \gamma_w v_j \geq \frac{1}{2}(\beta_w + \gamma_w)(v_i + v_j)$. If $\beta_w < \gamma_w$, we trivially have $\beta_w v_i + \gamma_w v_j > \beta_w(v_i + v_j)$. Thus, we obtain

$$\mathbf{E}[\mathcal{A}_L] \geq \left(\alpha_w + \min \left\{ \frac{\beta_w + \gamma_w}{2}, \beta_w \right\} \right) \text{OPT}_L \quad \text{in case } w \in \{2, 3, 4, 5\}. \quad (2)$$

The competitive ratio of \mathcal{A}_L is the minimum over all cases 1–5. We obtain the following two lemmas. If the algorithm is allowed to use the entire input sequence ($d = 1$), \mathcal{A}_L has a competitive ratio of $1/3.08$.

► **Lemma 4.6.** *With $c = 0.23053$ and $d = 1$, algorithm \mathcal{A}_L satisfies $\mathbf{E}[\mathcal{A}_L] \geq \frac{1}{3.08} \text{OPT}_L$.*

Note that 2-KS includes the secretary problem (case 1); thus, no algorithm for 2-KS can have a better competitive ratio than $1/e < 1/2.71$. In the final algorithm we set $d < 1$ to benefit from \mathcal{A}_S . The next lemma has already been used to prove Theorem 1.1 in Section 3.

► **Lemma 4.7.** *With $c = 0.42291$ and $d = 0.64570$, algorithm \mathcal{A}_L satisfies $\mathbf{E}[\mathcal{A}_L] \geq \frac{1}{6.65} \text{OPT}_L$.*

Proof of Lemmas 4.6 and 4.7. For the overall competitive ratio, we build the minimum over all cases. According to inequality (2), the competitive ratios for the two-item cases depend on $\beta_w \geq \gamma_w$ or $\beta_w < \gamma_w$. However, for the parameter pairs $(c, d) = (0.23053, 1)$ from

■ **Table 2** Competitive ratios of Algorithm 2 for the parameters from Lemmas 4.6 and 4.7 in different cases. Bold values indicate the minimum over all cases and thus the competitive ratio.

	c	d	two-item cases				
			case 1	case 2	case 3	case 4	case 5
Lemma 4.6	0.23053	1	0.33827	0.34898	0.32705	0.32705	0.32471
Lemma 4.7	0.42291	0.64570	0.17897	0.15039	0.16033	0.16033	0.16231

Lemma 4.6 and $(c, d) = (0.42291, 0.64570)$ from Lemma 4.7 we have $\beta_w \geq \gamma_w$ for any case $w \in \{2, 3, 4, 5\}$. This follows from a technical lemma provided in Appendix A (Lemma A.1). Hence, inequality (2) simplifies to $\mathbf{E}[\mathcal{A}_L] \geq \left(\alpha_w + \frac{\beta_w + \gamma_w}{2}\right) \text{OPT}_L$ in case $w \in \{2, 3, 4, 5\}$. Using the definitions of p_X from Table 1 and the symmetry property of Lemma 4.4 we get

$$\mathbf{E}[\mathcal{A}_L] / \text{OPT}_L \geq \begin{cases} p_1 & \text{case 1} \\ p_{12} + (p_1 + p_2)/2 & \text{case 2} \\ p_{13} + (p_1 + p_2 + p_3)/2 & \text{case 3} \\ p_{23} + (p_1 + p_2 + p_3)/2 & \text{case 4} \\ (p_1 + p_2 + p_3 + p_4)/2 & \text{case 5} . \end{cases} \quad (3)$$

Note that the algorithm attains the same competitive ratio in case 3 and 4, since $p_{13} = p_{23}$. Table 2 shows the competitive ratios for all five cases obtained from Equation (3). For the overall competitive ratio, we have

$$\mathbf{E}[\mathcal{A}_L] \geq \min \left\{ p_1, p_{12} + \frac{p_1 + p_2}{2}, p_{23} + \frac{p_1 + p_2 + p_3}{2}, \frac{p_1 + p_2 + p_3 + p_4}{2} \right\} \text{OPT}_L .$$

Hence, the competitive ratios are $0.32471 \geq 1/3.08$ and $0.15039 \geq 1/6.65$ for Lemma 4.6 and Lemma 4.7, respectively. ◀

Recall that in Algorithm 1, we can only benefit from \mathcal{A}_S if \mathcal{A}_L has not filled the knapsack completely. Thus, the following property is crucial in the final analysis.

▶ **Lemma 4.8.** *With probability of at least c/d , no item is packed by \mathcal{A}_L .*

Proof. Fix any set of dn items arriving in rounds $1, \dots, dn$. The most profitable item v^* from this set arrives in the sampling phase with probability c/d . If this event occurs, no item in rounds $cn + 1, \dots, dn$ beats v^* and \mathcal{A}_L will not select any item. ◀

We finally note that our approach from Section 4.1 provides a general framework to obtain algorithms for 2-KS using secretary algorithms with two choices. Although stronger algorithms than Algorithm 2 exist for the 2-secretary objective [3, 12] and similar objectives [40, 42], it is not clear if they would improve the performance of the overall algorithm. More sophisticated algorithms may use weaker thresholds to accept the first item, which decreases the probability considered in Lemma 4.8. This, in turn, reduces the expected profit gained from \mathcal{A}_S , as described above.

5 Small Items

For small items, we use solutions for the fractional problem variant and obtain an integral packing via randomized rounding. This approach has been applied successfully to packing LPs [27]; however, for the knapsack problem it is not required to solve LP relaxations in each

round (as in [27]). Instead, here, we build upon solutions of the classical greedy algorithm, which is well-known to be optimal for the fractional knapsack problem. Particularly, this algorithm is both efficient in running time and easy to analyze.

We next formalize the greedy solution for any set T of items. Let the *density* of an item be the ratio of its profit to its size. Consider any list L containing the items from T ordered by non-increasing density. We define the *rank* $\rho(i)$ of item i as its position in L and $\sigma(l)$ as the item at position l in L . Thus, $\sigma(l) = \rho^{-1}(l)$ denotes the l -th densest item. Let k be such that $\sum_{i=1}^{k-1} s_{\sigma(i)} < W \leq \sum_{i=1}^k s_{\sigma(i)}$. The fraction of item i in the greedy solution α is now defined as

$$\alpha_i = \begin{cases} 1 & \text{if } \rho(i) < k \\ \left(W - \sum_{i=1}^{k-1} s_{\sigma(i)}\right) / s_i & \text{if } \rho(i) = k \\ 0 & \text{else,} \end{cases}$$

i.e., we pack the $k - 1$ densest items integrally and fill the remaining space by the maximum feasible fraction of the k -th densest item. Let $\text{OPT}(T)$ and $\text{OPT}^*(T)$ denote the profits of optimal integral and fractional packings of T , respectively. It is not hard to see that α satisfies $\sum_{i \in T} \alpha_i v_i = \text{OPT}^*(T) \geq \text{OPT}(T)$ and $\sum_{i \in T} \alpha_i s_i = W$.

5.1 Algorithm

The algorithm \mathcal{A}_S for small items, which is formally defined in Algorithm 3, works as follows. After a sampling phase of dn rounds, in each round $\ell \geq dn + 1$ the algorithm computes a greedy solution $x^{(\ell)}$ for $I_S(\ell)$. Here, $I_S(\ell)$ denotes the subset of I_S revealed up to round ℓ . The algorithm packs the current online item i with probability $x_i^{(\ell)}$. However, generally, this can only be done if the remaining capacity of the knapsack is at least $\delta W \geq s_i$.

Note that in case of an integral coefficient $x_i^{(\ell)} \in \{0, 1\}$, the packing step is completely deterministic. Moreover, in any greedy solution $x^{(\ell)}$, there is at most one item i with fractional coefficient $x_i^{(\ell)} \in (0, 1)$. Therefore, in expectation, there is only a small number of rounds where the algorithm actually requests randomness.

► **Observation 5.1.** *Let X denote the number of rounds where Algorithm 3 packs an item with probability $x_i \in (0, 1)$. It holds that $\mathbf{E}[X] \leq \ln(1/d) \leq 0.44$.*

Proof. Consider any round ℓ and let $x^{(\ell)}$ be the greedy knapsack solution computed by Algorithm 3. By definition of $x^{(\ell)}$, at most one of the ℓ visible items has a fractional coefficient $x_i^{(\ell)} \in (0, 1)$. The probability that this item i arrives in round ℓ is $1/\ell$ in a random permutation. Let X_ℓ be an indicator variable for the event that Algorithm 3 packs an item at random in round ℓ . By the above argument, we have $\mathbf{Pr}[X_\ell = 1] \leq 1/\ell$. Since Algorithm 3 selects items starting in round $dn + 1$, we obtain $\mathbf{E}[X] = \sum_{\ell=dn+1}^n \mathbf{E}[X_\ell] \leq \sum_{\ell=dn+1}^n \frac{1}{\ell} \leq \ln \frac{1}{d} \leq 0.44$. ◀

Note that Algorithm 2 and the sequential approach (Algorithm 1) are deterministic algorithms. Therefore, our overall algorithm requests randomness in expectation in less than one round.

5.2 Analysis

Let α be the greedy (offline) solution for I_S and set $\Delta = \frac{1}{1-\delta}$. Recall that in round $dn + 1$, the knapsack might already have been filled by \mathcal{A}_L with large items in previous rounds. For now, we assume an empty knapsack after round dn and define this event as ξ . In the final analysis, we will use the fact that $\mathbf{Pr}[\xi]$ can be bounded from below, which is according to Lemma 4.8.

■ **Algorithm 3** Algorithm \mathcal{A}_S for small items.

Input : Random permutation of n $(1/3)$ -small items, a knapsack of capacity W , parameter $d \in (0, 1)$.

Output: A feasible (integral) packing of the knapsack.

Let ℓ be the current round and i be the online item of round ℓ .

if $\ell \leq dn$ **then**

 | Sampling phase – discard all items.

if $dn + 1 \leq \ell \leq n$ **then**

 | Let $x^{(\ell)}$ be the greedy solution for $I_S(\ell)$.

if the remaining capacity is at least δW **then**

 | Pack i with probability $x_i^{(\ell)}$.

► **Lemma 5.2.** Let $i \in I_S$ and $E_i(\ell)$ be the event that the item i is packed by \mathcal{A}_S in round ℓ . For $\ell \geq dn + 1$, it holds that $\Pr[E_i(\ell) \mid \xi] \geq \frac{1}{n}\alpha_i(1 - \Delta \ln \frac{\ell}{dn})$.

Proof. In a random permutation, item i arrives in round ℓ with probability $1/n$. In round $\ell \geq dn + 1$, the algorithm decides to pack i with probability $x_i^{(\ell)}$. Note that the rank of item i in $I_S(\ell)$ is less or equal to its rank in I_S . According to the greedy solution's definition, this implies $x_i^{(\ell)} \geq \alpha_i$. Finally, the δ -small item i can be packed successfully if the current resource consumption X is at most $(1 - \delta)W$. In the following, we investigate the expectation of X to give a probability bound using Markov's inequality at the end of this proof.

Let X_k be the resource consumption in round $k < \ell$. By assumption, the knapsack is empty after round dn , we have $X = \sum_{k=dn+1}^{\ell-1} X_k$. Let Q be the set of k visible items in round k . The set Q can be seen as uniformly drawn from all k -item subsets and any item $j \in Q$ is the current online item of round k with probability $1/k$. The algorithm packs any item j with probability $x_j^{(k)}$, thus

$$\mathbf{E}[X_k] = \sum_{j \in Q} \Pr[j \text{ occurs in round } k] s_j x_j^{(k)} = \frac{1}{k} \sum_{j \in Q} s_j x_j^{(k)} \leq \frac{W}{k},$$

where the last inequality holds because $x^{(k)}$ is a feasible solution for a knapsack of size W . By the linearity of expectation and the previous equation, the expected resource consumption up to round ℓ is $\mathbf{E}[X] = \sum_{k=dn+1}^{\ell-1} \mathbf{E}[X_k] \leq \sum_{k=dn+1}^{\ell-1} \frac{W}{k} \leq W \ln \frac{\ell}{dn}$. Using Markov's inequality, we obtain finally

$$\Pr[X < (1 - \delta)W] = 1 - \Pr[X \geq (1 - \delta)W] \geq 1 - \frac{\mathbf{E}[X]}{(1 - \delta)W} \geq 1 - \Delta \ln \frac{\ell}{dn}. \quad \blacktriangleleft$$

Using Lemma 5.2 we easily obtain the total probability that a specific item will be packed.

► **Lemma 5.3.** Let $i \in I_S$ and E_i be the event that the item i is packed by \mathcal{A}_S . It holds that $\Pr[E_i \mid \xi] \geq \alpha_i \left((1 - d)(1 + \Delta) - \Delta \ln \frac{1}{d} \right)$.

Proof. Summing the probabilities from Lemma 5.2 over all rounds $\ell \geq dn + 1$ gives

$$\begin{aligned} \Pr[E_i \mid \xi] &= \sum_{\ell=dn+1}^n \Pr[E_i(\ell) \mid \xi] \geq \sum_{\ell=dn+1}^n \frac{1}{n} \alpha_i \left(1 - \Delta \ln \frac{\ell}{dn} \right) \\ &= \frac{1}{n} \alpha_i \left(n - dn - \Delta \sum_{\ell=dn+1}^n \ln \frac{\ell}{dn} \right) = \alpha_i \left(1 - d - \frac{\Delta}{n} \sum_{\ell=dn+1}^n \ln \frac{\ell}{dn} \right). \end{aligned}$$

22:14 Online Knapsack and GAP in the Random Order Model

Since $\ln \frac{\ell}{dn}$ is monotonically increasing in ℓ , we can bound the last sum by the corresponding integral:

$$\sum_{\ell=dn+1}^n \ln \frac{\ell}{dn} \leq \int_{\ell=dn+1}^{n+1} \ln \frac{\ell}{dn} d\ell = (n+1) \ln \frac{n+1}{dn} - (n+1) - (dn+1) \ln \frac{dn+1}{dn} + (dn+1).$$

This implies $\lim_{n \rightarrow \infty} \frac{\Delta}{n} \sum_{\ell=dn+1}^n \ln \frac{\ell}{dn} \leq \Delta (\ln \frac{1}{d} - 1 + d)$. Rearranging terms gives the claim. \blacktriangleleft

The following lemma bounds the expected profit of the packing of \mathcal{A}_S , assuming ξ .

► **Lemma 5.4.** *It holds that $\mathbf{E}[\mathcal{A}_S \mid \xi] \geq ((1-d)(1+\Delta) - \Delta \ln \frac{1}{d}) \text{OPT}_S$.*

Proof. Let $\beta = (1-d)(1+\Delta) - \Delta \ln \frac{1}{d}$. By Lemma 5.3, the probability that an item i gets packed is $\Pr[E_i \mid \xi] \geq \alpha_i \beta$. Therefore,

$$\mathbf{E}[\mathcal{A}_S \mid \xi] = \sum_{i \in I_S} \Pr[E_i \mid \xi] v_i \geq \sum_{i \in I_S} \alpha_i \beta v_i \geq \beta \text{OPT}_S. \quad \blacktriangleleft$$

The conditioning on ξ can be resolved using Lemma 4.8. Thus we obtain the following lemma, which is the second pillar in the proof of Theorem 1.1 and concludes this section.

► **Lemma 5.5.** *With $c = 0.42291$ and $d = 0.64570$, we have $\mathbf{E}[\mathcal{A}_S] \geq \frac{1}{6.65} \text{OPT}_S$.*

Proof. By Lemma 4.8, the probability for an empty knapsack after round dn is $\Pr[\xi] \geq \frac{c}{d}$. Thus, from Lemma 5.4 with $\Delta = \frac{1}{1-1/3} = \frac{3}{2}$, we obtain

$$\mathbf{E}[\mathcal{A}_S] = \Pr[\xi] \mathbf{E}[\mathcal{A}_S \mid \xi] = \frac{c}{d} \left(\frac{5}{2}(1-d) - \frac{3}{2} \ln \frac{1}{d} \right) \text{OPT}_S \geq \frac{1}{6.65} \text{OPT}_S. \quad \blacktriangleleft$$

6 Extension to GAP

In this section we show that the sequential approach introduced in Section 3 can be easily adapted to GAP, yielding a $(1/6.99)$ -competitive randomized algorithm. We first define the problem formally.

GAP. We are given a set of items $I = [n]$ and a set of resources $R = [m]$ of capacities $W_r \in \mathbb{Q}_{>0}$ for $r \in R$. If item $i \in I$ is assigned to resource $r \in R$, this raises profit (value) $v_{i,r} \in \mathbb{Q}_{\geq 0}$, but consumes $s_{i,r} \in \mathbb{Q}_{>0}$ of the resource's capacity. The goal is to assign each item to at most one resource such that the total profit is maximized and no resource exceeds its capacity. We call the tuple $(v_{i,r}, s_{i,r})$ an *option* of item i and w.l.o.g. assume that options for all resources exist. This can be ensured by introducing dummy options with $v_{i,r} = 0$. In the online version of the problem, in each round an item is revealed together with its set of options. The online algorithm must decide immediately and irrevocably, if the item is assigned. If so, it has to specify the resource according to one of its options.

Again, we construct restricted instances I_L and I_S according to the following definition, which generalizes Definition 2.1. Let $\delta \in (0, 1)$.

► **Definition 6.1.** *We call an option $(v_{i,r}, s_{i,r})$ δ -large if $s_{i,r} > \delta W_r$ and δ -small if $s_{i,r} \leq \delta W_r$. Whenever δ is clear from the context, we say an option is large or small for short. Based on a given instance I for GAP, we define two modified instances I_L and I_S which are obtained from I as follows.*

- I_L : Replace each small option $(v_{i,r}, s_{i,r})$ by the large option $(0, W_r)$.
- I_S : Replace each large option $(v_{i,r}, s_{i,r})$ by the small option $(0, \delta)$.

Thus, I_L only contains large options and I_S only contains small options. However, by construction no algorithm will assign an item according to a zero-profit option. We define OPT , OPT_L , and OPT_S accordingly. Note that the inequality $\text{OPT} \leq \text{OPT}_L + \text{OPT}_S$ holds also for GAP.

The sequential framework of Algorithm 1 can be adapted in a straightforward manner by replacing terms like *packing* with *assignment to resource r* . Here, we set the threshold parameter to $\delta = 1/2$. In the following subsections, we specify algorithms \mathcal{A}_L and \mathcal{A}_S for $(1/2)$ -large and $(1/2)$ -small options, respectively.

6.1 Large Options

If each item consumes more than one half of a resource, no two items can be assigned to this resource. Thus, we obtain the following matching problem.

Edge-weighted bipartite matching problem. Given a bipartite graph $G = (L \cup R, E)$ and a weighting function $w: E \rightarrow \mathbb{Q}_{\geq 0}$, the goal is to find a bipartite matching $M \subseteq E$ such that $w(M) := \sum_{e \in M} w(e)$ is maximal. In the online version, the (offline) nodes from R and the number $n = |L|$ are known in advance, whereas the nodes from L are revealed online together with their incident edges. In the case of GAP, L is the set of items, R is the set of resources, and the weight of an edge $e = \{l, r\}$ is $w(e) = v_{l,r}$, i.e., the profit gained from assigning item l to resource r .

Under random arrival order, Kesselheim et al. [26] developed an optimal $(1/e)$ -competitive algorithm for this problem. Adapting this algorithm to the sequential approach with parameters c and d leads to the following algorithm \mathcal{A}_L : After sampling the first cn nodes, in each round ℓ the algorithm computes a maximum edge-weighted matching $M^{(\ell)}$ for the graph revealed up to this round. Let $l \in L$ be the online vertex of round ℓ . If l is matched in $M^{(\ell)}$ to some node $r \in R$, we call $e^{(\ell)} = \{l, r\}$ the *tentative edge* of round ℓ . Now, if r is still unmatched and $\ell \leq dn$, the tentative edge is added to the matching.

A formal description of this algorithm is given in Appendix B.1. The proof of the approximation guarantee relies mainly on the following two lemmas; for completeness, we give the proofs from [26] in Appendix B.1. The first lemma shows that the expected weight of any tentative edge can be bounded from below.

► **Lemma 6.2** ([26]). *In any round ℓ , the tentative edge (if it exists) has expected weight $\mathbf{E}[w(e^{(\ell)})] \geq \frac{1}{n} \text{OPT}_L$.*

However, we only gain the weight of the tentative edge $e^{(\ell)} = \{l, r\}$ if it can be added to the matching, i.e., if r has not been matched previously. The next lemma bounds the probability for this event from below.

► **Lemma 6.3** ([26]). *Let $\xi(r, \ell)$ be the event that the offline vertex $r \in R$ is unmatched after round ℓ . It holds that $\Pr[\xi(r, \ell)] \geq \frac{cn}{\ell}$.*

Using Lemmas 6.2 and 6.3, we can bound the competitive ratio of \mathcal{A}_L in the following lemma. Note that we obtain the optimal algorithm from [26] for $c = 1/e$ and $d = 1$.

► **Lemma 6.4.** *For $n \rightarrow \infty$, it holds that $\mathbf{E}[\mathcal{A}_L] \geq c \ln \frac{d}{c} \text{OPT}_L$.*

Proof. Let A_ℓ be the gain of the matching weight in round ℓ . As the tentative edge $e^{(\ell)} = \{l, r\}$ can only be added if r has not been matched in a previous round, we have $\mathbf{E}[A_\ell] = \mathbf{E}[w(e^{(\ell)})] \Pr[\xi(r, \ell)]$ for the event $\xi(r, \ell)$ from Lemma 6.3. Therefore, from

Lemmas 6.2 and 6.3 we have $\mathbf{E}[A_\ell] \geq \frac{1}{n} \text{OPT}_L \frac{cn}{\ell} = \frac{c}{\ell} \text{OPT}_L$. Summing over all rounds from $cn + 1$ to dn yields

$$\mathbf{E}[A_L] = \sum_{\ell=cn+1}^{dn} \mathbf{E}[A_\ell] \geq \left(c \sum_{\ell=cn+1}^{dn} \frac{1}{\ell} \right) \text{OPT}_L \geq c \ln \frac{dn+1}{cn+1} \text{OPT}_L .$$

Here, in the last step we used the fact $\sum_{\ell=cn+1}^{dn} \frac{1}{\ell} \geq \int_{cn+1}^{dn+1} \frac{1}{\ell} d\ell = \ln \frac{dn+1}{cn+1}$. The claim follows by $\lim_{n \rightarrow \infty} \ln \frac{dn+1}{cn+1} = \ln \frac{d}{c}$. ◀

6.2 Small Options

For δ -small options we use the LP-based algorithm \mathcal{A}_S from [27, Sec. 3.3]. On a high level, this algorithm works as follows: After a sampling phase of dn rounds, in each round ℓ the algorithm computes an optimal fractional solution for the instance revealed so far and uses the coefficients as probabilities for an integral assignment. In Appendix B.2 we prove the following lemma, where $\Delta = \frac{1}{1-\delta}$.

► **Lemma 6.5.** *For $n \rightarrow \infty$, it holds that $\mathbf{E}[A_S] \geq \frac{c}{d} \left((1 + \Delta)(1 - d) - \Delta \ln \frac{1}{d} \right) \text{OPT}_S$.*

Note that we obtain basically the same competitive ratio as in Lemma 5.4. Since Lemma 6.5 already addresses possible resource consumption due to assignments made by \mathcal{A}_L in earlier rounds, the factor c/d arises (see Lemma 6.3).

6.3 Proof of Theorem 1.2

Finally, we prove our main theorem for GAP.

Proof of Theorem 1.2. We set the threshold between large and small options to $\delta = 1/2$ and consider Algorithm 1 with the algorithms \mathcal{A}_L and \mathcal{A}_S as defined previously. By Lemma 6.4, the expected gain of profit in rounds $cn + 1, \dots, dn$ is $\mathbf{E}[A_L] \geq c \ln \frac{d}{c} \text{OPT}_L$. Further, we gain $\mathbf{E}[A_S] \geq \frac{c}{d} \left((1 + \Delta)(1 - d) - \Delta \ln \frac{1}{d} \right) \text{OPT}_S$ with $\Delta = 2$ in the following rounds, according to Lemma 6.5. For parameters $c = 0.5261$ and $d = 0.6906$, we obtain $c \ln \frac{d}{c} \geq \frac{c}{d} \left(3(1 - d) - 2 \ln \frac{1}{d} \right)$ and thus, using $\text{OPT}_L + \text{OPT}_S \geq \text{OPT}$,

$$\mathbf{E}[A_L] + \mathbf{E}[A_S] \geq \frac{c}{d} \left(3(1 - d) - 2 \ln \frac{1}{d} \right) (\text{OPT}_L + \text{OPT}_S) \geq \frac{1}{6.99} \text{OPT} . \quad \blacktriangleleft$$

■ **Figure 2** Input sequence considered in Lemma 4.3. The gray dashed slots represent items of rank greater than a .

A Missing Proofs for the Knapsack Result

Proof of Lemma 4.3. Let $i \in [n-1]$ and $j = i+1$. The proof follows the same structure as the proof of Lemma 4.2. Again, we construct the permutation by drawing the positions for items i, j, a first and afterwards all remaining items with position up to $\text{pos}(j)$. Fix positions $k = \text{pos}(i)$ and $l = \text{pos}(j)$. Again, $\text{pos}(a) \leq cn$ must hold by definition of a . The probability that a random permutation satisfies these three position constraints is $\beta := \frac{1}{n} \frac{1}{n-1} \frac{cn}{n-2}$. All remaining items up to position l must have rank greater than a (see Figure 2). Thus we need to draw $l-3$ items from a set of $n-3$ remaining items, from which $n-a$ have rank greater than a . This happens with probability $h(n-3, n-a, l-3)$. Using the law of total probability for $cn+1 \leq k < l \leq dn$ and $a \in \{j+1, \dots, n\}$, we obtain

$$\begin{aligned} p_{ij} &= \beta \sum_{k=cn+1}^{dn-1} \sum_{l=k+1}^{dn} \sum_{a=j+1}^n h(n-3, n-a, l-3) \\ &= \beta \sum_{k=cn+1}^{dn-1} \sum_{l=k+1}^{dn} \frac{1}{\binom{n-3}{l-3}} \sum_{a=j+1}^n \binom{n-a}{l-3} = \beta \sum_{k=cn+1}^{dn-1} \sum_{l=k+1}^{dn} \frac{\binom{n-j}{l-2}}{\binom{n-3}{l-3}}, \end{aligned}$$

where in the last step we used the equality $\sum_{a=j+1}^n \binom{n-a}{l-3} = \sum_{a=0}^{n-j-1} \binom{a}{l-3} = \binom{n-j}{l-2}$.

We next consider the asymptotic setting $n \rightarrow \infty$. For this purpose, we define $Q(l) = \binom{n-j}{l-2} / \binom{n-3}{l-3}$. For $(i, j) = (1, 2)$ we have $Q(l) = \binom{n-2}{l-2} / \binom{n-3}{l-3} = \frac{n-2}{l-2}$. The sum $\sum_{l=k+1}^{dn} \frac{n-2}{l-2}$ converges to $n \ln \frac{dn}{k}$ for $n \rightarrow \infty$. Further, $\lim_{n \rightarrow \infty} \sum_{k=cn+1}^{dn-1} n \ln \frac{dn}{k} = n(F(dn) - F(cn))$ for $F(x) := x \ln \frac{dn}{x} + x$. Hence,

$$\lim_{n \rightarrow \infty} p_{12} = \lim_{n \rightarrow \infty} \beta n \left(dn \ln \frac{dn}{dn} + dn - cn \ln \frac{dn}{cn} - cn \right) = c \left(d - c \ln \frac{d}{c} - c \right).$$

In the case $(i, j) = (2, 3)$ it holds that $Q(l) = \binom{n-3}{l-2} / \binom{n-3}{l-3} = \frac{n-l}{l-2}$ and we have $\lim_{n \rightarrow \infty} \sum_{l=k+1}^{dn} \frac{n-l}{l-2} = n \ln \frac{dn}{k} - dn + k$. Let $F(x) := nx \left(\ln \frac{dn}{x} - d + 1 \right) + \frac{x^2}{2}$. Again, by bounding the sum by the corresponding integral we obtain

$$\begin{aligned} & \lim_{n \rightarrow \infty} \sum_{k=cn+1}^{dn} n \ln \frac{dn}{k} - dn + k \\ &= F(dn) - F(cn) \\ &= dn^2 \left(\ln \frac{dn}{dn} - d + 1 \right) + \frac{d^2 n^2}{2} - cn^2 \left(\ln \frac{dn}{cn} - d + 1 \right) - \frac{c^2 n^2}{2} \\ &= n^2 \left(-d^2 + d + \frac{d^2}{2} - c \ln \frac{d}{c} + cd - c - \frac{c^2}{2} \right) \\ &= n^2 \left(d - c \ln \frac{d}{c} - c - \frac{d^2}{2} + cd - \frac{c^2}{2} \right). \end{aligned}$$

Multiplying the last term with $\lim_{n \rightarrow \infty} \beta = c/n^2$ gives the claim for p_{23} . ◀

Proof of Lemma 4.4. Suppose i is accepted first and j is accepted as the second item in the input sequence π . Consider the sequence π' obtained from π by swapping i with j . Since j and i are the first two elements beating the best sampling item in π' , Algorithm 2 will select j and i on input π' . Hence, the number of permutations must be the same for both events, which implies the claim. ◀

Proof of Lemma 4.5. The argument is similar to the proof of Lemma 4.4. Consider any input sequence π where i is selected first and j second. We know that the best item a from sampling has profit $v_a < v_j < v_i$ and thus any item k with $i < k < j$ must occur after j . Let π' be the sequence obtained from π by swapping i with k . Now, i is behind k and j , thus Algorithm 2 will accept k and j . Again, this proves $p_{ij} = p_{kj}$ since the numbers of corresponding permutations are equal. ◀

The next lemma is used in the proof of Lemma 4.7 to show that for the given lists of parameters, we have $\beta_w \geq \gamma_w$.

► **Lemma A.1.** Let $f(x) = 2 \ln x - 6x + 2x^2 - \frac{x^3}{3}$. For parameters c, d with $f(c) \geq f(d)$ it holds that $\beta_w \geq \gamma_w$ where $2 \leq w \leq 5$.

Proof. The function f is chosen in a way that $f(c) \geq f(d)$ is equivalent to $\beta_5 \geq \gamma_5$. This can be verified easily, using $\beta_5 = p_D = p_1$, $\gamma_5 = p_E + p_F + p_G = p_2 + p_3 + p_4$, and Lemma 4.2. Therefore, the claim for $w = 5$ holds by assumption. For $2 \leq w \leq 4$, the claims follow immediately from $f(c) \geq f(d)$ and the symmetry property of Lemma 4.4:

$$\begin{aligned}\beta_2 &= p_H = p_1 - p_{12} = p_1 - p_{21} \geq p_2 - p_{21} = p_J = \gamma_2 \\ \beta_3 &= p_I = p_1 - p_{13} = p_1 - p_{31} \geq p_2 + p_3 - p_{31} = p_E + p_L = \gamma_3 \\ \beta_4 &= p_D + p_K = p_1 + p_2 - p_{23} \geq p_1 - p_{32} \geq p_3 - p_{32} = p_M = \gamma_4.\end{aligned}$$

B Missing Proofs for the GAP Result

B.1 Large Options

► **Algorithm 4** Algorithm for edge-weighted bipartite matching from [26] (extended by our parameters c, d).

Input : Offline vertex set R , number of online vertices $n = |L|$,
parameters $c, d \in (0, 1)$ with $c < d$.

Output : Matching M .

Set $M = \emptyset$.

Let ℓ be the current round and l be the online vertex of round ℓ .

if $1 \leq \ell \leq cn$ **then**
 | Sampling phase – do not add any edge.

if $cn + 1 \leq \ell \leq dn$ **then**
 | Let $M^{(\ell)}$ be a maximum-weight matching for the graph in round ℓ .
 | Let $e^{(\ell)} \in M^{(\ell)}$ be the edge incident to l .
 | **if** $M \cup e^{(\ell)}$ is a matching **then**
 | | Add $e^{(\ell)}$ to M .

if $\ell > dn$ **then**
 | Do not add any edge.

Proof of Lemma 6.2. Let $e^{(\ell)}$ be the tentative edge of round ℓ and let $Q \subseteq L$ with $|Q| = \ell$ be the set of visible vertices from this round. Since each vertex from Q has the same probability of $1/\ell$ to arrive in round ℓ , we have

$$\mathbf{E} \left[w(e^{(\ell)}) \right] = \sum_{e=\{l,r\} \in M^{(\ell)}} \Pr[l \text{ arrives in round } \ell] w(e) = \frac{1}{\ell} w(M^{(\ell)}). \quad (4)$$

Let $M^* = M^{(n)}$ be a maximum weight (offline) matching and $M_Q^* = \{e = \{l, r\} \in M^* \mid l \in Q\}$. We have $w(M^{(\ell)}) \geq w(M_Q^*)$, since $M^{(\ell)}$ is an optimal and M_Q^* a feasible matching for the graph revealed in round ℓ . As Q can be seen as uniformly drawn among all ℓ -element subsets, each vertex l has probability ℓ/n to be in Q . It follows

$$\mathbf{E} \left[w(M^{(\ell)}) \right] \geq \mathbf{E} \left[w(M_Q^*) \right] = \sum_{e=\{l,r\} \in M^*} \Pr[l \in Q] w(e) = \frac{\ell}{n} w(M^*). \quad (5)$$

Combining (4) and (5) concludes the proof. \blacktriangleleft

Proof of Lemma 6.3. In each round k , the vertex r can only be matched if it is incident to the tentative edge $e^{(k)} \in M^{(k)}$ of this round, i.e., $e^{(k)} = \{l, r\}$ where $l \in L$ is the online vertex of round k . As l can be seen as uniformly drawn among all k visible nodes (particularly, independent from the order of the previous $k-1$ items), l has probability $1/k$ to arrive in round k . Consequently, r is not matched in round k with probability $1-1/k$. This argument applies to all rounds $cn+1, \dots, \ell$. Therefore,

$$\Pr[\xi(r, \ell)] \geq \prod_{k=cn+1}^{\ell} \left(1 - \frac{1}{k}\right) = \prod_{k=cn+1}^{\ell} \frac{k-1}{k} = \frac{cn}{\ell}. \quad \blacktriangleleft$$

B.2 Small Options

For δ -small options we use the LP-based algorithm from [27, Sec. 3.3] and analyze it within our algorithmic framework. In order to make this paper self-contained, we give a linear program for GAP (LP 1), the algorithm, and its corresponding proofs.

$$\begin{aligned} & \text{maximize} && \sum_{\substack{i \in I_S \\ r \in R}} v_{i,r} x_{i,r} \\ & \text{subject to} && \sum_{i \in I_S} s_{i,r} x_{i,r} \leq W_r && \forall r \in R \\ & && \sum_{r \in R} x_{i,r} \leq 1 && \forall i \in I_S \\ & && x_{i,r} \in \{0, 1\} && \forall (i, r) \in I_S \times R \end{aligned} \quad (\text{LP 1})$$

Let \mathcal{A}_S be Algorithm 5. After a sampling phase of dn rounds, in each round ℓ the algorithm computes an optimal solution $x^{(\ell)}$ of the relaxation of LP 1 for $I_S(\ell)$. Here, $I_S(\ell)$ denotes the instance of small options revealed so far. Now, the decision to which resource the current online item i is assigned, if at all, is made by randomized rounding using $x^{(\ell)}$: Resource $r \in R$ is chosen with probability $x_{i,r}^{(\ell)}$ and the item stays unassigned with probability $1 - \sum_{r \in R} x_{i,r}^{(\ell)}$. Note that it is only feasible to assign the item to the chosen resource if its remaining capacity is at least δW_r .

■ **Algorithm 5** GAP algorithm for small options from [27, Sec. 3.3].

Input : Random order sequence of small options,
 parameter $d \in (0, 1)$.

Output : Integral GAP assignment.

Let ℓ be the current round and i be the online item of round ℓ .

if $1 \leq \ell \leq dn$ **then**
 | Sampling phase – do not assign any item.

if $dn + 1 \leq \ell \leq n$ **then**
 | Let $x^{(\ell)}$ be an optimal fractional solution of LP 1 for $I_S(\ell)$.
 | Choose a resource r (possibly none), where r has probability $x_{i,r}^{(\ell)}$.
 | **if** the remaining capacity of r is at least δW_r **then**
 | | Assign i to r .

To analyze Algorithm 5, we consider the gain of profit in round $\ell \geq dn + 1$, denoted by A_ℓ . For this purpose, let $i^{(\ell)}$ be the item of that round and $r^{(\ell)}$ the resource chosen by the algorithm. Now, it holds that $\mathbf{E}[A_\ell] = \mathbf{E}[v_{i^{(\ell)}, r^{(\ell)}}] \Pr[i^{(\ell)} \text{ can be assigned to } r^{(\ell)}]$, where in the first term, the expectation is over the item arriving in round ℓ and the resource chosen by the algorithm. The latter term only depends on the resource consumption of $r^{(\ell)}$ in earlier rounds. In the next two lemmas we give lower bounds for both terms.

► **Lemma B.1** ([27, Sec. 3.3]). *For any round $\ell \geq dn + 1$, it holds that $\mathbf{E}[v_{i^{(\ell)}, r^{(\ell)}}] \geq \frac{1}{n} \text{OPT}_S$.*

Proof. The proof is similar to Lemma 6.2. As we consider a fixed round ℓ , we write i and r instead of $i^{(\ell)}$ and $r^{(\ell)}$ for ease of presentation. Further, we write $v(\alpha) := \sum_{j \in I_S} \sum_{s \in R} \alpha_{j,s} v_{j,s}$ for the profit of a fractional assignment α .

Fix any set Q of ℓ visible items in round ℓ . Let $x^{(n)}$ be an optimal (offline) solution to the relaxation of LP 1. Further, let $x^{(n)}|_Q$ denote the restriction of $x^{(n)}$ to the items in Q , i.e., $(x^{(n)}|_Q)_{j,s} = x_{j,s}^{(n)}$ if $j \in Q$ and $(x^{(n)}|_Q)_{j,s} = 0$ if $j \notin Q$. Since $x^{(n)}|_Q$ is a feasible and $x^{(\ell)}$ is an optimal solution for Q , we have $\mathbf{E}[v(x^{(\ell)})] \geq \mathbf{E}[v(x^{(n)}|_Q)]$. As in a random permutation each item has the same probability of ℓ/n to be in Q , it holds that

$$\mathbf{E}[v(x^{(\ell)})] \geq \mathbf{E}[v(x^{(n)}|_Q)] = \sum_{j \in I_S} \sum_{s \in R} \Pr[j \in Q] x_{j,s}^{(n)} v_{j,s} = \frac{\ell}{n} v(x^{(n)}) = \frac{\ell}{n} \text{OPT}_S. \quad (6)$$

Similarly, each item from Q is the current online item i with probability $1/\ell$. The resource s , to which an item j gets assigned, is determined by randomized rounding using $x_{j,s}^{(\ell)}$. Therefore we get

$$\mathbf{E}[v_{i,r}] = \sum_{j \in Q} \sum_{s \in R} \Pr[j = i, s = r] v_{j,s} = \sum_{j \in Q} \sum_{s \in R} \frac{1}{\ell} x_{j,s}^{(\ell)} v_{j,s} = \frac{1}{\ell} v(x^{(\ell)}). \quad (7)$$

Combining (6) and (7) gives the claim. ◀

Hence, by the previous lemma the expected gain of profit in each round is a $(1/n)$ -fraction of OPT_S , supposing the remaining resource capacity is large enough. The probability for the latter event is considered in the following lemma. Here, a crucial property is that we deal with δ -small options. Let $\Delta = \frac{1}{1-\delta}$.

► **Lemma B.2.** *For any round $\ell \geq dn + 1$, we have $\Pr[i^{(\ell)} \text{ can be assigned to } r^{(\ell)}] \geq \frac{c}{d} (1 - \Delta \ln \frac{\ell}{dn})$.*

Proof. Let ξ be the event that no item is assigned to r after round dn . Note that ξ does not necessarily hold, since \mathcal{A}_L might already have assigned items to r in earlier rounds. By Lemma 6.3, $\Pr[\xi] \geq \frac{c}{d}$. Therefore, it remains to show $\Pr[i^{(\ell)}$ can be assigned to $r^{(\ell)} \mid \xi] \geq 1 - \Delta \ln \frac{\ell}{dn}$.

For this purpose, assume that ξ holds and let X denote the resource consumption of r after round $\ell - 1$. Further, let X_k be the resource consumption of r in round $k < \ell$. We have $X = \sum_{k=dn+1}^{\ell-1} X_k$. Let Q be the set of k visible items in round k . The set Q can be seen as uniformly drawn from all k -item subsets and any item $j \in Q$ is the current online item of round k with probability $1/k$. Now, the algorithm assigns any item j to resource r with probability $x_{j,r}^{(k)}$, thus

$$\mathbf{E}[X_k] = \sum_{j \in Q} \Pr[j \text{ occurs in round } k] s_{j,r} x_{j,r}^{(k)} = \frac{1}{k} \sum_{j \in Q} s_{j,r} x_{j,r}^{(k)} \leq \frac{W_r}{k}, \quad (8)$$

where the last inequality follows from the capacity constraint for resource r in LP 1. By linearity of expectation and inequality (8), the expected resource consumption up to round ℓ is thus

$$\mathbf{E}[X] = \sum_{k=dn+1}^{\ell-1} \mathbf{E}[X_k] \leq \sum_{k=dn+1}^{\ell-1} \frac{W_r}{k} \leq W_r \ln \frac{\ell}{dn}. \quad (9)$$

Now, since $i^{(\ell)}$ is δ -small, $X < (1 - \delta)W_r$ implies $X + s_{i^{(\ell)},r^{(\ell)}} \leq W_r$ in which case the assignment is feasible. Using (9) and Markov's inequality, we obtain

$$\Pr[X < (1 - \delta)W_r] = 1 - \Pr[X \geq (1 - \delta)W_r] \geq 1 - \frac{\mathbf{E}[X]}{(1 - \delta)W_r} \geq 1 - \Delta \ln \frac{\ell}{dn}. \quad \blacktriangleleft$$

Now, the bound on the competitive ratio of \mathcal{A}_S from Lemma 6.5 follows.

Proof of Lemma 6.5. We add the expected profits in single rounds using Lemmas B.1 and B.2.

$$\begin{aligned} \mathbf{E}[\mathcal{A}_S] &= \sum_{\ell=dn+1}^n \mathbf{E}[A_\ell] = \sum_{\ell=dn+1}^n \mathbf{E}[v_{i^{(\ell)},r^{(\ell)}}] \Pr[i^{(\ell)} \text{ can be assigned to } r^{(\ell)}] \\ &\geq \sum_{\ell=dn+1}^n \frac{1}{n} \text{OPT}_S \frac{c}{d} \left(1 - \Delta \ln \frac{\ell}{dn}\right) = \frac{c}{dn} \left(\sum_{\ell=dn+1}^n 1 - \Delta \ln \frac{\ell}{dn}\right) \text{OPT}_S \\ &= \frac{c}{dn} \left(n - dn - \Delta \sum_{\ell=dn+1}^n \ln \frac{\ell}{dn}\right) \text{OPT}_S. \end{aligned}$$

Since $\frac{\ell}{dn}$ is monotone increasing in ℓ , we have $\sum_{\ell=dn+1}^n \ln \frac{\ell}{dn} \leq \int_{dn+1}^{n+1} \ln \frac{\ell}{dn} d\ell$ and this integral evaluates to $(n+1) \ln \frac{n+1}{dn+1} - (n+1) - (dn+1) \ln \frac{dn+1}{dn} + (dn+1)$. For $n \rightarrow \infty$, this approaches $n \ln \frac{1}{d} - n + dn$. Hence, we have $\lim_{n \rightarrow \infty} \mathbf{E}[\mathcal{A}_S] \geq \frac{c}{d} \left((1 + \Delta)(1 - d) - \Delta \ln \frac{1}{d}\right) \text{OPT}_S$. \blacktriangleleft

Fast and Deterministic Approximations for k -Cut

Kent Quanrud

Department of Computer Science, University of Illinois at Urbana-Champaign, USA

<http://www.kentquanrud.com>

quanrud2@illinois.edu

Abstract

In an undirected graph, a k -cut is a set of edges whose removal breaks the graph into at least k connected components. The minimum weight k -cut can be computed in $n^{O(k)}$ time, but when k is treated as part of the input, computing the minimum weight k -cut is NP-Hard [18]. For poly(m, n, k)-time algorithms, the best possible approximation factor is essentially 2 under the small set expansion hypothesis [37]. Saran and Vazirani [46] showed that a $(2 - \frac{2}{k})$ -approximately minimum weight k -cut can be computed via $O(k)$ minimum cuts, which implies a $\tilde{O}(km)$ randomized running time via the nearly linear time randomized min-cut algorithm of Karger [27]. Nagamochi and Kamidoi [42] showed that a $(2 - \frac{2}{k})$ -approximately minimum weight k -cut can be computed deterministically in $O(mn + n^2 \log n)$ time. These results prompt two basic questions. The first concerns the role of randomization. Is there a deterministic algorithm for 2-approximate k -cuts matching the randomized running time of $\tilde{O}(km)$? The second question qualitatively compares minimum cut to 2-approximate minimum k -cut. Can 2-approximate k -cuts be computed as fast as the minimum cut – in $\tilde{O}(m)$ randomized time?

We give a deterministic approximation algorithm that computes $(2 + \epsilon)$ -minimum k -cuts in $O(m \log^3 n / \epsilon^2)$ time, via a $(1 + \epsilon)$ -approximation for an LP relaxation of k -cut.

1 Introduction

Let $G = (V, E)$ be an undirected graph with m edges and n vertices, with positive edge capacities given by $c : E \rightarrow \mathbb{R}_{>0}$. A *cut* is a set of edges $C \subseteq E$ whose removal leaves G disconnected. For $k \in \mathbb{N}$, a k -cut is a set of edges $C \subseteq E$ whose removal leaves G disconnected into at least k components. The capacity of a cut C is the sum capacity $\bar{c}(C) = \sum_{e \in C} c_e$ of edges in the cut. The *minimum k -cut* problem is to find a k -cut C of minimum capacity $\bar{c}(C)$.

The special case $k = 2$, which is to find the minimum cut, is particularly well-studied. The minimum cut can be computed in polynomial time by fixing a source s and computing the minimum s - t cut (via s - t max-flow) for all choices of t . Nagamochi and Ibaraki [39, 40, 41] and Hao and Orlin [22] improved the running time to $\tilde{O}(mn)$ which, at the time, was as fast

as computing a single maximum flow. A randomized edge contraction algorithm by Karger and Stein [28] finds the minimum cut with high probability in $\tilde{O}(n^2)$ time; this algorithm is now a staple of graduate level courses on randomized algorithms. Karger [27] gave a randomized algorithm based on the Tutte–Nash–Williams theorem [50, 44] that computes the minimum weight cut with high probability in $\tilde{O}(m)$ time. The best deterministic running time for minimum cut is currently $O(mn + n^2 \log n)$, by Stoer and Wagner [48]. Computing the minimum capacity cut deterministically in nearly linear time is a major open problem. Recently, Kawarabayashi and Thorup [30] made substantial progress on this problem with a deterministic nearly linear time algorithm for computing the minimum *cardinality* cut in an unweighted simple graph. This algorithm was simplified by Lo, Schmidt, and Thorup [35], and a faster algorithm was obtained by Henzinger, Rao, and Wang [24]. For capacitated graphs, a $(2 + \epsilon)$ -approximate minimum cut can be computed in $O((m \log n + n \log^2 n)/\epsilon)$ deterministic time by an algorithm of Matula [38] (as observed by Karger [26]).

The general case $k > 2$ is more peculiar. Goldschmidt and Hochbaum [18] showed that for any fixed k , finding the minimum k -cut is polynomial time solvable, but when k is part of the input, the problem is NP-Hard. The aforementioned randomized contraction algorithm of Karger and Stein [28] computes a minimum k -cut with high probability in $\tilde{O}(n^{2(k-1)})$ time. Thorup [49] gave a deterministic algorithm that also leverages the Tutte–Nash–Williams theorem [50, 44] and runs in $\tilde{O}(mn^{2k-2})$ time; this approach was recently refined to improve the running time to $\tilde{O}(mn^{2k-3})$ deterministic time [10] and $O(n^{(1.981+o(1))k})$ randomized time [21] (where the $o(1)$ goes to zero as k increases). There are slightly faster algorithms for particularly small values of k [34] and when the graph is unweighted [20]. As far as algorithms with running times that are polynomial in k are concerned, Saran and Vazirani [46] showed that a $(2 - \frac{2}{k})$ -approximate k -cut can be obtained by $O(k)$ minimum cut computations. By the aforementioned min-cut algorithms, this approach can be implemented in $\tilde{O}(km)$ randomized time, $\tilde{O}(kmn)$ time deterministically, and $\tilde{O}(km)$ time deterministically in unweighted graphs. Alternatively, Saran and Vazirani [46] showed that the same approximation factor can be obtained by computing a Gomory–Hu tree and taking the k lightest cuts. The Gomory–Hu tree can be computed in n maximum flow computations, and the maximum flow can be computed deterministically in $\tilde{O}(m \min\{m^{1/2}, n^{2/3}\} \log U)$ time for integer capacities between 1 and U [17]. This gives a $\tilde{O}(mn \min\{m^{1/2}, n^{2/3}\} \log U)$ deterministic time $(2 - 2/k)$ -approximation for minimum k -cut, which is faster than $\tilde{O}(kmn)$ for sufficiently large k . (There are faster randomized algorithms for maximum flow [33, 36], but these still lead to slower randomized running times than $\tilde{O}(km)$ for k -cut.) An LP based 2-approximation was derived by Naor and Rabani [43], and a combinatorial 2-approximation was given by Ravi and Sinha [45] (see also [1]), but the running times are worse than those implied by Saran and Vazirani [46]. The best deterministic algorithm in the $\text{poly}(m, n, k)$ regime is due to Nagamochi and Kamidoi [42], who compute $(2 - \frac{2}{k})$ -approximately minimum k -cuts in $O(mn + n^2 \log n)$ deterministic time. The constant factor of 2 is believed to be essentially the best possible. Manurangsi [37] showed that under the small set expansion hypothesis, for any fixed $\epsilon > 0$, one cannot compute a $(2 - \epsilon)$ -approximation for the minimum k -cut in $\text{poly}(k, m, n)$ time unless $P = NP$.

The state of affairs for computing 2-approximate minimum k -cuts in $\text{poly}(m, n, k)$ -time parallels the status of minimum cut. The fastest randomized algorithm is an order of magnitude faster than the fastest deterministic algorithm, while in the unweighted case the running times are essentially equal. A basic question is whether there exists a deterministic algorithm that computes a 2-approximation in $\tilde{O}(km)$ time, matching the randomized running time. As Saran and Vazirani’s algorithm reduces k -cut to k minimum cuts, the gap

between the deterministic and randomized running times for k -cut is not only similar to, but a reflection of, the gap between the deterministic and randomized running times for minimum cut. An $\tilde{O}(m)$ deterministic algorithm for minimum cut would close the gap for 2-approximate k -cut as well.

A second question asks if computing a 2-approximate k -cut is qualitatively harder than computing the minimum cut. There is currently a large gap between the fastest algorithm for minimum cut and the fastest algorithm for 2-approximate minimum k -cut. Can one compute 2-approximate minimum k -cuts as fast as minimum cuts – in $\tilde{O}(m)$ randomized time? Removing the linear dependence on k would show that computing 2-approximate k -cuts is as easy as computing a minimum cut.

1.1 The main result

We make progress on both of these questions with a deterministic and nearly linear time $(2 + \epsilon)$ -approximation scheme for minimum k -cuts. To state the result formally, we first introduce an LP relaxation for the minimum k -cut due to Naor and Rabani [43].

$$\begin{aligned} \min \quad & \sum_e c_e x_e \text{ over } x : E \rightarrow \mathbb{R} \\ \text{s.t.} \quad & \sum_{e \in T} x_e \geq k - 1 \text{ for all spanning trees } T, \\ & 0 \leq x_e \leq 1 \text{ for all edges } e. \end{aligned} \tag{L}$$

The feasible integral solutions of the LP (L) are precisely the k -cuts in G . The main contribution of this work is a nearly linear time approximation scheme for (L).

► **Theorem 1.** *In $O(m \log^3(n)/\epsilon^2)$ deterministic time, one can compute an $(1 + \epsilon)$ -multiplicative approximation to (L).*

The integrality gap of (L) is known to be $(2 - 2/n)$ [43, 4]. Upon inspection, the rounding algorithm can be implemented in $O(m \log n)$ time, giving the following nearly linear time $(2 + \epsilon)$ -approximation scheme for k -cut.

► **Theorem 2.** *For sufficiently small $\epsilon > 0$, there is a deterministic algorithm that computes a k -cut with total capacity at most $(2 + \epsilon)$ times the optimum value to (L) in $O(m \log^3(n)/\epsilon^2)$ time.*

The algorithm should be compared with the aforementioned algorithms of Saran and Vazirani [46], which computes a $(2 - \frac{2}{k})$ -approximation to the minimum k -cut in $\tilde{O}(km)$ randomized time (with high probability), and of Nagamochi and Kamidoi [42], which computes a $(2 - \frac{2}{k})$ -approximate minimum k -cut in $O(mn + n^2 \log n)$ deterministic time. At the cost of a $(1 + \epsilon)$ -multiplicative factor, we obtain a deterministic algorithm with nearly linear running time for *all values of k* . The approximation factor converges to 2, and we cannot expect to beat 2 under the small set expansion hypothesis [37]. Thus, Theorem 2 gives a tight, deterministic, and nearly linear time approximation scheme for k -cut. Theorem 2 leaves a little bit of room for improvement: the hope is for a deterministic algorithm that computes $(2 - o(1))$ -approximate minimum k -cuts in $\tilde{O}(m)$ time. Based on Theorem 2, we conjecture that such an algorithm exists.

1.2 Overview of the algorithm

We give a brief sketch of the algorithm, for the sake of informing subsequent discussion on related work in Section 1.3. A more complete description of the algorithm begins in earnest in Section 2.

The algorithm consists of a nearly linear time approximation scheme for the LP (L), and a nearly linear time rounding scheme. The approximation scheme for solving the LP extends techniques from recent work [6], applied to the dual of an *indirect reformulation* of (L). The rounding scheme is a simplification of the rounding scheme by Chekuri et al. [4] for the more general Steiner k -cut problem, which builds on the primal-dual framework of Goemans and Williamson [15].

The first step is to obtain a $(1 + \epsilon)$ -multiplicative approximation to the LP (L). Here a $(1 + \epsilon)$ -multiplicative approximation to the LP (L) is a feasible vector x of cost at most a $(1 + \epsilon)$ -multiplicative factor greater than the optimum value.

The LP (L) can be solved exactly by the ellipsoid method, with the separation oracle supplied by a minimum spanning tree (abbr. MST) computation, but the running time is a larger polynomial than desired. From the perspective of fast approximations, the LP (L) is difficult to handle because it is an exponentially large mixed packing and covering problem, with exponentially many covering constraints alongside upper bounds on each edge. Fast approximation algorithms for mixed packing and covering problems (e.g. [53, 8]) give bicriteria approximations that meet either the covering constraints or the packing constraints but not both. Even without consideration of the objective function, it is not known how to find feasible points to general mixed packing and covering problems in time faster than via exact LP solvers. Alternatively, one may consider the dual of (L), as follows. Let \mathcal{T} denote the family of spanning trees in G .

$$\begin{aligned} \max \quad & (k-1) \sum_T y_T - \sum_{e \in E} z_e \text{ over } y : \mathcal{T} \rightarrow \mathbb{R} \text{ and } z : E \rightarrow \mathbb{R} \\ \text{s.t.} \quad & \sum_{T \ni e} y_T \leq c_e + z_e \text{ for all edges } e, \\ & y_T \geq 0 \text{ for all spanning trees } T \in \mathcal{T}, \\ & z_e \geq 0 \text{ for all edges } e. \end{aligned}$$

This program is not a positive linear program, and the edge potentials $z \in \mathbb{R}_{\geq 0}^E$ are difficult to handle by techniques such as [53, 6, 8]. It was not known, prior to this work, how to obtain any approximation to (L) (better than its integrality gap) with running time faster than the ellipsoid algorithm.

Critically, we consider the following larger LP instead of (L). Let \mathcal{F} denote the family of all forests in G .

$$\begin{aligned} \min \quad & \sum_e c_e x_e \text{ over } x : E \rightarrow \mathbb{R} \\ \text{s.t.} \quad & \sum_{e \in F} x_e \geq |F| + k - n \text{ for all forests } F \in \mathcal{F}, \\ & x_e \geq 0 \text{ for all edges } e \in E. \end{aligned} \tag{C}$$

(C) is also an LP relaxation for k -cut. In fact, (C) is equivalent to (L), as one can verify directly (see Lemma 5 below). (C) is obtained from (L) by adding all the knapsack covering constraints [2], which makes the packing constraints ($x_e \leq 1$ for each edge e) redundant.

Although the LP (C) adds exponentially many constraints to the original LP (L), (C) has the advantage of being a pure covering problem. Its dual is a pure packing problem, as follows.

$$\begin{aligned} & \text{maximize } \sum_{F \in \mathcal{F}} (|F| + k - n) y_F \text{ over } y : \mathcal{F} \rightarrow \mathbb{R} \\ & \text{s.t. } \sum_{F \ni e} y_F \leq c_e \text{ for all edges } e \in E, \\ & y_F \geq 0 \text{ for all forests } F \in \mathcal{F}. \end{aligned} \tag{P}$$

The above LP packs forests into the capacitated graph G where the value of a forest F depends on the number of edges it contains, $|F|$. The objective value $|F| + k - n$ of a forest F is a lower bound on the number of edges F contributes to any k -cut. Clearly, we need only consider forests with at least $n - k + 1$ edges.

To approximate the desired LP (C), we apply the MWU framework to the above LP (P), which generates $(1 \pm \epsilon)$ -multiplicative approximations to both (P) and its dual, (C). Implementing the MWU framework in nearly linear time is not immediate, despite precedent for similar problems. In the special case where $k = 2$, the above LP (P) fractionally packs spanning trees into G . A nearly linear time approximation scheme for $k = 2$ is given in previous work [6]. The general case with $k > 2$ is more difficult for two reasons. First, the family of forests that we pack is larger than the family of spanning trees. Second, (P) is a weighted packing problem, where the coefficients in the objective depends on the number of edges in the forest. When $k = 2$, we need only consider spanning trees with $n - 1$ edges, so all the coefficients are 1 and the packing problem is unweighted. The heterogeneous coefficients in the objective create technical complications in the MWU framework, as the Lagrangian relaxation generated by the framework is no longer solved by a MST. In Section 2, we give an overview of the MWU framework and discuss the algorithmic complications in greater depth. In Section 3 and Section 4, we show how to extend the techniques of [6] with some new observations to overcome these challenges and approximate the LP (P) in nearly the same time as one can approximately pack spanning trees. Ultimately, we obtain the following deterministic algorithm for approximating the LP (P).

► **Theorem 3.** *In $O(m \log^3(n)/\epsilon^2)$ deterministic time, one can compute $(1 \pm \epsilon)$ -multiplicative approximations to (P), (C) and (L).*

The second step, after computing a fractional solution x to (L) with Theorem 3, is to round x to a discrete k -cut. The rounding step is essentially that of Chekuri et al. [4] for Steiner k -cuts. Their case is more general than ours; we simplify their rounding scheme, and pay greater attention to the running time. The rounding scheme is based on the elegant primal-dual MST algorithm of Goemans and Williamson [15].

► **Theorem 4.** *Given a feasible solution x to (C), one can compute a k -cut C with cost at most $2(1 - 1/n)$ times the cost of x in $O(m \log n)$ time.*

Due to space constraints, Theorem 4 is deferred to Appendix A. Applying Theorem 4 to the output of Theorem 3 gives Theorem 2.

Computing the minimum k -cut via the LP (L) has additional benefits. First, computing a minimum k -cut with an approximation factor relative to the LP may be much stronger than the same approximation factor relative to the original problem, as LP's perform well in practice. Second, the solution to the LP gives a certificate of approximation ratio, as we can compare the rounded k -cut to the LP solution to infer an upper bound on the approximation ratio that may be smaller than 2.

Lastly, we note that some data structures can be simplified at the cost of randomization by using a randomized MWU framework instead [8]. These modifications are discussed at the end of Section 4.

1.3 Further related results and discussion

Fixed parameter tractability

The k -cut results reviewed above were focused on either exact polynomial-time algorithms for constant k or $(2 - o(1))$ -approximations in $\text{poly}(k, m, n)$ time, with a particular emphasis on the fastest algorithms in the $\text{poly}(k, m, n)$ time regime. There is also a body of literature concerning fixed parameter tractable algorithms for k -cut. Downey, Estivill-Castro, Fellows, Prieto-Rodriguez, and Rosamond [12] showed that k -cut is $W[1]$ -hard in k even for simple unweighted graphs; $W[1]$ -hardness implies that it is unlikely to obtain a running time of the form $f(k) \text{poly}(m, n)$ for any function f . On the other hand, Kawarabayashi and Thorup [29] showed that k -cut is fixed parameter tractable in the number of edges in the cut. More precisely, Kawarabayashi and Thorup [29] gave a deterministic algorithm that, for a given cardinality $s \in \mathbb{N}$, time, either finds a k -cut with at most s edges or reports that no such cut exists in $O\left(s^{s^{O(s)}} n^2\right)$ time. The running time was improved to $O\left(2^{O(s^2 \log s)} n^4 \log n\right)$ deterministic time and $\tilde{O}\left(2^{O(s) \log k} n^2\right)$ randomized time by Chitnis, Cygan, Hajiaghayi, Pilipczuk, and Pilipczuk [11].

Besides exact parameterized algorithms for k -cut, there is interest in approximation ratios between 1 and 2. Xiao, Cai, and Yao [51] showed that by adjusting the reduction of Saran and Vazirani [46] to use (exact) minimum ℓ -cuts – instead of minimum (2-)cuts, for any choice of $\ell \in \{2, \dots, k-1\}$ – one can obtain $\left(2 - \frac{\ell}{k} + O\left(\frac{\ell^2}{k^2}\right)\right)$ -approximate minimum k -cuts in $n^{O(\ell)}$ time. For sufficiently small $\epsilon > 0$, by setting $\ell \approx \epsilon k$, this gives a $n^{O(\epsilon k)}$ time algorithm for $(2 - \epsilon)$ -approximate minimum cuts.

The hardness results of Downey, Estivill-Castro, Fellows, Prieto-Rodriguez, and Rosamond [12] and Manurangsi [37] do not rule out approximation algorithms with approximation ratio better than 2 and running times of the form $f(k) \text{poly}(m, n)$ (for any function f). Recently, Gupta, Lee, and Li [19] gave a FPT algorithm that, for a particular constant $c \in (0, 1)$, computes a $(2 - c)$ -approximate k -cut in $2^{O(k^6)} \tilde{O}(n^4)$ time. This improves the running time of [51] for $\epsilon = c$ and k greater than some constant. Further improvements by Gupta et al. [20] achieved a deterministic 1.81 approximation in $2^{O(k^2)} n^{O(1)}$ time, and a randomized $(1 + \epsilon)$ -approximation (for any $\epsilon > 0$) in $(k/\epsilon)^{O(k)} n^{k+O(1)}$ time.

Knapsack covering constraints

We were surprised to discover that adding the knapsack covering constraints allowed for *faster* approximation algorithms. Knapsack covering constraints, proposed by Carr et al. [2] in the context of capacitated network design problems, generate a stronger LP whose solutions can be rounded to obtain better approximation factors [2, 31, 32, 3]. However, the larger LP can be much more complicated and is usually more difficult to solve. Recent work obtained a faster approximation scheme for approximating covering integer programs via knapsack covering constraints, but the dependency on ϵ is much worse, and the algorithm has a “weakly nearly linear” running time that suffers from a logarithmic dependency on the multiplicative range of input coefficients [9].

Fast approximations via LP's

Linear programs have long been used to obtain more accurate approximations to NP-Hard problems. Recently, we have explored the use of fast LP solvers to obtain *faster* approximations, including situations where polynomial time algorithms are known. In recent work [7], we used a linear time approximation to an LP relaxation for Metric TSP (obtained in [5]) to effectively sparsify the input and accelerate Christofides' algorithm. While nearly linear time approximations for complicated LP's are surprising in and of itself, perhaps the application to obtain faster approximations for combinatorial problems is more compelling. We think this result is an important data point for this approach.

2 Reviewing the MWU framework and identifying bottlenecks

In this section, let $\epsilon > 0$ be fixed. It suffices to assume that $\epsilon \geq 1/\text{poly}(n)$, since below this point one can use the ellipsoid algorithm instead and still meet the desired running time. For ease of exposition, we seek only a $(1 + O(\epsilon))$ -multiplicative approximation; a $(1 + \epsilon)$ -multiplicative approximation with the same asymptotic running time follows by decreasing ϵ by a constant factor.

2.1 k -cuts as a (pure) covering problem

As discussed above, the first (and most decisive) step towards a fast, fractional approximation to k -cut is identifying the right LP. The standard LP (L) is difficult because it is a mixed packing and covering problem, and fast approximation algorithms for mixed packing and covering problems lead to bicriteria approximations that we do not know how to round. On the other hand, extending (L) with all the knapsack cover constraints makes the packing constraints $x_e \leq 1$ redundant (as shown below), leaving the pure covering problem, (C). The LPs (L) and (C) have essentially equivalent solutions in the following sense.

► **Lemma 5.** *Any feasible solution $x \in \mathbb{R}_{\geq 0}^E$ to (L) is a feasible solution to (C). For any feasible solution x to (C), the truncation $x' \in \mathbb{R}_{\geq 0}^E$ defined by $x'_e = \max\{x_e, 1\}$ is a feasible solution to both (L) and (C).*

Proof. Let x be a feasible solution to (L). We claim that x is feasible in (C). Indeed, let F be a forest, and extend F to a tree T . Then

$$\sum_{e \in F} x_e = \sum_{e \in T} x_e - \sum_{e \in T \setminus F} x_e \geq k - 1 - |T \setminus F| = k - 1 - (n - 1 - |F|) = |F| + k - n,$$

as desired.

Conversely, let $x \in \mathbb{R}_{\geq 0}^E$ be a feasible solution to (C), and let x' be the coordinatewise maximum of x and $\mathbb{1}$. Since $x' \leq \mathbb{1}$, and the covering constraints in (L) are a subset of the covering constraints in (C), if x' is feasible in (C) then it is also feasible in (L). To show that x' is feasible in (C), let F be a forest. Let $F' = \{e \in F : x_e > 1\}$ be the edges in F truncated by x' and let $F'' = F \setminus F'$ be the remaining edges. Since (a) $x'_e = 1$ for all $e \in F'$ and $x'_e = x_e$ for all $e \in F''$, and (b) x covers F'' in (C), we have

$$\sum_{e \in F} x'_e = \sum_{e \in F'} x'_e + \sum_{e \in F''} x'_e \stackrel{(a)}{=} |F'| + \sum_{e \in F''} x_e \stackrel{(b)}{\geq} |F'| + |F''| + k - n = |F| + k - n,$$

as desired. ◀

While having many more constraints than (L), (C) is a pure covering problem, for which finding a feasible point (faster than an exact LP solver) is at least plausible. The dual of (C) is the LP (P), which packs forests in the graph and weights each forest by the number of edges minus $(n - k)$. The coefficient of a forest in the objective of (P) can be interpreted as the number of edges that forest must contribute to any k -cut.

2.2 A brief sketch of width-independent MWU

We apply a *width-independent* version of the MWU framework to the packing LP (P), developed by Garg and Könemann [14] for multicommodity flow problems and generalized by Young [52]. We restrict ourselves to a sketch of the framework and refer to previous work for further details.

The width-independent MWU framework is a monotonic and iterative algorithm that starts with an empty solution $y = 0$ to the LP (P) and increases y along forests that solve certain Lagrangian relaxations to (P). Each Lagrangian relaxation is designed to steer y away from packing forests that have edges that are already tightly packed. For each edge e , the framework maintains a weight w_e that (approximately) exponentiates the load of edge e w/r/t the current forest packing y , as follows:

$$\ln(c_e w_e) \approx \frac{\log n}{\epsilon} \frac{\sum_{F \ni e} y_F}{c_e}. \quad (1)$$

The weight can be interpreted as follows. For an edge e , the value $\frac{\sum_{F \ni e} y_F}{c_e}$ is the amount of capacity used by the current packing y relative to the capacity of the edge e . We call $\frac{\sum_{F \ni e} y_F}{c_e}$ the (relative) *load* on edge e and is ≤ 1 if y is a feasible packing. The weight w_e is exponential in the load on the edge, where the exponential is amplified by the leading coefficient $\frac{\log n}{\epsilon}$. Initially, the empty solution $y = \emptyset$ induces zero load on any edge and we have $w_e = \frac{1}{c_e}$ for each edge e .

Each iteration, the framework solves the following Lagrangian relaxation of (P):

$$\text{maximize } \sum_{F \in \mathcal{F}} (|F| + k - n) z_F \text{ over } z : \mathcal{F} \rightarrow \mathbb{R}_{\geq 0} \text{ s.t. } \sum_{e \in E} w_e \sum_{F \ni e} z_F \leq \sum_{e \in E} w_e c_e. \quad (\text{R})$$

Given a $(1 + O(\epsilon))$ -approximate solution z to the above, the framework adds δz to y for a carefully chosen value $\delta > 0$ (discussed in greater detail below). The next iteration encounters a different relaxation, where the edge weights w_e are increased to account for the loads increased by adding δz . Note that the edge weights w_e are monotonically increasing over the course of the algorithm.

At the end of the algorithm, standard analysis shows that the fractional forest packing y has objective value $(1 - O(\epsilon)) \text{OPT}$, and that $(1 - O(\epsilon))y$ satisfies all of the packing constraints. The error can be made one-sided by scaling y up or down. Moreover, it can be shown that at some point in the algorithm, an easily computable rescaling of w is a $(1 + O(\epsilon))$ -relative approximation for the desired LP (C) (see for example [13, 14, 5]). Thus, although we may appear more interested in solving the dual LP (P), we are approximating the desired LP (C) as well.

The choice of δ differentiates this “width-independent” MWU from other MWU-type algorithms in the literature. The step size δ is chosen small enough that no weight increases by more than an $\exp(\epsilon)$ -multiplicative factor, and large enough that some weight increases by (about) an $\exp(\epsilon)$ -multiplicative factor. The analysis of the MWU framework reveals that $\langle w, c \rangle \leq n^{O(1/\epsilon)}$ at all times. In particular, each weight can increase by an $\exp(\epsilon)$ -multiplicative factor at most $O(\frac{\ln n}{\epsilon^2})$ times, so there are at most $O(\frac{n \ln n}{\epsilon^2})$ iterations total.

2.3 Two bottlenecks

The MWU framework alternates between (a) solving the relaxation (R) induced by edge weights w_e and (b) updating the weights w_e for each edge in response to the solution to the relaxation. As the framework requires $O\left(\frac{m \log n}{\epsilon^2}\right)$ iterations, both parts must be implemented in polylogarithmic amortized time to reach the desired running time. A sublinear per-iteration running time seems unlikely by the following simple observations.

Consider first the complexity of simply expressing a solution. Any solution z to (R) is indexed by forests in G . A forest can have $\Omega(n)$ edges and requires $\Omega(n \log n)$ bits to specify. Writing down the index of just one forest in each of $O\left(\frac{m \log n}{\epsilon^2}\right)$ iterations takes $O\left(\frac{mn \log^2 n}{\epsilon^2}\right)$ time. The difficulty of even writing down a solution to (P) is not just a feature of the MWU framework. In general, there exists an optimal solution to (P) that is supported by at most m forests, as m is the rank of the implicit packing matrix. Writing down m forests also requires $\Omega(mn \log n)$ bits. Thus, either on a per-iteration basis in the MWU framework or w/r/t to the entire LP, the complexity of the output suggests a quadratic lower bound on the running time.

A second type of bottleneck arises from updating the weights. The weights w_e for each edge reflect the load induced by the packing y , per the formula (1). After computing a solution z to the relaxation (R), and updating $y \leftarrow y + \delta z$, we need to update the weights w_e to reflect the increased load from δz . In the worst case, δz packs into every edge, requiring us to update $O(m)$ individual weights. At the very least, δz should pack into the edges of at least one forest, and thus effect $\Omega(n)$ edges. Updating n edge weights in each iteration requires $O\left(\frac{mn \log n}{\epsilon^2}\right)$ time.

Even in hindsight, implementing either part – solving the relaxation or updating the weights – in isolation in sublinear time remains difficult. Our algorithm carefully plays both parts off each other, as co-routines, and amortizes against invariants revealed by the analysis of the MWU framework. The seemingly necessary dependence between parts is an important theme of this work and an ongoing theme from previous work [6, 5, 9].

3 Greedily finding forests to pack in $O(\log^2 n)$ amortized time

The MWU framework reduces (P) to a sequence of problems of the form (R). An important aspect of the Lagrangian approach is that satisfying the single packing constraint in (R) is much simpler than simultaneously satisfying all of the packing constraints in (P). With only 1 packing constraint, it suffices to (approximately) identify the best bang-for-buck forest F and taking as much as can fit in the packing constraint. The “bang-for-buck” ratio of a forest F is the ratio

$$\frac{|F| + k - n}{\sum_{e \in F} w_e},$$

where $|F|$ is the number of edges in F . Given a forest F (approximately) maximizing the above ratio, we set $z = \gamma e_F$ for γ as large as possible as fits in the single packing constraint. Note that, when $k = 2$, the optimal forest is the minimum weight spanning tree w/r/t w .

We first consider the simpler problem of maximizing the above ratio over forests F with exactly $|F| = \ell$ edges, for some $\ell > n - k$. Recall that the MST can be computed greedily by repeatedly adding the minimum weight edge that does not induce a cycle. Optimality of the greedy algorithm follows from the fact that spanning trees are the bases of a matroid called the *graphic matroid*. The forests of exactly ℓ edges are also the bases of a matroid; namely,

23:10 Fast and Deterministic Approximations for k -Cut

the restriction of the graphic matroid to forests of at most ℓ edges. In particular, the same greedy procedure computes the minimum weight forest of ℓ edges. Repeating the greedy algorithm for each choice of ℓ , one can solve (R) in $O(km \log n)$ time for each of $O\left(\frac{m \log n}{\epsilon^2}\right)$ iterations.

Stepping back, we want to compute the minimum weight forest with ℓ edges for a range of $k - 1$ values of ℓ , and we can run the greedy algorithm for each choice of ℓ . We observe that the greedy algorithm is oblivious to the parameter ℓ , except for deciding when to stop. We can run the greedy algorithm *once* to build the MST, and then simulate the greedy algorithm for any value of ℓ by taking the first ℓ edges added to the MST.

► **Lemma 6.** *Let T be the minimum weight spanning tree w/r/t w . For any $\ell \in [n - 1]$, the minimum weight forest w/r/t w with ℓ edges consists of the first ℓ minimum weight edges of T .*

Lemma 6 effectively reduces (R) to one MST computation, which takes $O(m \log n)$ time. Repeated over $O\left(\frac{m \log n}{\epsilon^2}\right)$ iterations, this leads to a $O\left(\frac{m^2 \log^2 n}{\epsilon^2}\right)$ running time. As observed previously [49, 6], the minimum weight spanning tree does not have to be rebuilt from scratch from one iteration to another, but rather adjusted dynamically as the weights change.

► **Lemma 7** (Holm, de Lichtenberg, and Thorup [25]). *In $O(\log^2 n)$ amortized time per increment to w , one can maintain the MST w/r/t w .*

The running time of Lemma 7 depends on the number of times the edge weights change, so we want to limit the number of weight updates exposed to Lemma 7. It is easy to see that solving (R) w/r/t a second set of weights \tilde{w} that is a $(1 \pm \epsilon)$ -multiplicative factor coordinate-wise approximation of w gives a solution that is a $(1 \pm \epsilon)$ -multiplicative approximation to (R) w/r/t w . We maintain the MST w/r/t an approximation \tilde{w} of w , and only propagate changes from w to \tilde{w} when w is greater than \tilde{w} by at least a $(1 + \epsilon)$ -multiplicative factor. As mentioned in Section 2, a weight w_e increases by a $(1 + \epsilon)$ -multiplicative factor at most $O\left(\frac{\log n}{\epsilon^2}\right)$ times. Applying Lemma 7 to the discretized weights \tilde{w} and amortizing against the total growth of weights in the system gives us the following.

► **Lemma 8.** *In $O\left(\frac{m \log^3 n}{\epsilon^2}\right)$ total time, one can maintain the MST w/r/t a set of weights \tilde{w} such that, for all $e \in E$, we have $\tilde{w}_e \in (1 \pm \epsilon)w_e$. Moreover, the MST makes at most $O\left(\frac{m \log n}{\epsilon^2}\right)$ edge updates total.*

Given such an MST T as above, and $\ell \in \{n - k + 1, \dots, n - 1\}$ we need the ℓ minimum (\tilde{w} -)weight edges to form an (approximately) minimum weight forest F of ℓ edges. However, the data structure of Lemma 7 does not provide a list of edges in increasing order of weight. We maintain the edges in sorted order separately, where each time the dynamic MST replaces one edge with another, we make the same update in the sorted list. Clearly, such a list can be maintained in $O(\log n)$ time per update by dynamic trees. Our setting is simpler because the range of possible values of any weight \tilde{w}_e is known in advance as follows. For $e \in E$, define

$$\mathcal{W}_e = \left\{ \frac{(1 + \epsilon)^i}{c_e} : i \in \left\{ 0, 1, \dots, O\left(\frac{\log n}{\epsilon^2}\right) \right\} \right\}.$$

Then $\tilde{w}_e \in \mathcal{W}_e$ for all $e \in E$ at all times. Define $\mathcal{L} = \{(e, \alpha) : \alpha \in \mathcal{W}_e\}$. The set \mathcal{L} represents the set of all possible assignments of weights to edges that may arise. As mentioned above, $|\mathcal{L}| = O\left(\frac{m \log n}{\epsilon^2}\right)$. Let B be a balanced binary tree over \mathcal{L} , where \mathcal{L} is sorted by increasing

order of the second coordinate \tilde{w}_e (and ties are broken arbitrarily). The tree B has height $\log|\mathcal{L}| = O(\log m)$ and can be built in $O(|\mathcal{L}|) = O\left(\frac{m \log n}{\epsilon^2}\right)$ time¹.

We mark the leaves based on the edges in T . Every time the MST T adds an edge e of weight \tilde{w}_e , we mark the corresponding leaf (e, \tilde{w}_e) as marked. When an edge e is deleted, we unmark the corresponding leaf. Lastly, when an edge $e \in T$ has its weight increased from α to α' , we unmark the leaf (e, α) and mark the leaf (e, α') . Note that only edges in T have their weight changed.

For each subtree of T , we track aggregate information and maintain data structures over the set of all marked leaves in the subtree. For a node b in B , let \mathcal{L}_b be the set of marked leaves in the subtree rooted at b . For each $b \in B$ we maintain two quantities: (a) the number of leaves marked in the subtree rooted at b , $|\mathcal{L}_b|$; and (b) the sum of edges weights of leaves marked in the subtree rooted at b , $W_b = \sum_{(e, \alpha) \in \mathcal{L}_b} \alpha$. Since the height of B is $O(\log n)$, both of these quantities can be maintained in $O(\log n)$ time per weight update.

► **Lemma 9.** *In $O(m \log(n)/\epsilon^2)$ time initially and $O(\log n)$ time per weight update, one can maintain a data structure that, given $\ell \in [n-1]$, returns in $O(\log n)$ time (a) the ℓ minimum weight edges of the MST (implicitly), and (b) the total weight of the first ℓ edges of the MST.*

With Lemma 7 and Lemma 9, we can now compute, for any $\ell \in [n-1]$, a $(1+\epsilon)$ -approximation to the minimum weight forest of ℓ edges, along with the sum weight of the forest, both in logarithmic time. To find the best forest, then, we need only query the data structure for each of the $k-1$ integer values from $n-k+1$ to $n-1$. That is, excluding the time to maintain the data structures, we can now solve the relaxation (R) in $O(k \log n)$ time per iteration.

At this point, we still require $O(km \log n)$ time just to solve the Lagrangian relaxations (R) generated by the MWU framework. (There are other bottlenecks, such as updating the weights at each iteration, that we have not yet addressed.) To remove the factor of k in solving (R), we require one final observation.

► **Lemma 10.** *The minimum ratio subforest of T can be found by binary search.*

Proof. Enumerate the MST edges $e_1, \dots, e_{n-1} \in T$ in increasing order of weight. For ease of notation, we denote $\tilde{w}_i = \tilde{w}_{e_i}$ for $i \in [n-1]$. We define a function $f : [k-1] \rightarrow \mathbb{R}_{>0}$ by

$$f(i) = \frac{i}{\sum_{j=1}^{n-k+i} \tilde{w}_j}.$$

For each i , $f(i)$ is the ratio achieved by the first $n-k+i$ edges of the MST. Our goal is to maximize $f(i)$ over $i \in [k-1]$. For any $i \in [k-2]$, we have

$$\begin{aligned} f(i+1) - f(i) &= \frac{i+1}{\sum_{j=1}^{n-k+i+1} \tilde{w}_j} - \frac{i}{\sum_{j=1}^{n-k+i} \tilde{w}_j} \\ &= \frac{(i+1) \sum_{j=1}^{n-k+i} \tilde{w}_j - i \sum_{j=1}^{n-k+i+1} \tilde{w}_j}{\left(\sum_{j=1}^{n-k+i+1} \tilde{w}_j\right) \left(\sum_{j=1}^{n-k+i} \tilde{w}_j\right)} = \frac{\sum_{j=1}^{n-k+i} \tilde{w}_j - i \tilde{w}_{n-k+i+1}}{\left(\sum_{j=1}^{n-k+i+1} \tilde{w}_j\right) \left(\sum_{j=1}^{n-k+i} \tilde{w}_j\right)}. \end{aligned}$$

Since the denominator $\left(\sum_{j=1}^{n-k+i+1} \tilde{w}_j\right) \left(\sum_{j=1}^{n-k+i} \tilde{w}_j\right)$ is positive, we have $f(i+1) \leq f(i) \iff i \tilde{w}_{n-k+i+1} \geq \sum_{j=1}^{n-k+i} \tilde{w}_j$. If $i \tilde{w}_{n-k+i+1} \geq \sum_{j=1}^{n-k+i} \tilde{w}_j$ for all $i \in [k-2]$, then $f(1) < f(2) <$

¹ or even less time if we build B lazily, but constructing B is not a bottleneck

23:12 Fast and Deterministic Approximations for k -Cut

$\dots < f(k-1)$, so $f(i)$ is maximized by $i = k-1$. Otherwise, let $i_0 \in [k-2]$ be the first value of i such that $f(i+1) \leq f(i)$. For $i_1 \geq i_0$, as (c) \tilde{w}_{e_i} is increasing in i , (d) $f(i_0+1) \leq f(i_0)$, we have

$$\begin{aligned} \sum_{j=1}^{n-k+i_1} \tilde{w}_j - i_1 w_{n-k+i_1+1} &= \sum_{j=1}^{n-k+i_0} \tilde{w}_j - i_0 \tilde{w}_{n-k+i_1+1} + \sum_{j=n-k+i_0+1}^{n-k+i_1} \tilde{w}_j - (i_1 - i_0) \tilde{w}_{n-k+i_1+1} \\ &\stackrel{(c)}{\leq} \sum_{j=1}^{n-k+i_0} \tilde{w}_j - i_0 \tilde{w}_{n-k+i_0+1} \stackrel{(d)}{\leq} 0. \end{aligned}$$

That is, $f(i_1+1) \leq f(i_1)$ for all $i_1 \geq i_0$. Thus f consists of one increasing subsequence followed by a decreasing subsequence, and its global maximum is the unique local maximum. \blacktriangleleft

By Lemma 10, the choice of ℓ can be found by calculating the ratio of $O(\log k)$ candidate forests. By Lemma 9, the ratio of a candidate forest can be computed in $O(\log n)$ time.

► **Lemma 11.** *Given the data structure of Lemma 9, one can compute a $(1 + O(\epsilon))$ -multiplicative approximation to (R) in $O(\log n \log k)$ time.*

The polylogarithmic running time in Lemma 11 is surprising when considering that solutions to (R) should require at least a linear number of bits, as discussed earlier in Section 2.3. In hindsight, a combination of additional structure provided by the MWU framework and the LP (P) allows us to apply data structures that effectively compress the forests and output each forest in polylogarithmic amortized time. Implicit compression of this sort also appears in previous work [6, 5, 9].

4 Packing greedy forests in $O(\log^2 n)$ amortized time

In Section 3, we showed how to solve (R) in polylogarithmic time per iteration. In this section, we address the second main bottleneck: updating the weights w after increasing y to $y + \delta z$ per the formula (1), where z is an approximate solution to the relaxation (R) and $\delta > 0$ is the largest possible value such that no weight increases by more than a $(1 + \epsilon)$ -multiplicative factor. As discussed in Section 2.3, this may be hard to do in polylogarithmic time when many of the edges $e \in E$ require updating.

A sublinear time weight update must depend heavily on the structure of the solutions generated to (R). In our case, each solution z to a relaxation (R) is of the form γe_F , where e_F is the indicator vector of a forest F and $\gamma > 0$ is a scalar as large as possible subject to the packing constraint in (R). We need to update the weights to reflect the loads induced by $\delta z = \delta \gamma e_F$, where δ is chosen large as possible so that no weight increases by more than an $\exp(\epsilon)$ -multiplicative factor. With this choice of δ , the weight update simplifies to the following formula. Let w denote the set of weights before the updates and w' denote the set of weights after the updates. For a solution $z = \gamma e_F$, we have

$$w'_e = \begin{cases} w_e & \text{if } e \notin F, \\ \exp\left(\frac{\epsilon \min_{f \in F} c_f}{c_e}\right) & \text{if } e \in F. \end{cases} \quad (2)$$

The weight update formula above can be interpreted as follows. Because our solution is supported along a single forest F , the only edges whose loads are effected are those in the forest F . As load is relative to the capacity of an edge e , the increase of the logarithm the weight w_e of an edge $e \in F$ is inversely proportional to its capacity. By choice of δ , the

minimum capacity edge $\arg \min_{f \in F} c_f$ has its weight increased by an $\exp(\epsilon)$ multiplicative factor. The remaining edges with larger capacity each have the logarithm of their weight increased in proportion to the ratio of the bottleneck capacity to its own capacity.

Simplifying the weight update formula does not address the basic problem of updating the weights of every edge in a forest F , *without visiting every edge in F* . Here we require substantially more structure as to how the edges in F are selected. We observe that although there may be $\Omega(n)$ edges in F , we can always decompose F into a logarithmic number of “canonical subforests”, as follows.

► **Lemma 12.** *One can maintain, in $O(\log n)$ time per update to the MST T , a collection of subforests $\mathcal{C}_T \subseteq \mathcal{F}$ such that:*

- (i) $|\mathcal{C}_T| = O(n \log n)$.
- (ii) *Each edge $e \in T$ is contained in $O(\log n)$ forests.*
- (iii) *For each $\ell \in [n - 1]$, the forest F consisting of the ℓ minimum weight edges in T decomposes uniquely into the disjoint union of $O(\log n)$ forests in \mathcal{C}_T . The decomposition can be computed in $O(\log n)$ time.*

In fact, the collection of subforests is already maintained implicitly in Lemma 9. Recall, from Section 3, the balanced binary tree B over the leaf set \mathcal{L} , which consists of all possible discretized weight-to-edge assignments and is ordered in increasing order of weight. Leaves are marked according to the edges in the MST T , and each node is identified with the forest consisting of all marked leaves in the subtree rooted at the node. For each $\ell \in [n - 1]$, the forest F_ℓ induced by the ℓ minimum weight edges in T is the set of marked leaves over an interval of \mathcal{L} . The interval decomposes into the disjoint union of leaves of $O(\log n)$ subtrees, which corresponds to decomposing F_ℓ into the disjoint union of marked leaves of $O(\log n)$ subtrees of B . That is, the forests of marked leaves induced by subtrees of B gives the “canonical forests” \mathcal{C}_T that we seek.

The following technique of decomposing weight updates is critical to previous work [6, 5, 9]; we briefly discuss the high-level ideas and refer to previous work for complete details.

Decomposing the solution into a small number of known static sets is important because weight updates can be simulated over a *fixed set* efficiently. The data structure `lazy-inc`, defined in [6] and inspired by techniques by Young [53], simulates a weight update over a fixed set of weights in such a way that the time can be amortized against the logarithm of the increase in each of the weights. As discussed above, the total logarithmic increase in each of the weights is bounded from above. The data structure `lazy-inc` is dynamic, allowing insertion and deletion into the underlying set, in $O(\log n)$ time per insertion or deletion [5].

We define an instance of `lazy-inc` at each node in the balanced binary tree B . Whenever a leaf is marked as occupied, the corresponding edge is inserted into each of $O(\log n)$ instances of `lazy-inc` at the ancestors of the leaf; when a leaf is marked as unoccupied, it is removed from each of these instances as well. Each instance of `lazy-inc` can then simulate a weight update over the marked leaves at its nodes in $O(1)$ constant time per instance, plus a total $O(\log n)$ amortized time. More precisely, the additional time is amortized against the sum of increases in the logarithms of the weights, which (as discussed earlier) is bounded above by $O(m \log(n)/\epsilon^2)$.

We also track, for each canonical forest, the minimum capacity of any edge in the forest. The minimum capacity ultimately controls the rate at which all the other edges increase, per (2).

Given a forest F induced by the ℓ minimum weight edges of T , we decompose F into the disjoint union of $O(\log n)$ canonical subforests of T . For each subforest we have precomputed the minimum capacity, and an instance of `lazy-inc` that simulates weight updates on all

edges in the subforest. The minimum capacity over edges in F determines the rate of increase, and the increase is made to each instance of `lazy-inc` in $O(1)$ time per instance plus $O(\log n)$ amortized time over all instances.

► **Lemma 13.** *Given a forest F generated by Lemma 11, one can update the edge weights per (2) in $O(\log^2 n)$ amortized time per iteration.*

Note that Lemma 13 holds only for the forests output by Lemma 11. We can not decompose other forests in G , or even other subforests of T , into the disjoint union $O(\log n)$ subforests. Lemma 12 holds specifically for the forests induced by the ℓ minimum weight edges of T , for varying values of ℓ . This limitation highlights the importance of coupling the oracle and the weight update: the running time in Lemma 11 for solving (R) is amortized against the growth of the weights, and the weight updates in Lemma 13 leverage the specific structure by which solutions to (R) are generated.

We note that the `lazy-inc` data structures can be replaced by random sampling in the randomized MWU framework [8]. Here one still requires the decomposition into canonical subforests; an efficient threshold-based sampling is then conducted at each subforest.

5 Putting things together

In this section, we summarize the main points of the algorithm and account for the running time claimed in Theorem 3.

Proof of Theorem 3. By standard analysis (e.g., [6, Theorem 2.1]), the MWU framework returns a $(1 - O(\epsilon))$ -multiplicative approximation to the packing LP (P) as long as we can approximate the relaxation (R) to within a $(1 - O(\epsilon))$ -multiplicative factor. This slack allows us to maintain the weight w_e to within a $(1 \pm O(\epsilon))$ -multiplicative factor of the “true weights” given (up to a leading constant) by (1). In particular, we only propagate a change to w_e when it has increased by a $(1 + \epsilon)$ -multiplicative factor. Each weight w_e is monotonically increasing and its growth is bounded by a $m^{O(\frac{1}{\epsilon})}$ -multiplicative factor, so each weight w_e increases by a $(1 + \epsilon)$ -multiplicative factor $O\left(\frac{\log m}{\epsilon^2}\right)$ times.

By Lemma 11, each instance of (R) can be solved in $O(\log^2 n)$ amortized time. Here the running time is amortized against the number of weight updates, as the solution can be updated dynamically in $O(\log^2 n)$ amortized time. By Lemma 13, the weight update w/r/t a solution generated by Lemma 11 can be implemented in $O(\log^2 n)$ amortized time. Here again the running time is amortized against the growth of the edge weights. Since there are $O\left(\frac{m \log n}{\epsilon^2}\right)$ total edge updates, this gives a total running time of $O\left(\frac{m \log^3 n}{\epsilon^2}\right)$. ◀

A Rounding fractional forest packings to k -cuts

In this section, we show how to round a fractional solution x to (L) a k -cut of cost at most twice the cost of x . The rounding scheme is due to Chekuri et al. [4] for the more general problem of Steiner k -cuts. The rounding scheme extends the primal-dual framework of Goemans and Williamson [15, 16]. In hindsight, we realized the primal-dual framework is only required for the analysis, and that the algorithm itself is very simple.

23:18 Fast and Deterministic Approximations for k -Cut

We first give a conceptual description of the algorithm, called **greedy-cuts**. The conceptual description suffices for the sake of analyzing the approximation guarantee. Later, we give implementation details and demonstrate that it can be executed in $O(m \log n)$ time.

To describe the algorithm, we first introduce the following definitions.

► **Definition 14.** Let F be a minimum weight spanning forest in a weighted, undirected graph, and order the edges of F in increasing order of weight (breaking ties arbitrarily). A greedy component of F is a connected component induced by a prefix of F . A greedy cut is a cut induced by a greedy component of F .

■ **Algorithm 1** A conceptual sketch of a deterministic rounding algorithm for k -cut.

```

greedy-cuts( $G = (V, E), c, x$ )

// conceptual sketch
1. let  $E' = \{e \in E : x_e \geq \frac{n-1}{2n}\}$ ,  $E \leftarrow E \setminus E'$ 
2. if  $E'$  is a  $k$ -cut then return  $E'$ 
3. let  $F$  be a minimum weight spanning forest in  $E$  w/r/t  $x$  w/  $\ell$  components
4. return the union of  $E'$  and the  $k - \ell$  minimum weight greedy cuts of  $F$ 

```

The rounding algorithm is conceptually very simple and a pseudocode sketch is given in Algorithm 1. We first take all the edges with $x_e > 1/2 + o(1)$. If this is already a k -cut, then it is a 2-approximation because the corresponding indicator vector is $\leq (2 - o(1))x$. Otherwise, we compute the minimum spanning forest F in the remaining graph, where the weight of an edge is given by x . Letting ℓ be number of components of F , we compute the $k - \ell$ minimum weight greedy cuts w/r/t F . We output the union of E' and the $k - \ell$ greedy cuts.

Chekuri, Guha, and Naor [4] implicitly showed that this algorithm has an approximation factor of $2(1 - 1/n)$. Their analysis is for the more general Steiner k -cut problem, where we are given a set of terminal vertices T , and want to find the minimum weight set of edges whose removal divides the graph into at least k components each containing a terminal vertex $t \in T$. The algorithm and analysis is based on the primal-dual framework of Goemans and Williamson [15, 16]. For the minimum weight Steiner tree problem, the primal-dual framework returns a Steiner tree and a feasible fractional cut packing in the dual LP. The cost of the Steiner cut packing is within a $2(1 - o(1))$ -multiplicative factor of the corresponding Steiner tree. Via LP duality, the Steiner tree and the cut packing mutually certify an approximation ratio of $2(1 - o(1))$. The cut packing certificate has other nice properties, and Chekuri, Guha, and Naor [4] show that the $k - 1$ minimum cuts in the support of the fractional cut packing give a 2-approximate Steiner k -cut.

For the (non-Steiner) k -cut problem, we want minimum cuts in the support of the fractional cut packing returned by the primal-dual framework applied to minimum spanning forests. To shorten the algorithm, we observe that (a) the primal-dual framework returns the minimum spanning forest, and (b) the cuts supported by the corresponding dual certificate are precisely the greedy cuts of the minimum spanning forest. Thus **greedy-cuts** essentially refactors the algorithm analyzed by Chekuri et al. [4].

► **Lemma 15** ([4]). **greedy-cuts** returns a k -cut of weight at most $2(1 - \frac{1}{n})\langle c, x \rangle$.

The connection to Chekuri et al. [4] is not explicitly clear because Chekuri et al. [4] rounded a slightly more complicated LP. The complication arises from the difficulty of solving (L)

directly for Steiner k -cut (which can be simplified by knapsack covering constraints, in hindsight). Morally, however, their proof extends to our setting here. For the sake of completeness, a proof of Lemma 15 is included in Appendix B.

■ **Algorithm 2** A detailed implementation of a deterministic rounding algorithm for k -cut.

```

greedy-cuts( $G = (V, E), c, x$ )
1. let  $E' = \{e \in E : x_e \geq \frac{n-1}{2n}\}$ ,  $E \leftarrow E \setminus E'$ 
2. if  $E'$  is a  $k$ -cut then return  $E'$ 
3. let  $F$  be a minimum weight spanning forest in  $E$  w/r/t  $x$  w/  $\ell$  components
// Arrange the greedily induced components as subtrees of a dynamic forest
4. for each  $v \in V$ 
    A. make a singleton tree labeled by  $v$ 
5. for each edge  $f = \{u, v\} \in F$  in increasing order of  $x_f$ 
    A. let  $T_u$  and  $T_v$  be the rooted trees containing  $u$  and  $v$ , respectively.
    B. make  $T_u$  and  $T_v$  children of a new vertex labeled by  $f$ 
// Compute the weight of each cut induced by a greedy component.
6. let each node in the dynamic forest have value 0
7. for each edge  $e = \{u, v\} \in E$ 
    A. add  $x_e$  to the value of every node on the  $u$ -to-root and  $v$ -to-root paths
    B. let  $w$  be the least common ancestor  $u$  and  $v$ 
    C. subtract  $2x_e$  from the value of every node on the  $w$  to root paths
8. let  $v_1, v_2, \dots, v_{k-\ell}$  be the  $k - \ell$  minimum value nodes in the dynamic forest.
   For  $i \in [k - \ell]$ , let  $C_i$  be the components induced by the leaves in the
   subtree rooted by  $v_i$ .
9. return  $E' \cup \partial(C_1) \cup \dots \cup \partial(C_{k-\ell})$ 

```

It remains to implement `greedy-cuts` in $O(m \log n)$ time. With the help of dynamic trees [47], this can be done in a straightforward fashion. We briefly describe the full implementation; pseudocode is given in Algorithm 2. Recall from the conceptual sketch above that `greedy-cuts` requires up to $k - 1$ minimum greedy cuts of a minimum spanning forest w/r/t x . To compute the value of these cuts, `greedy-cuts` first simulates the greedy algorithm by processing the edges in the spanning forest in increasing order of x . The greedy algorithm repeatedly adds an edge that bridges two greedy components. We assemble an auxiliary forest of dynamic trees where each leaf is a vertex, and each subtree corresponds to a greedy component induced by the vertices at the leaves of the subtree.

After building this dynamic forest, we compute the number of edges in each cut. We associate each node in the dynamic forest with the greedy component induced by its leaves, and given each node an initial value of 0. We process edges one at a time and add its weight to the value of every node corresponding to a greedy component cutting that edge. Now, an edge in the original graph is cut by a greedy component iff the corresponding subtree in the dynamic forest does not contain both its end points as leaves. We compute the least common ancestor of the endpoints in the dynamic forest in $O(\log n)$ time [23], and add the weight of edge to every node between the leaves and the common ancestor, excluding the common ancestor. Adding the weight to every node on a node-to-root path takes $O(\log n)$ time [47] in dynamic trees. After processing every edge, we simply read off the value of each greedy cut as the value of the corresponding node in the forest. Thus we have the following.

► **Lemma 16.** *greedy-cuts can be implemented in $O(m \log n)$ time.*

Together, Lemma 15 and Lemma 16 imply Theorem 4.

B Proofs for Appendix A

Chekuri et al. [4] gave a rounding scheme for the more general problem of Steiner k -cut and the analysis extends to the rounding schemes presented here. We provide a brief sketch for the sake of completeness as there are some slight technical gaps. The proof is simpler and more direct in our setting because we have a direct fractional solution to (L), while Chekuri et al. [4] dealt with a solution to a slightly more complicated LP. We note that our analysis also extends to Steiner cuts. We take as a starting point the existence of a dual certificate from the primal-dual framework.

► **Lemma 17** ([15, 16]). *Let F be a minimum spanning forest in a undirected graph $G = (V, E)$ weighted by $x \in \mathbb{R}_{\geq 0}^{E'}$. Let \mathcal{C} be the family of greedy cuts induced by F . Then there exists $y \in \mathbb{R}_{\geq 0}^{\mathcal{C}}$ satisfying the following properties.²*

- (a) For each edge $e \in E$, $\sum_{C \in \mathcal{C}: C \ni e} y_C \leq x_e$.
- (b) For each edge $e \in F$, $\sum_{C \in \mathcal{C}: C \ni e} y_C = x_e$.
- (c) $2\left(1 - \frac{1}{n}\right)\langle y, \mathbb{1} \rangle \geq \sum_{e \in F} x_e$.

We note that the dual variables y can be computed in $O(n)$ time (after computing the minimum spanning forest).

► **Lemma 18** ([4]). *greedy-cuts returns a k -cut with total cost $\leq 2\left(1 - \frac{1}{n}\right)\langle c, x \rangle$.*

Proof sketch. Let y be as in Lemma 17. We first make two observations about y . First, since $x_e \leq \frac{n}{2(n-1)}$ for all $e \in E'$, we have (by property (a) of Lemma 17) that $y_C \leq \frac{n}{2(n-1)}$ for all greedy cuts C . Second, by (e) property (c) of Lemma 17 and (f) the feasibility of x w/r/t the k -cut LP (L), we have

$$2\left(1 - \frac{1}{n}\right)\langle y, \mathbb{1} \rangle \stackrel{(e)}{\geq} \sum_{e \in T} x_e \stackrel{(f)}{\geq} k - 1.$$

Let C_1, \dots, C_{k-1} be the $k - 1$ minimum greedy cuts. Now, by (g) rewriting the sum of the $k - 1$ minimum greedy cuts as the solution of a minimization problem, (h) observing that $2\left(1 - \frac{1}{n}\right)y$ is a feasible solution to the minimization problem, (i) interchanging sums, and (j) property (a) of Lemma 17, we have

$$\begin{aligned} & \sum_{i=1}^{k-1} \bar{c}(C_i) \stackrel{(g)}{\leq} \min\{\langle y', \bar{c} \rangle : 0 \leq y' \leq \mathbb{1}, \text{support}(y') \subseteq \text{support}(y), \text{ and } \|y'\|_1 \geq k - 1\} \\ & \stackrel{(h)}{\leq} 2\left(1 - \frac{1}{n}\right)\langle y, \bar{c} \rangle = \sum_C y_C \sum_{e \in C} c_e \stackrel{(i)}{=} \sum_{e \in E'} c_e \sum_{C \ni e} y_C \stackrel{(j)}{\leq} \sum_{e \in E'} c_e x_e, \end{aligned}$$

as desired. ◀

² Here we do not require property (b), but we mention it anyway because it is important in other applications.

Global Cardinality Constraints Make Approximating Some Max-2-CSPs Harder

Abstract

Assuming the Unique Games Conjecture, we show that existing approximation algorithms for some Boolean Max-2-CSPs with cardinality constraints are optimal. In particular, we prove that Max-Cut with cardinality constraints is UG-hard to approximate within ≈ 0.858 , and that Max-2-Sat with cardinality constraints is UG-hard to approximate within ≈ 0.929 . In both cases, the previous best hardness results were the same as the hardness of the corresponding unconstrained Max-2-CSP (≈ 0.878 for Max-Cut, and ≈ 0.940 for Max-2-Sat).

The hardness for Max-2-Sat applies to monotone Max-2-Sat instances, meaning that we also obtain tight inapproximability for the Max- k -Vertex-Cover problem.

1 Introduction

Constraint satisfaction problems (CSPs) are one of the most fundamental objects studied in complexity theory. An instance of a CSP has a set of variables taking values over a certain domain and a set of constraints on tuples of these variables as an input. Probably the best known CSP is 3-Sat, in which the constraints are clauses, each clause is a disjunction of at most three literals, and each literal is either a variable or negation of a variable. In the satisfiability version of CSP problems, we are interested whether there is an assignment to the variables which satisfies all the constraints. Hardness of deciding satisfiability of CSPs is well understood, due to the dichotomy theorem [32] of Schaefer which shows that each CSP with variables taking values in a Boolean domain is either in P or NP-complete, and due to the more recent results of Bulatov [8] and Zhuk [35] which settle this question on general domains.

Another well-studied version is the Max-CSP, which is the optimization version in which we are interested in maximizing the number of constraints satisfied. This type of problem is NP-hard in most cases and we typically settle with finding a good estimate of the optimal solution, for which we rely on approximation algorithms. A common example of a constraint satisfaction problem in this setting is Max-Cut, in which the input consists of a graph G , and the goal is to partition the vertices into two sets such that the number of edges between the two parts is maximized. Approximability of Max-CSPs has been a major research topic which inspired many influential breakthroughs. One of the first surprising results was an algorithm of Goemans and Williamson [13], which uses semidefinite programming (SDP) to approximate the optimal solution to within a constant of $\alpha_{GW} \approx 0.878$. The SDP approach is also useful in approximating many other well known Max-CSPs, such as Max-3-Sat [19] within a constant of $7/8$ and Max-2-Sat [23] within $\alpha_{LLZ} \approx 0.9401$.

On the hardness of approximation side, the first NP-hardness results are based on the celebrated PCP theorem [1, 2] which provided a strong starting point for studying inapproximability. For example, a direct corollary of the PCP theorem shows that the Max-3-Sat problem cannot be approximated within $1 - \delta$ for some universal constant $\delta > 0$. By using the PCP theorem and parallel repetition [31] as a starting point, Håstad [17] proved optimal inapproximability for Max-3-Sat by showing that it cannot be approximated better than $7/8 + \epsilon$ for any $\epsilon > 0$.

However, despite further works relying on the similar techniques which improved our understanding of inapproximability for several additional CSPs, the progress on closing the gap between the best algorithm and the best hardness was at a standstill for some fundamental problems such as Max-Cut, until the Unique Games Conjecture (UGC) was introduced by Khot [20]. In particular, by assuming the UGC, optimality of the α_{GW} -approximation algorithm for Max-Cut and the α_{LLZ} -approximation algorithm for Max-2-Sat was shown in [21, 26] and [3], respectively. The strength of semidefinite programming for approximating Max-CSPs was corroborated in a breakthrough result of Raghavendra [28], which showed that assuming the UGC, a certain SDP relaxation achieves optimal approximation ratios for all Max-CSPs.

Locality of the constraints was of crucial importance in studying CSPs and Max-CSPs since their inception. Therefore, it is not a surprise that typical techniques fail when we work with CSPs for which feasible assignments need to satisfy some additional global constraints, and these problems almost always become harder. For example, while the satisfiability of a 2-Sat instance can be checked by a straightforward algorithm, Guruswami and Lee recently showed [14] that when the satisfying assignment needs to have exactly half of its variables set to true, this problem becomes NP-hard. Hardness of deciding satisfiability of CSPs in which we prescribe how many variables are assigned to certain values is well understood due to the dichotomy theorem of Bulatov and Marx [9], which shows that these problems are either NP-hard or in P, and gives a simple classification. Another type of global constraint is studied by Brakensiek et al. [7], who consider hardness of deciding CSPs in presence of modular constraints, which restrict cardinality of values in an assignment modulo a natural number M .

In this paper we are interested in optimization variants of CSPs with global cardinality constraints, i.e., constraints which specify the number of occurrences of each value from the domain in the assignment. We refer to these problems as CC-Max-CSPs. It is not hard to see that these problems are at least as hard to approximate as their unconstrained counterparts. CC-Max-CSPs have been actively studied in the past. For example the Max-Bisection problem, i.e., Max-Cut where the two partitions need to be of the same size, has been of

a particular interest, with a series of papers [12], [34],[16], [11], [30] obtaining improved approximation algorithms, until the most recent result which achieves an approximation ratio of 0.8776 [4], which is only $\approx 10^{-3}$ below the UG-hardness bound α_{GW} . The state-of-the-art algorithm [30] for the more general CC-Max-Cut problem achieves an approximation ratio of $\alpha_{cut}^{cc} \approx 0.858$. Another related CC-Max-CSP actively studied is CC-Max-2-Sat, and its monotone variant (a version in which negated literals are not allowed) Max- k -VC¹. The best algorithm [30] up to date for general CC-Max-2-Sat achieves an approximation ratio of α_{2sat}^{cc} , where $\alpha_{2sat}^{cc} \approx 0.929$, which improved on a series of increasingly stronger algorithms presented in [33], [6], and [18]. Manurangsi [25] showed that it is UG-hard to approximate Max- k -VC within a factor $\alpha_{AKS} \approx 0.944$ (note that this is slightly larger than the hardness of $\alpha_{LLZ} \approx 0.940$ for general Max-2-Sat).

Yet another well-studied CC-Max-CSP is the *Densest k -Subgraph* (Max- k -DS) problem, in which we are given a graph and the objective is to find a maximally dense induced subgraph on k vertices. Analogously to the Max- k -VC problem, Max- k -DS can be viewed as the monotone CC-Max-2-And problem. Max- k -DS is qualitatively very different from the previously discussed problems. It is not known to be approximable within a constant factor, and is in fact known to be hard to approximate to within almost polynomial factors assuming the Exponential Time Hypothesis [24], or to within any constant factor assuming the Small-Set Expansion Hypothesis [29].

Obtaining tight approximability results for CC-Max-CSPs presents an important research topic. Qualitatively, it is also interesting to determine whether adding a cardinality constraint to a non-trivial Max-CSP makes approximation strictly harder. For example, we know that CC-Max-2-Sat is as hard as Max-2-Sat, but it is still conceivable that they are equally hard. In particular, it would be interesting to answer the following question:

“Can CC-Max-2-Sat be approximated within α_{LLZ} ?”

So far the only result in this direction comes from [4] which shows that the “bisection version” (where the cardinality constraint is that exactly half of the variables must be set to true) of CC-Max-2-Sat can be approximated within α_{LLZ} . However, the approach taken in that algorithm does not immediately extend to handle general cardinality constraints. A similar question arises for the CC-Max-Cut problem, but here even the basic Max-Bisection problem is not known to be approximable within the Max-Cut constant $\alpha_{GW} \approx 0.878$. As far as we are aware, prior to this paper, the only examples of cardinality-constrained Max-CSPs being harder than their unconstrained counterparts were examples where the unconstrained version is easy (e.g. unconstrained Max- k -VC is monotone Max-2-Sat, and unconstrained Max- k -DS is monotone Max-2-And, which are both trivial).

Our Results

In this paper, we answer the above question negatively, by giving improved UG-hardness results for CC-Max-Cut and Max- k -VC.

► **Theorem 1.** *For every $\varepsilon > 0$, CC-Max-Cut is UG-hard to approximate within $\beta_{cut}^{cc} + \varepsilon$, where $\beta_{cut}^{cc} \approx 0.858$.*

► **Theorem 2.** *For every $\varepsilon > 0$, Max- k -VC is UG-hard to approximate within $\beta_{vc}^{cc} + \varepsilon$, where $\beta_{vc}^{cc} \approx 0.929$.*

¹ Max- k -VC is an abbreviation for maximum k vertex cover, in which we are given a graph and the task is to select a subset of k vertices covering as many of the edges as possible.

■ **Figure 1** Hardness ratio (red) vs. approximation constant (blue) as a function of cardinality constraint q for CC-Max-Cut (left), as well as Max- k -VC (right). We also use \times to highlight the approximation ratio known for Max-Bisection on the left plot, while \times represents the optimal approximation constant for the CC-Max-2-Sat problem in the special case $q = 1/2$.

Note that since CC-Max-Cut and Max- k -VC are special cases of CC-Max-2-Lin and CC-Max-2-Sat respectively, the corresponding hardness results apply to the latter problems as well.

The constants β_{vc}^{cc} and β_{cut}^{cc} are calculated numerically and their estimated values match the constants α_{2sat}^{cc} and α_{cut}^{cc} , which are the approximation ratios for corresponding problems achieved by the algorithm of Raghavendra and Tan [30]. We provide even stronger evidence that these constants match each other, by showing that β_{vc}^{cc} and β_{cut}^{cc} are calculated as minima of the same functions used for calculating their counterparts α_{vc}^{cc} and α_{cut}^{cc} , but over a slightly more restricted domain.

Moreover, in Section 3 we give refined statements of Theorem 1 and Theorem 2 which describe inapproximability of these problems as a function of the cardinality constraint $q \in (0, 1)$, which specifies the fraction of variables that need to be set to true. For now, we provide a visualization of these results in Figure 1.

Overview of proof ideas

The main observation behind the hardness results is that the reduction used to prove hardness of approximation for the Independent Set and Vertex Cover problems in bounded degree graphs [5] gives very strong soundness guarantees. In particular it shows that in the “no” case of the reduction, all induced subgraphs of the graph contain many edges, which in turn gives useful upper bounds on the number of edges cut by a bipartition of a given size, or the number of edges covered by a subgraph. This is also how [25] obtained the previous hardness of ≈ 0.944 for Max- k -VC. Thus our results use essentially the same reduction as [5] (which is in turn similar to the reduction for Max-Cut [21]). Note however that even though the graph produced by that reduction has a small vertex cover in the “yes” case, using that small vertex cover is not necessarily the best solution for the Max- k -VC problem on the graph. In particular for $q < 1/2$, it makes more sense to instead use the large independent set as the Max- k -VC solution in the yes case (the intuition being that since it is independent, it covers many edges relative to its size).

Another difference is that we have somewhat greater flexibility in choosing the noise distribution of our “dictatorship test” (the key component of essentially all UG-hardness results) The reason is that for Independent Set/Vertex Cover, the reduction needs “perfect completeness”, i.e., in the “yes” case it needs to produce graphs with large independent

sets/small vertex covers, whereas for e.g. Max- k -VC we are perfectly happy with graphs where there are sets of size k covering many, but not necessarily all, edges. This increased flexibility turns out to improve the hardness ratios for some range of the cardinality constraint q . For example, for the CC-Max-Cut problem with $q = 1/2$, this allows us to recover the α_{GW} -hardness for the Max-Bisection problem using the same reduction. However, at q further away from $1/2$, and in particular at the local minima in Figure 1, it turns out that this flexibility does not help. Thus in the global minimum at $q \approx 0.365$ for Max- k -VC, the reduction outputs a graph with a large independent set containing a q fraction of the vertices, and choosing that independent set is the optimal solution for the Max- k -VC instance. Similarly, at the local minimum with $q > 1/2$, the optimal solution to the Max- k -VC instance in the yes case is to pick an actual vertex cover of size q , and this point of the curve corresponds exactly to the hardness of 0.944 from [25].

Organization

This paper is organized as follows. In Section 2 we fix the notation, recall some well-known facts, and formally introduce the problems of interest. In Section 3 we give our improved inapproximability results. In Section 4 we give a brief overview of the algorithm of Raghavendra and Tan [30] in order to observe that the hardness ratios we get match the approximation ratios of the algorithm. Finally, in Section 5 we propose some possible directions for future research.

2 Preliminaries

2.1 Notational Conventions

In this paper we work with undirected (multi)graphs $G = (V, E)$. For a set $S \subseteq V$ of vertices we use S^c to denote its complement $S^c = V \setminus S$, and write $U \sqcup V$ for a disjoint union of sets U and V . The graphs are both edge and vertex weighted and the weights of vertices and edges are given by functions $w: V \rightarrow [0, 1]$, and $w: E \rightarrow [0, 1]$. For subsets $S \subseteq V$ and $K \subseteq E$ we interpret $w(S)$ and $w(K)$ as the sum of weights of vertices contained in S and edges in K , respectively. Furthermore, weights are normalized so that $w(V) = w(E) = 1$ and the weight of each vertex equals half the weight of all edges adjacent to it. Therefore, the weights of edges and vertices can be interpreted as probability distributions, and sampling a vertex with probability equal to its weight is the same as sampling an edge and then sampling one of its endpoints with probability $1/2$. For $S, T \subseteq V$, we write $w(S, T)$ for the total weight of edges from E which have one endpoint in S , and other in T . Note that, since we work with undirected graphs, the order of endpoints is not important, and therefore $w(S, T) = w(T, S)$. In other words, the weight of an edge $e = (u, v)$ contributes to $w(S, T)$ if either $(u, v) \in T \times S$ or $(u, v) \in S \times T$. We also have the identity

$$w(S, V) = w(S) + \frac{1}{2}w(S, S^c). \quad (1)$$

The set of all neighbours of a vertex v including v is denoted by $N(v)$, and the set of all neighbours of a set $S \subseteq V$ including S is denoted by $N(S)$. Let us also introduce the following definition.

► **Definition 3.** *A graph G is (q, ε) -dense if every subset $S \subseteq V$ with $w(S) = q$ satisfies $w(S, S) \geq \varepsilon$.*

We use $\phi(x) = \frac{1}{\sqrt{2\pi}}e^{-x^2/2}$ to denote the density function of a standard normal random variable, and $\Phi(x) = \int_{-\infty}^x \phi(y)dy$ to denote its cumulative distribution function (CDF). We also work with bivariate normal random variables, and to that end introduce the following function.

► **Definition 4.** Let $\rho \in [-1, 1]$, and consider two jointly normal random variables X, Y with mean 0 and covariance matrix $\text{Cov}(X, Y) = \begin{bmatrix} 1 & \rho \\ \rho & 1 \end{bmatrix}$. We define $\Gamma_\rho: [0, 1]^2 \rightarrow [0, 1]$ as

$$\Gamma_\rho(x, y) = \Pr [X \leq \Phi^{-1}(x) \wedge Y \leq \Phi^{-1}(y)].$$

We also write $\Gamma_\rho(x) = \Gamma_\rho(x, x)$. We have the following basic lemma (for a proof see Appendix A of [4]).

► **Lemma 5.** For every $\rho \in [-1, 1]$, and every $x, y \in [0, 1]$, we have

$$\Gamma_\rho(x, y) = \Gamma_\rho(1-x, 1-y) - 1 + x + y.$$

2.2 Problem Definitions

This paper is concerned with Max-Cut, Max-2-Lin, Max-2-Sat, and Max- k -VC problems with cardinality constraints. Let us give the definitions of these problems as integer optimization programs now. In these definitions instead of $\{0, 1\}$ we represent Boolean domain as $\{-1, 1\}$, and for that reason instead of cardinality constraint q we consider a *balance constraint* $r = 1 - 2q$.

► **Definition 6.** An instance \mathcal{F} of the cardinality constrained Max-2-Lin (CC-Max-2-Lin) problem with balance constraint $r \in (-1, 1)$ over variables $X = \{x_1, \dots, x_n\}$ taking values in $\{-1, 1\}$ is given by the following integer optimization program

$$\begin{aligned} \max \quad & \sum_{(i,j)=e_\ell \in E} \frac{1 + P_\ell x_i x_j}{2}, \\ \text{s.t.} \quad & \sum_{i \in V} x_i = nr, \end{aligned}$$

where $P_\ell \in \{-1, 1\}$ and the term $(1 + P_\ell x_i x_j)/2$ corresponds to the XOR constraint $x_i x_j = P_\ell$. In case $P_\ell = -1$ for all ℓ , the integer optimization program is an instance of CC-Max-Cut problem.

► **Definition 7.** An instance \mathcal{F} of the cardinality constrained Max-2-Sat (CC-Max-2-Sat) problem with balance constraint $r \in (-1, 1)$ over variables $X = \{x_1, \dots, x_n\}$ taking values in $\{-1, 1\}$ is given by the following integer optimization program

$$\begin{aligned} \max \quad & \sum_{(i,j)=e_\ell \in E} \frac{3 + P_\ell^1 x_i + P_\ell^2 x_j + P_\ell^3 x_i x_j}{4}, \\ \text{s.t.} \quad & \sum_{i \in V} x_i = nr, \end{aligned}$$

where $(P_\ell^1, P_\ell^2, P_\ell^3) \in \{(-1, -1, -1), (1, -1, 1), (-1, 1, 1), (1, 1, -1)\}$ corresponds to one of the four possible clauses

$$x_i \vee x_j, \quad \neg x_i \vee x_j, \quad x_i \vee \neg x_j, \quad \neg x_i \vee \neg x_j.$$

In case $(P_\ell^1, P_\ell^2, P_\ell^3) = (-1, -1, -1)$ for all ℓ , the integer optimization program is an instance of Max- k -VC problem.

The objective in the problems given by Definitions 6 and 7 is to find an assignment $z: X \rightarrow \{-1, 1\}$ which satisfies a (hard) global cardinality constraint and maximizes the number of satisfied soft constraints represented by the objective function. For an assignment z that satisfies global constraint of an instance \mathcal{F} we use $\text{Val}_z(\mathcal{F})$ to denote the value of the objective function under the assignment z . Furthermore, we use

$$\text{OptVal}(\mathcal{F}) = \max_{\substack{z: X \rightarrow \{-1, 1\} \\ \sum_{x \in X} z(x) = rn}} \text{Val}_z(\mathcal{F})$$

to denote the maximum value of the objective function over all assignments z satisfying the cardinality constraint.

The starting point of the hardness results in this paper is the Unique Games problems, which is defined as follows.

► **Definition 8.** A Unique Games instance $\Lambda = (\mathcal{U}, \mathcal{V}, \mathcal{E}, \Pi, [L])$ consists of an unweighted bipartite multigraph $(\mathcal{U} \sqcup \mathcal{V}, \mathcal{E})$, a set $\Pi = \{\pi_e: [L] \rightarrow [L] \mid e \in \mathcal{E} \text{ and } \pi_e \text{ is a bijection}\}$ of permutation constraints, and a set $[L]$ of labels. The value of Λ under the assignment $z: \mathcal{U} \sqcup \mathcal{V} \rightarrow [L]$ is the fraction of edges satisfied, where an edge $e = (u, v), u \in \mathcal{U}, v \in \mathcal{V}$ is satisfied if $\pi_e(z(u)) = z(v)$. We write $\text{Val}_c(\Lambda)$ for the value of Λ under z , and $\text{Opt}(\Lambda)$ for the maximum possible value over all assignments z .

The Unique Games Conjecture [20] can be formulated as follows ([22], Lemma 3.4).

► **Conjecture 9** (Unique Games Conjecture). For every constant $\gamma > 0$ there is a sufficiently large $L \in \mathbb{N}$, such that for a Unique Games instance $\Lambda = (\mathcal{U}, \mathcal{V}, \mathcal{E}, \Pi, [L])$ with a regular bipartite graph $(\mathcal{U} \sqcup \mathcal{V}, \mathcal{E})$, it is NP-hard to distinguish between

- $\text{Opt}(\Lambda) \geq 1 - \gamma$,
- $\text{Opt}(\Lambda) \leq \gamma$.

2.3 Analysis of Boolean Functions

One of the ubiquitous tools in the hardness of approximation area is Fourier analysis of Boolean functions. We now recall some of the well-known facts which are used in the paper. For a more detailed study, we refer to [27].

For $q \in [0, 1]$ and $n \in \mathbb{N}$ we write $\pi_q: \{0, 1\} \rightarrow [0, 1]$ for the probability distribution given by $\pi_q(1) = q, \pi_q(0) = 1 - q$. We also write $\pi_q^{\otimes n}$ for the probability distribution on n -bit strings $x \in \{0, 1\}^n$ where each bit is distributed according to π_q , independently. We use $L^2(\pi_q^{\otimes n})$ to denote the space of random variables $f: \{0, 1\}^n \rightarrow \mathbb{R}$ over the probability space $(\{0, 1\}^n, P(\{0, 1\}^n), \pi_q^{\otimes n})$, and interpret $\mathbf{E}[f]$ and $\mathbf{Var}[f]$ as expectation and variance of $f(X)$ when the X is drawn from $\pi_q^{\otimes n}$. Depending on context, the elements of $L^2(\pi_q^{\otimes n})$ will be interpreted as functions as well.

Let us now introduce some of the common objects used in the study of Boolean functions.

► **Definition 10.** Consider a function $f \in L^2(\pi_q^{\otimes n})$ and $i \in \{1, \dots, n\}$. The influence $\mathbf{Inf}_i[f]$ of the i -th argument on f is defined as

$$\mathbf{Inf}_i[f] = \mathbf{E}_{x \sim \pi_q^{\otimes n}} [\mathbf{Var}_{\tilde{x}_i \sim \pi_q} [f(x_1, \dots, x_{i-1}, \tilde{x}_i, x_{i+1}, \dots, x_n)]]$$

Minimal correlation between two q -biased bits is $\max(-q/(1 - q), -(1 - q)/q)$. For notational convenience, let us introduce the function κ which assigns to each value $q \in (0, 1)$ an interval $I \subseteq (-1, 0)$ as

$$\kappa(q) = \begin{cases} [-q/(1 - q), 0), & \text{if } q < 1/2, \\ (-1, 0), & \text{if } q = 1/2, \\ [-(1 - q)/q, 0), & \text{if } q > 1/2. \end{cases}$$

► **Definition 11.** For a fixed $x \in \{0, 1\}$, $q \in (0, 1)$ and $\rho \in \kappa(q)$ we write $y \sim N_\rho(x)$ to indicate that y is a ρ -correlated copy of x . In particular each bit y_i is equal to 1 with probability $q + \rho(1 - q)$ if $x_i = 1$, and $y_i = 1$ with probability $q - \rho q$ when $x_i = 0$, independently.

► **Definition 12.** Consider $q \in (0, 1)$ and $\rho \in \kappa(q)$. The noise operator $T_\rho: L^2(\pi_q^{\otimes n}) \rightarrow L^2(\pi_q^{\otimes n})$ is defined as

$$T_\rho f(x) = \mathbf{E}_{y \sim N_\rho(x)}[f(y)].$$

The following lemma gives a useful bound on the number of influential variables of $T_\rho f$.

► **Lemma 13.** Consider $q \in (0, 1)$, a function $f \in L^2(\pi_q^{\otimes n})$, and $\rho \in \kappa(q)$. Then, for any $\tau > 0$ we have that

$$|\{i \in [n] \mid \mathbf{Inf}_i[T_\rho f] \geq \tau\}| \leq \frac{\mathbf{Var}[f]}{\tau e \ln(1/|\rho|)}.$$

For a proof we refer to Lemma 3.4 of [15]. We also need to introduce the notion of noise stability, defined as follows.

► **Definition 14.** Let $q \in (0, 1)$, $\rho \in \kappa(q)$ and $f \in L^2(\pi_q^{\otimes n})$. The noise stability of function f at ρ is defined as

$$\mathbb{S}_\rho = \mathbf{E}[f \cdot T_\rho f].$$

Let us also recall the following variant of the ‘‘Majority is Stablest’’ theorem in the form that appeared in [5], and which follows from Theorem 3.1 in [10].

► **Theorem 15.** Let $q \in (0, 1)$ and $\rho \in \kappa(q)$. Then for any $\varepsilon > 0$, there exist $\tau > 0$ and $\delta > 0$ such that for every function $f \in L^2(\pi_q^{\otimes n})$, $f: \{-1, 1\}^n \rightarrow [0, 1]$ that satisfies

$$\max_{i \in [n]} \mathbf{Inf}_i[T_{1-\delta} f] \leq \tau,$$

we have

$$\mathbb{S}_\rho(f) \geq \Gamma_\rho(\mathbf{E}[f]) - \varepsilon.$$

3 Hardness Reduction

In this section we give our main hardness reduction. As discussed in the introduction, it is a generalization of the reduction of Theorem III.1 from [5].

► **Theorem 16.** For every $q \in (0, 1)$, $\varepsilon > 0$, and $\rho \in \kappa(q)$, there exists a $\gamma > 0$ and a reduction from Unique Games instances $\Lambda = (\mathcal{U}, \mathcal{V}, \mathcal{E}, \Pi, [L])$ to weighted multigraphs $G = (V, E)$ with the following properties:

- Completeness: If $\text{Opt}(\Lambda) \geq 1 - \gamma$, then there is a set $S \subseteq V$ such that $w(S) = q$ and $w(S, S^c) \geq 2q(1 - q)(1 - \rho) - 2\gamma$.
- Soundness: If $\text{Opt}(\Lambda) \leq \gamma$, then for every $r \in [0, 1]$, G is $(r, \Gamma_\rho(r) - \varepsilon)$ -dense.

Moreover, the running time of the reduction is polynomial in $|\mathcal{U}|, |\mathcal{V}|, |\mathcal{E}|$, and exponential in L .

Proof. Let $\nu: \{0, 1\}^2 \rightarrow [0, 1]$ be the probability distribution over two ρ -correlated q -biased bits. In other words, letting $t = (q - q^2)(1 - \rho)$, we have

$$\nu(0, 0) = 1 - q - t, \quad \nu(0, 1) = \nu(1, 0) = t, \quad \nu(1, 1) = q - t.$$

Let us now describe how the multigraph G can be constructed from Λ . We define the vertex set of G to be $V = \mathcal{V} \times \{0, 1\}^L = \{(v, x) \mid v \in \mathcal{V}, x \in \{0, 1\}^L\}$. In particular, for every vertex $v \in \mathcal{V}$ we create 2^L vertices of G , which we identify with L -bit strings in $\{0, 1\}^L$. We also write v^x for a vertex (v, x) of the graph G . The weights of vertices in G are given by

$$w(v^x) = \frac{1}{|\mathcal{V}|} \pi_q^{\otimes L}(x). \quad (2)$$

The edges of G are constructed in the following way. For every $u \in \mathcal{U}$, and for every two $v_1, v_2 \in N(u)$, we create an edge between vertices v_1^x, v_2^y with weight

$$\frac{1}{|\mathcal{U}|D^2} \nu^{\otimes L}(x \circ \pi_{e_1}, y \circ \pi_{e_2}), \quad \text{where } e_1 = (u, v_1), \quad e_2 = (u, v_2).$$

Expressed formally, the edge set E is

$$E = \{(e_1^x, e_2^y) \mid e_1 = (u, v_1), e_2 = (u, v_2), u \in \mathcal{U}, v_1, v_2 \in \mathcal{V}, x, y \in \{0, 1\}^L\}.$$

Since the marginal of the distribution ν over either the first or the second argument is a q -biased distribution on $\{0, 1\}^L$, the weight of all edges adjacent to a vertex v^x equals two times the weight of the vertex v^x . Furthermore, it is trivial to check that $w(V) = w(E) = 1$. The number of vertices in G is $|\mathcal{V}|2^L$, and the number of edges is $|\mathcal{U}|D^22^L$, so the construction is indeed polynomial in $|\mathcal{U}|, |\mathcal{V}|$ and $|\mathcal{E}|$.

Let us now prove completeness and soundness.

Completeness: Since $\text{Opt}(\Lambda) \geq 1 - \gamma$, there is a labeling $z: \mathcal{U} \sqcup \mathcal{V} \rightarrow [L]$ such that $\text{Val}_z(\Lambda) \geq 1 - \gamma$. Consider a set S given by

$$S = \{v^x \in V \mid x_{z(v)} = 1\}.$$

The weight of the set S is obviously q . Let us consider a set consisting of pairs of edges in \mathcal{E} which have a common vertex in \mathcal{U} , i.e. the set

$$\hat{E} = \{(e_1, e_2) \in \mathcal{E} \times \mathcal{E} \mid e_1 = (u, v_1), e_2 = (u, v_2), u \in \mathcal{U}, v_1, v_2 \in \mathcal{V}\},$$

and its subset \hat{E}_{good} consisting of edge pairs which are satisfied under the assignment z , or formally

$$\hat{E}_{\text{good}} = \{(e_1, e_2) \in \hat{E} \mid e_1 = (u, v_1), e_2 = (u, v_2), z(u) = \pi_{e_1}^{-1}(z(v_1)) = \pi_{e_2}^{-1}(z(v_2))\},$$

Since at least fraction $1 - \gamma$ of edges in \mathcal{E} are satisfied under z , at least fraction $(1 - \gamma)^2$ of edge pairs in \hat{E} is satisfied under z , i.e. $|\hat{E}_{\text{good}}| \geq (1 - \gamma)^2 |\hat{E}|$. For every $(e_1, e_2) \in \hat{E}_{\text{good}}$, $e_1 = (u, v_1), e_2 = (u, v_2)$, the edges between S and S^c created through the pair of edges (e_1, e_2) have the total weight of

$$\begin{aligned} \frac{1}{|\mathcal{U}|D^2} \Pr_{(x,y) \sim \nu^{\otimes L}} \left[(x \circ \pi_{e_1}^{-1})_{z(v_1)} \neq (y \circ \pi_{e_2}^{-1})_{z(v_2)} \right] &= \frac{1}{|\mathcal{U}|D^2} \Pr_{(x,y) \sim \nu^{\otimes L}} [x_{z(u)} \neq y_{z(u)}] \\ &= \frac{1}{|\mathcal{U}|D^2} (\nu(0, 1) + \nu(1, 0)) = \frac{1}{|\mathcal{U}|D^2} 2t. \end{aligned}$$

Therefore, we have $w(S, S^c) \geq 2t(1 - \gamma)^2 \geq 2q(1 - q)(1 - \rho) - 2\gamma$.

Soundness: Let us assume by contradiction that G is not $(r, \Gamma_\rho(r) - \varepsilon)$ -dense, and therefore that there is a set $S \subseteq V$ of weight $w(S) = r$ for which $w(S, S) < \Gamma_\rho(r) - \varepsilon$. For each $v \in \mathcal{V}$, let us define a function $S_v \in L^2(\pi_q^{\otimes L})$ to be the indicator function of S restricted

24:10 Global Cardinality Constraints Make Approximating Some Max-2-CSPs Harder

to the vertex v . In particular, we have that $S_v(x) = 1$ if and only if $v^x \in S$. Furthermore, for all $u \in \mathcal{U}$ let us define $S_u \in L^2(\pi_q^{\otimes L})$ as

$$S_u(x) = \mathbf{E}_{\substack{e=(u,v), \\ v \in N(u)}} [S_v(x \circ \pi_e^{-1})].$$

We have that

$$\begin{aligned} w(S, S) &= \mathbf{E}_{\substack{u \in \mathcal{U}, \\ e_1=(u,v_1), e_2=(u,v_2), \\ v_1, v_2 \in N(u)}} \left[\mathbf{E}_{(x,y) \sim \nu^{\otimes L}} [S_{v_1}(x \circ \pi_{e_1}^{-1}) S_{v_2}(y \circ \pi_{e_2}^{-1})] \right] \\ &= \mathbf{E}_{\substack{u \in \mathcal{U}, \\ (x,y) \sim \nu^{\otimes L}}} \left[\mathbf{E}_{\substack{e_1=(u,v_1), e_2=(u,v_2), \\ v_1, v_2 \in N(u)}} [S_{v_1}(x \circ \pi_{e_1}^{-1}) S_{v_2}(y \circ \pi_{e_2}^{-1})] \right] \\ &= \mathbf{E}_{u \in \mathcal{U}} \left[\mathbf{E}_{(x,y) \sim \nu^{\otimes L}} [S_u(x) S_u(y)] \right] = \mathbf{E}_{u \in \mathcal{U}} \left[\mathbf{E}_{x \sim \pi_q^{\otimes L}} [S_u(x) T_\rho S_u(x)] \right] = \mathbf{E}_{u \in \mathcal{U}} [\mathbb{S}_\rho(S_u)]. \end{aligned}$$

Let us define $\mu_u = \mathbf{E}_{x \sim \pi_q^{\otimes L}} [S_u(x)]$, and remark that due to regularity of Λ we have $\mathbf{E}_{u \in \mathcal{U}} [S_u] = r$. We claim that there is a set $\mathcal{U}' \subseteq \mathcal{U}$, $|\mathcal{U}'| \geq \varepsilon |\mathcal{U}|/2$ such that for every $u \in \mathcal{U}'$ we have $\mathbb{S}_\rho(S_u) < \Gamma_\rho(\mu_u) - \varepsilon/2$. Otherwise, we reach a contradiction by noticing that

$$\begin{aligned} \Gamma_\rho(r) - \varepsilon > w(S, S) &= \mathbf{E}_{u \in \mathcal{U}} [\mathbb{S}_\rho(S_u)] \geq (1 - \varepsilon/2) \left(\mathbf{E}_{u \in \mathcal{U}} [\Gamma_\rho(\mu_u)] - \varepsilon/2 \right) \\ &\geq \mathbf{E}_{u \in \mathcal{U}} [\Gamma_\rho(\mu_u)] - \varepsilon \geq \Gamma_\rho(r) - \varepsilon, \end{aligned}$$

where in the last inequality we used the fact that Γ_ρ is convex.

By Theorem 15 there is $\tau > 0$ and $\delta > 0$ such that for every $u \in \mathcal{U}'$ there is a significant coordinate $i \in [L]$ for which $\mathbf{Inf}_i[T_{1-\delta} S_u] \geq \tau$. For each $u \in \mathcal{U}'$ and for its significant coordinate i , by using the fact that \mathbf{Inf}_i is convex and Markov's inequality we conclude that for at least $\tau/2$ of $v \in N(u)$ we have

$$\mathbf{Inf}_{\pi_e(i)} [T_{1-\delta} S_v] \geq \tau/2, \quad e = (u, v).$$

For each $v \in \mathcal{V}$ let $[L]_v \subseteq [L]$ denote a set of labels defined by

$$[L]_v = \{i \in [L] \mid \mathbf{Inf}_i [T_{1-\delta} S_v] \geq \tau/2\}.$$

By Lemma 13 we have that $|[L]_v| \leq \frac{2}{\tau \varepsilon \ln(1/(1-\delta))}$. Let us now pick an assignment $z: \mathcal{U} \sqcup \mathcal{V} \rightarrow [L]$ of Λ using the following randomized procedure. For each $v \in \mathcal{V}$, pick $i \in [L]_v$ randomly, and set $z(v) = i$. If $[L]_v = \emptyset$, we pick $i \in [L]$ randomly. Then, for each $u \in \mathcal{U}$, we set $z(u) = i$ for the i that maximizes the number of edges satisfied. From the previous discussion we conclude that this labeling satisfies $\Omega(\varepsilon \tau^4 \ln^2(1/(1-\delta)))$ of constraints of Λ in expectation. But since this constant does not depend on γ this would be a contradiction if we started with a sufficiently small γ . \blacktriangleleft

3.1 Hardness for CC-Max-Cut

Now that we have proven Theorem 16, it is straightforward to prove the following theorem which gives a hardness result of CC-Max-Cut.

► **Theorem 17.** *For any $q \in (0, 1)$ and $\rho \in \kappa(q)$ it is UG-hard to approximate CC-Max-Cut with cardinality constraint q within $\beta_{cut}^{cc}(q, \rho) + \varepsilon$ where $\varepsilon > 0$ is arbitrary small and $\beta_{cut}^{cc}(q, \rho)$ is given by*

$$\beta_{cut}^{cc}(q, \rho) = \frac{1 - \Gamma_\rho(q) - \Gamma_\rho(1 - q)}{2(q - q^2)(1 - \rho)}.$$

Proof. By Theorem 16 there exists a family of multigraphs $G = (V, E)$ for which it is UG-hard to decide between the following two statements:

- There is a set $S \subseteq V, w(S) = q$, such that $w(S, S^c) \geq 2q(1 - q)(1 - \rho) - 2\gamma$.
- For any $r \in [0, 1]$ and every set $T \subseteq V, w(T) = r$ we have $w(T, T) \geq \Gamma_\rho(r) - \varepsilon$.

The second statement implies that for any $S \subseteq V, w(S) = q$, we have $w(S, S^c) = w(V, V) - w(S, S) - w(S^c, S^c) \leq 1 - \Gamma_\rho(q) - \Gamma_\rho(1 - q) + 2\varepsilon$. Therefore, by setting γ sufficiently small this shows UG-hardness of approximating CC-Max-Cut with cardinality constraint q within

$$\frac{1 - \Gamma_\rho(1 - q) - \Gamma_\rho(q)}{2q(1 - q)(1 - \rho)} + 2\varepsilon,$$

where $\varepsilon > 0$ is arbitrarily small. This reduction yields a weighted graph, which can be easily converted into an unweighted multigraph, using e.g. a simple reduction from Step 1 of Theorem 4.1. in [5]. ◀

3.2 Hardness for Max- k -VC

Next we give the hardness result for Max- k -VC.

► **Theorem 18.** *Consider $q \in (0, 1)$ and let $\rho \in \kappa(q)$. Then, it is UG-hard to approximate Max- k -VC with cardinality constraint q within $\beta_{vc}^{cc}(q, \rho) + \varepsilon$ where $\varepsilon > 0$ is arbitrary small and $\beta_{vc}^{cc}(q, \rho)$ is given by*

$$\beta_{vc}^{cc}(q, \rho) = \frac{1 - \Gamma_\rho(1 - q)}{q(1 + (1 - q)(1 - \rho))}.$$

Proof. As we have shown in Theorem 16, there is a family of multigraphs $G = (V, E)$ for which it is UG-hard to decide between the following two statements:

- There is a set $S \subseteq V, w(S) = q$, such that $w(S, S^c) \geq 2q(1 - q)(1 - \rho) - 2\gamma$.
- For any $r \in [0, 1]$ and every set $T \subseteq V, w(T) = r$ we have $w(T, T) \geq \Gamma_\rho(r) - \varepsilon$.

By (1), the first item implies that $w(S, V) = q(1 + q(1 - q)(1 - \rho)) - \gamma$. The second statement implies that for any $S \subseteq V, w(S) = q$, we have $w(S, V) = w(V, V) - w(S^c, S^c) \leq 1 - \Gamma_\rho(1 - q) + \varepsilon$. Therefore, by letting $\gamma \rightarrow 0$ this shows UG-hardness of approximating Max- k -VC with cardinality constraint q within

$$\frac{1 - \Gamma_\rho(1 - q)}{q(1 + (1 - q)(1 - \rho))} + \varepsilon,$$

where $\varepsilon > 0$ is arbitrarily small. As in the CC-Max-Cut case, this reduction yields a weighted graph, which can be converted into an unweighted multigraph by using the reduction from [5]. ◀

3.3 Hardness as a Function of the Cardinality Constraint

As we have concluded in Theorems 17 and 18, it is UG-hard to approximate CC-Max-Cut and Max- k -VC with cardinality constraint $q \in (0, 1)$ to within

$$\beta_{cut}^{cc}(q) = \inf_{\rho \in \kappa(q)} \beta_{cut}^{cc}(q, \rho), \quad \beta_{vc}^{cc}(q) = \inf_{\rho \in \kappa(q)} \beta_{vc}^{cc}(q, \rho),$$

respectively. For a fixed q it is not clear for which ρ the functions $\beta_{cut}^{cc}(q, \cdot)$ and $\beta_{vc}^{cc}(q, \cdot)$ are minimized. For the plots of the inapproximability curves in Figure 1, the optimization over ρ was done numerically. Interestingly, numerical calculations show that the worst-case value of the cardinality constraint $q < 1/2$ (the value of q at which the hardness ratio meets the approximation ratio) is the same for Max- k -VC and CC-Max-Cut, and in particular its value is $q^* \approx 0.365$. The value of the correlation parameter ρ for which this worst-case hardness is achieved is extremal, i.e., $\rho = -q^*/(1 - q^*) \approx -0.575$. However, the local minima at $q > 1/2$ in the two curves do not occur at the same value of q . For CC-Max-Cut the curve is symmetric around $1/2$ and the minimum occurs at $1 - q^* \approx 0.635$, but for the less symmetric Max- k -VC problem it occurs at ≈ 0.574 .

Furthermore, for all $q \leq q^*$ and also for $q > 1/2$ greater than the respective local minimum, the ρ minimizing both $\beta_{cut}^{cc}(q, \rho)$ and $\beta_{vc}^{cc}(q, \rho)$ is the minimum value of $\kappa(q)$. On the other hand, when q is close to $1/2$, the best choice of ρ does not equal $\min \kappa(q)$. For example, when $q = 1/2$, the hardness we obtain for CC-Max-Cut is the same as for the Max-Cut problem, attained using the value $\rho \approx -0.689$.

4 Approximation Algorithm

In this section we recall the algorithm of Raghavendra and Tan [30], somewhat reformulated in order to obtain explicit expressions for the approximation ratios that match the hardness results we obtain. We keep the exposition at a high level and skip over certain technical details, and refer the reader interested in the details to [30] or the follow-up work [4].

In order to find a good approximation for NP-hard integer optimization problems given in Definitions 6 and 7 we use semidefinite programming (SDP) relaxations. In particular, we extend the domain of variables $\{x_i\}_{i=1}^n$ from $\{0, 1\}$ to vectors on an n -sphere, which we denote by $v_i \in S^n$. We also introduce a vector $v_0 \in S^n$ which represents the value false (corresponding value is 1 in the integer program). Then, we replace x_i by the scalar product $\langle v_0, v_i \rangle$ and $x_i x_j$ with $\langle v_i, v_j \rangle$. For example, the semidefinite relaxation of the CC-Max-Cut program is given as

$$\begin{aligned} \max \quad & \sum_{(i,j)=e \in E} \frac{1 - \langle v_i, v_j \rangle}{2}, \\ \text{s.t.} \quad & \sum_{i \in V} \langle v_i, v_0 \rangle = rn. \end{aligned}$$

Furthermore, since $|x_i - x_j| \leq |x_i - x_k| + |x_k - x_j|$, we also demand from the vectors v_i to satisfy the triangle inequalities $\|v_i - v_j\|_2^2 \leq \|v_i - v_0\|_2^2 + \|v_0 - v_j\|_2^2$. In order to relax the notation we define $\mu_i = \langle v_0, v_i \rangle$, $\rho_{ij} = \langle v_i, v_j \rangle$, and write triangle inequalities as

$$\begin{aligned} \mu_i + \mu_j + \rho_{ij} &\geq -1, & \mu_i - \mu_j - \rho_{ij} &\geq -1, \\ -\mu_i + \mu_j - \rho_{ij} &\geq -1, & -\mu_i - \mu_j + \rho_{ij} &\geq -1. \end{aligned}$$

The triples (μ_1, μ_2, ρ) satisfying triangle inequalities will be called *configurations*. We denote the set of all configurations as $\mathbf{Conf} \subseteq [-1, 1]^3$. We can solve a semidefinite program up to desired accuracy in polynomial time. Then, the main challenge is finding a *rounding algorithm* which translates the vectors $\{v_i\}_{i=0}^n$ back to $\{-1, 1\}$ so that they satisfy the balance constraint, and such that the rounding does not incur a big loss in the objective value. Raghavendra and Tan used a randomized rounding procedure, which rounds vectors

$\{v_i\}_{i=0}^n$ to ± 1 integers $\{y_i\}_{i=1}^n$ in the following way. First, let us define $w_i = v_i - \mu_i v_0$, and let² $\bar{w}_i = w_i / \|w_i\|$. Then, we draw a vector g from the Gaussian distribution $\mathcal{N}(0, I^{n+1})$ and set the values of \bar{y}_i as

$$\bar{y}_i = \begin{cases} 1 & \text{if } \langle g, \bar{w}_i \rangle \geq \Phi^{-1}\left(\frac{1-\mu_i}{2}\right), \\ -1 & \text{otherwise.} \end{cases}$$

It is trivial to check that $\mathbf{E}[\bar{y}_i] = \mu_i$, so we have $\mathbf{E}\left[\sum_{i=1}^n \bar{y}_i\right] = rn$, and therefore the solution $\{\bar{y}_i\}_{i=1}^n$ satisfies the balance constraint in expectation. Furthermore, as shown in [30], using additional levels of the Lasserre hierarchy we can guarantee that with probability $1 - \delta$ the sampled solution $\{\bar{y}_i\}_{i=1}^n$ is $O(\delta)$ -far away from satisfying the balance constraint, where $\delta > 0$ can be chosen arbitrarily small. Therefore, we can change the values of at most $O(\delta)n$ variables \bar{y}_i to get a solution y_i exactly satisfying the balance constraint, while losing only an additional small factor $O(\delta)$ in the objective value. Thus, it is sufficient to show that the objective value of the \bar{y}_i 's is large.

Consider now the SDP relaxation for any of the integer programs \mathcal{F} given in either Definition 6 or Definition 7, and let $\text{SDPVal}(\mathcal{F})$ be the optimal value of the SDP relaxation for the instance \mathcal{F} . We have that $\text{SDPVal}(\mathcal{F}) \geq \text{OptVal}(\mathcal{F})$. Finally, let us define $\text{RndVal}(\mathcal{F})$ to be the expectation of the value of the objective function after randomized rounding procedure. The analysis of the approximation ratio for the algorithm boils down to proving $\text{RndVal}(\mathcal{F}) \geq \alpha \text{SDPVal}(\mathcal{F})$, where α is a constant that depends on the problem of interest. The way to calculate α is to look at the loss incurred by rounding at each constraint. Let us now show how this can be done for the CC-Max-Cut problem.

The expected value of each constraint $\frac{1-x_i x_j}{2}$ after rounding the SDP solution of CC-Max-Cut problem is $\frac{1-\mathbf{E}[\bar{y}_i \bar{y}_j]}{2}$, and therefore at each constraint the loss factor incurred by rounding is given as

$$\frac{1 - \mathbf{E}[\bar{y}_i \bar{y}_j]}{2} \cdot \frac{1}{(1 - \langle v_i, v_j \rangle) / 2}.$$

Thus, in order to calculate the approximation ratio, we need to bound this expression from below. Let us first note that

$$\mathbf{E}[\bar{y}_1 \bar{y}_2] = 4\Gamma_{\bar{\rho}}\left(\frac{1-\mu_1}{2}, \frac{1-\mu_2}{2}\right) + \mu_1 + \mu_2 - 1,$$

where $\bar{\rho}$ is given as

$$\bar{\rho} = \frac{\rho - \mu_1 \mu_2}{\sqrt{1 - \mu_1^2} \sqrt{1 - \mu_2^2}}.$$

Then, the approximation ratio is lower bounded by the quantity α_{cut}^{cc} defined as the solution of the optimization problem

$$\alpha_{cut}^{cc} = \min_{(\mu_1, \mu_2, \rho) \in \mathbf{Conf}} \frac{2 - 4\Gamma_{\bar{\rho}}\left(\frac{1-\mu_1}{2}, \frac{1-\mu_2}{2}\right) - \mu_1 - \mu_2}{1 - \rho}.$$

² We assume that $\|w_i\| \neq 0$, since we can introduce a small perturbation to the values v_i without affecting the objective value too much.

Computing α_{cut}^{cc} is a hard global optimization problem, and therefore we resort to numerical computations to estimate it (we remark that the same approach is taken for a similar function in [23] and [3]). Extensive numerical experiments show that the minimum is attained at $\mu_1 = \mu_2 = \mu$, while the ρ is on the boundary of the polytope **Conf**, $\rho = -1 + 2|\mu|$. More precisely, the minimum is attained at $\mu \approx 0.27$, and $\rho \approx -0.575$, and it has a value of approximately 0.858.

Assuming that the minimum is attained at the configuration of the form $(\mu, \mu, -1+2\mu)$, $\mu > 0$, constant α_{cut}^{cc} can be found as the minimum of a function

$$\frac{1 - 2\Gamma_{\bar{\rho}}\left(\frac{1-\mu}{2}, \frac{1-\mu}{2}\right) - \mu}{1 - \mu},$$

where $\mu \in (0, 1)$. If we introduce $q = (1 - \mu)/2$, we can reexpress this function as

$$\alpha_{cut}^{cc}(q) = \frac{2q - 2\Gamma_{\bar{\rho}}(q)}{2q} = \frac{1 - \Gamma_{\bar{\rho}}(q) - \Gamma_{\bar{\rho}}(1 - q)}{2q}, \quad q \in (0, 1/2),$$

where in the last equality we used Lemma 5. Furthermore, $\bar{\rho} = -q/(1 - q)$. Similar analysis for CC-Max-2-Lin shows that the approximation ratio is the minimal value of the same function.

Straightforward calculations show that $\beta_{cut}^{cc}(q, -q/(1 - q))$ from Theorem 17 equals the value of $\alpha_{cut}^{cc}(q)$. Therefore, under the (mild) assumption that worst-case configurations indeed take the special form as explained above, our hardness result is sharp and the algorithm for CC-Max-Cut of Raghavendra and Tan is optimal on general instances of CC-Max-Cut / CC-Max-2-Lin.

In completely analogous way, we can conclude that the approximation ratio for CC-Max-2-Sat and Max- k -VC problems can be calculated as the minimum of the following function

$$\alpha_{2sat}^{cc}(q) = \frac{1 - \Gamma_{\bar{\rho}}(1 - q)}{2q}, \quad q \in (0, 1/2),$$

where $\bar{\rho} = -q/(1 - q)$. Numerical experiments show that $\alpha_{2sat}^{cc} \approx 0.929$, and that the minimum is attained at $q \approx 0.365$.

Again we have that the corresponding hardness expression from Theorem 18 satisfies $\beta_{vc}^{cc}(q, -q/(1 - q)) = \alpha_{2sat}^{cc}(q)$, implying (under the assumption on worst-case configurations) that the algorithm for CC-Max-2-Sat of Raghavendra and Tan is optimal.

5 Conclusion and Some Open Questions

We studied some of the cardinality constrained 2-CSPs, and assuming the Unique Games Conjecture derived hardness results which show that approximation ratios achieved by the algorithm described in [30] are optimal for CC-Max-2-Sat (and its special case Max- k -VC) and CC-Max-2-Lin (and its special case CC-Max-Cut). It would be interesting to derive UG-hardness for related CC-Max-CSPs of arity 2, most interestingly for the Max- k -DS problem. While super-constant hardness for Max- k -DS is currently known under the closely related Small-Set Expansion Hypothesis [29], it is not yet known whether the UGC implies hardness of Max- k -DS.

We also think it would be valuable to study whether we can achieve better approximation ratios or derive stronger hardness results for CC-Max-2-CSP with fixed values of the cardinality constraint q . Can the hardness curves of Theorem 17 and Theorem 18 depicted in Figure 1 be matched algorithmically for every q ?

Another interesting research direction would be to come up with hardness results for some other well-know Max-CSPs like Max-3-Sat, or even more ambitiously to extend the results of Raghavendra [28] and obtain tight hardness for all cardinality-constrained Max-CSPs.

Robust Appointment Scheduling with Heterogeneous Costs

Abstract

Designing simple appointment systems that under uncertainty in service times, try to achieve both high utilization of expensive medical equipment and personnel as well as short waiting time for patients, has long been an interesting and challenging problem in health care. We consider a robust version of the appointment scheduling problem, introduced by Mittal et al. (2014), with the goal of finding simple and easy-to-use algorithms. Previous work focused on the special case where per-unit costs due to under-utilization of equipment/personnel are homogeneous i.e., costs are linear and identical. We consider the heterogeneous case and devise an LP that has a simple closed-form solution. This solution yields the first constant-factor approximation for the problem. We also find special cases beyond homogeneous costs where the LP leads to closed form optimal schedules. Our approach and results extend more generally to convex piece-wise linear costs.

For the case where the order of patients is changeable, we focus on linear costs and show that the problem is strongly NP-hard when the under-utilization costs are heterogeneous. For changeable order with homogeneous under-utilization costs, it was previously shown that an EPTAS exists. We instead find an extremely simple, ratio-based ordering that is 1.0604 approximate.

1 Introduction

Consider the problem of scheduling appointments in service operations where customers are served sequentially by a single server. Service times of customers are uncertain, and we wish to assign time slots for serving the customers in advance. An important practical setting where this problem arises everyday is in health care services, where there are numerous instances that require efficient scheduling of appointments, such as scheduling outpatient appointments in primary care and specialty clinics, scheduling surgeries for operating rooms, or appointments for MRI scans. Often in these settings the order in which patients undergo the procedure is known in advance. Then a day before the procedures, a hospital manager determines planned start times and how much time to allot to each procedure. If the manager allots too small an interval to a procedure, it could easily go overtime and delay the next procedure. The inconvenience and costs resulting from such a delay are referred to as the

Leibniz International Proceedings in Informatics

Schloss Dagstuhl – Leibniz-Zentrum für Informatik, Dagstuhl Publishing, Germany

overage cost for that procedure. On the contrary, if the manager assigns a very large interval, then the procedure will likely end much sooner. In this case the hospital incurs an *underage* cost as the equipment and personnel may be left idle until the scheduled start of the next procedure. We would like to design an appointment schedule that can achieve the desired trade-off between overage and underage costs.

In an influential survey on outpatient scheduling, Cayirli and Veral [6] concluded that the “biggest challenge for future research will be to develop easy-to-use heuristics”. Traditionally, most models for the problem are stochastic in nature and assume distributional knowledge of the uncertain service times. While such models are very powerful, estimating distributions accurately can require large amounts of data. There are many settings where such data is in fact available but, in applications related to health care appointment scheduling there is evidence (ref. [17, 18, 8]) that the amount of data available by surgery types, let alone by surgery types and surgeons, is extremely limited. Moreover, computing an objective function that involves finding the expectation of a high dimensional non-linear function can be computationally burdensome. Further, Mak et al. [18] and Mittal et al. [20] point out that methods proposed for solving stochastic models often use sophisticated subroutines, such as submodular function minimization and Monte-Carlo techniques, that may not always be practical. Robust optimization (e.g., [4, 5, 3]) offers an alternative framework to address uncertainty that avoids distributional assumptions. Instead, it uses deterministic uncertainty sets and performs a worst-case analysis w.r.t. to the uncertainty. This addresses the problems arising out of insufficient data and often these models are more tractable.¹ Indeed, for the case of appointment scheduling, Mittal et al. [20] introduced the following robust formulation for the problem.

Referring to the procedures/services in any given context simply as “jobs”, in the robust appointment scheduling problem we are given n jobs with uncertain service times $\{t_i\}$. Assume that the time t_i for job i can be anything in the range $[p_i - \hat{\delta}_i, p_i + \delta_i]$. The range is known to us but the value of t_i can be chosen adversarially. Our task is to propose an appointment start time for each job. A job will be available to process after this start time and jobs will be served in order of increasing index i . The order in which jobs are processed is fixed a priori. Due to uncertainty in service times, a job may have to wait to be processed after its appointed start time. The overage cost incurred per unit of wait is given by $o_i \geq 0$. Similarly, $u_i \geq 0$ is the per-unit underage cost associated with job i . Given a set of appointment start times, an adversary chooses the worst possible instantiation of service durations t_i i.e., one that maximizes the overall overage/underage cost. We seek start times to minimize this worst case total cost.

Mittal et al. [20] found closed-form optimal solutions for the special case of homogeneous underage costs i.e., $u_i = u$ for all jobs i . We study more general cases², where a direct generalization of their solution can be arbitrarily bad. Our central goal here is to find simple, easy to implement, and theoretically well founded algorithms. In the following we summarize our contributions and discuss closely related work.

¹ Sometimes at the expense of being too conservative.

² Arguably, just as processing times and uncertainty vary across procedures, so can personnel and equipment. Thus, in general the per-unit underage costs will vary across procedures. Moreover, it is also reasonable to assume that the per-unit cost changes with the amount of underage/overage. For instance, keeping patients waiting for another unit of time becomes less and less desirable with every unit of delay. This prompts the study of piece-wise linear overage and underage costs.

Robust Appointment Scheduling (RAS). We explore the structure of optimal appointment schedules and find several properties that all optimal schedules must satisfy. Somewhat surprisingly, we find that in every optimal appointment schedule, the case of all jobs underaged as well as the case of all jobs overaged are always worst-cases for the adversary’s problem. Casting these in the form of linear (in)equalities gives an LP, resulting in a 2-approximation. Further simplification yields a closed-form solution to the LP that could be implemented even on a spreadsheet. More generally, when the per-unit costs are allowed to change with the amount of overage/underage and the cost functions are piece-wise linear and convex (and non-decreasing), we are able to generalize these properties to obtain a 2-approximation for the problem via solving a min-cost flow problem on a graph with convex piece-wise linear arc costs.

Previously, Mittal et al. [20] examined the special case of identical underage costs and, quite remarkably, found a closed-form optimal solution in that case. While their analysis was tailored for the special case, our different approach allows us to characterize exactly when such a result holds, and we discover more general conditions under which there exists a closed-form optimal solution to the problem. We also show a similar extension for the case of convex piece-wise linear costs, where we give a simple iterative algorithm that gives an optimal allocation under additional assumptions on the cost functions.

Robust Appointment Scheduling and Ordering (RASO). While the order of patients is often fixed in advance, there are instances where patient order is flexible and simultaneously part of the decision making [6]. When underage costs are identical, Mittal et al. [20] established a key connection between RASO and the theory of scheduling jobs on a single machine to minimize the sum of a weighted nonlinear (concave) cost function of the completion times [19, 12, 25]. Focusing on the special case, we exploit this connection further to give an extremely practical ratio based ordering policy, inspired by Smith’s rule [24]. We call it the Customized-Smith rule (short C-Smith) and show that it is 1.0604-approximate. Further, we find an algorithm that is as good as C-Smith on every instance, but is also locally optimal w.r.t. pairwise swaps of neighboring jobs. Previously, Mittal et al. [20] showed that using the EPTAS for the related min-sum scheduling problem given by Stiller and Wiese [25], yields an EPTAS for RASO. The runtime of the EPTAS scales as $O(2^{1/\epsilon^T} n)$, and its implementation complexity makes it hard to use in practice. Mittal et al. [20] offered Smith’s rule as a practical alternative, with approximation ratio 1.137 due to a result in Höhn and Jacobs [12]. Finally, for the general case (arbitrary underage costs), we show the problem is strongly NP hard. We also briefly discuss the inefficacy of *list ordering* heuristics for the problem and give a heuristic with a matching lower bound.

Other related work. The existing literature on appointment scheduling is quite diverse and, in addition to the robust model we discussed above, includes numerous results on stochastic optimization models, queueing models, as well as distributionally robust optimization models. We only give a very brief review here and refer the reader to [6] for a broad overview of the challenges in scheduling appointment systems in health care, and to [18, 20] for more comprehensive surveys on past work. Starting with more recent work, Jiang et al. [14] consider a distributionally robust model and propose a MINLP formulation that can handle random no-shows. Mak et al. [18] consider a distributionally robust model given marginal moments for job durations, and formulate the problem as a tractable conic program. For the case of flexible job order, they show that under certain assumptions a simple variance based ordering can be optimal. Prior to [18], Kong et al. [16] first considered a distributionally

robust formulation but with cross-moments as opposed to marginal moments. They formulate the problem as a copositive cone program and propose a tractable SDP relaxation. Wang [26] modeled the problem using a queueing model where the processing times of the jobs are i.i.d. exponential and new jobs may be released over time. Wang [27] generalized the model to allow for different mean processing times for jobs. In a different direction, the problem was modeled as a two-stage stochastic linear program in Denton and Gupta [8]. For this problem, Robinson and Chen [23] compute near-optimal solutions using a Monte-Carlo integration technique. Kaandorp and Koole [15] considered a local search algorithm and proved that it converges to an optimal solution. Another stochastic model was introduced by Green et al. [11]. They considered the problem of outpatient appointment scheduling with emergency services and modeled it as a dynamic stochastic control problem. In highly influential work, Begen and Queyranne [2] considered a discrete stochastic model (where job durations are integer random variables with finite support). They showed that the problem reduces to an instance of submodular function minimization, under certain assumptions on the per-unit costs. Begen et al. [1] extended the idea, proving a similar result for a data-driven discrete stochastic model. Ge et al. [10] further extended the result of Begen and Queyranne [2], to the setting of convex piece-wise linear per-unit costs.

Assumptions on underage costs. Previous work on the stochastic and distributionally robust models discussed above, often assumes an upper bound on the variation in underage costs. Formally, consider jobs that are indexed in the order they are scheduled. So we have jobs $i \in \{1, \dots, n\}$, with per unit costs u_i, o_i . Now for instance, the result by Begen and Queyranne [2], assumes that there exists values $\alpha_i \leq o_i$ such that $u_{i+1} \leq u_i + \alpha_i - \alpha_{i+1}$ for every $i \in [n - 1]$. Descending underage costs for example, satisfy this condition. More generally, [14, 18, 16, 10] assume that $u_{i+1} \leq o_i + u_i$ for every $i \in [n - 1]$ (or that $u_i = u$ for all i). In effect, these assumptions are satisfied as long as the underage costs don't *increase* too sharply.

In contrast, we give a closed form optimal allocation for instances where the u_i values do not *decrease* too sharply. For example, our results yield a closed form optimal solution for the case of non-decreasing underage costs. This includes the case $u_{i+1} \geq u_i + o_i \forall i \in [n - 1]$, converse of the condition assumed in some previous work. If the per-unit underage costs are decreasing, we show that as long as the per-unit values are “large enough”, our LP still leads to a closed form optimal allocation. In practical terms, it is quite possible that the underage costs could be increasing or decreasing, preventing a direct comparison of our assumptions with past work. In fact, for the RASO problem where one has the flexibility to choose the order of jobs, an optimal order can have arbitrarily varying underage costs. From a technical viewpoint, our results complement previous work, indicating that perhaps the robust model is more tractable in instances where other models are not, and vice versa.

Overview of the paper. In Section 2, we introduce notation and formally state the problem. We also make certain observations that simplify the problem w.l.o.g.. Then in Section 3, we explore the appointment scheduling problem under fixed order. We first give our LP based approximation for general underage costs in Section 3.1. And later in Section 3.2, we tighten our LP formulation to obtain optimal closed form solutions under additional assumptions on the costs. In Section 4, we consider the problem of jointly finding an optimal order as well as appointment schedule (RASO). We show that the problem is NP hard in general and discuss the limitations of a classes of simple heuristics in Section 4.1. In Section 4.2, we focus on the ordering and scheduling problem in the special case of homogeneous underage costs. Here we discuss some disadvantages of existing results and propose two new heuristics to tackle some of the issues. Finally, we conclude with some open problems in Section 5.

2 Notation & Preliminaries

We start with a description of RAS, and define additional notation required for RASO in Section 4. Recall, we have n jobs to be served in order of increasing index $i \in \{1, \dots, n\}$. Service times are uncertain and modeled via a box uncertainty set: job i takes time t_i in the range $[p_i - \hat{\delta}_i, p_i + \delta_i]$. Here we assume that $0 \leq \hat{\delta}_i \leq p_i$ as well as $\delta_i \geq 0$, for all jobs i . We denote by $o_i \geq 0$ and $u_i \geq 0$ the per-unit overage cost and per-unit underage cost of job i , respectively. More generally, we represent overage and underage costs as *non-decreasing* functions $o_i(\cdot), u_i(\cdot)$ respectively. The case of constant per-unit costs is then given by $o_i(x) = o_i \cdot x$ and $u_i(x) = u_i \cdot x$. We would like to appoint job start times, $\{A_i\}_i$, such that every job arrives at its appointed time and is served as soon as possible after. Given $\{A_i\}_i$, consider an arbitrary instance of service times $\{t_i\}_i$, and let $\{C_i\}_i$ denote the completion times of jobs.³ If job i is delayed and ends after the appointed start time for job $i + 1$, we incur overage cost $o_i(C_i - A_{i+1})$. Similarly, if job i ends before the appointed start time for job $i + 1$, we incur underage cost $u_i(A_{i+1} - C_i)$. Therefore, the cost due to job i is $\max\{o_i(C_i - A_{i+1}), u_i(A_{i+1} - C_i)\}$. The RAS problem can now be stated as follows,

$$\min_{\{A_i\}_i} \underbrace{\left(\max_{t_i \in [p_i - \hat{\delta}_i, p_i + \delta_i] \forall i \in [n]} \sum_{i=1}^n \max\{o_i(C_i - A_{i+1}), u_i(A_{i+1} - C_i)\} \right)}_{\text{Adversary's problem, given appointment times } A_i}. \quad (1)$$

The adversary's problem in (1), finds a *worst possible profile/instance of service times* $T = (t_i) = (t_1, \dots, t_n)$, maximizing the cost, given the schedule $\{A_i\}_i$. Let $c(T, A, i) = \max\{o_i(C_i(T) - A_{i+1}), u_i(A_{i+1} - C_i(T))\}$ denote the cost of job i given allocation $\{A_i\}_i$ and time profile T . When the allocation is clear from the context, we use the shorthand $c(T, i)$. Let $c(T) = \sum_i c(T, i)$ denote the total cost due to profile T . It is not difficult to see that an optimal allocation needs to allocate at least $p_i - \hat{\delta}_i$ time for job i , so we let $p_i - \hat{\delta}_i = 0$ for every job i , w.l.o.g. (also in Lemma 6 of [20]). To simplify notation henceforth, we let service times be in the range $[0, \Delta_i]$, where $\Delta_i = \hat{\delta}_i + \delta_i$. Now, given appointment schedule $\{A_i\}_i$, consider equivalent variables x_i that represent the duration allocated for a job. We have, $x_i = A_{i+1} - A_i$, which is the difference between the start times of job $i + 1$ and job i . Equivalently, $A_i = \sum_{j=1}^{i-1} x_j$ for $i \geq 2$ and $A_1 = 0$, w.l.o.g. We call $\{x_i\}_i$, and sometimes by abuse of terminology $\{A_i\}_i$, the *allocation*. Note that in our model, job n is cost free since there is no appointment succeeding it ($A_{n+1} = \infty$). W.l.o.g. we may assume that job n also suffers from overage and underage based on its assigned end time (assign a dummy job to succeed job n). Note, if $u_i(\cdot) = 0$, we allot a very large time slot for job i and jobs on different sides of the slot become independent. Therefore, we let $u_i(\cdot) \neq 0$ for all i , w.l.o.g.. Also, if $o_n(\cdot) = 0$ we can assume that $x_n = 0$ and in fact ignore job n , therefore we also let $o_n(\cdot) \neq 0$, w.l.o.g.. To coalesce, the assumptions we have made w.l.o.g., so far:

(i) Service time for job i lies in $[0, \Delta_i]$; (ii) for every i , $u_i(\cdot) \neq 0$ ($u_i > 0$ in the constant per-unit case); and (iii) $o_n(\cdot) \neq 0$ ($o_n > 0$ in the constant per-unit case).

Finally, we say job i is *underaged* if it ends on or before time A_{i+1} , and *overaged* otherwise. However, if $\Delta_i = 0$ and job i starts/ends at A_{i+1} , we consider it to be both overaged and underaged (for technical reasons). Further, if job i takes time Δ_i to be served, we say it runs for *maximum time*. Note that if a job i is underaged in some worst-case $T = (t_i)$, then w.l.o.g., $t_i = 0$, as the underaged costs $u_i(\cdot)$ are non-decreasing functions for every i (similar

³ $C_i = \max\{C_{i-1}, A_i\} + t_i$ for all $i \geq 1$ with $C_0 = A_1 = 0$, w.l.o.g.

to Lemma 11 of [20]). Observe also that if a job i is underaged in some worst-case time profile, and it has zero cost, then i must end at A_{i+1} and take zero time. Otherwise, we have a strictly worse case by underaging i (simply reduce the time taken by i by some small $\epsilon > 0$).

Finally, let $S_i = \{i, i + 1, \dots, n\} = \{j | j \geq i\}$ be the subset of the last $n - i + 1$ jobs in the schedule. Let x_i^S denote the optimal time allocation for job i when considering only jobs in a subset S that contains i . When $S = [n]$ we often use shorthand x_i . The next section discusses a result from previous work and offers some intuition for our treatment of the general case that follows subsequently in Section 3.

2.1 Closed Form Optimal Solution of Mittal et al. [20]

Consider a single job, with per unit costs u, o and maximum time Δ . If this job is allotted time duration x , then the worst case cost is given by $\max\{u(x), o(\Delta - x)\}$, minimized at $x = \Delta \frac{o}{o+u}$ (recall, we assume that a dummy job always follows the last job, so the last job incurs overage cost for delays). Mittal et al. [20] showed that for constant per-unit underage costs, $u_i = u$ for every job $i \in [n]$, this formula generalizes and the optimal allocation is given simply by, $x_i = \Delta_i \frac{o(i)}{o(i)+u}$. Here $o(i)$ is the sum $\sum_{j=i}^n o_j$, of the per unit overage costs of the jobs succeeding job i . So each job is allotted a fraction of its maximum service time Δ_i , with a smaller fraction for larger values of u (to prevent large underage costs). Further, earlier jobs are allotted a larger fraction of their maximum time to prevent a large cascade of delays for jobs serviced later on.

Now, consider a natural generalization of this formula for heterogeneous underage costs given by, $x_i = \Delta_i \frac{o(i)}{o(i)+u_i}$. Unfortunately, this can be a suboptimal allocation even for two jobs with reasonable parameter values, and in general an arbitrarily bad approximation. For example, consider two jobs that are almost identical except that job 2 (which is scheduled later) has a small underage cost. Specifically, let $\Delta_1 = \Delta_2 = 1$ and suppose per unit costs $o_1 = o_2 = 1$ and $u_1 = M \geq 2$, but $u_2 = 1$. The allocation given by the formula sets x_1 to $\frac{2}{M+2}$ and x_2 to $\frac{1}{2}$. The worst case cost of this allocation is attained when both jobs are underaged or both overaged (more on this later), and equals $\frac{2M}{M+2} + \frac{1}{2}$. For large M , this value approaches $\frac{5}{2}$. Now instead, consider the following allocation, $y_1 = 0$ and $y_2 = \Delta_2 \frac{o_2}{o_2+u_2} + \Delta_1 \frac{o(1)}{o_2+u_2} = \frac{1}{2} + 1$ (we show later in Section 3.2, that this is in fact an optimal allocation). It is easily checked that the worst case cost is $\frac{3}{2}$ for this allocation. More generally, if we set o_1 and u_2 to a small value ϵ , the first allocation becomes arbitrarily bad. Intuitively, this demonstrates that if jobs that are later in the order have small underage costs, it is beneficial to allocate larger time to these later jobs to buffer for delays from earlier jobs. When this is not the case (such as for homogeneous underage costs), it is better to instead buffer by allocating larger fractions to jobs that are earlier in the order.

3 Robust Appointment Scheduling

3.1 Heterogeneous Per-unit Underage Costs

In this section, we focus on the case of constant per-unit costs o_i, u_i . The key behind our results lies in finding useful properties satisfied by optimal allocations. Towards that end, it will be instrumental to understand the worst cases (solutions to the adversaries' problem) for optimal allocations. Recall the adversary's objective: given $\{A_i\}_i$, maximize cost $c(T, A)$ over all possible time profiles T allowed by the uncertainty set. It turns out that for an arbitrary allocation, there could be a unique worst-case where some jobs are overaged while

others are underaged, and for some jobs the service time t_i is neither 0 nor Δ_i ⁴. It turns out though, that for any given allocation the adversary's problem can be reduced to an instance of finding longest paths on a directed acyclic graph with $n + 1$ nodes [21], and therefore can be solved in polynomial time. However, using this fact to find an optimal allocation does not obviously lead to a tractable problem. Instead, here we shall find properties in the form of linear inequalities that every optimal allocation satisfies. Using these, we formulate an LP relaxation for the problem and show that an optimal solution to the LP is 2-approximate.

As a natural next step, we then look for more structure to further tighten the formulation. Surprisingly, we find that the adversary's problem given an *optimal allocation* for problem (1) is easily solved; in every optimal allocation, $t_i = \Delta_i$ for every i (all jobs taking maximum time) and $t_i = 0$ for all i (all jobs taking zero time) are worst-cases. Combining this with other structural insights, in Section 3.2 we propose a strengthened formulation that leads to closed form optimal solutions under some assumptions on underage costs. In the lemmas that follow we introduce two properties of optimal allocations, leading to the first LP formulation.

► **Lemma 1.** *For every optimal allocation $\{x_i\}_i$, $\sum_{j=1}^k x_j \leq \sum_{j=1}^k \Delta_j$ for all $k = 1, \dots, n$.*

Proof. Given an optimal allocation $\{x_i\}_i$, let $\delta_k = \sum_{j=1}^k x_j - \sum_{j=1}^k \Delta_j$, for $k \in [n]$. Suppose, $\delta_k > 0$ for some k , and let k_0 be the smallest such k . Given this, notice that even if the first k_0 jobs take maximum time, job k_0 can never be overaged. Therefore, decreasing x_{k_0} decreases the underage cost of job k_0 ($u_{k_0} > 0$) and thus, also the worst-case cost. So the allocation $\{x'_i\}_i$ where, $x'_{k_0} = x_{k_0} - \delta_{k_0}$ and $x'_i = x_i$ for all other i is clearly a better allocation, contradiction. This lemma also follows as a direct corollary of Lemma 5 stated later on. ◀

► **Lemma 2.** *Given an allocation $\{x_i\}_i$ where $\sum_{j=1}^i x_j \leq \sum_{j=1}^i \Delta_j$ for all i , and a time profile $T = (t_i)$. The cost $c(T)$ of profile T is at most $\sum_{i=1}^n o(i)(\Delta_i - x_i) + \sum_{i=1}^n u_i x_i$.*

Proof. For any given time profile T , job i is either underaged with $c(T, i) \leq u_i x_i$ or overaged with cost at most $o_i \sum_{j \leq i} (\Delta_j - x_j)$. The latter follows from the fact that $C_i \leq \sum_{j \leq i} \Delta_j$ since $\sum_{j=1}^k x_j \leq \sum_{j=1}^k \Delta_j$ for all $k \in [i]$. Therefore, $\sum_{i=1}^n c(T, i) \leq \sum_{i=1}^n o_i \sum_{j=1}^i (\Delta_j - x_j) + \sum_{i=1}^n u_i x_i$. Rearranging the sum we have, $\sum_{i=1}^n o_i \sum_{j=1}^i (\Delta_j - x_j) = \sum_{j=1}^n (\Delta_j - x_j) o(j)$. ◀

Using the above results, the following LP now gives us an extremely simple approximation for the general problem that could be easily implemented on most systems.

$$\begin{aligned}
 \text{LP-1:} \quad & \min \sum_{j=1}^n (u_j - o(j)) y_j \\
 & \text{s.t.} \quad \sum_{j=1}^k (y_j - \Delta_j) \leq 0 \quad \forall k \in [n]; \\
 & \quad \quad y_j \geq 0 \quad \forall j \in [n].
 \end{aligned} \tag{2}$$

► **Theorem 3.** *LP-1 is a (tight) 2-approximation, and the following is an optimal solution to LP-1. Define $m_i = \arg \min_{j \geq i} (u_j - o(j))$, then for every i ,*

$$y_i = \begin{cases} 0 & \text{if } u_i - o(i) \geq 0 \text{ or } i \neq m_i \\ \sum_{j|m_j=i} \Delta_j & \text{otherwise.} \end{cases}$$

⁴ This is in contrast to Lemma 9 in [20] for the special case of $u_i = u \forall i$.

Proof. The proof of optimality for the proposed solution is easy to verify. To see the guarantee let us re-write the LP-1 objective as,

$$\min \sum_j u_j y_j + \sum_j o(j)(\Delta_j - y_j).$$

From constraints (2) and Lemma 2, this is an upper bound on the worst-case cost of any feasible solution to LP-1. Let $\{y_i^*\}$ denote an optimal solution to the LP. Lemma 1 implies that every optimal allocation $\{x_i\}$ is a feasible solution to LP-1. Further, $\sum_j u_j x_j$ denotes the cost when all jobs take zero time and $\sum_j o(j)(\Delta_j - x_j)$ is the cost of overaging all jobs with each job taking maximum time (Δ_i). Therefore, the worst-case cost of an optimal allocation, denoted OPT , is at least $\max\{\sum_j u_j x_j, \sum_j o(j)(\Delta_j - x_j)\}$ (we show later that these two costs are both in fact, equal to OPT). Therefore,

$$\sum_j u_j y_j^* + \sum_j o(j)(\Delta_j - y_j^*) \leq \sum_j u_j x_j + \sum_j o(j)(\Delta_j - x_j) \leq 2 OPT.$$

For a tight instance, consider two jobs $\{1, 2\}$ with $\Delta_1 = \epsilon \rightarrow 0$, $u_1 = 1/\epsilon$, $o_1 = 1/\epsilon - (1 + \epsilon)$ and $\Delta_2 = u_2 = o_2 = 1$. Therefore, $\frac{u_2}{u_2 + o_2} = 0.5 \lesssim \frac{u_1}{u_1 + o(1)}$. Consider the allocation $x_2 = 0.5$ and $x_1 = \epsilon \frac{o(1)}{u_1 + o(1)} \approx \epsilon/2$. It is easy to see that the worst-case of the allocation is when both jobs are underaged (overaged) and hence the cost of this allocation is $u_1 x_1 + u_2 x_2 \approx 1$. Now, consider the solution $y_2 = 0.5 + \frac{\Delta_1 o(1)}{u_2 + o_2} \approx 1$ and $y_1 = 0$. This is an optimal solution to the LP and the worst-case occurs when job 2 is underaged and job 1 is overaged. The worst-case cost of this allocation is $o_1 \Delta_1 + u_2 (y_2 - \Delta_1) \approx 2$. \blacktriangleleft

Beyond Constant Per-unit Costs

Suppose instead of scalar costs o_i, u_i , we have non-decreasing, piece-wise linear and convex cost functions $o_i(\cdot), u_i(\cdot)$. Then it is easy to check that Lemma 1 still holds. Similar to Lemma 2, we have that given an allocation $\{x_i\}_i$, satisfying Lemma 1, the cost $c(T)$ for any profile T is at most,

$$\sum_i u_i(x_i) + \sum_i o_i\left(\sum_{j \leq i} (\Delta_j - x_j)\right).$$

Now the problem of minimizing this objective subject to the linear constraints in LP-1, is a min cost flow problem with arc costs given by the overage and underage cost functions. More specifically, consider a directed graph with $n + 1$ nodes and $2n$ edges, where there is a directed edge from node i to node $n + 1$ with cost $u_i(\cdot)$ and an edge $i \rightarrow i + 1$ with cost $o_i(\cdot)$, for every $i \in [n]$. Finally, there is another edge from n to $n + 1$ with cost $o_n(\cdot)$. Finally, each node i has a supply of Δ_i and node $n + 1$ is a sink with demand $\sum_i \Delta_i$. Given a feasible flow in this graph, the flow on edge $(i \rightarrow n + 1)$ gives the time allocation for job i , and vice versa. Now, if the costs are piece-wise linear and convex, we have from the algorithm by Pinto and Shamir [22] for min flows with convex piece-wise linear costs, that the problem can be solved in polynomial (in n and the maximum number of pieces in the cost functions) time. The optimal solution to this problem is a 2-approximation, and the analysis closely resembles the proof of Theorem 3 (details deferred to full version).

3.2 Optimal Solution to RAS for Special Cases

Let us now investigate additional properties with the goal of strengthening our LP. We start by proving our claim from earlier – all jobs underaged (taking 0 time) and all jobs overaged (taking maximum time) are worst-cases for optimal allocations. We break down the proof

into smaller parts. The first lemma is very useful and appears often in proofs of other lemmas. The key insight behind the lemma is simple – when all jobs overaged is a worst-case, if the first job is forced to start late, then the case of all jobs overaged suffers maximum increase in cost, and is thus still a worst case.

► **Lemma 4.** *Given an arbitrary allocation $\{A_i\}_i$, where $t_i = \Delta_i$ for all i is a worst-case. Recall that w.l.o.g., $A_1 = 0$ and consider a modified problem for the adversary, where the first job is always forced to start at a later time t_0 instead of time $A_1 = 0$. Then, $T = (t_i)$ is also a worst-case for the modified problem.*

Proof. Let $T = (\Delta_i)$ denote the profile for all jobs taking maximum time. When job 1 starts at time 0, denote the cost of job i by $c(0, T, i)$. Since T is a worst-case by assumption, we have $c(0, T) \geq c(0, Z)$ for every profile Z . For the modified setting where job 1 starts at time $t > 0$, we claim that $c(t, Z, i) \leq c(0, Z, i) + o_i t$ for every Z . To see this, suppose job 1 starts at 0 and consider two cases: (i) i overaged in Z and (ii) i underaged in Z . In case (i), i will still be overaged when job 1 starts at time t and the completion time of i can increase by at most t . In case (ii), if i is still underaged when job 1 starts at time t , we are done. Else, i becomes overaged but the maximum overage cost is $o_i t$. Now for profile T , since all jobs are overaged when job 1 starts at time 0, $c(t, T, i) = c(0, T, i) + o_i t$. Therefore, $c(t, Z) \leq \sum_i (c(0, Z, i) + o_i t) \leq \sum_i c(0, T, i) + \sum_i o_i t = c(t, T)$. ◀

The next lemma says that we cannot have an optimal allocation where a certain job is underaged (overaged) in all the worst-case time profiles. Observe that if job i is always underaged, simply reducing the allocation x_i would give a strictly better allocation, contradicting optimality. Indeed, Lemmas 12 and 15 in [20] argue exactly this. However, that argument fails if there exists a worst-case where i is underaged with zero cost (occurs when $i - 1$ ends at A_{i+1} and $t_i = 0$, which we defined as a case of underage in Section 2). This gives rise to a subtle issue that demands a more involved argument (similarly for the case of overage). We postpone the formal proof to the full version.

► **Lemma 5.** *Given an optimal allocation, consider an arbitrary job i . There exists a worst-case $T = (t_i)$ where i is underaged and $t_i = 0$, as well as a worst-case where i is overaged (with some t_i that is not necessarily Δ_i).*

► **Lemma 6.** *In every optimal allocation, the case of all jobs underaged, i.e., $t_i = 0$ for every job i , is a worst-case.*

Proof. Let $\{A_i\}_i$ denote an optimal allocation. Lemma 5 implies there is a worst-case where job 1 takes zero time. We proceed via induction, assuming there is a worst-case $T = (t_i)$ where $t_i = 0$ for $i \in [k] = \{1, \dots, k\}$, i.e., all jobs in $[k]$ are underaged. We will show there exists a worst-case where all jobs in $[k + 1]$ are underaged.

Suppose that $k + 1$ is overaged in T (otherwise we are done). Lemma 5 implies there is a worst-case, denoted $T' = (t'_i)$, where job $k + 1$ is underaged and takes zero time. Let C_{k+1} denote the completion time of job $k + 1$ in T . Clearly, $C_{k+1} > A_{k+2}$ and $k + 1$ starts at A_{k+1} in T . Similarly, let C'_{k+1} denote the start/completion time of job $k + 1$ in T' . Then, $C'_{k+1} \leq A_{k+2}$. Now consider a new profile $Z = (z_i)$, formed by a combination of T and T' . We let $z_i = t'_i$ for $i \in [k]$ and $z_i = t_i$ for $i \in \{k + 2, \dots, n\}$. Since the completion times of job k are identical in T' and Z , we set $z_{k+1} = C_{k+1} - C'_{k+1} \leq C_{k+1} - A_{k+1} = t_{k+1}$. Therefore, job $k + 1$ ends at time C_{k+1} in Z . Now, observe that $\sum_{i \in [n]} c(Z, i) = \sum_{i=1}^k c(T', i) + \sum_{i=k+1}^n c(T, i)$. Since T is a worst-case, we also have $\sum_{i=1}^k c(T', i) + \sum_{i=k+1}^n c(T, i) \leq \sum_{i=1}^n c(T, i)$. Therefore, $\sum_{i=1}^k c(T', i) \leq \sum_{i=1}^k c(T, i)$. Now, consider another hybrid case Q , where jobs 1 to k are all

25:10 Robust Appointment Scheduling with Heterogeneous Costs

underaged and take zero time as in T and jobs $k+2$ to n are as in T' . Job $k+1$ starts/ends at A_{k+1} in Q and hence $c(T', k+1) \leq c(Q, k+1)$. Combining everything, $\sum_i c(T', i) \leq \sum_{i=1}^k c(T, i) + \sum_{k+1}^n c(T', i) \leq \sum_{i=1}^k c(T, i) + c(Q, k+1) + \sum_{k+2}^n c(T', i) = \sum_i c(Q, i)$. Hence, Q is a worst-case with jobs 1 to $k+1$ all underage. \blacktriangleleft

► **Lemma 7.** *In every optimal allocation, the case of all jobs overaged is a worst-case. Therefore, $t_i = \Delta_i$ for all i is a worst-case.*

Proof. Let $\{A_i\}_i$ denote an optimal allocation. Observe that if there exists a worst-case where jobs $S_k = \{k, \dots, n\}$ are all overaged for some k , then there exists a worst-case where all jobs in S_k are overaged and take maximum time. We proceed by induction and show that if there is a worst-case where every job in S_k is overaged, then there exists a worst-case where every job in S_{k-1} is overaged. For $k = n$, by Lemma 5 there is a worst-case where job n is overaged. Assume there exists a worst-case where jobs k to n are overaged, denoted as $T = (t_i)$.

Suppose that job $k-1$ is underage in profile T (otherwise we are done). Recall that $u_{k-1} > 0$ and $t_{k-1} = 0$, since k is underage in T . Then, since T is a worst-case profile; restricted to the subset S_k , the profile $\{t_i = \Delta_i\}_{i \geq k}$ is a worst-case with all jobs overaged, for allocation $\{A_i\}_{i \geq k}$. Now, by Lemma 5 for the set of all jobs $[n]$, there exists a worst-case where job $k-1$ is overaged, denoted $T' = (t'_i)$. Then, consider profile $Z = (z_i)$ with $z_i = t'_i$ for jobs in $S_1 - S_{k-1}$ and $z_i = \Delta_i$ for $i \in S_{k-1}$. Z is a worst-case profile since it matches the cost in T' for jobs in $S_1 - S_{k-1}$, and due to Lemma 4 the total costs for jobs in S_{k-1} can only be larger than the same total in T' . \blacktriangleleft

The following equation characterizes the worst-case cost of every optimal allocation $\{x_i\}_i$,

$$\sum_{i=1}^n o(i)(\Delta_i - x_i) = \sum_{i=1}^n u_i x_i. \quad (3)$$

We can already modify LP-1 by adding the equality above. However, this property alone is not sufficient to offer improved results even for identical underage costs. To that end, we introduce the following technical property.

► **Lemma 8.** *Given an optimal allocation $\{x_i\}_{i \in [n]}$,*

$$\sum_{j=k}^n (u_j + o(j))y_j \geq \sum_{j=k}^n o(j)\Delta_j \quad \text{for all } k \in [n]. \quad (4)$$

To get some intuition behind the lemma, consider the objective of minimizing $\sum_i u_i y_i$ for non-negative y_i subject to the equation (3). A greedy solution that sets $y_i = \frac{\sum_j \Delta_j o(j)}{u_i + o(i)}$ for $i = \arg \min_{j \in [n]} \frac{u_j}{u_j + o(j)}$ is optimal. Here the job with the minimum ratio $\frac{u_i}{u_i + o(i)}$, bears the entire burden of the equality (3). Lemma 8 says that this can only occur when $i = n$ and more generally, places a lower bound on the contribution to equality (3) from values y_k to y_n , for all k . The proof of the lemma is rather technical and is postponed to the full version, along with two accompanying helper lemmas. Consider now the strengthened formulation,

$$\begin{aligned}
 \text{LP-2:} \quad & \min \sum_{j=1}^n u_j y_j \\
 \text{s.t.} \quad & \sum_{j=1}^n (u_j + o(j)) y_j = \sum_{j=1}^n o(j) \Delta_j \tag{5} \\
 & \sum_{j=k}^n (u_j + o(j)) y_j \geq \sum_{j=k}^n o(j) \Delta_j \quad \forall k \in [n] \tag{6} \\
 & \sum_{j=1}^k (y_j - \Delta_j) \leq 0 \quad \forall k \in [n] \\
 & y_j \geq 0 \quad \forall j \in [n]
 \end{aligned}$$

Clearly, every optimal allocation is a feasible solution for the LP. However, an optimal solution to the LP need not have all jobs underaged (or overaged) as worst-case, and hence need not be an optimal allocation. This is demonstrated by the example used in Theorem 3, where it is easily checked that the additional constraints given by (5) and (6) do not improve the worst-case approximation bound from earlier. However, we show that under additional assumptions LP-2 yields optimal allocations.

The recipe behind proving this is as follows: (i) Using the assumptions, show that there is actually a closed-form optimal solution to the LP. (ii) Show that for this solution, all jobs underaged and all jobs overaged are worst-cases. In particular, using this recipe for the special case of homogeneous underage costs $u_i = u$ for every i , we find that $x_i = \frac{o(i)\Delta_i}{u+o(i)}$ for all $i \in [n]$ is an optimal solution to LP-2 and an optimal allocation. More generally, we have the following.

► **Theorem 9.** *If $u_i \leq u_{i+1} \frac{o(i)}{o(i+1)}$ for all $i \in [n-1]$, then the allocation given by $x_i = \frac{o(i)\Delta_i}{u+o(i)}$, $i \in [n]$, is an optimal allocation.*

This generalizes and offers a different perspective on Theorem 5 in [20] (since $u_i = u$ for every i , implies $u_i \leq u_{i+1} \frac{o(i)}{o(i+1)}$ for all $i \in [n-1]$). As a direct implication of the above, we have a closed form optimal allocation if if the underage costs are non-decreasing i.e.,

$$u_i \leq u_{i+1} \quad \forall i \in [n-1].$$

This includes for instance, the case of increasing underage costs where $u_{i+1} \geq u_i + o_i$. As we discussed earlier in Section 1, this complements the assumptions made in previous work, where the common assumption is that the underage costs are not increasing too drastically and in particular that, $u_{i+1} \leq u_i + o_i$ for all $i \in [n-1]$.

Next, we claim that even if $u_i > u_{i+1} \frac{o(i)}{o(i+1)}$ for some i , there may still exist an LP optimal solution that is also an optimal allocation. This generalizes Theorem 9. A direct corollary of the result is that if underage costs are “large enough”, we have a closed form optimal solution even if the costs otherwise vary arbitrarily. More specifically, if the underage costs are such that for ever pair of jobs $i-l$ and i with $u_{i-l} > u_i$, we have,

$$u_i \geq \sum_{j=1}^l o_{i-j}.$$

Then LP-2 leads to a closed form optimal allocation.

25:12 Robust Appointment Scheduling with Heterogeneous Costs

► **Theorem 10.** *Given n jobs with parameters such that for $i \in [n]$, whenever $i \neq m_i := \min(\arg \min_{j \geq i} \frac{u_j}{u_j + o(j)})$, we have $u_{m_i} \geq o(i) - o(m_i)$, then the following is both an optimal solution to the LP and an optimal allocation,*

$$x_k = \frac{\sum_{i|k=m_i} \Delta_i o(i)}{u_k + o(k)} \quad \text{for all } k \in [n].$$

Optimal Allocation Beyond Constant Per-unit Costs

For non-decreasing, piece-wise linear and convex costs $o_i(\cdot), u_i(\cdot)$, let $\bar{o}_i, \underline{o}_i$ denote the largest and smallest slope for $o_i(\cdot)$ and, $\bar{u}_i, \underline{u}_i$ the largest and smallest slope for $u_i(\cdot)$. By generalizing insights from the case of constant per-unit costs, we show that Algorithm 1 finds the optimal allocation when $\underline{u}_{i+1} \geq \bar{u}_i$, for all $i \in [n-1]$. This condition is satisfied for instance if $u_i(x) = u \cdot x$ for all $i \in [n]$, and $o_i(\cdot)$ is an arbitrary non decreasing, convex piece-wise linear function. Similar to the case of constant per-unit costs, our assumption complements assumptions made in previous work on the stochastic setting of the problem. For instance, in the stochastic setting Ge et al. [10], gave a polynomial time algorithm for non decreasing, piece-wise linear and convex costs when $\bar{u}_{i+1} \leq \underline{u}_i + \underline{o}_i$, for all $i \in [n-1]$.

■ **Algorithm 1** Allocation for Non-Linear Costs.

-
- 1: **for** $i = n$ **to** 1 **do**
 - 2: $\hat{o}_i(x) := \sum_{j \geq i} \left(o_j(\Delta_i - x + \sum_{k|i < k \leq j} (\Delta_k - x_k)) - o_j(\sum_{k|i < k \leq j} (\Delta_k - x_k)) \right)$
 - 3: $x_i = \underset{x \geq 0}{\operatorname{argmin}} \max\{u_i(x), o_i(\Delta_i - x) + \hat{o}_i(x)\}$
 - 4: **Output:** $\{x_i\}_i$
-

► **Remark.** Given two sets of jobs $S_{k-1} = \{k-1, \dots, n\}$ and $S_k = \{k, \dots, n\}$. Let the output of Algorithm 1 over set S_{k-1} be $\{x_i^{k-1}\}$, and over set S_k be $\{x_i^k\}$. Then we have, $x_i^{k-1} = x_i^k$ for all $i \in S_k$. Also, note that the algorithm takes n iterations, each involves a minimization of the maximum of two convex piece-wise linear functions (as $u_i(x)$ and $o_i(\Delta_i - x) + \hat{o}_i(x)$ are both piece-wise linear and convex in x). Therefore, each step involves finding the minimum of a convex piece-wise linear function. Hence, the algorithm runs in polynomial time (in n and the number of pieces in the cost functions).

4 Robust Appointment Scheduling and Ordering

So far, we assumed that jobs are given to us in fixed order and our task was to find an optimal appointment schedule. Focusing on the case of constant per-unit costs, we now consider the joint problem of finding an ordering and an appointment schedule such that the resulting cost is minimized. More formally, consider a permutation π over the set $[n]$, that determines the order of appointments. So given an ordering π , job i is the $\pi(i)$ -th appointment in the schedule. We let A_i, C_i denote the start time and the completion time of the i -th appointment (or the $\pi^{-1}(i)$ -th job). The joint scheduling and ordering problem can now be stated as,

$$\min_{\pi: [n] \rightarrow [n], \{A_i\}_i} \max_{t_i \in [0, \Delta_i] \forall i} \sum_{i=1}^n \max\{o_{\pi^{-1}(i)}(C_i - A_{i+1}), u_{\pi^{-1}(i)}(A_{i+1} - C_i)\}. \quad (7)$$

Recall that under homogeneous underage costs $u_i = u \forall i$, we have a closed form solution for the problem for fixed permutation π . Letting $o(i) = \sum_{j|\pi(j) \geq \pi(i)} o_j$, the objective in this special case can be more simply stated as,

$$\min_{\pi: [n] \rightarrow [n]} \sum_{i=1}^n \frac{\Delta_i o(i) u}{o(i) + u}.$$

Let us call this problem RASO-H for brevity. Mittal et al. [20] showed that RASO-H reduces to an instance of min-sum scheduling with concave costs $1|| \sum w_j f(C_j)$. Here given jobs j with processing time p_j , weight w_j , and a concave function $f(\cdot)$ over completion times C_j , the goal is to find an ordering that achieves the following,

$$\min_{\{C_j\}_j} \sum_{j=1}^n w_j f(C_j). \tag{8}$$

Indeed, letting $w_j = \Delta_j$, $p_j = o_j$ and $f(C_j) = \frac{u C_j}{C_j + u}$, we see that any ordering π for RASO-H is equivalent to an order π' in $1|| \sum w_j f(C_j)$. Here $\pi'(j) = n - \pi(j) + 1$ (i.e., orders are reversed as we move between the two problems). This reduces RASO-H to an instance of $1|| \sum w_j f(C_j)$, while preserving the objective value. Therefore, algorithms for $1|| \sum w_j f(C_j)$ can be used directly for RASO-H without any loss in guarantee. Using a result in [12], the following rule,

Smith's rule: Schedule jobs in the order of descending ratios $\frac{w_j}{p_j}$ (or ascending ratios $\frac{\Delta_j}{o_j}$),

is 1.137 approximate for RASO-H. In fact, there is an EPTAS for RASO-H due to the EPTAS for $1|| \sum w_j f(C_j)$ [25]. However, the hardness of RASO with a single underage cost, and more generally of $1|| \sum w_j f(C_j)$, remains an intriguing open problem in scheduling theory [25, 19, 12, 20].

In the upcoming section, we consider the general problem for which no results were previously known. We give evidence indicating that the problem becomes much harder without the homogeneous underage costs assumption.

4.1 RASO with General Underage Costs

We show that RASO is strongly NP-hard when there are at least two different underage costs via a reduction from the strongly NP hard problem of min-sum scheduling on identical parallel machines, $P|| \sum w_j C_j$ (problem SS13 in Garey and Johnson [9]). Further, we also show that no list ordering rule (such as Smith's rule) can be better than $O(n)$ approximate for the problem, ruling out the existence of "simple" approximation heuristics. We defer the details and proofs to the full version.

To develop approximation heuristics for RASO, unlike RASO-H, we cannot rely on a closed-form solution for the optimal allocation problem to simplify the problem. However, we do have a closed-form solution with cost guaranteed to be within a constant factor of the optimal due to Theorem 3. This does not immediately lead to a tractable problem, and taking a different approach we instead consider the closed form allocation given by the formula $x_i = \frac{\Delta_i o(i)}{u_i + o(i)}$. Given order π , let $o(i) = \sum_{j|\pi(j) \geq \pi(i)} o_j$. For this allocation rule the ordering problem simplifies to,

$$\min_{\pi: [n] \rightarrow [n]} \sum_{j=1}^n \frac{\Delta_j o(j) u_j}{o(j) + u_j}. \tag{9}$$

This is equivalent to a min-sum scheduling problem of the form,

$$\min_{\{C_j\}_j} \sum_j f_j(C_j).$$

Here C_j is the completion time of job j which has processing time $p_j = o_j$. Functions $f_j(C_j) = \Delta_j u_j \frac{C_j}{C_j + u_j}$ are concave, but now we have a different function for each job. We show (details in full version) that given an α approximation for $1 \|\sum_j f_j(C_j)$, there is a $4\alpha n$ approximation for RASO. The additional factor of $4n$ arises from the fact that (9) does not represent the true objective (7). Recall that the closed form allocation formula $x_j = \Delta_j \frac{o(j)}{o(j) + u_j}$, is not only suboptimal but can be arbitrarily worse than the optimal allocation for certain orders. So it is perhaps surprising that using this allocation we can still achieve some approximation bound. Note that for the min-sum scheduling problem, $1 \|\sum f_j(C_j)$, [7] gives a $4 + \epsilon$ approximation for arbitrary f_j . Using this algorithm, we have a $(16 + \epsilon)n$ approximation for RASO. We also show that no heuristic that orders jobs based on a simple ratio can beat $\Omega(n)$. Here we use the term “simple ratio” to refer to any real valued function evaluated independently for each job, using only the job parameters (o_i, Δ_i, u_i) . A list ordering heuristic for this function then simply orders jobs in ascending or descending order of the function values.

4.2 Homogeneous Underage Costs

In this section, we develop some easy to implement heuristics with improved approximations for RASO-H. As we mentioned earlier, the computational complexity of RASO-H and more generally, $1 \|\sum w_j f(C_j)$ with concave cost function f , remains open but, there is a scaling based EPTAS for RASO-H due to the EPTAS for $1 \|\sum w_j f(C_j)$. The EPTAS is non-trivial and not easy to implement in practice. Practical heuristics such as Smith’s rule, can be suboptimal for RASO-H even with just two jobs. This motivates us to consider the following heuristic,

Customized-Smith’s rule (C-Smith): Schedule jobs in ascending order of $\frac{\Delta_i}{o_i(o_i + u)}$.

This straightforward heuristic is optimal for two jobs by design, and has an approximation guarantee of β , where $1.06036 < \beta < 1.06043$. While the order output by C-Smith is optimal for two jobs, we could more generally seek an order that is optimal w.r.t. exchanging the order of any two consecutive jobs. Let us call such an order *locally optimal*. The schedule output by both Smith and C-Smith is not locally optimal. In fact, no list-ordering heuristic can be locally optimal for all instances of RASO-H. To address this we introduce Algorithm 2, which outputs a locally optimal order. While not as simple as C-Smith, it is still fairly easy to implement – at each step, it computes a new set of ratios for the remaining jobs and picks the one with the best ratio, removing it from further consideration. However, a naive implementation has runtime $O(n^2)$, in contrast to $O(n \log n)$ for list ordering heuristics.

We show that Algorithm 2 outputs a solution that is at least as good as C-Smith on every instance. Thus, it is also β approximate. There exist instances for which the algorithm is not optimal. However, we leave finding the exact guarantee of the algorithm as an open problem.

► **Theorem 11.** *For every instance of RASO-H, Algorithm 2 outputs an order that is at least as good as the order given by C-Smith.*

The proof is deferred to the full version. It remains to show the β approximation for C-Smith. For this analysis it will be much more convenient both for clarity as well as notation, to focus on analyzing C-Smith for the scheduling problem $1 \|\sum_j w_j f(C_j)$, where

Algorithm 2 Locally Optimal Algorithm.

- 1: **Initialize:** $S = \emptyset, o(S) = 0$
- 2: **for** $i = 1$ to n **do**
- 3: Find,

$$j = \operatorname{argmax}_{k \in [n] \setminus S} \frac{\Delta_k}{o_k(o_k + o(S) + 1)}.$$

In case of a tie, pick the job with largest overage cost.

- 4: $\pi(j) = n - i + 1, S = S \cup \{j\}, o(S) = o(S) + o_j$
 - 5: **Output:** $\pi(\cdot)$
-

$f(C_j) = \frac{C_j^u}{C_j + u}$ and $w_j = \Delta_j, p_j = o_j$. Note that we can let $u = 1$ w.l.o.g. Also recall, there is a cost preserving bijection between orders for $1 \parallel \sum_j w_j f(C_j)$ and RASO-H – reversing the order when moving from one to the other. Therefore, we will show the following equivalent theorem.

► **Theorem 12.** *For some constant $\beta \in [1.06036, 0.6043]$. scheduling jobs in descending order of $\frac{w_j}{p_j(p_j+1)}$ is exactly β approximate for the scheduling problem $1 \parallel \sum_j w_j \frac{C_j}{C_j+1}$.*

To prove the above theorem, we establish several intermediate results that characterize and simplify the worst-case instance for C-Smith. First, we show that there is a worst-case instance for C-Smith where all jobs are tied and in fact have ratio 1. This is shown via a generalization of Lemma 3.5 in [12] (Lemma 21 in [25]). Then, we show that in the worst-case C-Smith orders jobs in ascending order of processing times and the optimal order is the exact reverse. Interestingly, this is the opposite of Lemma 3.6 in [12] (Proposition 20 in [25]) for Smith’s rule, where the optimal order is ascending in p_i and the worst order is descending. Given these properties, we can formulate a non-convex optimization problem in infinitely many variables, the optimal value of which is the approximation ratio, and every optimal solution is a worst-case instance. To then get lower and upper bounds on the optimum value, we utilize properties specific to our objective $f(x) = \frac{x}{x+1}$ to approximate the problem (which has infinitely many variables) with a family of optimization problems, that while still non-convex, have a finite number of variables. More complex objectives from the family give a tighter upper bound on true approximation ratio, but the number of variables involved increases. We find the global optimum to a problem in the family with five variables, and this closely matches our lower bound. We solve such a non-convex problem to global optimality by establishing upper and lower bounds on variables and using linear cuts, both of which allow us to then effectively use a nonlinear globally optimal MINLP solver, Couenne [13] (details in full version).

5 Conclusion & Open Problems

We considered the robust appointment scheduling problem with general underage costs. For the appointment scheduling problem with fixed jobs order, we found a simple LP that gives a 2-approximation for the problem under constant per-unit costs. Then we further refined this LP, resulting in a closed form solution for optimal allocations in special cases (generalizing previous results in the robust model, and complementing similar results in other models). We also showed that our results and approach extend more generally to convex piece-wise

linear costs. When seeking an optimal allocation for the general case using our approach, more complications arise and it is not clear if one can still construct a linear (or convex) program such that an optimal solution to the program is also an optimal allocation. We leave finding an optimal solution for the general case (or showing hardness), as an open problem.

In the second setting, we considered the problem of jointly finding the optimal order and allocation given that order for the case of constant per-unit costs. For the case of heterogeneous underage costs, we show that the problem is strongly NP hard and no list ordering policy can do better than $\Omega(n)$ to approximate the optimal value. We also gave a heuristic that achieves this bound. Finding a better approximation for this setting remains another interesting open problem. For the case of homogeneous underage costs, we designed two simple and practical heuristics that are guaranteed to be with ≈ 1.06 of the optimal.

Abstract

In the Shortest Common Superstring (SCS) problem, one is given a collection of strings, and needs to find a shortest string containing each of them as a substring. SCS admits $2\frac{11}{23}$ -approximation in polynomial time (Mucha, SODA'13). While this algorithm and its analysis are technically involved, the 30 years old Greedy Conjecture claims that the trivial and efficient Greedy Algorithm gives a 2-approximation for SCS.

We develop a graph-theoretic framework for studying approximation algorithms for SCS. The framework is reminiscent of the classical 2-approximation for Traveling Salesman: take two copies of an optimal solution, apply a trivial edge-collapsing procedure, and get an approximate solution. In this framework, we observe two surprising properties of SCS solutions, and we conjecture that they hold for all input instances. The first conjecture, that we call Collapsing Superstring conjecture, claims that there is an elementary way to transform any solution repeated twice into the same graph G . This conjecture would give an elementary 2-approximate algorithm for SCS. The second conjecture claims that not only the resulting graph G is the same for all solutions, but that G can be computed by an elementary greedy procedure called Greedy Hierarchical Algorithm.

While the second conjecture clearly implies the first one, perhaps surprisingly we prove their equivalence. We support these equivalent conjectures by giving a proof for the special case where all input strings have length at most 3 (which until recently had been the only case where the Greedy Conjecture was proven). We also tested our conjectures on millions of instances of SCS.

We prove that the standard Greedy Conjecture implies Greedy Hierarchical Conjecture, while the latter is sufficient for an efficient greedy 2-approximate approximation of SCS. Except for its (conjectured) good approximation ratio, the Greedy Hierarchical Algorithm provably finds a 3.5-approximation, and finds *exact* solutions for the special cases where we know polynomial time (not greedy) exact algorithms: (1) when the input strings form a spectrum of a string (2) when all input strings have length at most 2.

1 Introduction

The *shortest common superstring problem* (abbreviated as SCS) is: given a set of strings, find a shortest string that contains all of them as substrings. This problem finds applications in genome assembly [33, 24], and data compression [9, 8, 28]. We refer the reader to the excellent surveys [10, 21] for an overview of SCS, its applications and algorithms. SCS is known to be **NP**-hard [9] and even **MAX-SNP**-hard [3], but it admits constant-factor approximation in polynomial time.

The best known approximation ratios are $2\frac{11}{23}$ due to Mucha [22] and $2\frac{11}{30}$ due to Paluch [23] (see [12, Section 2.1] for an overview of the previous approximation algorithms and inapproximability results). While these approximation algorithms use an algorithm for Maximum Weight Perfect Matching as a subroutine, the 30 years old *Greedy Conjecture* [28, 30, 31, 3] claims that the trivial *Greedy Algorithm*, whose pseudocode is given in Algorithm 1, is 2-approximate. Ukkonen [32] shows that for a fixed alphabet, the Greedy Algorithm can be implemented in linear time. It should be noted that GA is not deterministic as we do not specify how to break ties in case when there are many pairs of strings with maximum overlap. For this reason, GA may produce different superstrings for the same input.

■ Algorithm 1 Greedy Algorithm (GA).

Input: set of strings \mathcal{S} .

Output: a superstring for \mathcal{S} .

- 1: **while** \mathcal{S} contains at least two strings **do**
 - 2: extract from \mathcal{S} two strings with the maximum overlap
 - 3: add to \mathcal{S} the shortest superstring of these two strings
 - 4: **return** the only string from \mathcal{S}
-

► **Greedy Conjecture.** *For any set of strings \mathcal{S} , $\text{GA}(\mathcal{S})$ constructs a superstring that is at most twice longer than an optimal one.*

Blum et al. [3] prove that the Greedy Algorithm returns a 4-approximation of SCS, and Kaplan and Shafrir [15] improve this bound to 3.5. A slight modification of the Greedy Algorithm gives a 3-approximation of SCS [3], and other greedy algorithms are studied from theoretical [3, 25] and practical perspectives [26, 4].

It is known that the Greedy Conjecture holds for the case when all input strings have length at most 3 [30, 7], and it was recently shown to hold in the case of strings of length 4 [18]. Also, the Greedy Conjecture holds if the Greedy Algorithm happens to merge strings in a particular order [35, 19]. The Greedy Algorithm gives a 2-approximation of a different metric called compression [30]. The compression is defined as the sum of the lengths of all input strings minus the length of a superstring (hence, it is the number of symbols saved with respect to a naive superstring resulting from concatenating the input strings).

Most of the approaches for approximating SCS are based on the *overlap graph* or the equivalent *suffix graph*. The suffix graph has input strings as nodes, and a pair of nodes is joined by an arc of weight equal to their suffix (see Section 2.1 for formal definitions of overlap and suffix). SCS is equivalent to (the asymmetric version of) the Traveling Salesman Problem (TSP) in the suffix graph. While TSP cannot be approximated within any polynomial time computable function unless $\mathbf{P} = \mathbf{NP}$ [27], its special case corresponding to SCS can be

approximated within a constant factor.¹ We do not know the full characterization of the graphs in this special case, but we know some of their properties: Monge inequality [20] and Triple inequality [35]. These properties are provably not sufficient for proving Greedy Conjecture [35, 19].

While the overlap and suffix graphs give a convenient graph structure, our current knowledge of their properties is provably not sufficient for showing strong approximation factors. Thus, the known approximation algorithms (including the Greedy Algorithm) estimate the approximation ratio via the overlap graph, and also separately take into account some string properties not represented by the overlap graph. The goal of this work is to develop a simple combinatorial framework which captures all features of the input strings needed for proving approximation ratios of algorithms.

1.1 Our contributions

We continue the study of the so-called *hierarchical graph* introduced by Golovnev et al. [13]. (See also [5] for a related notion of the superstring graph.) This graph is designed specifically for the SCS problem, in some sense it generalizes de Bruijn graph, and it contains more information about the input strings than just all pairwise overlaps. Given an instance of SCS, the vertex set of the corresponding hierarchical graph is just the set of substrings of all the input strings. For a string s and two symbols α, β , the graph contains the arcs: $(s, s\alpha)$ and $(\beta s, s)$. Now, every superstring of the given set of string corresponds to an Eulerian walk in the hierarchical graph (which passes through the vertices corresponding to the input strings), and vice versa. (See Section 2.2 for formal definition and statements.)

1.1.1 Collapsing Conjecture

We define a simple normalization procedure of a walk in the hierarchical graph: replace the pair of arcs $(\alpha s, \alpha s\beta), (\alpha s\beta, s\beta)$ with the pair $(\alpha s, s), (s, s\beta)$ as long as it does not violate connectivity of the walk. It is easy to see that such a normalization never increases the length of the corresponding solution of SCS. First, we observe a surprising property of this normalization procedure: if one takes *any* solution, doubles all of its arcs in the hierarchical graph, and then applies the normalization procedure, then the resulting set of arcs is always the same (i.e., it does not depend on the initial solution). Collapsing Conjecture makes this observation formal (see Section 3). Note that this conjecture implies an extremely simple 2-approximate algorithm for Shortest Common Superstring: take any solution (for example, write down all input strings one after another), then double each arc in the hierarchical graph, and apply the simple normalization procedure. This procedure will result in some superstring S . On the other hand, if one started with an optimal solution, doubled each of its arcs, and normalized the result, then the resulting solution would have length at most twice the length of the optimal solution. By Collapsing Conjecture, this resulting superstring would also be S , which implies that S is a 2-approximation.

¹ We remark that SCS is also a special case of TSP for costs satisfying the triangle inequality. This case of TSP can be approximated within a constant factor [29], but this factor is currently much worse than that for SCS.

1.1.2 Greedy Hierarchical Conjecture

We also propose a simple and natural greedy algorithm for SCS in the hierarchical graph: start from the nodes corresponding to the input strings, and greedily build an Eulerian walk passing through all of them. While this Greedy Hierarchical Algorithm (GHA) is as simple as the Greedy Algorithm (GA), it provably performs better in some cases. For example, there are two well-known polynomially solvable special cases of SCS: strings of length 2 and a spectrum of a string. While GA does not always find optimal solutions in these cases, GHA solves them exactly (see Sections B.1 and B.2).

Greedy Hierarchical Conjecture (see Section 4) claims that the set of arcs produced by GHA exactly matches the set of arcs from the Collapsing Conjecture: whichever initial solution one takes, after doubling its arcs and normalization, the resulting set of arcs is exactly the solution found by GHA. Clearly, this conjecture implies Collapsing Conjecture. Perhaps surprisingly, we prove that the two conjectures are equivalent (see Section 5.1): if all doubled solutions after normalization result in the same set of arcs, then this set of arcs is the GHA solution.

The weak form of Greedy Hierarchical Conjecture claims that GHA is a 2-approximate algorithm for SCS. We prove (see Section 5.2) that GHA is an instantiation of GA with some tie-breaking rule. That is, there is an algorithm which always merges some pair of strings with the longest overlap and outputs the same solution as GHA. This result has two consequences. First, by the known results for GA, we immediately have that GHA finds a 3.5-approximation for SCS. Second, this gives us that Greedy Conjecture implies Weak Greedy Hierarchical Conjecture.

1.1.3 Evidence for the Conjectures

We support the Collapsing Conjecture (and the equivalent Greedy Hierarchical Conjecture) by proving its special case and verifying it empirically. We prove the conjecture for the special case where all input strings have length at most 3, which until recently had been the only case where the Greedy Conjecture was proven (see Section A). Despite testing the conjecture on millions of datasets (both hand-crafted and generated randomly according to various distributions), we have not found a counter-example. Note that even the Weak Greedy Hierarchical Conjecture suffices for getting a 2-approximation for SCS, and this conjecture is not harder to prove than the standard Greedy Conjecture. We implemented the Greedy Hierarchical Algorithm [11], and we invite the reader to its web interface [34] to see step by step executions of the described algorithms and to verify the conjectures on custom datasets.

2 Definitions

2.1 Shortest Common Superstring Problem

For a string s , by $|s|$ we denote the length of s . For strings s and t , by $\text{overlap}(s, t)$ we denote the longest suffix of s that is also a prefix of t . By $\text{pref}(s, t)$ we denote the first $|s| - |\text{overlap}(s, t)|$ symbols of s . Similarly, $\text{suff}(s, t)$ is the last $|t| - |\text{overlap}(s, t)|$ symbols of t . By $\text{pref}(s)$ and $\text{suff}(s)$ we denote, respectively, the first and the last $|s| - 1$ symbols of s . See Figure 1 for a visual explanation. We denote the empty string by ε .

Throughout the paper by $\mathcal{S} = \{s_1, \dots, s_n\}$ we denote the set of n input strings. We assume that no input string is a substring of another (such a substring can be removed from \mathcal{S} in the preprocessing stage). Note that SCS is a *permutation problem*: to find a shortest

■ **Figure 1** Pictorial explanations of pref, suff, and overlap functions.

string containing all s_i 's in a *given order* one just overlaps the strings in this order, see Figure 2. (This simple observation relates SCS to other permutation problems, including various versions of the Traveling Salesman Problem.) It will prove convenient to view the SCS problem as a problem of finding an optimum permutation. It should be noted at the same time that the correspondence between permutations and superstrings is not one-to-one: there are superstrings that do not correspond to any permutation. For example, the concatenation of input strings is clearly a superstring, but it ignores the fact that neighbor strings may have non-trivial overlaps and for this reason may fail to correspond to a permutation. Still, clearly, any *shortest* superstring corresponds to a permutation of the input strings.

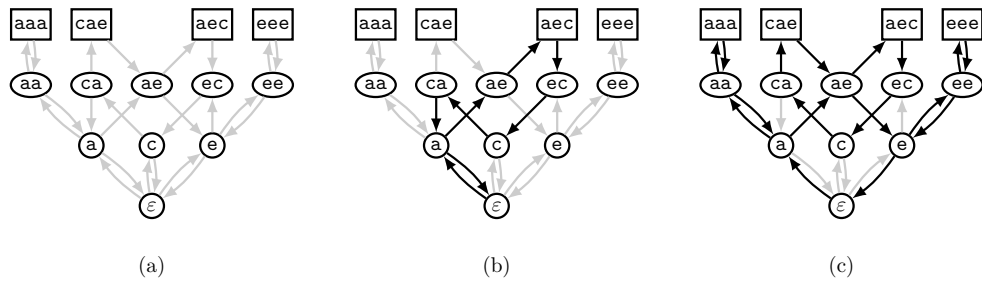

■ **Figure 2** SCS is a permutation problem. The length of a superstring corresponding to a permutation $(s_{i_1}, \dots, s_{i_n})$ is $|s_{i_1}|$ plus the sum of the lengths of suffixes of consecutive pairs of strings. It is also equal to $\sum_{i=1}^n |s_i| - \sum_{j=1}^{n-1} |\text{overlap}(s_{i_j}, s_{i_{j+1}})|$.

2.2 Hierarchical Graph

For a set of strings \mathcal{S} , the *hierarchical graph* $HG = (V, E)$ is a weighted directed graph with $V = \{v : v \text{ is a substring of some } s \in \mathcal{S}\}$. For every $v \in V, v \neq \varepsilon$, the set of arcs E contains an *up-arc* $(\text{pref}(v), v)$ of weight 1 and a *down-arc* $(v, \text{suff}(v))$ of weight 0. The meaning of an up-arc is appending one symbol to the end of the current string (and that is why it has weight 1), whereas the meaning of a down-arc is cutting down one symbol from the beginning of the current string. Figure 3(a) gives an example of the hierarchical graph and shows that the terminology of up- and down-arcs comes from placing all the strings of the same length at the same level, where the i -th level contains strings of length i . In all the figures in this paper, the input strings are shown in rectangles, while all other vertices are ellipses.

What we are looking for in this graph is a shortest walk from ε to ε going through all the nodes from \mathcal{S} . It is not difficult to see that the length of a walk from ε to ε equals the length of the string spelled by this walk. This is just because each up-arc has weight 1 and adds one symbol to the current string. See Figure 3(b) for an example.

26:6 Collapsing Superstring Conjecture

■ **Figure 3** (a) Hierarchical graph for the dataset $\mathcal{S} = \{\text{aaa}, \text{cae}, \text{aec}, \text{eee}\}$. (b) The walk $\varepsilon \rightarrow \text{a} \rightarrow \text{ae} \rightarrow \text{ec} \rightarrow \text{c} \rightarrow \text{ca} \rightarrow \text{a} \rightarrow \varepsilon$ has length (or weight) 4 and spells the string aeca of length 4. (c) An optimal superstring for \mathcal{S} is aaecaeee . It has length 9, corresponds to the permutation $(\text{aaa}, \text{aec}, \text{cae}, \text{eee})$, and defines the walk of length 9 shown in black.

Hence, the SCS problem is equivalent to finding a shortest closed walk from ε to ε that visits all nodes from \mathcal{S} . Note that a walk may contain repeated nodes and arcs. The multiset of arcs of such a walk must be Eulerian (each vertex must have the same in- and out-degree, and the set of arcs must be connected). It will prove convenient to define an *Eulerian solution* in a hierarchical graph as an Eulerian multiset of arcs D that goes through ε and all nodes from \mathcal{S} . Given such a solution D , one can easily recover an Eulerian cycle (that might not be unique). This cycle spells a superstring of \mathcal{S} of the same length as D . Figure 3(c) shows an optimal Eulerian solution.

A solution to SCS defines a permutation $(s_{i_1}, \dots, s_{i_n})$ of the input strings, and this permutation naturally gives a “zig-zag” Eulerian solution in the hierarchical graph:

$$\varepsilon \rightarrow s_{i_1} \rightarrow \text{overlap}(s_{i_1}, s_{i_2}) \rightarrow s_{i_2} \rightarrow \text{overlap}(s_{i_2}, s_{i_3}) \rightarrow \dots \rightarrow s_{i_n} \rightarrow \varepsilon. \tag{1}$$

This Eulerian solution is shown schematically in Figure 4(a). This schematic illustration is over simplified as the shown path usually has many self-intersections. Still, this point of view is helpful in understanding the algorithms presented later in the text. Figure 4(b) shows an “untangled” optimal Eulerian solution from Figure 3(c): by contracting nodes with equal labels into the same node, one gets exactly the solution from Figure 3(c).

■ **Figure 4** (a) A schematic illustration of a normalized Eulerian solution. (b) Untangled optimal Eulerian solution from Figure 3(c).

Not every Eulerian solution in the hierarchical graph has a nice zig-zag structure described above. In the next section, we introduce a normalization procedure (that we call collapsing) that allows us to focus on nice Eulerian solutions only.

2.3 Normalizing a Solution

In this section, we describe a natural way of normalizing an Eulerian solution D . Informally, it can be viewed as follows. Imagine that all arcs of D form one circular thread, and that there is a nail in every node $s \in \mathcal{S}$ corresponding to an input string. We apply “gravitation” to the thread, i.e., we replace every pair of arcs $(\text{pref}(v), v)$, $(v, \text{suff}(v))$ with a pair $(\text{pref}(v), \text{pref}(\text{suff}(v)))$, $(\text{pref}(\text{suff}(v)), \text{suff}(v))$, if there is no nail in v and if this does not disconnect D . We call this *collapsing*, see Figure 5.

■ **Figure 5** Collapsing a pair of arcs is replacing a pair of dashed arcs with a pair of solid arcs: general case (left) and example (right). The “physical meaning” of this transformation is that to get **bac** from **aba** one needs to cut **a** from the beginning and append **c** to the end and these two operations commute.

A formal pseudocode of the collapsing procedure is given in Algorithm 2. The pseudocode, in particular, reveals an important exception (not covered in Figure 5): if $|v| = 1$, then $\text{pref}(\text{suff}(v))$ is undefined and we just remove the pair of arcs $(\text{pref}(v), v)$ and $(v, \text{suff}(v))$.

■ **Algorithm 2** Collapse.

Input: hierarchical graph $HG(V, E)$, Eulerian solution D , node $v \in V$.

- 1: **if** $(\text{pref}(v), v), (v, \text{suff}(v)) \in D$ **then**
 - 2: $D \leftarrow D \setminus \{(\text{pref}(v), v), (v, \text{suff}(v))\}$
 - 3: **if** $|v| > 1$ **then**
 - 4: $D \leftarrow D \cup \{(\text{pref}(v), \text{pref}(\text{suff}(v))), (\text{pref}(\text{suff}(v)), \text{suff}(v))\}$
-

Algorithm 3, that we call Collapsing Algorithm (CA), uses the property described above to normalize any solution. It drops down all pairs of arcs that are not needed for connectivity. (Recall that a set of edges is called an Eulerian solution if it is connected and goes through all initial nodes and ε .)

■ **Algorithm 3** Collapsing Algorithm (CA).

Input: set of strings \mathcal{S} , Eulerian solution D in HG .

Output: Eulerian solution D' : $|D'| \leq |D|$

- 1: **for** level l in HG in descending order **do**
 - 2: **for** all $v \in V$ s.t. $|v| = l$ in lexicographic order: **do**
 - 3: **while** $(\text{pref}(v), v), (v, \text{suff}(v)) \in D$ and collapsing it keeps D an Eulerian solution **do**
 - 4: $\text{COLLAPSE}(HG, D, v)$
 - 5: **return** D
-

It is easy to show (we prove this formally in Claim 2 on page 14) that any normalized solution is of the form (1). But it is not true that every zig-zag solution of the form (1) is a normalized solution: see Figure 6 for an example. The normalization procedure does not just turn a solution into some standard form, but it may also decrease its length.

■ **Figure 6** (a) An Eulerian solution corresponding to the permutation (ae, aa, ca) . (b) The solution from (a) after normalization results in a shorter solution corresponding to the permutation (ca, aa, ae) . This example also shows that though collapsing a pair of edges is a local change in the graph, it may drastically change the resulting superstring. In this case, it replaces a superstring $aeaaca$ with a shorter superstring $caae$.

3 Collapsing Conjecture

We are now ready to conjecture an astonishing structural property of the hierarchical graph:

Take any Eulerian solution, double every arc of it, and normalize the resulting solution; the result is the same for all initial solutions!

For the formal statement of the conjecture we use the following notation: If U and V are two multisets, then $U \sqcup V$ is the multiset W such that each $w \in W$ has multiplicity equal to the sum of multiplicities it has in sets U and V . Formally, the conjecture is stated as follows.

► **Collapsing Conjecture.** *For any set of strings \mathcal{S} and any two Eulerian solutions D_1, D_2 of \mathcal{S} ,*

$$CA(\mathcal{S}, D_1 \sqcup D_1) = CA(\mathcal{S}, D_2 \sqcup D_2).$$

Figures 7 and 8 illustrate the action of the Collapsing Algorithm for optimal and naive solutions, respectively. Note that the resulting solutions are equal. When processing level $l > 1$ nodes, the collapsing procedure does not change the total length of the solution. What one normally sees at the beginning of the $l = 1$ iteration is an Eulerian solution with many redundant pairs of arcs of the form (a, ϵ) , (ϵ, a) . It is exactly this stage of the algorithm where the total length of a solution is decreased by the Collapsing Algorithm.

We have verified the conjecture on millions of datasets (both handcrafted and randomly generated), and we invite the reader to see its visualizations and to check the conjecture on arbitrary datasets at the webpage [34]. Moreover, we support the conjecture by proving that it holds in the (NP-hard) special case where the input strings have length at most 3 in Section A.

If the Collapsing Conjecture is true, then there is a simple and natural 2-approximate algorithm for SCS: take *any* Eulerian solution (e.g., merge the input strings in arbitrary order), double it, and apply the Collapsing Algorithm. Under the conjecture, this results in the same Eulerian solution as for doubled optimal solution and hence the length of the result is at most twice the optimal length.

4 Greedy Hierarchical Conjecture

In this section, we present one more curious property of the Collapsing Algorithm that reveals its intricate connection to greedy algorithms. For this, we introduce the so called Greedy Hierarchical Algorithm (GHA) that constructs an Eulerian solution in a stingy fashion, i.e., tries to add as few arcs as possible:

■ **Figure 7** Stages of applying the Collapsing Algorithm to the dataset $\{aaa, cae, aec, eee\}$ and its **optimal** solution. (a) We start by doubling every arc of the optimal solution from Figure 3(c). (b) After collapsing all nodes at level $l = 3$. (c) After processing the node aa at level $l = 2$. Note that the algorithm leaves a pair of arcs (a, aa) , (aa, a) as they are needed to connect the component $\{aa, aaa\}$ to the rest of the solution. (d) After processing the ae node. The algorithm collapses all pairs of arcs for this node as it lies in the same component as the node c . (e) After processing the ca node. (f) After processing the ec node. (g) After processing the ee node. Note that at this point the solution has exactly the same length as at the very beginning (at stage (a)). (h) Finally, after collapsing all the unnecessary pairs of arcs from the level $l = 1$.

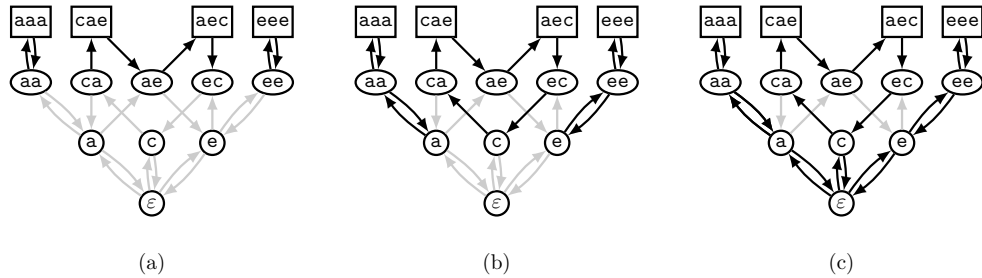

Proceed nodes from top to bottom. For each node, ensure that it is balanced and connected to the rest of the solution.

This is best illustrated with an example, see Figure 9. We start constructing an Eulerian solution D by processing the nodes at level 3. The solution D must visit all these four nodes, so we add all incoming and outgoing arcs to D , see Figure 9(a). We then process the level 2. The node aa is balanced, but if we skip it, it will not be connected to the rest of the solution, so we add to D the arcs (a, aa) and (aa, a) . The node ae is balanced, we do nothing for it. The node ca is imbalanced, so we add an arc (c, ca) to D . We balance the node ec similarly. The node ee is processed similarly to the node aa . The result of processing the second level is shown in Figure 9(b). On the last stage we connect the nodes a, b , and c to ε to ensure connectivity, see Figure 9(c). Hence, when processing level l , we only add arcs between levels l and $l - 1$.

26:10 Collapsing Superstring Conjecture

■ **Figure 8** Stages of applying the Collapsing Algorithm to the dataset $\{aaa, cae, aec, eee\}$ and its **naïve** solution resulting from overlapping the input strings in the same order as they are given. (a) The solution of length 10 corresponding to the superstring **aaacaeccee**. (b) The doubled solution. (c) After collapsing the $l = 3$ level. (d) After collapsing the $l = 2$ level. (e) After collapsing the $l = 1$ level.

■ **Figure 9** (a) After processing the $l = 3$ level. (b) After processing the $l = 2$ level. Note that for the node **aa** we add two lower arcs ((a, aa) and (aa, a)) since otherwise the corresponding weakly connected component $(\{aa, aaa\})$ will not be connected to the rest of the solution. At the same time, when processing the node **ae** we observe that it lies in a weakly connected component that contains imbalanced nodes (**ca** and **ec**), hence there is no need to add two lower arcs to **ae**. (c) After processing the $l = 1$ level. The resulting solution has length 10 and is, therefore, suboptimal (compare it with the optimal solution shown in Figure 3(c)).

More formally, GHA first considers the input strings \mathcal{S} . Since we assume that no $s \in \mathcal{S}$ is a substring of another $t \in \mathcal{S}$, there is no down-path from t to s in HG . This means that any walk through ε and \mathcal{S} goes through the arcs $\{(pref(s), s), (s, suff(s)) : s \in \mathcal{S}\}$. The algorithm adds all of them to the constructed Eulerian solution D and starts processing all the nodes level by level, from top to bottom. At each level, we process the nodes in the lexicographic order. If the degree of the current node v is imbalanced, we balance it by adding an appropriate number of incoming (i.e., $(pref(v), v)$) or outgoing (i.e., $(v, suff(v))$)

arcs from the previous (i.e., lower) level. In the case when v is balanced, we just skip it. The only exception when we cannot skip it is when v lies in an Eulerian component and v is the last chance of this component to be connected to the rest of the arcs in D . (See, for example, the vertex **aa** in Figure 9(a)). The pseudocode is given in Algorithm 4.

■ **Algorithm 4** Greedy Hierarchical Algorithm (GHA).

Input: set of strings \mathcal{S} .
Output: Eulerian solution D .

```

1:  $HG(V, E) \leftarrow$  hierarchical graph of  $\mathcal{S}$ 
2:  $D \leftarrow \{(\text{pref}(s), s), (s, \text{suff}(s)) : s \in \mathcal{S}\}$ 
3: for level  $l$  from  $\max\{|s| : s \in \mathcal{S}\}$  downto 1 do

9:        $u \leftarrow$  the lexicographically largest string among shortest strings in  $\mathcal{C}$ 
10:      if  $\mathcal{C}$  is Eulerian,  $\varepsilon \notin \mathcal{C}$ , and  $v = u$  then
11:         $D \leftarrow D \cup \{(\text{pref}(v), v), (v, \text{suff}(v))\}$ 
12: return  $D$ 

```

While GHA is almost as simple as the standard Greedy Algorithm (GA), GHA has several provable advantages over GA:

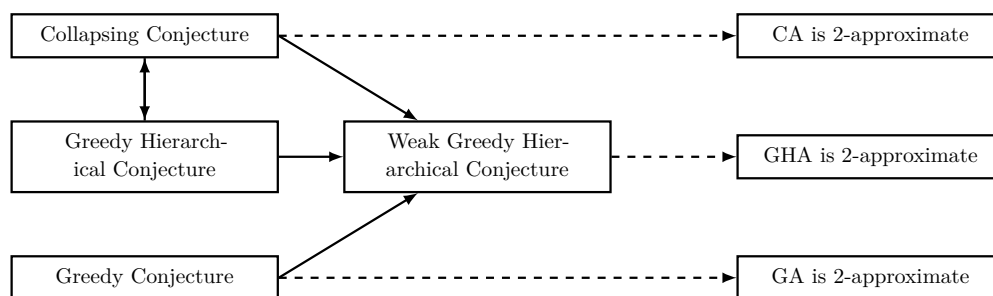

One advantage of GHA over GA is that GHA is more flexible in the following sense. On every step, GA selects two strings and fixes tightly their order. GHA instead works to ensure connectivity. When the resulting set D is connected, an actual order of input strings is given by the corresponding Eulerian cycle through D . This is best illustrated on the following toy example. For the dataset $\mathcal{S} = \{\mathbf{ae}, \mathbf{ea}, \mathbf{ee}\}$, GA might produce a suboptimal solution \mathbf{aeae} if it merges the strings \mathbf{ae} and \mathbf{ea} at the first step. At the same time, it is not difficult to see that GHA finds an optimal solution for \mathcal{S} .

Another advantage of GHA is that, in contrast to GA, it solves *exactly* two well known polynomially solvable special cases of SCS: when the input strings have length at most two and when the input strings form a k -spectrum of an unknown string (that is, the input strings constitute all k -substrings of a string). We prove this formally in Sections B.1 and B.2. Informally, this happens because for such datasets there are no connectivity issues for GHA: for k -spectrum, after processing the highest level GHA gets a weakly connected component; for 2-SCS, after processing the level 2, GHA gets several weakly connected components such that different components do not share common letters and therefore are completely independent. Figure 6(b) illustrates this: while GA may produce a permutation $(\mathbf{ca}, \mathbf{ae}, \mathbf{aa})$, GHA constructs an optimal permutation $(\mathbf{ca}, \mathbf{aa}, \mathbf{ae})$.

In Section B.3, we also show a dataset where GHA produces a solution that is almost two times longer than the optimal one.

In Section 5.2, we show that the approximation guarantee of GHA is no worse than that of GA. Combining with the result of Kaplan and Shafrir [15], this implies immediately that GHA is 3.5-approximate. Moreover, we prove that the standard Greedy Conjecture implies 2-approximation of GHA, which makes it natural to study the approximation ratio of GHA.

26:12 Collapsing Superstring Conjecture

■ **Figure 10** Relations between the conjectures (left), and the 2-approximate algorithms they imply (right). Collapsing and Greedy Hierarchical Conjectures are equivalent. They imply the weak version of the Greedy Hierarchical Conjecture, which also follows from the standard Greedy Conjecture. Each conjecture implies that the corresponding algorithm finds a 2-approximate solution for SCS.

We are now ready to state our second conjecture: the results of the Collapsing Algorithm and Greedy Hierarchical Algorithm coincide!

► **Greedy Hierarchical Conjecture.** *For any set of strings \mathcal{S} and any Eulerian solution D ,*

$$CA(\mathcal{S}, D \sqcup D) = GHA(\mathcal{S}).$$

While the Greedy Hierarchical Conjecture implies that GHA finds a 2-approximate solution, we separately state this weak version of the conjecture.

► **Weak Greedy Hierarchical Conjecture.** *GHA is a factor 2 approximation algorithm for the Shortest Common Superstring problem.*

5 Relations between the Conjectures

In this section we prove some relations between the Collapsing and Greedy conjectures. Namely, in Section 5.1 we prove the equivalence of Collapsing and Greedy Hierarchical conjectures. In Section 5.2 we prove that the standard Greedy Conjecture implies Weak Hierarchical Greedy Conjecture (which is sufficient for a simple 2-approximate greedy algorithm for SCS). Finally, it is easy to see that Greedy Hierarchical Conjecture implies its weak version: indeed, if every doubled solution results in the solution obtained by GHA, then GHA does not exceed twice the optimal superstring length. In Figure 10, we show the proven relations between the conjectures, together with 2-approximate algorithm which follow from each of the conjecture.

5.1 Equivalence of Collapsing and Greedy Hierarchical Conjectures

In this section we prove the equivalence of Collapsing Conjecture and Greedy Hierarchical Conjecture. Recall that Collapsing Conjecture claims that for any pair of Eulerian solutions D_1 and D_2 for the input strings \mathcal{S} , we have

$$CA(\mathcal{S}, D_1 \sqcup D_1) = CA(\mathcal{S}, D_2 \sqcup D_2).$$

The Greedy Hierarchical Solution extends this statement to

$$CA(\mathcal{S}, D_1 \sqcup D_1) = GHA(\mathcal{S}).$$

Greedy Hierarchical Conjecture trivially implies Collapsing conjecture, and in order to prove their equivalence, it suffices to show that the collapsing procedure applied to the doubled GHA solution results in the GHA solution:

$$CA(\mathcal{S}, GHA(\mathcal{S}) \sqcup GHA(\mathcal{S})) = GHA(\mathcal{S}).$$

► **Theorem 1.** *For any set of strings \mathcal{S} ,*

$$CA(\mathcal{S}, GHA(\mathcal{S}) \sqcup GHA(\mathcal{S})) = GHA(\mathcal{S}).$$

Proof. Let us denote two copies of the $GHA(\mathcal{S})$ solution by B and R , which stand for a blue-copy and a red-copy. We will prove the theorem statement by showing that $CA(R \sqcup B)$ collapses all arcs of B and keeps untouched the arcs of R , as this implies that $CA(R \sqcup B) = R = GHA(\mathcal{S})$. For this, without loss of generality assume that the Collapsing Algorithm collapses blue arcs first, that is, if for a vertex v , CA can collapse a blue pair of arcs $(\text{pref}(v), v), (v, \text{suff}(v))$, it does so. Recall that CA processes vertices in the descending order of levels (Algorithm 3, line 1). We will prove that before processing level l , all the arcs above it (i.e., the arcs with at least one vertex at a level $> l$) do satisfy the desired property: all blue arcs are collapsed, and all red arcs are untouched.

The base case trivially holds for $l := \max\{|s| : s \in \mathcal{S}\}$, since the set of arcs above the level l is empty. Assume the claim is true for the level $k > 0$, and let us prove the claim for the level $k - 1$. Note that regardless of the number of collapse operations applied to B , B remains a set of walks: indeed, the collapse procedure keeps the balance of incoming and outgoing arcs for each vertex. By the induction hypothesis all the blue arcs above the level k are collapsed, so we have that if for a vertex v at level k there is an arc $(\text{pref}(v), v)$ in B , then there is also an arc $(v, \text{suff}(v))$ in B , and vice versa. Recall that CA collapses blue arcs when possible, and since every vertex has the same number of blue incoming and outgoing arcs, all pairs collapsed at the level k are monotone.

Now let us show that no red pair can be collapsed. Indeed, if for some vertex v at level k there is a red pair $(\text{pref}(v), v), (v, \text{suff}(v))$, then by construction of GHA v is either in \mathcal{S} or is the last chance of the corresponding component $\mathcal{C} \ni v$ to be connected to the remaining arcs in R (note that the first case is a subcase of the second one, as then \mathcal{C} contains only one vertex). It follows that if CA collapses such a pair of arcs, then v has no blue arcs (as they have been collapsed before the red arcs), and all other vertices in the component \mathcal{C} at the level k collapsed all arcs (since v is the last vertex in \mathcal{C} in lexicographic order). Therefore, this pair is also the last chance of \mathcal{C} to be connected to the rest of the arcs in R , thus, CA cannot collapse it.

It remains to show that all blue pairs at level k are collapsed. This trivially holds because no red pair is collapsed, and, thus, the connectivity of $R \sqcup B$ is maintained by R . This finishes the proof. ◀

5.2 Greedy Implies Greedy Hierarchical

Consider a permutation of the input strings. We say that it is a *valid greedy permutation* if it can be constructed by the Greedy Algorithm: there exist $n - 1$ merges of the n input strings that lead to this permutation such that at every step the two merged strings have the largest overlap. We will prove that GHA always returns a solution which corresponds to a greedy permutation of the input string. That is, while the standard Greedy Algorithm does not determine how to break ties, the Greedy Hierarchical Algorithm is a specific instantiation of the Greedy Algorithm with some tie-breaking rule.

We will use the following simple property of solutions constructed by the GHA algorithm.

▷ **Claim 2.** Let D be an Eulerian solution constructed by GHA. Then D has a “zig-zag” form as in (1).

Proof. First we prove that D is normalized, that is, any application of the collapsing procedure of Algorithm 2 to D will violate the property of Eulerian solution. Indeed, Algorithm 2 can only collapse pairs of arcs of the form $(\text{pref}(s), s), (s, \text{suff}(s))$. The Greedy Hierarchical Algorithm adds such pairs to its solution in two cases: (i) s is an input string (line 2 of Algorithm 4); (ii) s is the the lexicographically largest among the shortest strings in its Eulerian component (line 11 of Algorithm 4). Now note that in the former case, the collapsing procedure applied to s would violate the property that D must contain all input strings, and in the latter case, the collapsing procedure would violate the connectivity property of D .

We finish the proof by showing that every normalized solution is of the form (1). Let $\pi = (s_1, \dots, s_n)$ be the permutation of the input strings corresponding to a normalized Eulerian solution D . Let us follow the arcs of D in the order of the permutation π , and let P be the set of arcs between the input strings s_i and s_{i+1} . We will prove that P is the union of the sets of arcs of the paths $s_i \rightarrow \text{overlap}(s_i, s_{i+1})$ and $\text{overlap}(s_i, s_{i+1}) \rightarrow s_{i+1}$. If P contains a pair of consecutive up- and down-arcs, that is, there exists a pair of arcs $(\text{pref}(s), s), (s, \text{suff}(s))$ in P , then this pair would have been collapsed by Algorithm 2, line 2. Therefore, the path P consists of a number of down-arcs followed by a number of up-arcs. It remains to show that the number of down-arcs in P is $d = |s_i| - |\text{overlap}(s_i, s_{i+1})|$. Note that by the definition of $\text{overlap}(\cdot, \cdot)$, the number of down-arcs in P is at least d . On the other hand, if the number of down-arcs in P is strictly greater than d , then both the down-path and up-path in P contain the vertex $\text{overlap}(s_i, s_{i+1})$. This implies that the pair of arcs $(\text{pref}(s), s), (s, \text{suff}(s))$ for $s = \text{overlap}(s_i, s_{i+1})$ would have been collapsed by Algorithm 2, line 2, as it does not violate the connectivity of the solution. Therefore, the number of down-arcs in P is exactly d , which implies that P is the path $s_i \rightarrow \text{overlap}(s_i, s_{i+1})$ followed by the path $\text{overlap}(s_i, s_{i+1}) \rightarrow s_{i+1}$. ◻

► **Theorem 3.** Every permutation $\pi = (s_1, \dots, s_n)$ of the input strings constructed by GHA is a valid greedy permutation.

Proof. Consider the following algorithm A : it starts with the sequence (s_1, \dots, s_n) obtained by GHA, and at every step it merges two neighboring strings in this sequence that have the largest overlap. It is a greedy algorithm, but instead of considering all pairwise overlaps, it only considers overlaps of neighboring strings in the sequence. Of course, in the end, this algorithm constructs exactly the permutation π . To show that π is a valid greedy permutation, we show that at every iteration of A no two strings have longer overlap than the two strings merged by A .

Consider, for the sake of contradiction, the first iteration when the algorithm A merges some pair of neighboring strings with overlap of length k whereas there are non-neighboring strings p and q with $v = \text{overlap}(p, q)$, $|v| > k$. At this point, p is a merger of input strings s_a, s_{a+1}, \dots, s_b and q is a merger of input strings s_c, s_{c+1}, \dots, s_d . Then, from the assumption that no input string contains another input string, we have that $v = \text{overlap}(p, q) = \text{overlap}(s_b, s_c)$. Since the algorithm A merges neighboring strings in the decreasing order of overlap lengths, we have that $|\text{overlap}(s_b, s_{b+1})| \leq k < |v|$ and $|\text{overlap}(s_{c-1}, s_c)| \leq k < |v|$.²

Now we consider the Eulerian solution D constructed by GHA in the hierarchical graph. By Claim 2, D has a “zig-zag” form, thus, it contains all arcs from the path $s_b \rightarrow \text{overlap}(s_b, s_{b+1}) \rightarrow s_{b+1}$, and all arcs from the path $s_{c-1} \rightarrow \text{overlap}(s_{c-1}, s_c) \rightarrow s_c$.

² In the case when s_b is the last string in the solution (or s_c is the first string in the solution) we think of it being followed by ε , and $|\text{overlap}(s_b, \varepsilon)| = 0 < |v|$ still holds.

■ **Figure 11** (a) In the Eulerian solution the node $v = \text{overlap}(s_b, s_c)$ has a pair of lower arcs. (b) For this reason, above v , there is an Eulerian component.

Recall that $v = \text{overlap}(s_b, s_c)$, and that $|\text{overlap}(s_b, s_{b+1})| < |v|$ and $|\text{overlap}(s_{c-1}, s_c)| < |v|$. In particular, the paths $s_b \rightarrow \text{overlap}(s_b, s_{b+1})$ and $\text{overlap}(s_{c-1}, s_c) \rightarrow s_c$ pass through the vertex v , which implies that the vertex v in the solution D has at least one incoming arc from the previous level and at least one outgoing arc to the previous level (see Figure 11(a)). Such a pair of arcs in the Eulerian solution D constructed by GHA may only occur when v is the last chance of its connected component to be connected to the rest of the solution (see line 11 of Algorithm 4). This, in turn, implies that right before the pair of arcs $(\text{pref}(v), v)$ and $(v, \text{suff}(v))$ was added to the Eulerian solution, there was an Eulerian component where v was the lexicographically largest among all shortest nodes. This component is shown schematically in Figure 11(b). All overlap-nodes (the nodes which are equal to $\text{overlap}(s_i, s_{i+1})$) of this component lie on levels $\geq k$. Note that the pair $(\text{pref}(v), v)$ and $(v, \text{suff}(v))$ is added to the solution by GHA exactly once (line 11 of Algorithm 4). Therefore, any path following the arcs of D , after going through the arc $(\text{pref}(v), v)$ must traverse the overlying component containing s_b and s_c (as otherwise the path could not reach the overlying component). In turn, this implies that after considering all overlaps of length $|v| > k$, s_b and s_c are already merged into one string, so they cannot be merged at this stage. ◀

Theorem 3 has two immediate corollaries.

► **Corollary 4.** *The Greedy Conjecture implies the Weak Greedy Hierarchical Conjecture: if the Greedy Algorithm is 2-approximate, then so is the Greedy Hierarchical Algorithm.*

Since every valid greedy permutation is a 3.5-approximation to the Shortest Common Superstring problem [15], we have the following corollary.

► **Corollary 5.** *GHA is a factor 3.5 approximation algorithm for the Shortest Common Superstring problem.*

6 Further Directions and Open Problems

The most immediate open problems are to prove the Collapsing Conjecture or the Weak Greedy Hierarchical Conjecture.

6.1 Applications of Hierarchical Graphs

It would also be interesting to find other applications of the hierarchical graphs. We list two such potential applications below.

Exact algorithms. Can one use hierarchical graphs to solve SCS exactly in time $(2 - \varepsilon)^n$?

It was shown in Section 1 that the SCS problem is a special case of the Traveling Salesman Problem. The best known exact algorithms for Traveling Salesman run in time $2^n \text{poly}(|\text{input}|)$ [2, 14, 17, 16, 1]. These algorithms stay the best known for the SCS problem as well. The hierarchical graphs were introduced [13] for an algorithm solving SCS on strings of length at most r in time $(2 - \varepsilon)^n$ (where ε depends only on r). Can one use the hierarchical graph to solve exactly the general case of SCS in time $(2 - \varepsilon)^n$ for a constant ε ?

Genome assembly. The hierarchical graph in a sense generalizes de Bruijn graph. The latter one is heavily used in genome assembly [24]. Can one adopt the hierarchical graph for this task? For this, one would need to come up with a compact representation of the graph (as datasets in genome assembly are massive) as well as with a way of handling errors in the input data. Cazaux and Rivals [6] propose a linear-space counterpart of the hierarchical graph.

6.2 Optimal Cycle Covers

A superstring corresponds to a Hamiltonian path in the overlap graph, thus, a minimum-weight cycle cover gives a natural lower bound on its length. The Greedy Conjecture claims that a greedy solution never exceeds twice the length of an optimal solution. It is also believed (see, e.g., [35, 19]) that the greedy solution does not exceed the length of an optimal solution plus the length of an optimal cycle cover. This has interesting counterparts in the hierarchical graphs.

- Note that an optimal cycle cover in the overlap graph can be constructed by a straightforward greedy algorithm: keep taking heavy edges till the cycle cover is constructed. The proof of correctness of this algorithm relies on the Monge inequality. Interestingly, to construct an optimal cycle cover in the hierarchical graph, it suffices to invoke the Greedy Hierarchical Algorithm with lines 7–11 commented out! In a sense, the Monge inequality is satisfied in the hierarchical graph automatically as it contains more information about input strings than just its pairwise overlaps.
- As discussed in Section A, for strings of length 3 even a more general fact than Collapsing Conjecture holds: it suffices to have double edges adjacent to input strings. One simple way to force a particular solution to satisfy this property is to double every edge of it. At the same time, adding a shortest cycle cover to it is guaranteed to be as good.
- Hence, the more general version of the Collapsing Conjecture is the following: take any solution, add any cycle cover to it, and collapse; the result is always the same. We tested this stronger conjecture and did not find any counter-examples.

A Proof of Collapsing Conjecture for Strings of Length 3

In this section, we show that the Collapsing Conjecture holds for the special case when input strings have length at most three. Remarkably, this follows from a more general theorem stated below.

► **Theorem 6.** *Let \mathcal{S} contain strings of length at most 3 and let L be an Eulerian solution that for each $s \in \mathcal{S}$ contains at least two copies of arcs $(\text{pref}(s), s)$ and $(s, \text{suff}(s))$. Then $CA(\mathcal{S}, L) = GHA(\mathcal{S})$.*

It is not difficult to see that the theorem indeed implies the Collapsing Conjecture: clearly, $L = D \sqcup D$, where D is an Eulerian solution, satisfies the condition. Moreover, this also works for $L = D_1 \sqcup D_2$, where D_1, D_2 are arbitrary Eulerian solutions, and for $L = D \sqcup CC$, where CC is a cycle cover, i.e., a set of cycles that go through all input strings. The main difference between an Eulerian solution and a cycle cover is that the later is not required to be connected. For this reason, any Eulerian solution is also a cycle cover (but not vice versa) and hence an *optimal* cycle cover is definitely not longer than an optimal Eulerian solution: $OPT \leq OPT_{CC}$. Hence, Theorem 6 says that the result of GHA is not just no longer than $2 \cdot OPT$, but even no longer than $OPT + OPT_{CC}$.

Before proving Theorem 6, we introduce some notation and prove two auxiliary results. Recall that the Collapsing Algorithm processes the nodes level by level. Denote by L_i an intermediate Eulerian solution right before it starts collapsing the nodes at level i (that is, in L_i all the nodes at levels $> i$ are already collapsed). For an arbitrary Eulerian solution U , by $\text{above}(U, i)$ denote the part of U that lies above the level i : $\text{above}(U, i) = \{(u, v) \in U : |u|, |v| \geq i\}$. We show that $\text{above}(D, i) = \text{above}(L_i, i)$ for every i . This is enough since then

$$CA(\mathcal{S}, L) = \text{above}(L_0, 0) = \text{above}(D, 0) = GHA(\mathcal{S}).$$

► **Lemma 7.** *Let w be a walk from u to v in an Eulerian solution with all its nodes at levels $\leq k$. Consider a single collapsing step for a node t that is either an intermediate node of w at level k or is a node at level $< k$ that does not belong to w . Then w is still a walk from u to v in the resulting solution.*

Proof. Indeed, if t does not belong to w , then collapsing it does not change w at all. Otherwise t is an intermediate node of w at level k . Since w does not have any node above level k , w goes through $(\text{pref}(t), t), (t, \text{suff}(t))$. Clearly, collapsing t keeps w a walk. ◀

► **Lemma 8.** *Let v be a node in L_2 at level $1 \leq l \leq 2$ (i.e., $l = |v|$). Then there is a walk from ε to v and a walk from ε to v in L_1 that does not contain nodes at level 3.*

Proof. We start by proving that there is a walk from v to ε for $|v| = 2$ (the existence of a walk from ε to v is proved in a similar fashion).

Consider a walk w from v to ε in L (there is such a walk as L is an Eulerian solution). All repeated nodes in w may be removed, so one may assume that w passes through its nodes at level 3 exactly once. Then, it is sufficient to show that each such node is collapsed.

Consider a node s of w at level 3 and a pair of arcs $(\text{pref}(s), s), (s, \text{suff}(s)) \in w$ going through it. If s is not at input string (i.e., $s \notin \mathcal{S}$), then CA collapses this pair of arcs and this does not disconnect w . On the other hand, if s is an input string ($s \in \mathcal{S}$), then there are two copies of $(\text{pref}(s), s), (s, \text{suff}(s))$ in L . At least one copy of this pair is collapsed in L and therefore belongs to L_2 .

The statement for v with $|v| = 1$ follows from Lemma 7. \blacktriangleleft

Proof of Theorem 6. As discussed above, it suffices to prove that $\text{above}(D, i) = \text{above}(L_i, i)$ for every $i = 2, 1, 0$.

Level $i = 2$. The base case $i = 2$ is straightforward: clearly, the Collapsing Algorithm leaves exactly one copy of arcs $(\text{pref}(s), s)$ and $(s, \text{suff}(s))$ for every $s \in \mathcal{S}$ and fully collapses all other nodes at level 3. Then, $\text{above}(L_2, 2) = \text{above}(D, 2)$ as $(\text{pref}(s), s), (s, \text{suff}(s))$ for $s \in \mathcal{S}$ are the only edges between levels 2 and 3 in D .

Level $i = 1$. Note that $\text{above}(L_2, 2) \subseteq L_2$ and L_2 is an Eulerian cycle. Hence, $\text{above}(L_2, 2)$ is a collection of walks. Consider such a walk w and consider two cases.

- w is a closed walk. Let v be the lexicographically largest node of w at level 2. What we want to show is that in L_1 this closed walk w is connected to the rest of L_1 through a pair of arcs $(\text{pref}(v), v), (v, \text{suff}(v))$ only.

By Lemma 8, there is a path from v to ε in L_2 and hence $(v, \text{suff}(v)) \in L_2$; similarly, $(\text{pref}(v), v) \in L_2$. Since v is lexicographically largest at level 2 in w , when CA starts processing the node v , all other nodes at level 2 in w are fully collapsed, i.e., for any such node u , $(\text{pref}(u), u) \notin L_1$ and $(u, \text{suff}(u)) \notin L_1$. Moreover, CA does not collapse the pair of arcs $(\text{pref}(v), v), (v, \text{suff}(v))$ as this would disconnect w from the rest of the solution.

- w is not closed. Denote by v_1 and v_k its first and last nodes. All other nodes of w in $\text{above}(L_2, 2)$ are balanced. What we want to show is that in L_1 the only edges between levels 1 and 2 that connect w to the rest of the solution are $(\text{pref}(v_1), v_1)$ and $(v_k, \text{suff}(v_k))$.

We prove this for v_k (for v_1 is it shown similarly). By Lemma 8, there is a path from v_k to ε in L_2 and hence $(v_k, \text{suff}(v_k)) \in L_2$. The algorithm CA always works with an Eulerian solution and hence every node is balanced at every stage (i.e., its in-degree is equal to its out-degree). This means that $(v_k, \text{suff}(v_k)) \in L_1$ and that all intermediate nodes of w are not connected to level 1 nodes in L_1 .

Level $i = 0$. Note that $\text{above}(L_1, 1)$ is a collection of walks. The case of a non-closed walk in this case is easy as it must be connected to ε directly. For this reason, we focus on a closed walk w in $\text{above}(L_1, 1)$.

We show that for every node v of w with $|v| = 1$, L_1 contains arcs (ε, v) and (v, ε) (recall that for $|v| = 1$, $\text{pref}(v) = \text{suff}(v) = \varepsilon$). This suffices as then CA (when processing level one nodes) collapses all nodes of w at level 1 except for the lexicographically largest one, and this is exactly how w is connected to ε in D_0 . Below, we show that $(\varepsilon, v) \in L_1$. It then follows that $(v, \varepsilon) \in L_1$ (as L_1 must be Eulerian).

Lemma 8 guarantees that L_1 contains a path from v to ε that does not contain nodes at level 3. If the first arc of this path goes down to ε , then there is nothing to prove. Hence, consider a case when the first arc goes up to a node u (and hence $v = \text{pref}(u)$). The next arc then must go down to $\text{suff}(u)$. Hence, $(\text{pref}(u), u), (u, \text{suff}(u)) \in D_1$. This

26:20 Collapsing Superstring Conjecture

may happen in two cases only: either u is an input string (i.e., $u \in \mathcal{S}$) or u is the last chance of its component to be connected to the rest of the solution (i.e., exactly for this reason GHA added these two edges to the solution). The former case is straightforward: then there were at least two copies of the arcs $(\text{pref}(u), u), (u, \text{suff}(u))$ and CA collapsed at least one copy. Let us then focus on the latter case.

Let $x, y \in \mathcal{S}$ be such that $u = \text{suff}(y)$ and $c := \text{suff}(x) = \text{pref}(y)$, see the picture below (solid arcs belong to L , dashed arc belong to L_2).

Note that

$$v = \text{pref}(u) = \text{pref}(\text{suff}(y)) = \text{suff}(\text{pref}(y)) = \text{suff}(c).$$

Hence, $(c, v), (v, u) \in L_2$ (resulting from collapsing at least one pair of arcs $(c, y), (y, u) \in L$). L_2 also contains a pair of arcs $(\text{pref}(x), \text{suff}(\text{pref}(x))), (\text{suff}(\text{pref}(x)), c)$. When processing the node c , CA collapses the pair of arcs $(\text{pref}(c), c), (c, v)$ as there is an arc (v, u) . Hence, $(\varepsilon, v) \in L_1$, as required. (It may be the case that $x = y$. Then $x = \mathbf{aaa}$, $v = \{a\}$. Then the first pair of arcs of the considered path is $\mathbf{a} \rightarrow \mathbf{aa} \rightarrow \mathbf{a}$ and one may just drop them.)

As a final remark, note that if a walk $w \in \text{above}(L_i, i)$ is connected to the rest of a solution through some a of arcs $(\text{pref}(v), v), (u, \text{suff}(u))$ (v and u may coincide), then any other balanced node in w at level i can be fully collapsed, as every such collapse, thanks to Lemma 7, does not disconnect w or any other walk from $\text{above}(L_i, i)$ from the rest of the solution. ◀

B Greedy Hierarchical Algorithm and Special Cases of SCS

B.1 Strings of Length 2

Gallant et al. [9] show that SCS on strings of length 3 is NP-hard, but SCS on strings of length at most 2 is solvable in polynomial time. In this section we show that GHA finds an optimal solution in this case as well. We note that the standard Greedy Algorithm does not necessarily find an optimal solution in this case. For example, if $\mathcal{S} = \{\mathbf{ab}, \mathbf{ba}, \mathbf{bb}\}$, the Greedy Algorithm may first merge \mathbf{ab} and \mathbf{ba} , which would lead to a suboptimal solution \mathbf{ababb} (recall also Figure 6).

First, we can assume that all input strings from \mathcal{S} have length exactly 2. Indeed, since we assume that no input string is a substring of another input string, all strings of length 1 are unique symbols which do not appear in other strings. Take any such s_i of length 1. The optimal superstring length for \mathcal{S} is k if and only if the optimal superstring length for $\mathcal{S} \setminus \{s_i\}$ is $k - 1$. The Greedy Hierarchical Algorithm has the same behavior: In Step 2, GHA will include the arcs $(\varepsilon, s_i), (s_i, \varepsilon)$ in the solution, and it will never touch the vertex s_i again (because it is balanced and connected to ε). Thus, s_i adds 1 to the length of the Greedy Hierarchical Superstring as well. By the same reasoning, we can assume that each string of length two is primitive, i.e., contains two distinct symbols.

When considering primitive strings $\mathcal{S} = \{s_1, \dots, s_n\}$ of length exactly 2, it is convenient to introduce the following directed graph $G = (V, E)$, where V contains a vertex for every symbol which appears in strings from \mathcal{S} . The graph has $|E| = n$ arcs corresponding to n input strings: for every string $s_i = ab$, there is an arc from a to b . It is known [9] that the length of an optimal superstring in this case is $n + k$ where k is the minimum number such that E can be decomposed into k directed paths, or, equivalently:

► **Proposition 9** ([9]). *Let G be the graph defined above, and let $G_1 = (V_1, E_1), \dots, G_c = (V_c, E_c)$ be its weakly connected components. Then the length of an optimal superstring is*

$$n + \sum_{i=1}^c \max \left(1, \sum_{v \in V_i} \frac{|\text{indegree}(v) - \text{outdegree}(v)|}{2} \right). \quad (2)$$

We will now show that in this case, GHA finds an optimal solution.

► **Lemma 10.** *Let $\mathcal{S} = \{s_1, \dots, s_n\}$ be a set of strings of length at most 2, and let s be an optimal superstring for \mathcal{S} . Then $\text{GHA}(\mathcal{S})$ returns a superstring of length $|s|$.*

Proof. We showed above that it suffices to consider the case of n primitive strings $\{s_1, \dots, s_n\}$ of length exactly 2. For $1 \leq i \leq n$, let $s_i = a_i b_i$, where $a_i \neq b_i$. Consider the partial greedy hierarchical solution D after the Step 2 of the GHA algorithm: $D = \{(a_i, a_i b_i), (a_i b_i, b_i) : 1 \leq i \leq n\}$. (We abuse notation by identifying the set of arcs D with the graph induced by D .) This partial solution has n up-arcs, so its current weight is n .

Note that by the definition of the graph G above, G contains an arc (a, b) if and only if D has the arcs (a, ab) and (ab, b) of the graph HG. Thus, the indegree (outdegree) of a vertex a in G equals the indegree (outdegree) of the vertex a in the partial solution D . Also, two vertices a and b of G belong to one weakly connected component in G if and only if they belong to one weakly connected component in D . Therefore, the expression (2) in G has the same value in the partial solution graph D . (Indeed, the vertices of D corresponding to strings of length 2 are balanced and do not form weakly connected components.)

Now we proceed to Steps 3–11 of GHA. GHA will go through all strings of length 1, and add $|\text{indegree}(v) - \text{outdegree}(v)|$ arcs for each unbalanced vertex v . The Steps 8–11 ensure that each weakly connected component adds at least a pair of arcs. Since exactly a half of added arcs are up-arcs, we have increased the weight of the partial solution D by

$$\sum_{i=1}^c \max \left(1, \sum_{v \in V_i} \frac{|\text{indegree}(v) - \text{outdegree}(v)|}{2} \right). \quad \blacktriangleleft$$

B.2 Spectrum of a String

By a k -spectrum of a string s (of length at least k) we mean a set of all substrings of s of length k . Pevzner et al. [24] give a polynomial time exact algorithm for the case when the input strings form a spectrum of an unknown string. We show that GHA also finds an optimal solution in this case.

► **Lemma 11.** *Let $\mathcal{S} = \{s_1, \dots, s_n\}$ be a k -spectrum of an unknown string s . Then $\text{GHA}(\mathcal{S})$ returns a superstring of length at most $|s|$.*

Proof. Since s has n distinct substrings of length k , $|s| \geq n + k - 1$. We will show that GHA finds a superstring of length $n + k - 1$. After Step 2 of GHA, the partial solution $D = \{(\text{pref}(s), s), (s, \text{suff}(s)) : s \in \mathcal{S}\}$. In particular, D is of weight n . For $1 \leq i \leq k - 1$,

26:22 Collapsing Superstring Conjecture

let u_i be the first i symbols of s , and let v_i be the last i symbols of s . Note that u_{k-1} and v_{k-1} are the only unbalanced vertices of the partial solution D after Step 2: all other strings of length $k-1$ appear equal number of times as prefixes and suffixes of strings from \mathcal{S} . Therefore, while processing the level $\ell = k-1$, GHA will add one arc to each of the vertices u_{k-1} and v_{k-1} , and will not add arcs to other strings of length $k-1$.

In general, while processing the level $\ell = i$, GHA adds one up-arc to u_i and one down-arc to v_i . In order to show this, we consider two cases. If $u_i \neq v_i$, then u_i has an incoming arc from the previous step and does not have outgoing arcs, therefore GHA adds an up-arc to u_i in Step 6. Similarly, GHA adds a down-arc from v_i . Note that there are no other strings of length $i < k-1$ in the partial solution, so the algorithm moves to the next level. In the case when $u_i = v_i$, we have that all vertices are balanced, but the string u_i is now the shortest string in this only connected component \mathcal{C} of the graph. Therefore, for $i > 0$ we have $\varepsilon \notin \mathcal{C}$, and GHA adds an up- and down-arc to u_i in Step 11.

We just showed that GHA solution for a k -spectrum of a string has the initial set of arcs $D = \{(\text{pref}(s), s), (s, \text{suff}(s)) : s \in \mathcal{S}\}$, and also the arcs $\{(u_{i-1}, u_i), (v_i, v_{i-1}) : 1 \leq i \leq k-1\}$. Thus, the total number of up-arcs (and the weight of the solution) is $n + k - 1$. ◀

B.3 Tough Dataset

There is a well-known dataset consisting of just three strings where the classical greedy algorithm produces a superstring that is almost twice longer than an optimal one: $s_1 = \text{cc}(\text{ae})^n$, $s_2 = (\text{ea})^{n+1}$, $s_3 = (\text{ae})^n \text{cc}$. Since $\text{overlap}(s_1, s_3) = 2n$, while $\text{overlap}(s_1, s_2) = \text{overlap}(s_2, s_3) = 2n - 1$, the greedy algorithm produces a permutation (s_1, s_3, s_2) (or (s_2, s_1, s_3)). I.e., by greedily taking the massive overlap of length $2n$ it loses the possibility to insert s_2 between s_1 and s_3 and to get two overlaps of size $2n - 1$. The resulting superstring has length $4n + 6$. At the same time, the optimal superstring corresponds to the permutation (s_1, s_2, s_3) and has length $2n + 8$.

The algorithm GHA makes a similar mistake on this dataset, see Figure 12. When processing the node $(\text{ea})^n$, GHA does not add two lower arcs to it and misses a chance to connect two components. It is then forced to connect these two components through ε . This example shows that GHA also does not give a better than 2-approximation for SCS.

■ **Figure 12** Top: optimal solution for the dataset $\{cc(ae)^n, (ea)^{n+1}, (ae)^nc\}$. Bottom: solution constructed by GHA.

Improved Algorithms for Time Decay Streams

Abstract

In the time-decay model for data streams, elements of an underlying data set arrive sequentially with the recently arrived elements being more important. A common approach for handling large data sets is to maintain a *coreset*, a succinct summary of the processed data that allows approximate recovery of a predetermined query. We provide a general framework that takes any offline-coreset and gives a time-decay coreset for polynomial time decay functions.

We also consider the exponential time decay model for k -median clustering, where we provide a constant factor approximation algorithm that utilizes the online facility location algorithm. Our algorithm stores $O(k \log(h\Delta) + h)$ points where h is the half-life of the decay function and Δ is the aspect ratio of the dataset. Our techniques extend to k -means clustering and M -estimators as well.

1 Introduction

The *streaming model* of computation has become an increasingly popular model for processing massive datasets. In this model, the data is presented sequentially, and the objective is to answer some pre-defined query. The overwhelmingly large size of the dataset imposes a number of restrictions on any algorithm designed to answer the pre-defined query. For example, a streaming algorithm is permitted only a few passes, or in many cases, only a single pass over the data. Moreover, the algorithm should also use space sublinear in, or even logarithmic in, the size of the data. For more details on the background and applications of the streaming model, [4, 45, 1] provide excellent surveys.

Informally, a coreset for a given problem is a small *summary* of the dataset such that the *cost* of any candidate solution on the coreset is approximately the same as the cost in the original set. Coresets have been used in a variety of problems, including generalized facility locations [29], k -means clustering [31, 9], principal component analysis [33], and ℓ_p -regression [24]. Coresets also have a number of applications in distributed models (see [39, 44, 6, 3], for example). To maintain the coresets throughout the data stream, one possible approach is the so called merge-and-reduce method, in which the multiple sets may be adjusted and combined. Several well-known coreset constructions [37, 17] for the k -median and k -means problems are based on the merge-and-reduce paradigm.

1.1 Motivation

Many applications discard obsolete data, choosing to favor relatively recent data to base their queries. This motivates the *time decay* model, in which there exists a function w so that the weight of the t^{th} most recent item is $w(t)$. Note that this is a generalization of both the *insertion-only* streaming model, where $w(t) = 1$ for all t , and the *sliding-window* model, where $w(t) = 1$ for the most recent W items, and $w(t) = 0$ for $t > W$. In this paper, we study the problem of maintaining coresets over a polynomial decay model, where $w(t) = \frac{1}{t^s}$ for some parameter $s > 0$, and an exponential decay model, where $w(t) = 2^{\frac{T-t+1}{h}}$ at time T for some *half-life* parameter $h > 0$.

Although exponential decay model is well-motivated by natural phenomena that exhibit half-life behavior, [20] notices that exponential decay and the sliding window model is often insufficient for many applications because the decay occurs too quickly and suggests that polynomial decay may be a reasonable alternative for some applications, such as availability of network links. For example, consider a network link that fails at every time between 10 and 60 and a second network link that fails once at time 75. Intuitively, it seems like the second link should be better, but under many parameters, the exponential decay model and sliding window model will both agree that the first link is better. Fortunately, under the polynomial decay model, events that occur near the same time have approximately the same weight, and we will obtain some view in which the first link is preferred [40]. In practice, time decay functions have been used in natural language understanding to give more importance to recent utterances than the past ones [47].

Organization. The rest of the paper is organized as follows. In Section 2, we summarize the main results of the paper and the algorithmic approaches. In Section 3, we discuss the related work, and in Section 4, we formalize the problem and discuss the preliminaries required. In Sections 5 and 6, we handle the polynomial and exponential decay, respectively, in detail, wherein we present the algorithmic details as well as the complete analysis.

2 Our Contributions

We summarize our results and give a high-level idea of our approach for problems in the polynomial and exponential decay models in the following subsections respectively. The reader is encouraged to go through Sections 5 and 6 for details.

2.1 Polynomial decay

In the polynomial decay model, a stream of points P arrives sequentially and the weight of the t^{th} most recent point, denoted as $w(t)$, is $w(t) = \frac{1}{t^s}$ where $s > 0$ is a given constant parameter of the decay function. We first state a theorem that shows that we can use an offline coreset construction mechanism to give a coreset for the polynomial decay model.

► **Theorem 1.** *Given an algorithm that takes a set of n points as input and constructs an ϵ -coreset of $F(n, \epsilon)$ points in $\mathcal{O}(nT(\epsilon))$ time, there exists a polynomial decay algorithm that maintains an ϵ -coreset while storing $\mathcal{O}\left(\epsilon^{-1} \log n F\left(n, \frac{\epsilon}{\log n}\right)\right)$ points and with update time $\mathcal{O}\left(\epsilon^{-1} \log n F(n, \epsilon) T(\epsilon/\log n)\right)$.*

Theorem 1 applies to any time-decay problem on data streams that admits an approximation algorithm using coresets. Among its applications are the problems of k -median and k -means clustering, M -estimator clustering, projective clustering, and subspace approximation. We list a few of these results in Table 1. Our result is a generalization of the *vanilla* merge-and-reduce approach used to convert offline coresets to streaming counterparts. In particular, plugging in $s = 0$, we get the vanilla streaming model, and the theorem recovers the corresponding guarantees.

■ **Table 1** Coresets for some problems in polynomial decay streams.

Problem	Coreset size	Offline algorithm
Metric k -median clustering	$\mathcal{O}\left(\frac{s}{\epsilon^3} k \log k \log^4 n\right)$	[30]
Metric k -means clustering	$\mathcal{O}\left(\frac{s}{\epsilon^3} k \log k \log^4 n\right)$	[9]
Metric M -estimator	$\mathcal{O}\left(\frac{s}{\epsilon^3} k \log k \log^4 n\right)$	[9]
j^{th} subspace approximation	$\mathcal{O}\left(\frac{j^2 s}{\epsilon^4} \log^8 n \log\left(\frac{\log n}{\epsilon}\right)\right)$	[30]
Low rank approximation	$\mathcal{O}\left(\frac{s}{\epsilon^2} kd \log n\right)$	[34]

Approach. A natural starting point would be to attempt to generalize existing sliding window algorithms to time decay models. These algorithms typically use a histogram data structure [14], in which multiple instances of streaming algorithms are started at various points in time, one of which well-approximates the objective evaluated on the data set represented by the sliding window. However, generalizing these histogram data structures to time-decay models does not seem to work since the weights of all data points changes upon each new update in time-decay model, whereas streaming algorithms typically assume static weights for each data point.

Instead, our algorithm partitions the stream into blocks, where each block represents a disjoint collection of data point between certain time points. Each arriving element initially begins as its own block, containing one element. The algorithm maintains an unweighted coreset for each block, and merges blocks (i.e corresponding coresets) as they become older. However, at the end, each block is to be weighted according to some function, and so the algorithm chooses to merge blocks when the weights of the blocks become “close”. Thus, a coreset for each block will represent the set of points well, as the weights of the points in each block do not differ by too much.

2.2 Exponential decay

We also provide an algorithm that achieves a constant approximation for k -median clustering in the exponential decay model. Our guarantees also extend to k -means clustering and M -estimators.

Given a set P of points in a metric space, let Δ denote its aspect ratio i.e the ratio between the largest and (non-zero) smallest distance between any two points in P . The weight of the t^{th} most recent point at time T is $w(t) = 2^{\frac{T-t+1}{h}}$ where $h > 0$ is the half-life parameter of the exponential decay function.

► **Theorem 2.** *There exists a streaming algorithm that given a stream P of points with exponentially decaying weights, with aspect ratio Δ and half-life h , produces an $\mathcal{O}(1)$ -approximate solution to k -median clustering. The algorithm runs in $\mathcal{O}(nk \log(h\Delta))$ time and uses $\mathcal{O}(k \log(h\Delta) + h)$ space.*

Approach. Although our previous framework will work for other decay models, the algorithm may use prohibitively large space. The intuition behind the polynomial decay approach is that a separate coreset is maintained for each set of points that roughly have the same weight. In other words, the previous framework maintains a separate coreset each time the weight of the points decrease by some constant amount, so that if R is the ratio between the largest weight and the smallest weight, then the total number of coresets stored by the algorithm is roughly $\log R$. In the polynomial decay model, the number of stored coresets is $\mathcal{O}(\log n)$, but in the exponential decay model, the number of stored coresets would be $\mathcal{O}(n)$, which would no longer be sublinear in the size of the input. Hence, we require a new approach for the exponential decay model.

Instead, we use the online facility location (OFL) algorithm of Meyerson [43] as a subroutine to solve k -median clustering in the exponential decay model. In the online facility location problem, we are given a metric space along with a facility cost for each point/location that appears in the data stream. The objective is to choose a (small) number of facility locations to minimize the total facility cost plus the service cost, where the service cost of a point is its distance to the closest facility. For more details, please see Section 6.

Our algorithm for the exponential time decay model proceeds on the data stream, working in phases. Each phase corresponds to an increasing “guess” for the value of the *cost* of the optimal clustering. Using this guess, each phase queries the corresponding instance of OFL. If the guess is *correct*, then the subroutine selects a bounded number of facilities. On the other hand, if either the cost or the number of selected facilities surpasses a certain quantity, then the guess for the optimal cost must be incorrect, and the algorithm triggers a phase change. Upon a phase change, our algorithm uses an offline k -median clustering algorithm to cluster the facility set and produces exactly k points. It then runs a new instance of OFL with a larger guess, and continues processing the data stream.

However, there is a slight subtlety in this analysis. The number of points stored by OFL is dependent on the weights of the point. In an exponential decay function, the ratio between the largest weight and smallest weight of points in the data set may be exponentially large. Thus to avoid OFL from keeping more than a logarithmic number of points, we force OFL to terminate after seeing $\log(h\Delta)$ points during a phase. Furthermore, we store points verbatim until we see $k + h$ *distinct* points, upon whence we will trigger a phase change. We show that forcing this phase change does indeed correspond with an increase in the guess of the value for the optimal cost.

3 Related Work

The first insertion-only streaming algorithm for the k -median clustering problem was presented in 2000 by Guha, Mishra, Motwani, and O’Callaghan [36]. Their algorithm uses $\mathcal{O}(n^\epsilon)$ space for a $2^{\mathcal{O}(1/\epsilon)}$ approximation, for some $0 < \epsilon < 1$. Subsequently, Charikar *et al* [16] present an $\mathcal{O}(1)$ -approximation algorithm for k -means clustering that uses $\mathcal{O}(k \log^2 n)$ space. Their algorithm uses a number of phases, each corresponding to a different guess for the value of the cost of optimal solution. The guesses are then used in the online facility location (OFL) algorithm of [43], which provides a set of centers whose number and cost allows the algorithm

to reject or accept the guess. This technique is now one of the standard approaches for handling k -service problems. Braverman *et al* [13] improve the space usage of this technique to $\mathcal{O}(k \log n)$. [11] and [12] develop algorithms for k -means clustering on sliding windows, in which expired data should not be included in determining the cost of a solution.

Another line of approach for k -service problems is the construction of coresets, in particular when the data points lie in the Euclidean space. Har-Peled and Mazumdar [37] give an insertion-only streaming algorithm for k -medians and k -means that provides a $(1 + \epsilon)$ -approximation, using space $\mathcal{O}(k\epsilon^{-d} \log^{2d+2} n)$, where d is the dimension of the space. Similarly, Chen [17] introduced an algorithm using $\mathcal{O}(k^2 d \epsilon^{-2} \log^8 n)$ space, with the same approximation guarantees.

Cohen and Strauss [20] study problems in time-decaying data streams in 2003. There are a number of results [40, 22, 21, 23] in this line of work, but the most prominent time-decay model is the sliding window model. Datar *et al* [25] introduced the exponential histogram as a framework in the sliding window for estimating statistics such as count, sum of positive integers, average, and ℓ_p norms. This initiated an active line of research, including improvements to count and sum [35], frequent itemsets [18, 10], frequency counts and quantiles [2, 42], rarity and similarity [26], variance and k -medians [5] and other geometric and numerical linear algebra problems [28, 15, 8].

4 Preliminaries

Let \mathcal{X} be the set of possible points in a space with metric d . A weighted set is a pair (P, w) with a set $P \subset \mathcal{X}$ and a weight function $w : P \rightarrow [0, \infty)$. A query space is a tuple (P, w, f, Q) that combines a weighted set with a set Q of possible queries and a function $f : \mathcal{X} \times Q \rightarrow [0, \infty)$. A query space induces a function

$$\bar{f}(P, w, q) = \sum_{p \in P} w(p) f(p, q).$$

We now instantiate the above with some simple examples.

► **Example 3** (k -means). Let Q be all sets of k points in \mathbb{R}^d , and for $C \in Q$ define $f(p, C) = \min_{c \in C} d^2(p, c)$. The k -means cost of (P, w) to C is

$$\sum_{p \in P} w(p) \min_{c \in C} d^2(p, c).$$

► **Example 4** (k -median). Let Q be all sets of k points in \mathbb{R}^d , and for $C \in Q$ define $f(p, C) = \min_{c \in C} d(p, c)$. The k -median cost of (P, w) to C is

$$\sum_{p \in P} w(p) \min_{c \in C} d(p, c).$$

Note that both k -median and k -means are captured in $\bar{f}(P, w, C)$. We now define an ϵ -coreset.

► **Definition 5** (ϵ -coreset). A ϵ -coreset for the query space (P, w, f, Q) is a tuple (Z, u) , where $Z \subseteq \mathcal{X}$ is a set of points and $u : Z \rightarrow [0, \infty)$ are their corresponding weights, such that for every $q \in Q$

$$(1 - \epsilon)\bar{f}(P, w, q) \leq \bar{f}(Z, u, q) \leq (1 + \epsilon)\bar{f}(P, w, q).$$

An important property of coresets is that they are *closed* under operations like union and composition. We formalize this below.

► **Proposition 6** (Merge-and-reduce, [17]). *Coresets satisfy the following two properties.*

1. *If \mathcal{S}_1 and \mathcal{S}_2 are ϵ -coresets of disjoint sets \mathcal{P}_1 and \mathcal{P}_2 respectively, then $\mathcal{S}_1 \cup \mathcal{S}_2$ is an ϵ -coreset of $\mathcal{P}_1 \cup \mathcal{P}_2$.*
2. *If \mathcal{S}_1 is an ϵ -coreset of \mathcal{S}_2 and \mathcal{S}_2 is a δ -coreset of \mathcal{S}_3 , then \mathcal{S}_1 is a $((1+\epsilon)(1+\delta)-1)$ -coreset of \mathcal{S}_3 .*

We now define approximate triangle inequality, a property that allows us to extend our results obtained in metric spaces to ones with *semi-distance* functions. In particular, this allows us to extend results for k -median clustering to k -means and M -estimators in exponential decay streams.

► **Definition 7** (λ -approximate triangle inequality). *A function $d(\cdot, \cdot)$ on a space \mathcal{X} satisfies the λ -approximate triangle inequality if for all $x, y, z \in \mathcal{X}$,*

$$d(x, z) \leq \lambda(d(x, y) + d(y, z)).$$

5 Polynomial Decay

We consider a time decay, wherein a point p in the stream, which arrived at time t , has weight $w(p) = (T - t + 1)^{-s}$ at time $T > t$, for some parameter $s > 0$. Equivalently, the t^{th} most recent element has weight t^{-s} for some $s > 0$.

We present a general framework which, for given problem, takes an offline coreset construction algorithm and adapts it to polynomial decay streams. Our technique can be viewed as a generalization of merge-and-reduce technique of Bentley and Saxe [7]. We also briefly discuss some applications towards that end. We start with stating our main theorem for polynomial decay streams.

► **Theorem 8.** *Given an offline algorithm that takes a set of n points as input and constructs an ϵ -coreset of $F(n, \epsilon)$ points in $\mathcal{O}(nT(\epsilon))$ time, there exists a polynomial decay algorithm that maintains an ϵ -coreset while storing $\mathcal{O}(\epsilon^{-1}s \log n F(n, \epsilon/\log n))$ points and with update time*

$$\mathcal{O}(\epsilon^{-1}s \log n F(n, \epsilon) T(\epsilon/\log n)).$$

Notation. We use \mathbb{N} to denote the set of natural numbers. We use CS-RAM to denote an offline coreset construction algorithm, which given n points, constructs an ϵ -coreset in time $\mathcal{O}(nT(\epsilon))$ and takes space $F(n, \epsilon)$. We abuse notation by using $F(n, \epsilon)$ to also refer to the corresponding coreset.

5.1 Algorithm

We start with giving a high-level intuition of the algorithm. Given a stream of points, the algorithm implicitly maintains a partition of the streams into disjoint *blocks*. A block is a collection of consecutive points in the stream, and is represented by two positive integers a and b as $[a, b]$, where a represents the position of the first point in the block and b the last point, relative to the start of the stream. Let the set of blocks be denoted by \mathcal{B} . Our algorithm stores points of a given block by maintaining a coreset for the points in that block. As the stream progresses, we merge older blocks i.e. the corresponding coresets. Informally, the merge happens when the weights of the blocks become *close*.

We first define a set of integer *markers* x_i , which for a given $i \in \mathbb{N}$, depends on the decay parameter s and target ϵ . These markers dictate when to merge blocks as the stream progresses. For a given $i \in \mathbb{N}$, we define x_i to be the minimum integer greater than or equal to 2^i such that

$$\frac{1 - \epsilon}{(x_i - 2^i + 1)^s} \leq \frac{1 + \epsilon}{x_i^s}.$$

Equivalently, we can write $\left(\frac{x_i}{x_i - 2^i + 1}\right)^s \leq \frac{1+\epsilon}{1-\epsilon}$. Note that each of the 2^i points following x_i in the stream, has weight within $\frac{1+\epsilon}{1-\epsilon}$ times the weight of x_i . Moreover, x_i 's can be exactly pre-computed from the equation and we therefore assume that these are implicitly stored by the algorithm. Each new element in the stream starts as a new block. As mentioned before, the blocks are represented by two integers $[a, b]$ and the points are stored as a coreset. When a block $[a, b]$ reaches x_i , then algorithm merges all of $[x_i - 2^i + 1, x_i]$ points into a single coreset. In the end, the algorithm outputs the *weighted* union of the coresets of the blocks.

To visualize this, consider the integer line, and suppose that we have x_i 's marked on the positive side of the line, for example $x_1 = 2, x_2 = 4 \dots$. The tuple indices of the blocks represent the relative position of the point in the stream, with the start being 1 and the end point being n . At the start, the stream is on the non-positive end with the first point at 0. As the time progresses, the stream moves to the right side. Therefore, when we observe the first element, it moves to the point 1. We then store it as a new block, represented by $[1, 1]$; we also simultaneously store a coreset corresponding to it. As time progresses, a block reaches x_i for some i which can be formally expressed as $a + x_i \leq n$. We then merge all blocks in the range $[a, a + 2^i - 1]$. Note that by definition of x_i , we would have observed all these elements and also we will not merge partial blocks. We present this idea in full in Algorithm 1 and intuition in Figure 1. We remark that when we construct coresets, we use an offline algorithm CS-RAM which given a set of n points P and a query space (P, w, f, q) produces an ϵ -coreset.

■ **Figure 1** The algorithm merges blocks in each interval $[a, a + 2^i - i]$ for $a \leq n - x_i$.

■ **Algorithm 1** ϵ -coreset for polynomial decaying streams.

Input: Stream P , polynomial decay function $w(t) = \frac{1}{t^s}$, for some $s > 0$, an offline coreset construction algorithm CS-RAM

Output: $(1 + \epsilon)$ coreset.

- 1: Initialize $\mathcal{B} = \emptyset$
 - 2: **for** each element p_n of the stream **do**
 - 3: Insert $[n, n]$ into \mathcal{B} as a new block and construct a coreset
 - 4: **for** each block $[a, b] \in \mathcal{B}$ **do**
 - 5: **if** $a + x_i < n$ for some i **then**
 - 6: Merge the blocks in $[a, a + 2^i - 1]$ and *reduce* to get an $\frac{\epsilon}{3 \log n}$ -coreset
 - 7: **end if**
 - 8: **end for**
 - 9: **end for**
 - 10: **for** each block $[a, b] \in \mathcal{B}$ **do**
 - 11: Give the block weight $u(a, b) = \frac{1}{2} \left(\frac{1-\epsilon}{a^s} + \frac{1+\epsilon}{b^s} \right)$
 - 12: **end for**
-

5.2 Analysis

We first show that a weighted combination of blocks gives us an ϵ -coreset. For a block $[a, b]$, let the weight of the block be denoted as $u(a, b)$. We set $u(a, b) = \bar{u}$ where \bar{u} satisfies

$$\frac{1 - \epsilon}{a^s} \leq \bar{u} \leq \frac{1 + \epsilon}{b^s}.$$

The following lemma shows that any such \bar{u} produces a 3ϵ -coreset.

► **Lemma 9.** *Let (Z, u) be an ϵ -coreset for (P, w, f, Q) . Let $\bar{u} : Z \rightarrow [0, \infty)$ be such that $(1 - \epsilon)u(z) \leq \bar{u}(z) \leq (1 + \epsilon)u(z)$ for every $z \in Z$, then (Z, \bar{u}) is a 3ϵ -coreset for (P, w, f, Q) .*

Proof. Since (Z, u) is an ϵ -coreset for (P, w, f, Q) , therefore for every $q \in Q$,

$$\begin{aligned} (1 - \epsilon)\bar{f}(P, w, q) &\leq \bar{f}(Z, u, q) \leq (1 + \epsilon)\bar{f}(P, w, q) \\ \iff (1 - \epsilon) \sum_{p \in P} w(p)f(p, q) &\leq \sum_{z \in Z} u(z)f(z, q) \leq (1 + \epsilon) \sum_{p \in P} w(p)f(p, q) \\ \iff (1 - \epsilon)^2 \sum_{p \in P} w(p)f(p, q) &\leq \sum_{z \in Z} \bar{u}(z)f(z, q) \leq (1 + \epsilon)^2 \sum_{p \in P} w(p)f(p, q). \end{aligned}$$

Note that for $\epsilon < 1$, we have $(1 - 2\epsilon)\bar{f}(P, w, q) \leq (1 - \epsilon)^2\bar{f}(P, w, q) \leq \bar{f}(Z, \bar{u}, q) \leq (1 + \epsilon)^2\bar{f}(P, w, q) \leq (1 + 3\epsilon)\bar{f}(P, w, q)$. Therefore (Z, \bar{u}) is a 3ϵ -coreset for (P, w, f, Q) . ◀

Having assigned weights to the blocks, we can take the union to get the coreset of \mathcal{B} . For simplicity, we choose $u(a, b) = \frac{1}{2} \left(\frac{1-\epsilon}{a^s} + \frac{1+\epsilon}{b^s} \right)$ in Algorithm 1. We now present a lemma that bounds the number of blocks maintained by the algorithm.

► **Lemma 10.** *Given a polynomial decay stream of n points as input to Algorithm 1, the number of blocks produced is $\mathcal{O}(\epsilon^{-1} s \log n)$.*

Proof. Consider any two adjacent blocks. By the definition of the x_i 's, the ratio between the weights of the oldest and youngest elements is at least $(1 + \epsilon)/(1 - \epsilon)$. In the full stream, the oldest element has weight $1/n^s$ and the youngest element has weight 1. Let B be the number of blocks so that $\left(\frac{1+\epsilon}{1-\epsilon} \right)^{[B]} \leq n^s$. Solving for B , we get $B \leq \frac{s \log n}{\log((1+\epsilon)/(1-\epsilon))}$. We will now lower bound the denominator using the numerical inequality $\ln(1+x) \geq \frac{2x}{2+x}$ for $x > 0$; equivalently $\log(1+x) \geq c \cdot \frac{2x}{2+x}$ for $x > 0$ and $c = \Theta(1)$. We get $\log\left(\frac{1+\epsilon}{1-\epsilon}\right) = \log\left(1 + \frac{2\epsilon}{1-\epsilon}\right) \geq 2c\epsilon$, and therefore we have $B = \mathcal{O}(\epsilon^{-1} s \log n)$. ◀

We now give the proof of the main theorem for the polynomial decay model.

Proof of Theorem 8. From Proposition 6, we get that when we merge disjoint blocks, we do not sacrifice the coreset approximation parameter ϵ . However, when we reduce, for instance two ϵ -coresets, we get a 2ϵ -coreset. For n points observed in the stream, note that there would be at most $\log n$ reduces. This follows from the fact that the size of successive blocks increase exponentially. Therefore using an offline ϵ' -coreset construction algorithm CS-RAM with $\epsilon' = \epsilon/3 \log n$, we get that merging and reducing the blocks produces an $\epsilon/3$ -coreset (by Proposition 6). Finally, from Lemma 9, we get that taking a union of these blocks weighted by $u(a, b) = \frac{1}{2} \left(\frac{1-\epsilon}{a^s} + \frac{1+\epsilon}{b^s} \right)$ gives us an ϵ -coreset.

For the space bound, we have from Lemma 10 that the number of blocks is $\mathcal{O}(\epsilon^{-1} s \log n)$. Since we maintain an $\epsilon/\log n$ coreset for each block, we get that the offline coreset construction algorithm takes space $F(n, \epsilon/\log n)$. Therefore, we get that the space complexity is

$\mathcal{O}(\epsilon^{-1} s \log n F(n, \epsilon/\log n))$. For update time, note that for n points, we have $\mathcal{O}(\epsilon^{-1} s \log n)$ blocks and we use an $(\epsilon/\log n)$ -coreset algorithm which takes time $\mathcal{O}(F(n, \epsilon) T(\epsilon/\log n))$ per block. We therefore get a total time of $\mathcal{O}(\epsilon^{-1} s \log n F(n, \epsilon) T(\epsilon/\log n))$ ◀

Applications. Coresets have been designed for a wide variety of geometric, numerical linear algebra and learning problems. Some examples include k -median and k -means clustering [17], low rank approximation [46], ℓ_p regression [19], projective clustering [27], subspace approximation [32], kernel methods [48], Bayesian inference [38] etc. We instantiate our framework with a few of these problems, and present the results in Table 1.

6 Exponential Decay

We now discuss another model of time decay in which the weights of previous points decay exponentially with time. Analogous to our polynomial decay model, a point that first appeared in the stream at time $t \leq T$ has weight $2^{\frac{T-t+1}{h}}$ at time T , where the parameter $h > 0$ is the half-life of the decay function. We however consider a different viewpoint to simplify the analysis; we maintain that the weight of a point observed at time t is *fixed* to be $2^{t/h}$ where $h > 0$ is the half-life parameter. These are equivalent since the ratio of weights between successive points is the same in both the models.

Online Facility Location. We first discuss the problem of Online Facility Location (OFL) as our algorithm uses it as a sub-routine. The problem of facility location, given a set of points $P \subseteq \mathcal{X}$, called *demands*, a distance function $d(\cdot, \cdot)$ and fixed cost $f > 0$, conventionally called the facility cost, asks to find a set of points \mathcal{C} that minimizes the following objective.

$$\min_{\mathcal{C} \subseteq \mathcal{X}} \sum_{p \in P} \min_{c \in \mathcal{C}} d(p, c) + |\mathcal{C}| f$$

Informally, it seeks a set of points such that the *cumulative* cost of serving the demands (known as *service cost*), which is $d(p, c)$ and opening new facilities f , is minimized. Online Facility Location is the variant of the above problem in the streaming setting, wherein the facility assignments and service costs incurred are irrevocable. That is to say, once a point is assigned to a facility, it cannot be reassigned to a different facility at a later point in time, even if the newer facility is closer. A simple and popular algorithm to this problem is by Meyerson [43], wherein upon receiving a point, it calculates its distance to the nearest facility and flips a coin with bias equal to the distance divided by facility cost. If the outcome is heads (or 1), it opens a new facility, otherwise the nearest point serves this demand and it incurs a service cost, equal to the distance. From here on, we abuse notation and use OFL to refer to the algorithm of Meyerson [43].

6.1 Algorithm

Our algorithm for exponential decaying streams is a variant of the popular k -median clustering algorithm [13, 16], which uses OFL as a sub-routine. We first briefly discuss the algorithm of [13] and then elucidate on how we adapt this to exponential decay streams. The algorithm operates in *phases*, where in each phase it maintains a *guess*, denoted by L , to the lower bound on optimal cost. It then uses this guess to instantiate the OFL algorithm of [43] on a set of points in the stream. If the service cost of OFL grows high or the number of facilities grows large, it infers that the guess is too low and triggers a *phase change*. It then increases the guess by a factor of β (to be set appropriately) and the facilities are put back at the start of the stream and another round of OFL is run.

27:10 Improved Algorithms for Time Decay Streams

Notation. We first define and explain some key quantities. The *aspect ratio* of a set is defined as the ratio between the largest distance and the smallest non-zero distance between any two points in the set. We use Δ to denote the aspect ratio of the stream P . For simplicity of presentation, we assume that the minimum non-zero distance between two points is at least 1. We define W as the total weight of the first $h \log \Delta$ points in the stream divided by the minimum weight. Suppose the stream starts at $t = z$, then for any $h = \Omega(1)$,

$$W = \frac{1}{2^{z/h}} \sum_{t=z}^{h \log(\Delta+1)} 2^{t/h} = \frac{\Delta}{2^{1/h} - 1} = \Theta(h\Delta).$$

For a set $P \subseteq (\mathcal{X}, d)$, we use $\text{OPT}_k(P)$ to denote the optimal k -median clustering cost for the set. For two sets P and S , we use $\text{COST}(P, S)$ to denote the cost of clustering P with S as medians. Whenever we use OPT , it corresponds to the optimal cost of k -median clustering of the stream seen till the point in context. We use KM-RAM to denote an offline constant c_r -approximate k -median clustering algorithm in the random access model (RAM). Given a set of points P and a positive integer k , KM-RAM outputs (\mathcal{C}, λ) , where \mathcal{C} is a set of k points and $\lambda = \text{COST}(P, \mathcal{C}) \leq c_r \cdot \text{OPT}_k(P)$.

Our Algorithm. Our algorithm, inspired from [16, 13], works in phases. We however have important differences. Each of our phases are again sub-divided into two *sub-phases*. In the first sub-phase we execute OFL same as [16, 13] and after each point we check if the cost or the number of facilities is too large. If this is indeed the case, we trigger a phase change. However, if we read $h \log \Delta$ points in a phase, then we move on to the second sub-phase of the algorithm. Here we simply count points and store them verbatim. Upon reading $k + h$ points, we trigger a phase change. The intuition for this sub-phase is that a phase change is triggered when OPT increases by a factor of β . After $h \log \Delta$ points, subsequent points are so heavy relative to points of the previous phase that any service cost will be large enough to ensure OPT has increased. Therefore, we restrict the algorithm to read at most $h \log \Delta + k + h$ points in a single phase. When we start a new phase, we cluster the existing facility set to extract exactly k points using an off-the-shelf constant approximate KM-RAM algorithm and continue processing the stream. We present the above idea in full in Algorithm 2. We now state our main theorem for exponential decay streams.

► **Theorem 11.** *There exists a streaming algorithm that given a stream P of exponential decaying points with aspect ratio Δ and half-life h , produces an $\mathcal{O}(1)$ -approximate solution to k -median clustering. The algorithm runs in $\mathcal{O}(nk \log(h\Delta))$ time and uses $\mathcal{O}(k \log(h\Delta) + h)$ space.*

6.2 Analysis

We first analyze the service cost and space complexity of OFL. For the t^{th} point in the stream p_t , the weight of p_t , denoted $w(p_t)$, is $w(p_t) = 2^{t/h}$. The following two lemmas will establish bounds on the service cost and number of facilities of OFL.

► **Lemma 12.** *When OFL is run on a stream of n points with exponentially decaying weights, with facility cost $f = \frac{L}{k(1+\log W)}$ where $L > 0$, it produces a service cost of at most $6\text{OPT}_k(P) + 2L$ with probability at least $1/2$.*

Proof. The proof follows the standard analysis of Online Facility Location. Let P is the set of points read in a phase. Instead of looking at $|P|$ distinct points with varying weights, we view it as *repeated* points of unit or minimum weight. The total number of points is therefore at most $W = \Theta(h\Delta)$.

■ **Algorithm 2** k -median clustering in exponential decay streams.

Input: k , stream P , an offline constant approximate k -median clustering algorithm KM-RAM.

```

We remind the reader that $\text{OPT}_k(P) = \min_{K \subseteq P, |K|=k} \sum_{p \in P} \min_{y \in K} d(p, y)$ is the optimal cost and $\text{COST}(P)$ is the total service cost incurred by OFL. Let \mathcal{C}^* be the set of corresponding facilities allocated by OPT, and c_i^* 's denote the optimum k facilities where $i \in [k]$ and C_i^* the set of points from P served by the facility c_i^* . Let $A_i = \sum_{x \in C_i^*} d(x, c_i^*)$ be the service cost of C_i^* . We now further partition each region into *rings*. Let S_i^1 be the first ring around c_i^* that contains half the nearest points in C_i^* . Formally, $S_i^1 = \arg \min_{K, |K|=|C_i^*|/2} \sum_{x \in K} d(x, c_i^*)$.

27:12 Improved Algorithms for Time Decay Streams

Furthermore, S_i^2 is the second ring around c_i^* containing one-quarter of the points in C_i^* and so on. Therefore, we can inductively define $S_i^j = \arg \min_{K, |K|=|C_i^*|/2^j} \sum_{x \in K \setminus \cup_{l=1}^{j-1} S_i^l} d(x, c_i^*)$.

Note that S_i^j may not be uniquely identifiable, but their existence suffices for the sake of analysis. Let $A_i^j = \sum_{x \in S_i^j} d(x, c_i)$ be the cost of set S_i^j . For a point p , use d_p^* and d_p for its optimal cost and cost incurred in the algorithm respectively.

We look at two cases. In the first case, suppose each region has a facility open; let the facility of S_i^j be s_i^j . We look at the cost incurred by subsequent points arriving in this region. Consider the set S_i^j and let q be a facility in S_i^j . A subsequent point p incurs a cost $d_p = d(p, q)$. By triangle inequality, we have $d_p \leq d_p^* + d_q^*$. By definition of S_i^j , we have $d_q^* \leq d_z^*$ for any point $z \in S_i^{j+1}$. We sum over all z in S_i^{j+1} and get $d_q^* \leq \frac{A_i^{j+1}}{|S_i^{j+1}|}$. We therefore get $d_p \leq d_p^* + \frac{A_i^{j+1}}{|S_i^{j+1}|}$.

Summing over all points in S_i^j , we get $\text{COST}(S_i^j, s_i^j) \leq A_i^j + \frac{|S_i^j| A_i^{j+1}}{|S_i^{j+1}|} = A_i^j + 2 \cdot A_i^{j+1}$. Summing over all j 's, we get $\text{COST}(C_i^*, c_i^*) \leq 3A_i$. Finally, summing over i 's, we get that in the first case $\text{COST}(P, C^*) \leq 3\text{OPT}_k(P)$. We now look at the second case wherein each region has a facility open. The number of points is at most W , therefore, the number of regions is at most $k(1 + \log(W))$. The expected service cost incurred by a region before opening a facility is at most f (See Fact 1, [41]). Therefore, the total service cost $\leq f k(1 + \log(W)) = L$. Combining the two cases, we get that $\text{COST}(P, C^*) \leq 3\text{OPT}_k(P) + L$. Note that when we store points verbatim, we do not incur any service cost. With a simple application of Markov inequality, we get that with probability at least $1/2$, $\text{COST}(P, C^*) \leq 6\text{OPT}_k(P) + 2L$. ◀

► **Lemma 13.** *When OFL is run on a stream of n points with exponentially decaying weights, with facility cost $f = \frac{L}{k(1 + \log W)}$ where $L > 0$, the number of facilities produced is at most $(2 + \frac{6}{L} \text{OPT}_k(P))k(1 + \log W)$, with probability at least $1/2$.*

Proof. Considering the points as repeated points of minimum weight, the total number of points is at most W and the total number of regions is at most $k(1 + \log W)$. One facility in each region gives us $k(1 + \log W)$ facilities. After opening a facility in a region, each subsequent point has probability $\frac{d_p}{f}$ to open a facility. Therefore, the expected number of facilities is $\sum_p \frac{d_p}{f}$. We showed in Lemma 12 that $\sum_p d_p \leq 3 \text{OPT}_k(P)$. Hence, the expected number of facilities is at most $\frac{3\text{OPT}_k(P)}{f} = \frac{3\text{OPT}_k(P)k(1 + \log W)}{L}$. A simple application of Markov's inequality completes the proof. ◀

k -median clustering. We now state some key lemmas that will help us establish that the algorithm produces a $\mathcal{O}(1)$ approximation to the k -median clustering cost. We then show how these come together and present the detailed guarantees in Theorem 17.

► **Lemma 14.** *At every phase change, with probability at least $1/2$, $\text{OPT}_k(P) > L$ if $\beta \leq 2$ and $\gamma \geq 9$.*

Proof. The phase change is triggered in two ways, either the cost or the number of facilities grows large (more precisely, cost more than γL or the number of facilities greater than $(\gamma - 1)k(1 + \log W)$), or we read too many points. Let us look at the first case. Assume that $L \geq \text{OPT}_k(P)$, then from Lemma 12 and 13, we get that with probability at least $1/2$, $\text{COST} \leq 8L$ and the number of facilities is $\leq 8k(1 + \log W)$ respectively. However with $\gamma \geq 9$, neither of the two conditions are met and therefore the premise that a phase change was triggered gives us a contradiction. Hence, in the first case, we get $L < \text{OPT}_k(P)$ with probability at least $1/2$.

In the other case, we store points exactly (incurring no additional cost). The only danger in this case is performing a phase change too early (before OPT has doubled). Let $\underline{\text{OPT}}$ be the value of OPT at the beginning of the phase, which we assume starts at time $t = z$. Since points cannot be at distance greater than Δ , then

$$\begin{aligned}\underline{\text{OPT}} &\leq \Delta(1 + 2^{1/h} + \dots + 2^{z/h}) \\ &\leq \Delta \frac{2^{(z+1)/h} - 1}{2^{1/h} - 1}\end{aligned}$$

Now let $\overline{\text{OPT}}$ be the value of OPT after terminating the phase (which occurs after reading $k + h$ distinct points after the initial $h \log \Delta$ points of the phase). We must prove that $\overline{\text{OPT}} \geq 2\underline{\text{OPT}}$. Observe that after reading $k + h$ distinct points, we must cluster at least h points across a distance of at least 1 (since we can have at most k centers). The weights of these points begin at $2^{(z+h \log \Delta+1)/h}$. Therefore,

$$\begin{aligned}\overline{\text{OPT}} &\geq \underline{\text{OPT}} + \sum_{i=z+h \log \Delta}^{z+h \log \Delta+h} 2^{i/h} \\ &= \underline{\text{OPT}} + \frac{2^{(z+h \log_2(\Delta)+h)/h} - 2^{(z+h \log_2(\Delta))/h}}{2^{1/h} - 1} \\ &\geq \underline{\text{OPT}} + \Delta \left(\frac{2^{(z+1)/h} - 1}{2^{1/h} - 1} \right) \\ &\geq 2\underline{\text{OPT}},\end{aligned}$$

where the second inequality follows from straightforward arithmetic. Let L' be the value of L in the previous phase. Thus,

$$\overline{\text{OPT}} \geq 2\underline{\text{OPT}} > 2L' = \frac{2}{\beta} L$$

where the second inequality holds with probability at least $1/2$, as justified above. Setting $\beta \leq 2$ completes the proof. \blacktriangleleft

► **Lemma 15.** *At any part in the algorithm, we have $\text{COST}(P, \mathcal{C}) \leq \left(\gamma + \frac{1+c_r\beta}{\beta-1} \right) L$.*

Proof. We know that the increase of $\text{COST}(P, \mathcal{C})$ in the current phase is upper bounded by the variable COST (see Algorithm 2). In a single phase, we have $\text{COST} \leq \gamma L$. Therefore, outside the phase loop, we just need to show that it is at most $\frac{1+c_r\beta}{\beta-1} L$. Note that it changes only by the KM-RAM algorithm, which incurs cost of $\lambda \leq c_r \gamma L$. Suppose that it holds in the previous phase and let L' be the value of L in the previous phase. Then the cost outside the loop is $\gamma L' + \frac{1+c_r\beta}{\beta-1} L' + \lambda \leq \frac{1+c_r\beta}{\beta-1} L$, which finishes the proof. \blacktriangleleft

► **Lemma 16.** *With probability at least $1/2$, $L \leq \left(1 + \frac{1}{\gamma} + \frac{1+c_r\beta}{\gamma(\beta-1)} \right) \text{OPT}_k(P)$.*

Let L' and \mathcal{C}' denote the values of L and \mathcal{C} in the previous phase. We condition on the event that $L' < \text{OPT}_k(P)$, which we know from Lemma 14 occurs with probability at least $1/2$. From the update equation of L , we either have $L = \beta L'$ or $L = \frac{\lambda}{c_r \gamma}$. In the first case, we directly get $L \leq \beta \text{OPT}_k(P)$. With $\beta \leq 2$, we get the claim of the lemma. We now look at the second case, where we have $\gamma c_r L \leq \lambda \leq c_r \text{OPT}_k(\mathcal{C}')$ from the guarantee of the KM-RAM algorithm. It is easy to see that $\text{OPT}_k(\mathcal{C}') \leq \text{OPT}_k(P) + \text{COST}(P, \mathcal{C}')$ by a simple application of triangle inequality on all the points. Moreover, from Lemma 15, we have $\text{COST}(P, \mathcal{C}') \leq \left(\gamma + \frac{1+c_r\beta}{\beta-1} \right) L' \leq \left(\gamma + \frac{1+c_r\beta}{\beta-1} \right) \text{OPT}_k(P)$. Combining these, we get $L \leq \left(\frac{1}{\gamma} + 1 + \frac{1+c_r\beta}{\gamma(\beta-1)} \right) \text{OPT}_k(P)$.

We now restate the theorem for the exponential decay model but tailored to Algorithm 2 with all the algorithmic details precisely stated.

► **Theorem 17.** *Let P be a stream of n points with exponential decaying weights parametrized by the half-life parameter h and let k be some positive integer. Algorithm 2 run with $\beta \leq 2, \gamma \geq 9, W = \mathcal{O}(h\Delta)$ on the stream P outputs k points, which produce an $\mathcal{O}(1)$ approximation to the optimal cost of k -median clustering on P with high probability. The algorithm runs in time $\mathcal{O}(nk \log W)$ and uses space $\mathcal{O}(k \log W + h)$.*

Proof. Combining Lemma 15 and 16, we get that

$$\text{COST}(P, \mathcal{C}) \leq \left(\gamma + \frac{1 + c_r \beta}{\beta - 1} \right) \left(\frac{1}{\gamma} + 1 + \frac{1 + c_r \beta}{\gamma(\beta - 1)} \right) \text{OPT}_k(P).$$

Setting $\beta = 2, \gamma = 10$ and $c_r = 3$ gives us that $\text{COST}(P, \mathcal{C}) \leq 40 \text{OPT}_k(P)$.

We emphasize that we give a *streaming* guarantee, that is, given a fixed point in the stream, it will hold for all the points seen till then. Note that in the proofs of Lemma 14 and 16, we only need that the random event hold with probability at least $1/2$ *only* in the previous phase. We can therefore amplify the probability of success by running $\log(1/\delta)$ parallel instances to get the bounds to hold with probability at least $1 - \delta$. The space bound of the algorithm is $\mathcal{O}(k \log W + h) = \mathcal{O}(k \log(h\Delta) + h)$, which simply follows from the condition in the algorithm that we don't allow the number of facilities to grow beyond $\mathcal{O}(k(1 + \log(W)))$ combined with the fact that we store $k + h$ points verbatim in the second sub-phase. ◀

Extensions. As in [41], our algorithm can easily be extended to other distance functions that satisfy the approximate triangle inequality (see Definition 7). In particular, we get constant approximate algorithms for k -means clustering and M -estimators in the exponential decay model.

Abstract

Graph coloring problems are a central topic of study in the theory of algorithms. We study the problem of partially coloring *partially colorable graphs*. For $\alpha \leq 1$ and $k \in \mathbb{Z}^+$, we say that a graph $G = (V, E)$ is α -partially k -colorable, if there exists a subset $S \subset V$ of cardinality $|S| \geq \alpha|V|$ such that the graph induced on S is k -colorable. Partial k -colorability is a more robust structural property of a graph than k -colorability. For graphs that arise in practice, partial k -colorability might be a better notion to use than k -colorability, since data arising in practice often contains various forms of noise.

We give a polynomial time algorithm that takes as input a $(1 - \epsilon)$ -partially 3-colorable graph G and a constant $\gamma \in [\epsilon, 1/10]$, and colors a $(1 - \epsilon/\gamma)$ fraction of the vertices using $\tilde{O}\left(n^{0.25+O(\gamma^{1/2})}\right)$ colors. We also study natural semi-random families of instances of partially 3-colorable graphs and partially 2-colorable graphs, and give stronger bi-criteria approximation guarantees for these family of instances.

1 Introduction

Graph coloring problems are a central topic of study in the theory of algorithms [33, 17, 4, 20]. An undirected graph $G = (V, E)$ is said to be k -colorable if there exists an assignment of colors $f : V \rightarrow [k]$ such that $f(u) \neq f(v)$ for each $\{u, v\} \in E$. For a graph G , the minimum value of k for which it is k -colorable is called its chromatic number. Computing a 3-coloring of a 3-colorable graph is a fundamental NP-hard problem. Efficiently computing a coloring of a 3-colorable graph which only uses a few colors is a major open problem in the study of algorithms. The current best known algorithm colors a 3-colorable graph on n vertices using $O(n^{0.199})$ colors [20]. We study the problem of coloring partially colorable graphs.

► **Definition 1.** *An undirected graph $G = (V, E)$ is defined to be α -partially k -colorable, denoted by α -PkC, if there exists a subset $V_{\text{good}} \subset V$ such that $|V_{\text{good}}| \geq \alpha|V|$ and the graph induced on V_{good} is k -colorable. We will call such a set V_{good} the set of good vertices, and $V_{\text{bad}} \stackrel{\text{def}}{=} V \setminus V_{\text{good}}$ the set of bad vertices.*

We remark that for a given graph the partitioning of the vertex set V into V_{good} and V_{bad} may not be unique. In such cases, the claims we make in this paper will hold for any such fixed partition.

It is well known that for a fixed k , the problem of determining whether a given graph is k -colorable is an NP-hard problem [18]. Therefore, determining whether a graph belongs to 1 -PkC is an NP-hard problem, and hence, computing the largest value of α for which a graph belongs to α -PkC is also an NP-hard problem.

Note that a graph that is $(1 - \epsilon)$ -partially 3-colorable can have chromatic number as large as $|V_{\text{bad}}| = \epsilon n$. Therefore, the notion of the chromatic number of the graph does not capture the structural property (3-colorability) satisfied by most of the graph. Partial k -colorability is a more robust structural property than k -colorability. Therefore, for graphs that arise in practice, partial k -colorability might be a better notion to use than k -colorability, since data arising in practice often contains various forms of noise; the notion of bad vertices can be used to capture some types of noisy vertices in the graph.

Other notions of partial k -coloring

Another related notion of partial coloring is the following.

► **Definition 2.** *An undirected graph $G = (V, E)$ is defined to be α -partially k -colorable, if there exists a coloring of the vertices $f : V \rightarrow [k]$ such that for at least $\alpha|E|$ edges $\{u, v\}$, $f(u) \neq f(v)$.*

This definition, which asks that the coloring should “satisfy” at least α fraction of the edges, can be viewed as the *edge* version of partial k -colorability, whereas Definition 1 can be viewed as the *vertex* version of partial k -colorability. For a fixed constant k , computing the maximum value of α for which the input graph satisfies Definition 2 can be formulated as a Max-2-CSP with alphabet size k ; approximation algorithms for Max-2-CSPs have been extensively studied in the literature [29, 30, 7] etc. Therefore, we focus our attention on Definition 1.

1.1 Our Results

We give an efficient (bi-criteria) approximation algorithm for coloring partially 3-colorable graphs.

► **Theorem 3.** *There exists a polynomial time algorithm that takes as input a $(1 - \epsilon)$ -P3C graph $G = (V, E)$ and any fixed choice of $\gamma \in [\epsilon, 1/100]$, and produces a set $S \subset V$ such that $|S| \leq (3\epsilon/\gamma)|V|$ and a coloring of $V \setminus S$ using $\tilde{O}(n^{0.25+O(\gamma^{1/2})})$ colors¹.*

We point out that the above theorem gives a bi-criteria approximation guarantee which exhibits the tradeoff between the size of the set S , and the number of colors used to color the remaining graph $G[V \setminus S]$. In particular, setting $\gamma = \sqrt{\epsilon}$ in the above theorem gives

¹ $\tilde{O}(\cdot)$ hides factors polylogarithmic in n .

us the following guarantee. Given a $(1 - \epsilon)$ -P3C graph, one can color $(1 - \sqrt{\epsilon})$ -fraction of its vertices using $\tilde{O}(n^{0.25 + \epsilon^{1/4}})$ -colors. Using similar techniques we can give an efficient approximation algorithm for the partial 2-coloring setting as well. For completeness, we formally state the result below² :

► **Proposition 4.** *There exists a polynomial time algorithm that takes as input a $(1 - \epsilon)$ -P2C graph $G = (V, E)$ and any fixed choice of $\gamma \in [\epsilon, 1/100]$, and produces a set $S \subset V$ such that $|S| \leq (\epsilon/\gamma) |V|$ and a coloring of $V \setminus S$ using $\tilde{O}(n^{C\gamma})$ colors, for some constant $C > 0$.*

The proof of the above proposition can be found in the full version and uses exactly the same techniques as Theorem 3. We also study a semi-random family of partially colorable graphs α -PkC^R(n, p), which we define as follows.

► **Definition 5.** *An instance of α -PkC^R(n, p) is generated as follows.*

1. Let V be a set of n vertices. Arbitrarily partition V into sets V_{good} and V_{bad} such that $|V_{\text{good}}| \geq \alpha n$.
2. Add edges between an arbitrary number of arbitrarily chosen pairs of vertices in V_{good} such that the graph induced on V_{good} is k -colorable.
3. Add edges between an arbitrary number of arbitrarily chosen pairs of vertices in V_{bad} .
4. Between each pair of vertices in $V_{\text{good}} \times V_{\text{bad}}$, independently add an edge with probability p . We call this set of edges E_0 .
5. Add arbitrary number of edges between pairs of vertices of $V_{\text{good}} \times V_{\text{bad}}$. We call this set of edges E_1 .

Output the resulting graph.

In the study of approximation algorithms for NP-hard problems, there have been many works studying algorithms random and semi-random instances of various problems [11, 15, 21, 24, 25]. Random and semi-random instances are often good models for instances arising in practice; designing algorithms specifically for such instances, whose performance guarantee is significantly better than guarantees for general instances, could have more applications in practice. Moreover, from a theoretical perspective, designing algorithms for semi-random instances helps us to better understand what aspects of a problem make it intractable. We study our semi-random model α -PkC^R(n, p) for the same reasons. The following is our main result.

► **Theorem 6.** *Suppose there exists an efficient algorithm which colors a 3-colorable graph using n^θ colors. Then the following holds for all choices of $\epsilon = \Omega(\log n/n)$ and $p \geq (\epsilon\theta^{-2})^{O(\theta)}$. There exists a polynomial time algorithm that takes as input a graph G sampled from $(1 - \epsilon)$ -P3C^R(n, p) and produces a set S such that $|S| = O(\epsilon\theta^{-2}np^{-O(1/\theta)})$ and a coloring of $V \setminus S$ using at most n^θ colors with high probability. Moreover, the algorithm runs in time $n^{O(1/\theta)}\text{poly}(n)$.*

In particular, instantiating the above theorem with the algorithm from [20], w.h.p., we can color $(1 - O(\epsilon))n$ fraction of vertices with $\tilde{O}(n^{0.199})$ -colors. We also study the partial 2-coloring problem in the semi-random setting. Our guarantees for this setting are as follows:

► **Theorem 7.** *Let $\epsilon = \Omega(\log n/n)$ and $p > \sqrt{\epsilon}$. Then, there exists a polynomial time algorithm that takes as input a graph G sampled from $(1 - \epsilon)$ -P2C^R(n, p), and with high probability, produces a set $S \subseteq V$ such that $|S| = O(\epsilon np^{-2})$ and the induced subgraph on the remaining vertices $G[V \setminus S]$ is 2-colorable.*

² We implicitly use the algorithm in the degree reduction step of the algorithm from Theorem 3. See Claim 18 for details.

In particular, in the above theorem the number of vertices removed is bounded by $O(\epsilon n)$ which is stronger than the best known bound of $O(\sqrt{\log n} \cdot \epsilon n)$ [1] in the adversarial setting.

1.2 Related Work

3-colorable graphs. There is extensive literature on algorithms for coloring 3-colorable graphs. Wigderson [33] gave a simple combinatorial algorithm that used $O(n^{\frac{1}{2}})$ colors. Blum [9] improved the number of colors used to $\tilde{O}(n^{\frac{3}{8}})$. These algorithms used purely combinatorial techniques. Karger, Motwani and Sudan [17] used semidefinite programming to develop an algorithm, which when balanced with Wigderson’s technique [33] used $\tilde{O}(n^{\frac{1}{4}})$ colors. Blum and Karger [10] improved the number of colors used to $\tilde{O}(n^{\frac{3}{14}})$ by combining the techniques used in [9] and [17]. Arora, Chlamtac and Charikar [3] got the bound down to $\tilde{O}(\Delta^{0.21111})$ using techniques from the ARV algorithm [5], which was further improved by Chlamtac [12] to $\tilde{O}(n^{0.2072})$ using SDP hierarchies. Using new combinatorial techniques, Kawarabayashi and Thorup improved the approximation bound to $\tilde{O}(n^{0.2049})$ in [19]. Subsequently, by combining their techniques with [12], they were able to give a approximation of $\tilde{O}(n^{0.19996})$ [20], which is the current state of the art.

Partially 2-colorable graphs. The partial 2-coloring problem, better known as Odd Cycle Transversal (OCT) in the literature, has also been studied extensively. Formally, the setting here is as follows. We are given a $(1 - \epsilon)$ -partially 2-colorable graph $G = (V, E)$ and the objective is to find a set S of minimum size such that $G[V \setminus S]$ is 2-colorable (i.e., odd cycle free). Yannakakis first showed that it is NP-Complete in [34]. Later, Khot and Bansal [6] showed that OCT is hard to approximate to any constant factor, assuming the Unique Games Conjecture. From the algorithmic side, via a reduction through the Min2CNF Deletion problem, [16] gave a $O(\log n)$ approximation for the problem. This was later improved to $O(\sqrt{\log n})$ by [1] by using techniques from the Arora-Rao-Vazirani [5] algorithm for sparsest cut. This problem has also been studied under the lens of parameterized complexity. In [31], Reed et al. showed that OCT is fixed parameter tractable when parameterized by the number of bad vertices, following which a sequence of works [6, 28, 23] gave algorithms with improved running times.

Partially 3-colorable graphs. In contrast to the 3-colorable setting, there has been very little work on coloring partially 3-colorable graph. The paper which is closest to our setting is by Kumar, Louis and Tulsiani [22], which also addresses the partial 3-coloring problem, albeit in a more restrictive setting. Assuming that the $(1 - \epsilon)$ -partially 3-colorable graph has threshold rank r and the 3-coloring on the good vertices satisfies certain pseudorandomness properties, they give an algorithm which 3-colors $1 - O(\gamma + \epsilon)$ fraction of vertices in time $(r \cdot n)^{O(r)}$.

Graph problems in Semi-random Models. The semi-random model used in this paper is similar to semi-random models which have been considered for the Max-Independent Set problem [11] [15] [32] [26]. Semi-random models offer a natural way of understanding the complexity of problems in settings which are less restrictive than worst case complexity, but are still far from being average case. While semi-random models were first introduced for studying graph coloring in [11], it has also subsequently been used to study several other fundamental problems such as Unique Games [21], Graph Partitioning [24], Clustering [25], to name a few. The problem of coloring 3-colorable graphs has also been studied in average-case and planted models. Alon and Kahale [2] gave an efficient algorithm that finds an exact

3-Coloring of a random 3-Colorable graph with high probability. David and Fiege [13] studied the complexity of finding a planted random/adversarial 3-coloring for both adversarial and random host graphs.

1.3 Discussion and Proof Overview

Adversarial Model. The key component in most approximation algorithms for 3-coloring involves solving a SDP relaxation of the 3-coloring problem, and followed by a randomized rounding procedure for coloring the graph. The standard SDP relaxation for 3-coloring is the following which was introduced in [17]:

► **SDP 8** (Exact 3-Coloring SDP).

$$\begin{aligned} & \text{minimize} && 0 \\ & \text{subject to} && v_i \cdot v_j \leq -\frac{1}{2} \quad \forall \{i, j\} \in E \\ & && \|v_i\|^2 = 1 \quad \forall i \in V \end{aligned}$$

SDP 8 doesn't optimize any objective function, it finds a feasible solution which satisfies all the constraints of SDP. The intended solution to the above SDP is as follows. Let $\sigma : V \rightarrow \{1, 2, 3\}$ be any legal coloring of G . Furthermore, let $u_1, u_2, u_3 \in \mathbb{R}^2$ be any three unit vectors satisfying $\langle u_i, u_j \rangle = -1/2$ for every $i, j \in \{1, 2, 3\}, i \neq j$. We identify the vector u_i with the color i , and assign $v_j = u_{\sigma(j)}$ for every $j \in V$. It can be easily verified that this is a feasible solution to the above SDP. As is usual, while the SDP in general may not return the above vector coloring, one can round a feasible vector coloring to color the graph using not too many colors [17]. The approximation guarantee is usually of the form Δ^c (for some $c \in (0, 1)$), where Δ is the maximum degree of the graph.

Since in general, one cannot hope to have a degree bound on the graph, the above step is usually preceded by a *degree reduction* sub-routine. Note that if a graph is 3-colorable (more generally k -colorable), then the graph induced on the neighbours of any vertex v is 2-colorable (more generally $k - 1$ colorable). Since a 2-colorable graph can be colored with 2 colors efficiently, the graph induced on any vertex and its neighbours can be colored efficiently with 3 colors. Therefore, fixing a threshold Δ , this procedure iteratively removes vertices (and their neighbours) having degree larger than Δ from the graph while coloring them with few colors, and terminates when maximum degree of the remaining graph is at most Δ . In particular, if the degree reduction step uses $f(n, \Delta)$ colors, then the total number of colors used by the algorithm is at most $f(n, \Delta) + \Delta^c$. Then one can optimize the choice of Δ for giving the best possible approximation guarantee. This degree reduction approach and its variants, first studied by Wigderson [33], has been subsequently used in almost all known approximation algorithms for graph coloring

In translating the above template to the setting of partially 3-colorable graphs, we face several immediate challenges. SDP 8 is guaranteed to return a feasible solution only for 3-colorable graphs, it might be infeasible if the graph is not 3-colorable. If we could compute the set of good vertices then we could use SDP 8 only on the set of good vertices. However, in general, the problem of identifying the set of good vertices is NP-hard (Fact 27). Finally, the preprocessing steps for degree reduction rely heavily on the combinatorial structural properties of the neighborhood of vertices in *exactly* 3-colorable graphs, which, in general, may not be satisfied by *partially* 3-colorable graphs.

Our approach is to begin with an SDP relaxation that tries to solve both problems together: identifying the set of bad vertices, and coloring the set of good vertices. We introduce variables w_1, w_2, \dots, w_n where the i^{th} variable w_i is meant to indicate if vertex

i is bad. Additionally, for every edge $(i, j) \in E$, we introduce slack variables z_{ij} which are meant to indicate if at least one of the vertices i, j is bad. Using the slack variables we relax the edge constraints as $\langle v_i, v_j \rangle \leq -1/2 + (3/2)z_{ij}$. Finally, we connect the edge indicator variables with vertex indicator variables using constraints of the form $z_{ij} \leq w_i + w_j$. Since we want the set of bad vertices to be small, our objective function will be to minimize $\sum_{i \in V} w_i$. Our SDP relaxation is the following.

► **SDP 9** (Partial 3-Coloring SDP).

$$\begin{aligned}
 & \text{minimize} && \sum_{i \in V} w_i \\
 & \text{subject to} && \langle v_i, v_j \rangle \leq -\frac{1}{2} + \frac{3}{2}z_{ij} && \forall \{i, j\} \in E \\
 & && z_{ij} \leq w_i + w_j && \forall \{i, j\} \in E \\
 & && 0 \leq z_{ij} \leq 1 && \forall \{i, j\} \in E \\
 & && 0 \leq w_i \leq 1 && \forall i \in V \\
 & && \|v_i\|^2 = 1 && \forall i \in V
 \end{aligned}$$

Since the optimal “integer solution” forms a feasible solution to the SDP relaxation, it is easy to show that for a $(1 - \epsilon)$ -partially 3-colorable graph, the optimal of the above SDP is at most ϵn . Therefore by Markov’s inequality, we get that for a large fraction of $i \in [n]$, the w_i variables are small. Let $V' \subset V$ be the set of vertices with small w_i . Since $|V \setminus V'| = O(\epsilon n)$, we can focus on coloring the induced subgraph $G' = G[V']$. G' has the following nice property: *for every edge (i, j) in G' , the corresponding edge constraint is approximately satisfied i.e., $\langle v_i, v_j \rangle \leq -1/2 + o_\epsilon(1)$, where the second term goes to 0 as ϵ goes to 0.* We call such graphs as being approximately vector 3-colorable (See Definition 11 for a formal description). We use this property crucially in designing our preprocessing step.

We observe that the neighborhood of any vertex in an approximately vector 3-colorable graph is approximately vector 2-colorable. Furthermore, we show that approximately vector 2-colorable graphs are *short odd cycle* free. Graphs having this property are known to have large independent sets which can be found efficiently [27]. Thus one can find such large independent sets recursively to color the neighborhood of large degree vertices using a small number of colors.

For the randomized rounding step, we observe that hyperplane rounding based procedures are naturally robust to small perturbations, and the arguments for analyzing the guarantees of such procedures hold even when the edge constraints are approximately satisfied. In particular, we can use known randomized rounding algorithm as is, while adapting the analysis to account for the edge constraints being satisfied approximately.

Semi-random model. While the guarantees of our algorithm from the adversarial setting also apply to the semi-random instances, here we seek to achieve the best known approximation bounds for exactly 3-colorable graphs. We begin by describing two distinct classes of instances which illustrate the technical challenges in designing such an algorithm.

In this setting, the adversary is free to choose $G[V_{\text{bad}}]$ in a way such that it is noisy and has large chromatic number (e.g, graphs sampled from Erdos Renyi random model). For such instances, it is easy to see that the only way an algorithm can have good approximation guarantees is when it can eliminate a significant fraction of from V_{bad} . Then, for a start, one can hope to address this setting by first using a preprocessing step that deletes V_{bad} and then running the best possible approximation algorithm on the graph induced on the remaining vertices.

On the other hand, the adversary can also choose $G[V_{\text{bad}}]$ in a way so that it is *structurally indistinguishable* from the good subgraph $G[V_{\text{good}}]$. For instance, suppose the good subgraph $G[V_{\text{good}}]$ is a randomly sampled unbalanced bipartite graph, where the smaller side (which we call V_S) has size at most ϵn . Then the adversary can choose V_{bad} to be an independent set, in which case the entire graph is 3-colorable. In particular, it is information theoretically impossible to distinguish the set V_S from V_{bad} , since they are both independent sets and the edges incident on them are identically distributed. While the instances constructed here make it difficult to identify V_{good} , they are also naturally easy instances for us. In particular, these instances are also $(1 - \epsilon)$ -partially 2-colorable, and one can use tools for coloring partially 2-colorable graphs to color these instances with small number of colors.

However, the two cases above clearly do not cover the full range of instances that we can encounter in our model. Therefore, we need a way to relax the above two characterizations which allows for a seamless transition from one class of instances to other. It turns out that we can robustly characterize both classes of instances by the number of *vertex disjoint short odd cycles* present in the graph. Informally, if the number of short odd cycles is large, then with high probability, they will show up in the neighborhood of the bad vertices, and therefore this can be used to identify and eliminate V_{bad} . We can then simply run the best known approximation algorithm on the remaining induced graph $G[V_{\text{good}}]$. On the other hand, if the number of short odd cycles is small, by eliminating a small fraction of vertices, we can make the graph short odd cycle free. Finally, as discussed in the adversarial model setting, such graphs can be colored efficiently using a small number of colors by recursively finding large independent sets [27].

2 Preliminaries

We introduce some notation used frequently in this paper. Throughout the paper, for a $(1 - \epsilon)$ -partially 3-colorable graph $G = (V, E)$, we will write $V = V_{\text{good}} \uplus V_{\text{bad}}$ where V_{good} and V_{bad} are the set of good vertices and bad vertices as defined in Definition 1. For a subset $V' \subseteq V$, we use $G[V']$ to denote the subgraph induced on the set of vertices V' . For a subgraph $G' \subseteq G$, we shall use $\text{vert}(G')$ to denote the vertex set of G' . Additionally, for any vertex $i \in \text{vert}(G')$, we use $N_{G'}(i)$ denote the set of neighbors of i in the graph G' . We use $\mathbb{1}(\cdot)$ to denote the indicator function, and $\tilde{O}(\cdot)$ to hide terms which are polylogarithmic in the number of vertices.

Approximate Vector Coloring

We begin by recalling the notion of vector coloring of a graph which was introduced in [17].

► **Definition 10 (Vector Coloring).** *Given a positive integer $k \in \mathbb{N}$, we say that a graph $G = (V, E)$ is k -vector colorable if there exists unit vectors $v_1, v_2, \dots, v_n \in \mathbb{R}^d$ for some $d \in \mathbb{N}$ which satisfy*

$$\langle v_i, v_j \rangle \leq -\frac{1}{k-1} \quad \forall \{i, j\} \in E.$$

We will use the notion of *approximate vector colorings* of a graph, which we define as follows.

► **Definition 11 (Approximate Vector Coloring).** *Given a positive integer $k \in \mathbb{N}$ and a $\gamma > 0$, we say that a graph $G = (V, E)$ is (k, γ) -vector colorable if there exists unit vectors $v_1, v_2, \dots, v_n \in \mathbb{R}^d$ for some $d \in \mathbb{N}$ which satisfy*

$$\langle v_i, v_j \rangle \leq -\frac{1}{k-1} + \gamma \quad \forall \{i, j\} \in E.$$

Observe that a graph that $(k, 0)$ vector colorable is vector- k -colorable. We now state a couple of lemmas which illustrate some useful properties of approximate vector colorings. In [17], it was observed that the vector chromatic number of sub-graph induced on the neighborhood of a vertex is strictly less than the vector chromatic number of the actual graph. In the following lemma, we observe that this property can be extended to approximate vector colorings as well.

► **Lemma 12.** *Let $G = (V, E)$ be $(3, \gamma)$ -vector colorable, for some $0 < \gamma < 1/10$. Then for any vertex $i \in V$, the graph induced on $N(i)$ is $(2, 4\gamma)$ -vector colorable.*

The next lemma says that approximately vector 2-colorable graphs cannot contain short odd cycles.

► **Lemma 13.** *Let $G = (V, E)$ be a $(2, \gamma)$ -vector colorable, where $\gamma \leq 1/16$. Then G does not contain odd cycles of length at most $1/8\sqrt{\gamma}$.*

The proofs of the two lemmas above can be found in Appendix B.

Coloring graphs without short odd cycles

A key combinatorial tool used in our paper is the following Ramsey theoretic result which says that graphs without short odd cycles contain large independent sets which can be found efficiently.

► **Lemma 14** ([27]). *There exists a constant $\epsilon_0 \in (0, 1)$ such that for every choice of $0 < \epsilon < \epsilon_0$ the following holds. Let $G = (V, E)$ be a graph without odd cycles of length at most $1/\epsilon$. Then, G contains an independent set of size at least $|V|^{1-2\epsilon}$. Furthermore, there exists a polynomial time algorithm which finds such an independent set.*

Consequently, given a graph without short odd cycles, one can color it efficiently using a small number of colors, as stated in the following corollary.

► **Corollary 15.** *There exists a constant $\epsilon_0 \in (0, 1)$ for which the following holds. Given a graph $G = (V, E)$ which does not contain odd cycles of length at most $1/\epsilon$ where $\epsilon < \epsilon_0$, there exists a polynomial time algorithm which can compute a coloring of G using $\tilde{O}(n^{2\epsilon})$ colors.*

Establishing the above corollary using Lemma 14 is straightforward, and just uses the fact that one can keep removing large independent sets in the graph using Lemma 14, and recurse on the remaining vertices. For the sake of completeness, we include a proof in Appendix C.

3 Approximation algorithm for General Setting

In this section, we prove our approximation guarantees in the adversarial model, as formally stated in the following theorem:

► **Theorem 16** (Theorem 3 restated). *There exists a polynomial time algorithm that takes as input a $(1 - \epsilon)$ -P3C graph $G = (V, E)$ and any fixed choice of $\gamma \in [\epsilon, 1/100]$, and produces a set $S \subset V$ such that $|S| \leq (3\epsilon/\gamma)|V|$ and a coloring of $V \setminus S$ using $\tilde{O}(n^{0.25+O(\gamma^{1/2})})$ colors.*

The algorithm for the above theorem is described in Algorithm 1. In the following subsections, we prove the correctness of the above algorithm. The proof of Theorem 3 can be broken down into the analysis of steps (i),(ii) and (iii) of the Partial-3-Coloring algorithm. Broadly, we show the following: In step (i), we show that the optimal of the SDP-P3C is

Algorithm 1 Partial-3-Coloring.

- 1 Set $\Delta = n^{3/4}$;
- 2 Solve the Partial-3-Coloring SDP (SDP-P3C):

$$\begin{aligned}
 & \text{minimize } \sum_{i \in V} w_i \\
 & \text{subject to } \langle v_i, v_j \rangle \leq -\frac{1}{2} + \frac{3}{2} z_{ij} & \forall \{i, j\} \in E \\
 & \quad z_{ij} \leq w_i + w_j & \forall \{i, j\} \in E \\
 & \quad 0 \leq z_{ij} \leq 1 & \forall \{i, j\} \in E \\
 & \quad 0 \leq w_i \leq 1 & \forall i \in V \\
 & \quad \|v_i\|^2 = 1 & \forall i \in V
 \end{aligned}$$

(i) *Thresholding:*

Let $S \leftarrow \{i \in V \mid w_i \geq \gamma/3\}$;

- 3 Let $G' \leftarrow G[V \setminus S]$ be the graph obtained after deleting S ;

(ii) *Coloring Large Degree vertices:*

while $\exists i \in G'$ such that $\deg_{G'}(i) \geq \Delta$ **do**

- 4 | Color $G'[\{i\} \cup N_{G'}(i)]$ using $\tilde{O}(n^C \sqrt{\gamma})$ colors using the algorithm guaranteed by Corollary 15;
- 5 | Remove $\{i\} \cup N_{G'}(i)$ from G' ;

6 end

(iii) *Coloring Low Degree vertices:*

Use *randomized rounding* from Theorem 19 to color the remaining vertices in G' ;

small (i.e., at most ϵn), therefore by averaging, the fraction of large w vertices is small. Furthermore, the graph induced on the surviving vertices must satisfy the edge constraints from the SDP with small slack γ , and therefore must be approximately vector 3-colorable. As is usual in coloring algorithms, we first iteratively color large degree (i.e., $\geq \Delta$) vertices and their neighborhoods using small number of colors until the graph has degree bounded by Δ (Claim 18). Finally, the remaining graph is also approximately vector 3-colorable, and has degree bounded by Δ . Therefore, using a hyperplane based randomized rounding procedure to iteratively find large independent sets in G' , we can give a $\tilde{O}(\Delta^{1/3+O(\sqrt{\gamma})})$ coloring of the remaining vertices (Theorem 19). In the following subsection, we formally prove the steps described above.

To begin with, we first show that the thresholding step throws away at most a small fraction of vertices.

▷ **Claim 17 (Removing Large Slack Vertices).** Let $S \subset V$ be as constructed in the thresholding step. Then $|S| \leq 3\epsilon n/\gamma$.

We defer the proof of the above claim to Appendix A. From the above claim, the graph $G' = G[V \setminus S]$ induced on the remaining vertices satisfies the following properties:

1. The graph G' contains at least $(1 - 3\epsilon/\gamma)n$ vertices.
2. The graph G' is $(3, \gamma)$ -vector colorable. In particular, the vectors $(v_i)_{i \in V \setminus S}$ themselves are a $(3, \gamma)$ -vector coloring of G' .

28:10 Approximation Algorithms for Partially Colorable Graphs

The second point shall be used crucially in the analysis of the remaining two steps. The next claim bounds the number of colors used while coloring the large degree vertices in step (ii).

▷ **Claim 18 (Degree Reduction).** In step (ii), over all the iterations of the while loop, the algorithm uses at most $(n/\Delta)\tilde{O}(n^{C\sqrt{\gamma}})$ colors, where $C > 0$ is a constant.

Proof. Fix any vertex $i \in G'$, and let $\tilde{G}_i = G'[N(i)]$ the graph induced on the neighborhood of vertex i . Since the graph G' is $(3, \gamma)$ -vector colorable, using Lemma 12 we know that \tilde{G}_i is $(2, 4\gamma)$ -vector colorable. Furthermore, from Lemma 13, we know that G' does not contain odd cycles of length at most $1/(8\sqrt{4\gamma})$. Therefore, we can use Corollary 15 to obtain a $\tilde{O}(n^{C\sqrt{\gamma}})$ coloring of $\tilde{G}_i \cup \{i\}$. Finally, note that each iteration of the for loop removes and colors at least $\Delta + 1$ vertices of the graph. Therefore, the total number of iterations of the for loop is bounded by n/Δ . Since in each such iteration we can color the vertex and its neighborhood using $n^{C\sqrt{\gamma}}$ number of colors, the claim follows. ◁

After steps (i) and (ii), we are left with the graph $G' = (V', E')$ which is $(3, \gamma)$ -vector colorable graph and has degree at most Δ . In particular, for every edge $(i, j) \in E'$, the corresponding vectors satisfy $\langle v_i, v_j \rangle \leq -\frac{1}{2} + \gamma$. Since the independent set based rounding technique [17] [3] for coloring vector 3-colorable graphs is *robust*, we can still use it to round the vector coloring of approximately 3-colorable graphs with similar guarantees, as formally stated in the following theorem.

► **Theorem 19.** *Let $G = (V, E)$ be a graph with maximum degree Δ which is $(3, \alpha)$ -vector colorable. Then there exists an efficient randomized algorithm that can color it using $O\left((\ln \Delta)^{1/2} \Delta^{\frac{\frac{3}{4} + \alpha - \alpha^2}{(\frac{3}{2} - \alpha)^2}} \ln n\right)$ colors.*

In particular, if $\alpha \leq 1/10$, then the algorithm uses at most $\tilde{O}\left((\ln \Delta)^{1/2} \Delta^{\frac{1}{3} + 10\alpha}\right)$, where \tilde{O} hides polylogarithmic factors in n .

The proof of the above theorem is an extension of the proofs from [17, 3] to the setting of approximately vector 3-colorable graphs. Due to space constraints, we skip the proof here and provide it in the full version. Here for simplicity assume that $\gamma \leq 1/10$. Instantiating the above theorem with $G = G'$ and $\alpha = \gamma$, we get that G' is colored using $\tilde{O}(\Delta^{1/3+10\gamma})$ colors. Overall, the algorithm throws away at most $2\epsilon/\gamma$ fraction of vertices in step (i). Furthermore, it uses a total of $\tilde{O}\left((n/\Delta)n^{O(\sqrt{\gamma})} + \Delta^{1/3+10\gamma}\right)$ colors in steps (ii) and (iii) respectively. Setting $\Delta = n^{3/4}$ in the previous expression, we get that the algorithm uses at most $\tilde{O}(n^{1/4+O(\sqrt{\gamma})})$ colors. This concludes the analysis of the Partial-3-Coloring algorithm and the proof of Theorem 3.

4 Algorithm for Semi-random instances

In this section, we prove Theorem 6, which we again state here for convenience.

► **Theorem 20 (Theorem 6 restated).** *Suppose there exists an efficient algorithm which colors a 3-colorable graph using n^θ colors. Then the following holds for all choices of $\epsilon = \Omega(\log n/n)$ and $p \geq (\epsilon\theta^{-2})^{O(\theta)}$. There exists a polynomial time algorithm that takes as input a graph G sampled from $(1 - \epsilon)$ -P3C^R(n, p) and produces a set S such that $|S| = O(\epsilon\theta^{-2}np^{-O(1/\theta)})$ and a coloring of $V \setminus S$ using at most n^θ colors with high probability. Moreover, the algorithm runs in time $n^{O(1/\theta)}\text{poly}(n)$.*

Algorithm 2 P3C-Random.

```

1 Let  $\mathcal{A}$  be the algorithm which can color 3-colorable graphs using  $n^\theta$  colors;
2 Set  $\delta = \theta/10$ ;

   {Many short odd cycles}:
3 for every vertex  $v \in V$  do
4   | Let  $G_v := G[N_G(v)]$  the subgraph induced by the neighborhood of  $G$ ;
5   | Greedily construct a maximal set  $\mathcal{C}_v$  of vertex disjoint odd cycles of length at
   |   most  $1/\delta$  in  $G_v$ ;
6 end
7 Construct set  $S \leftarrow \{v \in V : |\mathcal{C}_v| \geq 2\epsilon n\}$ ;
8 Let  $G_0 \leftarrow G[V \setminus S]$  be the graph obtained after deleting  $S$ ;
9 Let  $\sigma_1$  be the coloring of  $V \setminus S$  obtained by running algorithm  $\mathcal{A}$  on  $G_0$ . Let  $L$ 
   denote the number of colors used by the algorithm;

   {Few short odd cycles}:
10 Compute a maximal set  $\mathcal{C} = \{C_1, C_2, \dots, C_m\}$  of vertex disjoint odd cycles in  $G$  of
    length at most  $1/\delta$  using greedy algorithm;
11 Let  $V' = V \setminus \left(\bigcup_{i \in [m]} \text{vert}(C_i)\right)$ ;
12 Use the algorithm guaranteed by Corollary 15 to give a  $\tilde{O}(n^{4\delta})$  coloring  $\sigma_2$  of  $G[V']$ ;

   {Output best coloring}:
13 if  $|S| \leq \epsilon n$  and  $L \leq n^\theta$  then
14   | Output coloring  $\sigma_1$  of  $V \setminus S$ 
15 end
16 else
17   | Output coloring  $\sigma_2$  of  $V'$ ;
18 end

```

We begin by describing the algorithm for the semi-random setting:

The algorithm proceeds case wise depending on whether there exists many vertex disjoint short odd cycles in G . If it does, then since V_{bad} is small, $G[V_{\text{good}}]$ must also contain many vertex disjoint odd cycles. We show that these short cycles will show up in the neighborhood of the bad vertices with high probability, which can be used to identify them. On removing these vertices, we will be left with a 3-colorable graph. On the other hand, if the number of short odd cycles is small, we can remove them. The remaining graph will still contain most of the vertices and will be short odd cycle free. We can then use Lemma 14 to recover large independent sets. Finally, since the odd cycles we consider are of length at most $1/\delta$, we can work with a *maximal* set of vertex disjoint odd cycles, instead of the largest cardinality set of vertex disjoint odd cycles, while only losing a factor of $1/\delta$ in our analysis.

4.1 Correctness of the P3C-Random algorithm

Let $\mathcal{C}^* = \{C_1^*, C_2^*, \dots, C_{m^*}^*\}$ be a *fixed largest cardinality set of vertex disjoint odd cycles* of length at most $1/\delta$ in $G[V_{\text{good}}]$. In particular, \mathcal{C}^* and consequently m^* , does not depend on the realization of the random and adversarial edges (i.e., the E_0 and E_1 edges) between V_{good} and V_{bad} . We break our analysis into two cases depending on whether m^* is small or large.

28:12 Approximation Algorithms for Partially Colorable Graphs

Case (i): $m^* > 4\epsilon n / (\delta p^{1/\delta})$. For ease of exposition, we say that an odd cycle C in graph G is *good* if it consists of only good vertices, otherwise we call it *bad*. The first claim shows the set \mathcal{C}_v must be small for good vertices.

▷ **Claim 21.** For every good vertex $v \in V$, we have $|\mathcal{C}_v| \leq \epsilon n$.

Proof. Fix a good vertex $v \in V_{\text{good}}$. We claim that a good cycle C can never appear in the neighborhood of a good vertex. For contradiction, let C be a good odd cycle appearing in the neighborhood of v . Let $\tilde{G} = G[\text{vert}(C) \cup \{v\}]$ be the subgraph induced on the vertex v and the vertices from cycle C . Since $\tilde{G} \subseteq G[V_{\text{good}}]$, the subgraph \tilde{G} is also 3-colorable. Hence, the neighborhood of v in the induced subgraph \tilde{G} must be 2-colorable, and therefore it cannot contain odd cycles, and in particular C . This gives us the contradiction.

Hence, any odd cycle which appears in the neighborhood $N_G(v)$ must be bad. Since the number of bad vertices is bounded by ϵn , and the cycles in \mathcal{C}_v are vertex disjoint, the claim follows. ◁

On the other hand, with high probability, we show that $|\mathcal{C}_v|$ is large for all the bad vertices.

▷ **Claim 22.** With probability at least $1 - e^{-O(\epsilon n)}$, every vertex $v \in V_{\text{bad}}$ satisfies $|\mathcal{C}_v| \geq 2\epsilon n$.

Proof. Consider the subgraph $G'(V, E_0)$ consisting of edges from E_0 (i.e., the randomly distributed set of edges). Fix a bad vertex $v \in V_{\text{bad}}$, and let $G_v = G[N_G(v)]$ denote the subgraph induced by the neighborhood of v . We shall first give a high probability lower bound on the number of odd cycles from \mathcal{C}^* which can appear in $N_G(v)$. Recall that $|\mathcal{C}^*| = m^*$. We also point out again that the choice of \mathcal{C}^* is not affected by the choice of E_0 and E_1 edges, and can be fixed ahead.

For every $i \in [m^*]$, we define $Z_i := \mathbb{1}(\text{vert}(C_i^*) \subseteq N_{G'}(v))$ to be the indicator random variable that the i^{th} cycle appears in the neighborhood of vertex v in the graph G' . Note that these random variables depend only on the realization of the E_0 edges. Then we have

$$\begin{aligned} \mathbb{E}_G[Z_i] &\geq \Pr_{E_0}[\text{vert}(C_i^*) \subseteq N_G(v)] &&\geq \Pr_{E_0}[\text{vert}(C_i^*) \subseteq N_{G'}(v)] \\ &= \Pr_{E_0}[\forall j \in \text{vert}(C_i^*), j \in N_{G'}(v)] \\ &\geq p^{|\mathcal{C}_i^*|} \geq p^{1/\delta} \end{aligned}$$

Here the last step uses the fact that any cycle $C_i^* \in \mathcal{C}^*$ has length at most $1/\delta$. It follows that

$$\mathbb{E}_G \left[\sum_{i \in [m^*]} Z_i \right] = \sum_{i \in [m^*]} \mathbb{E}_G[Z_i] \geq m^* p^{1/\delta} \geq (4\epsilon/\delta)n \quad (1)$$

Furthermore, since the cycles $C_1^*, C_2^*, \dots, C_{m^*}^*$ are vertex disjoint, the corresponding random variables Z_1, Z_2, \dots, Z_{m^*} are also independent. Therefore using Chernoff bound we get that

$$\Pr_G \left[\sum_{i \in [m^*]} Z_i < (2\epsilon/\delta)n \right] \leq \Pr_G \left[\sum_{i \in [m^*]} Z_i < \frac{1}{2} \mathbb{E} \left[\sum_{i \in [m^*]} Z_i \right] \right] \leq e^{-\epsilon n/4\delta} \quad (2)$$

Now let $\mathcal{C}_v^* = \{C_i^* : i \in [m^*], Z_i = 1\}$ be the set of cycles from \mathcal{C}^* which appear in the neighborhood of v in graph G due to the E_0 edges. Furthermore, let $\tilde{\mathcal{C}}_v$ be a *largest cardinality* set of vertex disjoint odd cycles of length at most $1/\delta$ in G_v (which contains edges from both E_0 and E_1). Then by definition we have $|\tilde{\mathcal{C}}_v| \geq |\mathcal{C}_v^*|$. On the other hand, by construction, the set \mathcal{C}_v is a *maximal set* of such vertex disjoint odd cycles in G_v , and therefore, it must be a δ -approximation to the largest cardinality set $\tilde{\mathcal{C}}_v$ i.e., $|\mathcal{C}_v| \geq \delta|\tilde{\mathcal{C}}_v|$ (see Proposition 26). Therefore using Equation 2, with probability at least $1 - e^{-\epsilon n/4\delta}$ we have

$$|\mathcal{C}_v| \geq \delta|\tilde{\mathcal{C}}_v| \geq \delta|\mathcal{C}_v^*| \geq 2\epsilon n$$

Hence, for any fixed vertex $v \in V_{\text{bad}}$, w.h.p. we have $|\mathcal{C}_v| \geq 2\epsilon n$. Therefore, by a union bound and using the lower bound on ϵ , we get that $\Pr_G [\exists v \in V_{\text{bad}} : |\mathcal{C}_v| < 2\epsilon n] \leq \epsilon n e^{-\epsilon n/4\delta} \leq n e^{-\epsilon n/8\delta}$. \triangleleft

Combining the two claims above, it follows that w.h.p. the set $(V \setminus S)$ must exactly be the set of good vertices, and therefore $G[V \setminus S]$ must be 3-colorable. Hence algorithm \mathcal{A} will give a n^θ coloring of $G[V \setminus S]$.

Case (ii): $m^* \leq 4\epsilon n/(\delta p^{1/\delta})$. Let $\mathcal{C} = \mathcal{C}_{\text{good}} \uplus \mathcal{C}_{\text{bad}}$ be the partition of \mathcal{C} into the set of good and bad cycles respectively. Then, since $\mathcal{C}_{\text{good}}$ is a set of vertex disjoint odd cycles of length at most $1/\delta$ in $G[V_{\text{good}}]$, it follows that $|\mathcal{C}_{\text{good}}| \leq |\mathcal{C}^*| \leq 4\epsilon n/(\delta p^{1/\delta})$. Furthermore, by arguments similar to the proof of Claim 21, we have $|\mathcal{C}_{\text{bad}}| \leq \epsilon n$. Therefore, combining the two bounds, we have $|\mathcal{C}| \leq 5\epsilon n/(\delta p^{1/\delta})$. Since every cycle $C \in \mathcal{C}$ contains at most $1/\delta$ vertices, the total number of vertices thrown away at this step is at most $5\epsilon n/(\delta^2 p^{1/\delta})$. Furthermore, using the *maximality* of \mathcal{C} , we know that the induced subgraph $G' = G[V']$ must be free of odd cycles of length at most $1/\delta$. Therefore, using Corollary 15, we can color G' using $\tilde{O}(n^{2\delta})$ colors. This concludes the analysis of case (ii).

Putting Things Together. If case (i) holds, then w.h.p., in the *Many short odd cycles* block of the algorithm, the set S constructed is identical to V_{bad} , in which case the algorithm \mathcal{A} will find a n^θ -coloring of $G[V \setminus S] = G[V_{\text{good}}]$. In particular, this implies that the conditions of the “if” block will be satisfied and the algorithm will return a n^θ -coloring of $(1 - \epsilon)n$ vertices.

On the other hand, if case (ii) holds, we know that $m \leq 5\epsilon n/(p^{1/\delta}\delta)$, and the *Few short odd cycles* block deletes at most $5\epsilon n/(p^{1/\delta}\delta^2)$ vertices, and colors the remaining vertices using $\tilde{O}(n^{2\delta})$ colors. Then the *else* block of the algorithm will return a $\tilde{O}(n^{2\delta})$ coloring of $(1 - 5\epsilon n/(p^{1/\delta}\delta^2))n$ vertices. Since the *else* block is evaluated only when the conditions of the *if* block are not satisfied, it follows that in this case, the algorithm will throw away at most $\max(\epsilon n, 5\epsilon n/(\delta^2 p^{1/\delta})) = O(\epsilon n/\delta^2 p^{1/\delta})$ vertices, and color the remaining graph with at most $\max(n^\theta, \tilde{O}(n^{2\delta})) = n^\theta$ colors.

Combining the two above cases gives us Theorem 6.

5 Conclusion

In this work we consider the problem of coloring partial 3-colorable graphs in adversarial and semi-random settings. In the adversarial setting, we give an efficient approximation algorithm which can color $(1 - O(\epsilon^c))$ -fraction of vertices using $\tilde{O}(n^{0.25+\epsilon^c})$ colors. On the other hand, the best known approximation guarantees for 3-colorable graphs is $n^{0.199}$ [20]. An obvious open question here is to achieve analogous approximation bounds for partially 3-colorable graphs as well.

One direct way to improve on our approximation bounds in the adversarial setting is through the use of more efficient degree reduction mechanisms as typically done in the exact 3-coloring setting [10],[19, 20] using combinatorial techniques like Blum’s coloring tools [8]. However, these tools rely on fragile combinatorial properties present in 3-colorable graphs (e.g. two vertices whose common neighborhood is not an independent set must have the same color in any legal coloring), and as such, it is not obvious how to extend these techniques to the setting of partially 3-colorable graphs.

In the semi-random model, we show how any efficient algorithm for exact 3-coloring that uses n^θ colors can be leveraged to obtain an efficient algorithm in this setting which uses the same number of colors with high probability and also does not remove too many vertices. An obvious next step would be to see if similar results can also be obtained for partially k -colorable graphs with $k > 3$. Another interesting question would be to see if one can design efficient approximation algorithms with similar guarantees, where the adversary can also delete the randomly sampled edges.

A Proof of Claim 17

We begin by showing that the optimal of SDP-P3C is at most ϵn . Let $V = V_{\text{good}} \cup V_{\text{bad}}$ be any partition of the vertex sets into good and bad vertices such that (a) $G[V_{\text{good}}]$ is 3-colorable and (b) $|V_{\text{bad}}| \leq \epsilon n$. Using this partition we now construct a 2-dimensional feasible solution $(\widehat{v}, \widehat{w}, \widehat{z})$ to SDP-P3C as follows. We set the \widehat{w}_i and \widehat{z}_{ij} variables as

$$\widehat{w}_i = \begin{cases} 0, & \text{if } i \in V_{\text{good}} \\ 1, & \text{otherwise} \end{cases} \quad \text{and} \quad \widehat{z}_{ij} = \begin{cases} 0, & \text{if } i, j \in V_{\text{good}} \\ 1, & \text{otherwise} \end{cases}$$

Furthermore, we set $\{\widehat{v}_i\}_{i \in V_{\text{good}}}$ be a vector 3-coloring of $G[V_{\text{good}}]$, and for every $i \in V_{\text{bad}}$ we set $\widehat{v}_i = [1 \ 0]$. We quickly verify that the \widehat{v}, \widehat{w} and the \widehat{z} variables constructed as above form a feasible solution to the SDP. By construction, for every $i \in V$ we have $\widehat{w}_i \in [0, 1]$ and $\|\widehat{v}_i\|^2 = 1$, and for every edge $(i, j) \in E$ we have $z_{ij} \in [0, 1]$. Furthermore, for any edge (i, j) we also have

$$\widehat{z}_{ij} = \mathbb{1}(\{i \in V_{\text{bad}}\} \vee \{j \in V_{\text{bad}}\}) \leq \mathbb{1}(\{i \in V_{\text{bad}}\}) + \mathbb{1}(\{j \in V_{\text{bad}}\}) = \widehat{w}_i + \widehat{w}_j$$

All that remains to verify is that the variables also satisfy the approximate vector coloring constraints. We look at two cases: if $i, j \in V_{\text{good}}$, then $\widehat{v}_i, \widehat{v}_j$ come from the vector 3-coloring of $G[V_{\text{good}}]$ and therefore they satisfy $\langle \widehat{v}_i, \widehat{v}_j \rangle \leq -\frac{1}{2} \leq -\frac{1}{2} + \widehat{z}_{ij}$. On the other hand if $i \in V_{\text{bad}}$ or $j \in V_{\text{bad}}$ then by construction we have $\widehat{z}_{ij} = 1$, and therefore $\langle \widehat{v}_i, \widehat{v}_j \rangle \leq \|\widehat{v}_i\| \|\widehat{v}_j\| = 1 = -\frac{1}{2} + \frac{3}{2}\widehat{z}_{ij}$.

Therefore, we have established that $(\widehat{z}, \widehat{w}, \widehat{v})$ are a feasible solution for SDP-P3C. Since by construction $\widehat{w}_i = \mathbb{1}\{i \in V_{\text{good}}\}$, and the $|V_{\text{bad}}| \leq \epsilon n$, it follows that the SDP optimal $\sum_{i \in V} w_i$ is at most $\sum_{i \in V} \widehat{w}_i \leq \epsilon n$. Therefore, using Markov's inequality, we get

$$|S| = n \cdot \Pr_{i \sim V} [w_i \geq \gamma/3] \leq n \cdot \frac{3 \sum_{i \in V} w_i}{n\gamma} = \frac{3\epsilon n}{\gamma}$$

B Auxiliary Lemmas

In this section we give the proofs of Lemmas 12 and 13.

B.1 Proof of Lemma 12

The proof of this lemma follows along the lines of Lemma 4.3 from [17], which says that subgraphs induced by neighborhoods of vertices in vector 3-colorable graphs are vector 2-colorable. Without loss of generality, let $N_G(i) = \{1, 2, \dots, r\}$ and let $\{v_1, v_2, \dots, v_r\}$ be the set of vectors which are a $(3, \gamma)$ -vector coloring of $N_G(i)$. For every $j \in [r]$, we can write $v_j = v_j^{\parallel} + v_j^{\perp}$ where v_j^{\parallel} and v_j^{\perp} are the projections of v_j along v_i and $(\text{span}(v_i))^{\perp}$ respectively. Finally, for every $j \in [r]$ we define $\tilde{v}_j := v_j^{\perp} / \|v_j^{\perp}\|$ to be unit vector given by the projection of v_j on the subspace $(\text{span}(v_i))^{\perp}$. It can be easily verified that $\tilde{v}_1, \tilde{v}_2, \dots, \tilde{v}_r$ is a $(2, 4\gamma)$ -vector coloring of the graph induced on $N(v)$. To see this, fix any $j \in V$. By construction, we have $\|v_j^{\parallel}\| = |\langle v_i, v_j \rangle| \geq \frac{1}{2} - \gamma$, and therefore $\|v_j^{\perp}\| = \sqrt{1 - \|v_j^{\parallel}\|^2} \leq \sqrt{\frac{3}{4} + \gamma - \gamma^2}$. Therefore for any $j, j' \in [r]$ such that $(j, j') \in E$, using the orthonormal decomposition of v_j and $v_{j'}$ we have

$$\begin{aligned}
\langle \tilde{v}_j, \tilde{v}_{j'} \rangle &= \left\langle \frac{v_j^\perp}{\|v_j^\perp\|}, \frac{v_{j'}^\perp}{\|v_{j'}^\perp\|} \right\rangle = \frac{1}{\|v_j^\perp\| \|v_{j'}^\perp\|} \left(\langle v_j, v_{j'} \rangle - \langle v_j^\parallel, v_{j'}^\parallel \rangle \right) \\
&= \frac{1}{\|v_j^\perp\| \|v_{j'}^\perp\|} \left(\langle v_j, v_{j'} \rangle - \langle v_i, v_j \rangle \langle v_i, v_{j'} \rangle \right) \\
&\leq \frac{1}{\left(\frac{3}{4} + \gamma - \gamma^2\right)} \left(-1/2 + \gamma - \left(\frac{1}{2} - \gamma\right)^2 \right) \\
&\leq -1 + 4\gamma
\end{aligned}$$

Since the above holds for any pair of vertices $j, j' \in [r]$ which forms an edge, the claim follows.

B.2 Proof of Lemma 13

Let v_1, v_2, \dots, v_n be the $(2, \gamma)$ -vector coloring of G . For contradiction, let C be an odd cycle in G of length $r \leq 1/(8\sqrt{\gamma})$. Without loss of generality, let $C = \{1, 2, \dots, r\}$, such that for every $i \in [r]$, the pair $\{i, (i \bmod r) + 1\}$ forms an edge. Let $r = 2k + 1$. Now for any $i \in [r]$, we have $-1 \leq \langle v_i, v_{i+1} \rangle \leq -1 + \gamma$. Since v_i, v_{i+1} are unit vectors, we have

$$\|v_i + v_{i+1}\|^2 = \|v_i\|^2 + \|v_{i+1}\|^2 + 2\langle v_i, v_{i+1} \rangle \leq 2\gamma \quad (3)$$

which implies that $\|v_i + v_{i+1}\| \leq 2\sqrt{\gamma}$ i.e, any consecutive pair of vectors are *almost anti-podal*. Then, for any $i \in [r]$ we also get that

$$\|v_i - v_{i+2}\| \leq \|v_i + v_{i+1}\| + \|v_{i+1} + v_{i+2}\| \leq 4\sqrt{\gamma} \quad (4)$$

We shall now use the above observations to arrive at a contradiction. From the upper bound on r , we have $k \leq (r - 1)/2 \leq 1/(16\sqrt{\gamma})$, and hence using Eq. 4 we get that

$$\|v_1 - v_r\| \leq \sum_{j=0}^{k-1} \|v_{1+2j} - v_{1+2(j+1)}\| \leq 4k\sqrt{\gamma} < 1/4 \quad (5)$$

But on the other hand, since v_1, v_r are consecutive vertices in the cycles C , we also have $\langle v_1, v_r \rangle \leq -1 + \gamma$ which implies that $\|v_1 - v_r\| \geq \sqrt{4 - 4\gamma} > 1$, which give us the contradiction.

C Proof of Corollary 15

Consider Algorithm IndSetColoring for coloring by iteratively finding large independent sets.

Algorithm 3 IndSetColoring.

Input: Graph $G = (V, E)$

- 1 Initialize $t \leftarrow 1$ and $G_1 \leftarrow G$;
- 2 **while** $G_t \neq \phi$ **do**
- 3 Let I_t be the independent set from Lemma 14 instantiated with G_t ;
- 4 Set $G_{t+1} \leftarrow G_t \setminus I_t$;
- 5 Update $t \leftarrow t + 1$;
- 6 **end**
- 7 Output coloring $I_1 \uplus I_2 \uplus \dots \uplus I_t$;

28:18 Approximation Algorithms for Partially Colorable Graphs

In the above algorithm, we use Lemma 14 to iteratively remove independent sets I_1, I_2, \dots, I_t , where each independent set forms a color class. Let $G_t = G[V \setminus (I_1 \cup I_2 \cup \dots \cup I_t)]$ denote the graph on the surviving vertices after t iterations. We claim that in every $T = n^{2\epsilon}$ applications of Lemma 14 at least a constant fraction of vertices are removed, i.e., for any iteration t , we have $|\text{Vert}(G_{t+T})| \leq (1 - 1/2^{1-2\epsilon})|\text{Vert}(G_t)|$.

This can be shown as follows. Let $n_t = |\text{Vert}(G_t)|$ denote the number of vertices in graph G_t . Then, we can assume that $|\text{vert}(G_{t+T})| > n_t/2$ (otherwise we are done). Then, in T iterations the number of vertices removed can be lower bounded by

$$\sum_{j=1}^T |I_{j+T}| \geq \sum_{j=1}^T |\text{Vert}(G_{t+j})|^{1-2\epsilon} \geq n^{2\epsilon} (n_t/2)^{1-2\epsilon} \geq n_t/2^{(1-2\epsilon)} \quad (6)$$

where the first inequality follows from the guarantee of Lemma 14. Therefore, in $\tilde{O}(n^{2\epsilon})$ iterations, all the vertices will be accounted for.

D Partial 2-Coloring in the Semi-random model

In this section, we give an efficient approximation algorithm for partial 2-coloring problem in the semi-random model with tighter guarantees. The following theorem formally states our guarantees for this setting.

► **Theorem 23** (Theorem 7 restated). *Let $\epsilon = \Omega(\log n/n)$ and $p > \sqrt{\epsilon}$. Then, there exists a polynomial time algorithm that takes as input a graph G sampled from $(1 - \epsilon)$ -P2C^R(n, p), and with high probability, produces a set $S \subseteq V$ such that $|S| = O(\epsilon np^{-2})$ and the induced subgraph on the remaining vertices $G[V \setminus S]$ is 2-colorable.*

The algorithm for the above theorem (described as Algorithm 4) is quite similar to P3C-Random algorithm, but overall, the algorithm and its analysis are much simpler. We begin by describing the algorithm.

Algorithm 4 P2C-Random.

1 For every vertex  $v \in V$ , compute a greedy triangle count as follows:
2 for  $v \in V$  do
3   | Let  $G_v = G[N_G(v)]$  be the graph induced on the neighborhood of  $v$ ;
4   | Construct a maximal matching  $T(v)$  in  $G_v$  using greedy algorithm;
5   | Set  $t(v) \leftarrow |T(v)|$ ;
6 end
7 Let  $S \leftarrow \{v \in V : t(v) \geq 2\epsilon n\}$ ;
8 Let  $G_0 = G[V \setminus S]$ ;
9 Let  $G_1 \subseteq G$  be the independent set obtained using the 2-factor approximation for
   Vertex Cover on  $G$ ;
10 if  $|\text{vert}(G_0)| \geq |\text{vert}(G_1)|$  and  $G_0$  is bipartite then
11   | Output bipartite graph  $G_0$ ;
12 end
13 else
14   | Output independent set  $G_1$ ;
15 end

```

The key difference here is that the algorithm uses triangles as forbidden subgraphs for identifying bad vertices instead of neighborhoods with short odd cycles. As before, the algorithm broadly addresses two cases depending on the size of the maximum matching in $G[V_{\text{good}}]$. Suppose the subgraph $G[V_{\text{good}}]$ contains a linear sized matching M . Then, for every bad vertex $v \in V_{\text{bad}}$, with high probability, at least one of the matching edges from M will appear in the neighborhood of v , which together will form a triangle, which can then be used to identify the bad vertices. On the other hand, if the size of maximum matching in $G[V_{\text{good}}]$ is small, then the subgraph $G[V_{\text{good}}]$ and consequently G must admit a small sized vertex cover. Therefore, using the greedy approximation algorithm for vertex cover, we can find a small sized vertex cover, whose complement must be a large independent set (which is 1-colorable).

D.1 Proof of Theorem 7

Let $M \subseteq G[V_{\text{good}}]$ be a *fixed matching of maximum size* in $G[V_{\text{good}}]$, and let $m^* := |M|$ denote the size of the maximum matching. We point out that the matching M^* is not affected by the realization of edges between V_{good} and V_{bad} (i.e., the E_0 and E_1 edges). As before, we break the analysis into two cases depending on whether m^* is small or large.

Case (i): $m^* \geq (8\epsilon/p^2)n$. This case is similar to case (i) of the proof of Theorem 6. We begin by stating and proving two lemmas which say that the greedy triangle count $t(v)$ is small for all the good vertices, and large for all the bad vertices.

► **Lemma 24.** *For every good vertex $v \in V_{\text{good}}$, we have $t(v) \leq \epsilon n$*

Proof. Fix a good vertex $v \in V_{\text{good}}$, and let $T(v)$ be a set of edges as constructed in the algorithm. Observe that every edge $(a, b) \in T(v)$ along with vertex v induces a triangle in G . Furthermore, since $G[V_{\text{good}}]$ is bipartite (and hence triangle free), any triangle $T \subseteq G$ must contain at least one bad vertex. Therefore, as the vertex v is good, every edge $e \in T(v)$ must contain at least one bad vertex. Finally, we observe that the edges in $T(v)$ are vertex disjoint, and there are at most ϵn bad vertices, which together implies that $t(v) = |T(v)| \leq \epsilon n$. ◀

► **Lemma 25.** *With probability at least $1 - e^{-O(\epsilon n)}$, for every vertex $v \in V_{\text{bad}}$, we have $t(v) \geq 2\epsilon n$.*

Proof. Let G' be the subgraph on G consisting of edges from E_0 (i.e., the randomly sampled set of edges). Recall that $M = \{(a_i, b_i)\}_{i \in [m^*]} \subseteq G[V_{\text{good}}]$ is the fixed maximum matching in $G[V_{\text{good}}]$ of size m^* . Let $Z_i := \mathbb{1}(\{a_i, b_i \in N_{G'}(v)\})$ be the indicator variable for the event that a_i, b_i are neighbors of v in the graph G' . Then,

$$\mathbb{E}_{G'} \left[\sum_{i \in [m^*]} Z_i \right] = \sum_{i \in [m^*]} \Pr_{G'} [\{a_i, b_i \in N_{G'}(v)\}] = m^* p^2 \geq 8\epsilon n \quad (7)$$

Furthermore, since the edges in M are vertex disjoint, the random variables Z_1, \dots, Z_{m^*} are independent and identical. Therefore using Chernoff bound we get

$$\Pr_{G'} \left[\sum_{i \in [m^*]} Z_i \leq 4\epsilon n \right] \leq \Pr_{G'} \left[\sum_{i \in [m^*]} Z_i \leq \frac{1}{2} \mathbb{E} \sum_{i \in [m^*]} Z_i \right] \leq e^{-O(\epsilon n)} \quad (8)$$

Let $M_v = \{(a_i, b_i) : i \in [m^*], Z_i = 1\}$ be the set of matching edges from M^* appearing in the neighborhood of v in the graph G' . Furthermore, let \tilde{M}_v be a maximum matching in the subgraph $G_V := G[N_G(v)]$ induced on the neighborhood of v (which contains both E_0 and E_1

edges). Then, by definition we have $|\tilde{M}_v| \geq |M_v|$. On the other hand, by construction, the set $T(v)$ is a maximal matching in the induced subgraph G_v . Since a maximal matching is a 2-approximation to the maximum matching, it follows that $|T(v)| \geq |\tilde{M}_v|/2 \geq |M_v|/2 \geq 2\epsilon n$.

Therefore, for a fixed bad vertex $v \in V_{\text{bad}}$, with probability at least $1 - e^{-O(\epsilon n)}$, we have $t(v) \geq 2\epsilon n$. The claim now follows by taking a union bound over all vertices $v \in V_{\text{bad}}$. ◀

Therefore, combining Lemmas 24 and 25, we know that with probability at least $1 - e^{-O(\epsilon n)}$, we have $t(v) \leq \epsilon n$ if and only if $v \in V_{\text{good}}$. Conditioned on this event, the set S must exactly be the set of bad vertices, in which case $G[V \setminus S] = G[V_{\text{good}}]$ is bipartite.

Case (ii): $m^* \leq (8\epsilon/p^2)n$. Since the size of maximum matching in $G[V_{\text{good}}]$ is at most $(8\epsilon/p^2)n$, and $G[V_{\text{good}}]$ is bipartite, by König's theorem (Theorem 2.1.1 [14]), it follows that the minimum vertex cover of $G[V_{\text{good}}]$ has size at most $(8\epsilon/p^2)n$. Then G has a vertex cover of size at most $(8\epsilon/p^2)n + \epsilon n \leq (10\epsilon/p^2)n$. Therefore, the greedy approximation algorithm for vertex cover returns a vertex cover S' of size at most $(20\epsilon/p^2)n$, and consequently, $V \setminus S'$ will be an independent set of size at least $(1 - (20\epsilon/p^2))n$.

Putting things together. In case (i), the algorithm throws away at most ϵn vertices and returns a 2-colorable graph, with probability at least $1 - e^{-O(\epsilon n)}$. In case (ii), the algorithm throws away at most $O(\epsilon/p^2)n$ vertices, and returns an independent set. Combining the two cases gives us the guarantees for Theorem 7.

E Maximal and Maximum Short Odd Cycle sets

► **Proposition 26.** *For any graph $G := (V, E)$, and parameter $\delta \in (0, 1)$ the following holds. Let \mathcal{C} be a maximal set of vertex disjoint odd cycles in G of length at most $1/\delta$, and let $\tilde{\mathcal{C}}$ be a set of largest cardinality of vertex disjoint odd cycles in G of length at most $1/\delta$. Then $|\mathcal{C}| \geq \delta|\tilde{\mathcal{C}}|$.*

Proof. Since \mathcal{C} is a maximal set of vertex disjoint odd cycles of length at most $1/\delta$, for every odd cycle $\tilde{C} \in \tilde{\mathcal{C}}$, there exists an odd cycle $C \in \mathcal{C}$ such that $C \cap \tilde{C} \neq \emptyset$ i.e., \tilde{C} is hit by C . Now we observe that (i) the cycles in \mathcal{C} are vertex disjoint and (ii) each cycle $C \in \mathcal{C}$ has size at most $1/\delta$. Hence, it follows that any cycle $C \in \mathcal{C}$ hits at most $1/\delta$ cycles in $\tilde{\mathcal{C}}$. Since every cycle in $\tilde{\mathcal{C}}$ is hit by some cycle in \mathcal{C} , we must have $|\mathcal{C}| \geq \frac{|\tilde{\mathcal{C}}|}{1/\delta} = \delta|\tilde{\mathcal{C}}|$. ◀

F Identifying the set of Good Vertices is NP-hard

► **Fact 27.** *For all $k \in \mathbb{N}$, given a graph α -partially k -colorable graph $G = (V, E)$ it is NP-Hard to identify a set $V_{\text{good}} \subset V$ of size at least αn such that $G[V_{\text{good}}]$ is k -colorable*

Proof. For $\alpha = 1 - 1/2n$, this is exactly the k -Coloring problem which is NP-Hard [18]. ◀

Towards Optimal Moment Estimation in Streaming and Distributed Models

Abstract

One of the oldest problems in the data stream model is to approximate the p -th moment $\|\mathcal{X}\|_p^p = \sum_{i=1}^n \mathcal{X}_i^p$ of an underlying non-negative vector $\mathcal{X} \in \mathbb{R}^n$, which is presented as a sequence of $\text{poly}(n)$ updates to its coordinates. Of particular interest is when $p \in (0, 2]$. Although a tight space bound of $\Theta(\epsilon^{-2} \log n)$ bits is known for this problem when both positive and negative updates are allowed, surprisingly there is still a gap in the space complexity of this problem when all updates are positive. Specifically, the upper bound is $O(\epsilon^{-2} \log n)$ bits, while the lower bound is only $\Omega(\epsilon^{-2} + \log n)$ bits. Recently, an upper bound of $\tilde{O}(\epsilon^{-2} + \log n)$ bits was obtained under the assumption that the updates arrive in a *random order*.

We show that for $p \in (0, 1]$, the random order assumption is not needed. Namely, we give an upper bound for worst-case streams of $\tilde{O}(\epsilon^{-2} + \log n)$ bits for estimating $\|\mathcal{X}\|_p^p$. Our techniques also give new upper bounds for estimating the empirical entropy in a stream. On the other hand, we show that for $p \in (1, 2]$, in the natural coordinator and blackboard distributed communication topologies, there is an $\tilde{O}(\epsilon^{-2})$ bit max-communication upper bound based on a randomized rounding scheme. Our protocols also give rise to protocols for heavy hitters and approximate matrix product. We generalize our results to arbitrary communication topologies G , obtaining an $\tilde{O}(\epsilon^2 \log d)$ max-communication upper bound, where d is the diameter of G . Interestingly, our upper bound rules out natural communication complexity-based approaches for proving an $\Omega(\epsilon^{-2} \log n)$ bit lower bound for $p \in (1, 2]$ for streaming algorithms. In particular, any such lower bound must come from a topology with large diameter.

1 Introduction

The streaming and distributed models of computation have become increasingly important for the analysis of massive datasets, where the sheer size of the input imposes stringent restrictions on the resources available to algorithms. Examples of such datasets include internet traffic logs, sensor networks, financial transaction data, database logs, and scientific data streams (such as huge experiments in particle physics, genomics, and astronomy). their prevalence, there is a large body of literature devoted to designing extremely efficient algorithms for analyzing streams and enormous datasets. We refer the reader to [4, 52] for surveys of these algorithms and their applications.

Formally, the data stream model studies the evolution of a vector $\mathcal{X} \in \mathbb{Z}^n$, called the frequency vector. Initially, \mathcal{X} is initialized to be the zero-vector. The frequency vector then receives a stream of m coordinate-wise updates of the form $(i_t, \Delta_t) \in [n] \times \{-M, \dots, M\}$ for some $M > 0$ and time step $t \in [m]$. Each update (i_t, Δ_t) causes the change $\mathcal{X}_{i_t} \leftarrow \mathcal{X}_{i_t} + \Delta_t$. If we restrict that $\Delta_t \geq 0$ for all $t \in [m]$, this is known as the *insertion-only* model. If the updates $\Delta_t \in \{-M, \dots, M\}$ can be both positive and negative, then this is known as the *turnstile*-model. The p -th frequency moment of the frequency vector at the end of the stream, F_p , is defined as $F_p = \sum_{i=1}^n |\mathcal{X}_i|^p$. For simplicity (but not necessity), it is generally assumed that $m, M = \text{poly}(n)$.

The study of frequency moments in the streaming model was initiated by the seminal 1996 paper of Alon, Matias, and Szegedy [1]. Since then, nearly two decades of research have been devoted to understanding the space and time complexity of this problem. An incomplete list of works which study frequency moments in data streams includes [16, 36, 6, 58, 35, 45, 12, 44, 11, 15, 11, 7, 13]. For $p > 2$, it is known that polynomial in n (rather than logarithmic) space is required for F_p estimation [16, 36]. In the regime of $p \in (0, 2]$, the space complexity of F_p estimation in the turnstile model is now understood, with matching upper and lower bounds of $\Theta(\epsilon^{-2} \log(n))$ bits to obtain a $(1 \pm \epsilon)$ approximation of F_p . Here, for $\epsilon > 0$, a $(1 \pm \epsilon)$ approximation means an estimate \tilde{F}_p such that $(1 - \epsilon)F_p \leq \tilde{F}_p \leq (1 + \epsilon)F_p$. For insertion only streams, however, the best known lower bound is $\Omega(\epsilon^{-2} + \log(n))$ [58]. Moreover, if the algorithm is given query access to an arbitrarily long string of random bits (known as the random oracle model), then the lower bound is only $\Omega(\epsilon^{-2})$. On the other hand, the best upper bound is to just run the turnstile $O(\epsilon^{-2} \log(n))$ -space algorithm.

In this work, we make progress towards resolving this fundamental problem. For $p < 1$, we resolve the space complexity by giving an $\tilde{O}(\epsilon^{-2} + \log n)^1$ -bits of space upper bound. In the random oracle model, our upper bound is $\tilde{O}(\epsilon^{-2})^2$, which also matches the lower bound in this setting. Prior to this work, an $\tilde{O}(\epsilon^{-2} + \log(n))$ upper bound for F_p estimation was only known in the restricted *random-order* model, where it is assumed that the stream updates are in a uniformly random ordering [13]. Our techniques are based on novel analysis of the behavior of the p -stable random variables used in the $O(\epsilon^{-2} \log(n))$ upper bound of [35], and also give rise to a space optimal algorithm for entropy estimation.

We remark that F_p estimation in the range $p \in (0, 1)$ is useful for several reasons. Firstly, for p near 1, F_p estimation is often used as a subroutine for estimating the empirical entropy of a stream, which itself is useful for network anomaly detection ([47], also see [31] and the references therein). Moment estimation is also used in weighted sampling algorithms for data streams [50, 42, 38] (see [23] for a survey of such samplers and their applications). Here, the goal is to sample an index $i \in [n]$ with probability $|\mathcal{X}_i|^p / F_p$. These samplers can be used to find heavy-hitters in the stream, estimate cascaded norms [2, 50], and design representative histograms of \mathcal{X} on which more complicated algorithms are run [28, 27, 55, 29, 33, 24]. Furthermore, moment estimation for fractional p , such as $p = .5$ and $p = .25$, has been shown to be useful for data mining [22].

¹ the \tilde{O} here suppresses a single $(\log \log n + \log 1/\epsilon)$ factor, and in general we use \tilde{O} and $\tilde{\Omega}$ to hide $\log \log n$ and $\log 1/\epsilon$ terms.

² This space complexity is measured *between updates*. To read and process the $\Theta(\log(n))$ -bit identity of an update, the algorithm will use an additional $O(\log(n))$ -bit working memory tape during an update. Note that all lower bounds only apply to the space complexity between updates, and allow arbitrary space to process updates.

For the range of $p \in (1, 2]$, we prove an $\tilde{O}(\epsilon^{-2})$ -bits of max-communication upper bound in the distributed models most frequently used to prove *lower bounds* for streaming. This result rules out a large and very commonly used class of approaches for proving lower bounds against the space complexity of streaming algorithms for F_p estimation. Our approach is based on a randomized rounding scheme for p -stable sketches. We show that our rounding scheme can be additionally applied to design improved protocols for the distributed heavy hitters and approximate matrix product problems. We now introduce the model in which all the aforementioned results hold.

1.1 Multi-Party Communication

In this work, we study a more general model than streaming, known as the message passing multi-party communication model. All of our upper bounds apply to this model, and our streaming algorithms are just the result of special cases of our communication protocols. In the message passing model, there are m players, each positioned at a unique vertex in a graph $G = (V, E)$. The i -th player is given as input an integer vector $X_i \in \mathbb{Z}^n$. The goal of the players is to work together to jointly approximate some function $f : \mathbb{R}^n \rightarrow \mathbb{R}$ of the aggregate vector $\mathcal{X} = \sum_{i=1}^m X_i$, such as the p -th moment $f(\mathcal{X}) = F_p = \|\mathcal{X}\|_p^p = \sum_{i=1}^n |\mathcal{X}_i|^p$. In the message passing model, as opposed to the *broadcast* model of communication, the players are only allowed to communicate with each other over the edges of G . Thus player i can send a message to player j only if $(i, j) \in E$, and this message will only be received by player j (and no other). At the end of the protocol, it is assumed that at least one player holds the approximation to $f(\mathcal{X})$. The goal of multi-party communication is to solve the approximation problem using small total communication between all the players over the course of the execution. More specifically, the goal is to design protocols that use small *max-communication*, which is the total number of bits sent over any edge of G . Our protocols hold in an even more restricted setting, known as the *one-shot* setting, where each player is allowed to communicate exactly once over the course of the entire protocol.

We now observe that data streams can be modeled as a special case of one-shot multi-party communication. Here, the graph G in question is the line graph on m vertices. If the updates to the data stream vector are $(i_1, \Delta_1), \dots, (i_m, \Delta_m)$, then the t -th player has input $X_t \in \mathbb{Z}^n$, where $(X_t)_{i_t} = \Delta_t$ and $(X_t)_j = 0$ for $j \neq i_t$. The aggregate vector $\mathcal{X} = \sum_{i=1}^m X_i$ is just the frequency vector at the end of the stream, and the space complexity of any algorithm is just the max-communication used over any edge of the corresponding communication protocol. Since we are primarily interested in insertion only streams, in this work we will consider the *non-negative data* model, where $X_i \in \{0, 1, \dots, M\}^n$ for all input vectors X_i , for some $M > 0$ (as in streaming, we assume $M = \text{poly}(n, m)$ for simplicity). Note that an equivalent condition is that each $X_i \in \mathbb{R}_{\geq 0}^n$ such that the entries of X_i can be stored in $O(\log M)$ -bits.

We are now ready to introduce our results for moment estimation in the message passing model. Let d be the *diameter* of the communication graph G . Our first result is a protocol for F_p estimation when $p \in (1, 2]$ which uses a max communication of $\tilde{O}(\epsilon^{-2} \log d)$ bits. Using similar techniques, we also obtain a (optimal for $d = \Theta(1)$) bound of $\tilde{O}(\epsilon^{-2} \log n \log d)$ for the heavy hitters problem, which is to find the coordinates of \mathcal{X} which contribute at least an ϵ fraction of the total $\sqrt{F_2} = \|\mathcal{X}\|_2$ of \mathcal{X} . For $p \in (0, 1)$, we give an $\tilde{O}(\epsilon^{-2})$ upper bound for F_p estimation. Notice that this is independent of the graph topology, and thus holds for the line graph, where we derive our $\tilde{O}(\epsilon^{-2})$ upper bound for F_p estimation in the random oracle streaming model. We then show how the streaming algorithm can be derandomized to not require a random oracle, now using an optimal $\tilde{O}(\epsilon^{-2} + \log(n))$ -bits of space. Our techniques also result in an $\tilde{O}(\epsilon^{-2})$ upper bound for additively approximating the empirical entropy of the vector \mathcal{X} .

Our results for $p \in (1, 2]$ have interesting implications for any attempts to prove *lower-bounds* for streaming algorithms that estimate F_p , which we now describe. The link between streaming and communication complexity is perhaps one of the most fruitful sources of space lower bounds for algorithms in computer science. Namely, nearly all lower bounds for the space complexity of randomized streaming algorithms are derived via reductions from communication problems. For an incomplete list of such reductions, see [58, 61, 45, 42, 46, 10, 16, 57, 48, 49, 40] and the references therein. Now nearly all such lower bounds (and all of the ones that were just cited) hold in either the 2-party setting (G has 2 vertices), the coordinator model, or the black-board model. In the coordinator model there are m players, each with a single edge to a central coordinator (i.e., G is a star graph on $m + 1$ vertices). Note that the diameter d of the coordinator graph is 2. In the multi-player black-board model, every message that is sent is written to a shared blackboard that can be read by all players. Observe that any one-way protocol for the coordinator model immediately results in a protocol with the same communication for the blackboard model. Namely, each player simply writes what it would have sent to the coordinator on the blackboard, and at the end of the protocol the blackboard contains all the information that the coordinator would have had. For these three settings, our protocol gives an $\tilde{O}(\epsilon^{-2})$ max-communication upper bound for F_p estimation, $p \in (1, 2]$. This completely rules out the approach for proving lower bounds against F_p estimation in a stream via any of these three techniques. In particular, it appears that any lower bound for F_p estimation via communication complexity in this regime of p will need to use a graph with $\Omega(n)$ diameter, such as the line graph, without a black-board.

The coordinator and black-board models have also been studied in many other settings than for proving lower bounds against streaming. For instance, in the *Distributed Functional Monitoring* literature [25, 63, 60, 34, 56, 37], each player is receiving a continuous stream of updates to their inputs X_i , and the coordinator must continuously update its approximation to $f(\mathcal{X})$. The black-board model is also considered frequently for designing communication upper bounds, such as those for set disjointness [6, 16, 30]. Finally, there is substantial literature which considers numerical linear algebra and clustering problems in the coordinator model [61, 20, 5, 62]. Thus, our upper bounds can be seen as a new and useful contribution to these bodies of literature as well.

1.2 Our Contributions

As noted, the upper bounds in this paper all hold in the general multi-party message passing model, over an arbitrary topology G . Our algorithms also have the additional property that they are *one-shot*, meaning that each player is allowed to communicate exactly once. Our protocols pre-specify a central vertex $\mathcal{C} \in V$ of G . Specifically, \mathcal{C} will be a *center* of G , which is a vertex with minimal max-distance to any other vertex. Our protocols then proceed in d rounds, where d is the diameter of G . Upon termination of the protocols, the central vertex \mathcal{C} will hold the estimate of the protocol. We note that \mathcal{C} can be replaced by any other vertex v , and d will then be replaced by the max distance of any other vertex to v . A summary of our results is given in Table 1.

We first formally state our general result for F_p estimation, $1 < p \leq 2$. Note that, while we state all our results for constant probability of success, by repeating $\log(1/\delta)$ times and taking the median of the estimates, this is boosted to $1 - \delta$ in the standard way.

► **Theorem 12.** *For $p \in (1, 2]$, there is a protocol for $(1 \pm \epsilon)$ approximating F_p which succeeds with probability $3/4$ in the message passing model. The protocol uses a max communication of $O(\frac{1}{\epsilon^2}(\log \log n + \log d + \log 1/\epsilon))$ bits, where d is the diameter of G .*

■ **Table 1** For the communication problems above, the bounds are for the max-communication (in bits) across any edge. For the streaming problems, the bounds are for the space requirements of the algorithm. Here, d is the diameter of the communication network G . For all problems except point estimation, there is a matching $\Omega(\epsilon^{-2})$ lower bound. The problem of point estimation itself has a matching $\Omega(\epsilon^{-2} \log n)$ lower bound for graphs with constant d .

For graphs with constant diameter, such as the coordinator model, our max communication bound of $\tilde{O}(\epsilon^{-2})$ matches the $\Omega(\epsilon^{-2})$ lower bound [58, 17], which follows from a 2-player reduction from the Gap-Hamming Distance problem. For $p = 2$, our *total communication* in the coordinator model matches the $\Omega(m^{p-1}/\epsilon^2)$ total communication lower bound (up to $\log \log(n)$ and $\log(1/\epsilon)$ terms) for non-one shot protocols [60]. For one shot protocols, we remark that there is an $\Omega(m/\epsilon^2)$ total communication lower bound for any $p \in (0, 2] \setminus \{1\}$ (see Appendix A). As discussed previously, our result also has strong implications for streaming algorithms, demonstrating that no $\Omega(\epsilon^{-2} \log n)$ lower bound for F_p estimation, $p \in (1, 2]$, can be derived via the common settings of 2-party, coordinator, or blackboard communication complexity.

Our main technique used to obtain Theorem 12 is a new randomized rounding scheme for p -stable sketches. We next show that this randomized rounding protocol can be applied to give improved communication upper bounds for the *point-estimation* problem. Here, the goal is to output a vector $\tilde{X} \in \mathbb{R}^n$ that approximates \mathcal{X} well coordinate-wise. The result is formally given below in Theorem 14.

► **Theorem 14.** *Consider a message passing topology $G = (V, E)$ with diameter d , where the i -th player is given as input $X^i \in \mathbb{Z}_{\geq 0}^n$ and $\mathcal{X} = \sum_{i=1}^m X^i$. Then there is a communication protocol which outputs an estimate $\tilde{\mathcal{X}} \in \mathbb{R}^n$ of \mathcal{X} such that $\|\tilde{\mathcal{X}} - \mathcal{X}\|_\infty \leq \epsilon \|\mathcal{X}_{tail(\epsilon^{-2})}\|_2$ with probability $1 - 1/n^c$ for any constant $c \geq 1$. Here $\mathcal{X}_{tail(\epsilon^{-2})}$ is \mathcal{X} with the ϵ^{-2} largest (in absolute value) coordinates set equal to 0. The protocol uses a max communication of $O(\frac{1}{\epsilon^2} \log(n)(\log \log n + \log d + \log 1/\epsilon))$.*

For graphs with small diameter, our protocols demonstrate an improvement over the previously best known sketching algorithms, which use space $O(\epsilon^{-2} \log^2(n))$ to solve the point estimation problem [18]. Note that there is an $\Omega(\epsilon^{-2} \log n)$ -max communication lower bound for the problem. This follows from the fact that point-estimation also solves the L_2 heavy-hitters problem. Here the goal is to output a set $S \subset [n]$ of size at most $|S| = O(\epsilon^{-2})$ which contains all $i \in [n]$ with $|X_i| \geq \epsilon \|\mathcal{X}\|_2$ (such coordinates are called heavy hitters). The lower bound for heavy hitters is simply the result of the space required to store the $\log(n)$ -bit identities of all possible ϵ^{-2} heavy hitters. Note that for the heavy hitters problem alone, there is an optimal streaming $O(\epsilon^{-2} \log(n))$ -bits of space upper bound called BPTree [9]. However, BPTree cannot be used in the general distributed setting, since it crucially relies on the sequential nature of a stream.

Next, we demonstrate that F_p estimation for $p < 1$ is in fact possible with max communication independent of the graph topology. After derandomizing our protocol, this results in a optimal streaming algorithm for F_p estimation, $p < 1$, which closes a long line of research on the problem for this particular range of p [58, 35, 45, 44, 15, 13].

► **Theorem 21.** *For $p \in (0, 1)$, there is a protocol for F_p estimation in the message passing model which succeeds with probability $2/3$ and has max-communication of $O(\frac{1}{\epsilon^2}(\log \log n + \log 1/\epsilon))$.*

► **Theorem 22.** *There is a streaming algorithm for F_p estimation, $p \in (0, 1)$, which outputs a value \tilde{R} such that with probability at least $2/3$, we have that $|\tilde{R} - \|X\|_p| \leq \epsilon \|X\|_p$. The algorithm uses $O((\frac{1}{\epsilon^2}(\log \log n + \log 1/\epsilon) + \frac{\log 1/\epsilon}{\log \log 1/\epsilon} \log n)$ -bits of space. In the random oracle model, the space is $O(\frac{1}{\epsilon^2}(\log \log n + \log 1/\epsilon))$.*

The above bound matches the $\Omega(\epsilon^{-2})$ max communication lower bound of [58] in the shared randomness model, which comes from 2-party communication complexity. Moreover, our streaming algorithm matches the $\Omega(\log n)$ lower bound for streaming when a random oracle is not allowed. As an application of our protocol for F_p estimation, $p < 1$, we demonstrate a communication optimal protocol for additive approximation of the empirical *Shannon entropy* $H(\mathcal{X})$ of the aggregate vector \mathcal{X} . Here, $H = H(\mathcal{X})$ is defined by $H = \sum_{i=1}^n p_i \log(1/p_i)$ where $p_i = |\mathcal{X}_i|/\|\mathcal{X}\|_1$ for $i \in [n]$. The goal of our protocols is to produce an estimate $\tilde{H} \in \mathbb{R}$ of H such that $|\tilde{H} - H| \leq \epsilon$. Our result is as follows.

► **Theorem 26.** *There is a multi-party communication protocol in the message passing model that outputs a ϵ -additive error of the Shannon entropy H . The protocol uses a max-communication of $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon))$ -bits.*

Note that for a *multiplicative* approximation of the Shannon entropy, there is a $\tilde{\Omega}(\epsilon^{-2})$ lower bound [14]. For additive estimation, [43] gives a $\Omega(\epsilon^{-2} \log(n))$ lower bound in the turnstile model. Using a similar reduction, we prove a matching $\Omega(\epsilon^{-2})$ lower bound for additive ϵ approximation in the insertion only model (see Appendix B for the proof). Furthermore, our protocol directly results in an $\tilde{O}(\epsilon^{-2})$ -bits of space, insertion only *streaming* algorithm for entropy estimation in the random oracle model. Here, the random oracle model means that the algorithm is given query access to an arbitrarily long string of random bits. We note that many lower bounds in communication complexity (and all of the bounds discussed in this paper except for the $\Omega(\log n)$ term in the lower bound for F_p estimation) also apply to the random oracle model. Previously, the best known algorithm for the insertion only random oracle model used $O(\epsilon^{-2} \log(n))$ -bits [47, 21], whereas the best known algorithm for the non-random oracle model uses $O(\epsilon^{-2} \log^2(n))$ -bits (the extra factor of $\log(n)$ comes from a standard application of Nisan's pseudo-random generator [53]).

► **Theorem 27.** *There is a streaming algorithm for ϵ -additive approximation of the empirical Shannon entropy of an insertion only stream in the random oracle model, which succeeds with probability $3/4$. The space required by the algorithm is $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon))$ bits.*

Finally, we show how our techniques can be applied to the important numerical linear algebraic primitive of *approximate matrix product*, which we now define.

► **Definition 1.** *The multi-party approximate matrix product problem is defined as follows. Instead of vector valued inputs, each player is given $X_i \in \{0, 1, \dots, M\}^{n \times t_1}$ and $Y_i \in \{0, 1, \dots, M\}^{n \times t_2}$, where $\mathcal{X} = \sum_i X_i$ and $\mathcal{Y} = \sum_i Y_i$. Here, it is generally assumed that $n \gg t_1, t_2$ (but not required). The players must work together to jointly compute a matrix $R \in \mathbb{R}^{t_1 \times t_2}$ such that $\|R - \mathcal{X}^T \mathcal{Y}\|_F \leq \epsilon \|\mathcal{X}\|_F \|\mathcal{Y}\|_F$, where for a matrix $A \in \mathbb{R}^{n \times m}$, $\|A\|_F = (\sum_{i=1}^n \sum_{j=1}^m A_{i,j}^2)^{1/2}$ is the Frobenius norm of A .*

► **Theorem 29.** *There is a protocol which outputs, at the central vertex \mathcal{C} , a matrix $R \in \mathbb{R}^{t_1 \times t_2}$ which solves the approximate communication protocol with probability $3/4$ ³. The max communication required by the protocol is $O(\epsilon^{-2}(t_1 + t_2)(\log \log n + \log 1/\epsilon + \log d))$, where d is the diameter of the communication topology G .*

We remark that an upper bound of $O(\epsilon^{-2}(t_1 + t_2) \log n)$ was already well-known from sketching theory [59], and our main improvement is removing the $\log(n)$ factor for small diameter graphs, such as the coordinator model where distributed numerical linear algebra is usually considered.

1.3 Other Related Work

As mentioned, a closely related line of work is in the *distributed functional monitoring model*. Here, there are m machines connected to a central coordinator (the coordinator topology). Each machine then receives a stream of updates, and the coordinator must maintain at all time steps an approximation of some function, such as a moment estimation or a uniform sample, of the union of all streams. We note that there are two slightly different models here. One model is where the items (coordinates) being updated in the separate streams are considered disjoint, and each time an insertion is seen it is to a unique item. This model is considered especially for the problem of maintaining a uniform sample of the items in the streams [25, 34, 56, 37]. The other model, which is more related to ours, is where each player is receiving a stream of updates to a *shared* overall data vector $\mathcal{X} \in \mathbb{R}^n$. This can be seen as a distributed streaming setting, where the updates to a centralized stream are split over m servers, and is considered in [60, 25, 3]. For the restricted setting of *one-way* algorithms, which only transmit messages from the sites to the coordinators, any such algorithm can be made into a one-shot protocol for the multi-party message passing model. Here, each machine just simulates a stream on their fixed input vectors X_i , and sends all the messages that would have been sent by the functional monitoring protocol.

Perhaps the most directly related result to our upper bound for F_p estimation, $p \in (1, 2]$, is in the distributed functional monitoring model, where Woodruff and Zhang [60] show a $O(m^{p-1} \text{poly}(\log(n), 1/\epsilon) + m\epsilon^{-1} \log(n) \log(\log(n)/\epsilon))^4$ *total communication* upper bound. We remark here, however, that the result of [60] is incomparable to ours for several reasons. Firstly, their bounds are only for total communication, whereas their max communication can be substantially larger than $O(1/\epsilon^2)$. Secondly, while it is claimed in the introduction that the protocols are one way (i.e., only the players speak to the coordinator, and not vice versa), this is for their threshold problem and not for F_p estimation⁵. As remarked before, there is an $\Omega(m/\epsilon^2)$ total communication lower bound for one-way protocols, which demonstrates that their complexity could not hold in our setting (we sketch a proof of this in Appendix A).

³ We remark that there are standard techniques to boost the probability of the matrix sketching results to $1 - \delta$, using a blow-up of $\log(\delta)$ in the communication. See e.g. Section 2.3 of [59]

⁴ We remark that the $\text{poly}(\log(n), 1/\epsilon)$ terms here are rather large, and not specified in the analysis of [60].

⁵ The reason for this is as follows. Their algorithm reduces F_p estimation to the threshold problem, where for a threshold τ , the coordinator outputs 1 when the F_p first exceeds $\tau(1 + \epsilon)$, and outputs 0 whenever the F_p is below $\tau(1 - \epsilon)$. To solve F_p estimation, one then runs this threshold procedure for the $\log(mMn)/\epsilon$ thresholds $\tau = (1 + \epsilon), (1 + \epsilon)^2, \dots, (mMn)^2$ in parallel. However, the analysis from [60] only demonstrates a total communication of $O(k^{1-p} \text{poly}(\log(n), \epsilon^{-1}))$ for the time steps *before* the threshold τ is reached. Once the threshold is reached, the communication would increase significantly, thus the coordinator must inform all players when a threshold τ is reached so that they stop sending messages for τ , violating the one-way property. This step also requires an additive k messages for each of the $O(\epsilon^{-1} \log(n))$ thresholds, which results in the $O(m\epsilon^{-1} \log(n) \log(\log(n)\epsilon))$ term.

The message passing model itself has been the subject of significant research interest over the past two decades. The majority of this work is concerned with *exact* computation of Boolean functions of the inputs. Perhaps the canonical multi-party problem, and one which has strong applications to streaming, is set disjointness, where each player has a subset $S_i \subset [n]$ and the players want to know if $\bigcap_{i=1}^m S_i$ is empty. Bar-Yossef et al. [6] demonstrated strong bounds for this problem in the black-board model. This lower bound resulted in improved (polynomially sized) lower bounds for streaming F_p estimation for $p > 2$. These results for disjointness have since been generalized and improved using new techniques [16, 30, 41, 8]. Finally, we remark that while most results in the multi-party message passing model are not topology dependent, Chattopadhyay, Radhakrishnan, and Rudra have demonstrated that tighter topology-dependent lower bounds are indeed possible in the message passing model [19].

2 Preliminaries

Let f be a function $f : \mathbb{R}^n \rightarrow \mathbb{R}$. Let $G = (V, E)$ be a connected undirected graph with m vertices, i.e. $V = \{1, \dots, m\}$. In the message passing model on the graph topology G , there are m players, each placed at a unique vertex of G , with unbounded computational power. Player i is given as input only a vector $X_i \in \mathbb{Z}^n$, which is known as the Number in Hand (NIH) model of communication. Let $\mathcal{X} = \sum_{i=1}^m X_i$ be the aggregate vector of the players inputs. The goal of the players is to jointly compute or approximate the function $f(\mathcal{X})$ by carrying out some previously unanimously agreed upon communication protocol. It is assumed that the graph topology of G is known to all players.

In this paper, we are concerned with the non-negative input model. Namely, the inputs X_i satisfy $X_i \in \{0, 1, \dots, M\}^n$ for all players i . Note an equivalent assumption to is that $(X_i)_j \geq 0$ for all i , and that the $(X_i)_j$'s can be specified in $O(\log(M))$ bits.

► **Remark 2.** For ease of presentation, we assume that $m, M = O(n^c)$ for some constant c . This allows us to simplify complexity bounds and write $\log(nmM) = O(\log n)$. This is a common assumption in the streaming literature, where m corresponds to the length of the stream. We remark, however, that all our results hold for general m, n, M , by replacing each occurrence of n in the communication complexity with (mnM) .

During execution of the protocol, a player $i \in V$ is only allowed to send a message to a player j if $(i, j) \in E$. Thus, players may only communicate directly with their neighbors in the graph G . In contrast to the *broadcast* and *blackboard* models of communication, in the message passing model the message sent by player i to player j is only received by player j , and no other player. Upon termination of the protocol, at least one player must hold an approximation of the value $f(\mathcal{X})$. For the protocols considered in this paper, this player will be fixed and specified by the protocol beforehand. We use $\mathcal{C} \in V$ to denote the distinguished player specified by the protocol to store the approximation at the end of the execution.

Every such communication protocol in this model can be divided into rounds, where on the j -th round some subset $S_j \subseteq V$ of the players simultaneously send a message across one of their edges. Although it is not a restriction in the message passing model, our protocols satisfy the additional property that each player communicates *exactly once*, across one of its edges, and that each player will receive messages from its neighbors in exactly one round. Specifically, for each player i , there will be exactly one round j where some subset of its neighbors send player i a message, and then player i will send a single message in round $j + 1$, and never again communicate. Such protocols are called *one-shot* protocols.

The *total communication* cost of a protocol is the total number of bits sent in all the messages during its execution. The *max-communication* of a protocol is the maximum number of bits sent across any edge over the execution of the protocol. Communication protocols can be either deterministic or randomized. In this paper we consider the standard *public-coin* model of communication, where each player is given shared access to an arbitrarily long string of random bits. This allows players to jointly utilize the same source of randomness without having to communicate it.

Our protocols for F_p estimation will utilize the p -stable distribution, D_p , which we will now introduce. For $p = 2$, the distribution D_2 is the just standard Gaussian distribution. Note for $p < 2$, the distributions have heavy tails – they decay like x^{-p} . Thus, for $p < 2$, the variance is infinite, and for $p \leq 1$, the expectation is undefined.

► **Definition 3.** For $0 < p \leq 2$, there exists a probability distribution D_p called the p -stable distribution. If $Z \sim D_p$, $p < 2$, then the characteristic function of D_p is given by $\mathbb{E}[e^{itZ}] = e^{-|t|^p}$. For $p = 2$, D_2 is the standard Gaussian distribution. Moreover, for any n , and any $x \in \mathbb{R}^n$, if $Z_1, \dots, Z_n \sim D_p$ are independent, then $\sum_{i=1}^n Z_i x_i \sim \|x\|_p Z$, where $Z \sim D_p$, and \sim means distributed identically to.

Standard methods for generating p -stable random variables are discussed in [54]. Note that all protocols in this paper will generate these variables only to precision $1/\text{poly}(n)$. For a distribution D_p , we write D_p^n to denote the product distribution of D_p . Thus $Z \sim D_p^n$ means $Z \in \mathbb{R}^n$ and Z_1, \dots, Z_n are drawn i.i.d. from D_p . For reals $a, b \in \mathbb{R}$, we write $a = (1 \pm \epsilon)b$ to denote the containment $a \in [(1 - \epsilon)b, (1 + \epsilon)b]$. For an integer $t \geq 0$, we write $[t]$ to denote the set $\{1, 2, \dots, t\}$.

3 Message Passing F_p Estimation, $p > 1$

In this section, we provide our algorithm for F_p estimation, $1 \leq p \leq 2$, in the message passing model. We begin by specifying the distinguished vertex $\mathcal{C} \in V$ which will hold and output the F_p approximation at the end of the protocol. For a vertex $v \in G$, define its eccentricity $\text{ecc}(v) = \max_{u \in V} d(v, u)$, where $d(v, u)$ is the graph distance between v, u . We then set $\mathcal{C} \in V$ to be any vertex with minimal eccentricity. Such a vertex is known as a center of G . We now fix a shortest path spanning tree T for G , rooted at the distinguished player \mathcal{C} . The spanning tree T has the property that the path between \mathcal{C} and any vertex $v \in V$ in the tree T is also a shortest path between \mathcal{C} and v in G . Thus the distance between \mathcal{C} and any vertex $v \in V$ is the same in T as it is in G . The fact that the depth of T is at most d , where d is the diameter of G , now follows naturally. Such a shortest path spanning tree T can be easily obtained via a breath first search. First, we will need a technical Lemma about the behavior of p -stables. To prove it, we first use the following fact about the tails of p stables, which can be found in [54].

► **Proposition 4.** If $Z \sim D_p$ for $0 < p < 2$, then $\Pr[|Z| \geq \lambda] \leq O(\frac{1}{\lambda^p})$.

Also, we use the straightforward fact that $\|X_i\|_p^p \leq \|\sum_{i=1}^m X_i\|_p^p$ for non-negative vectors X_i and $p \geq 1$.

► **Fact 5.** If $X_1, \dots, X_m \in \mathbb{R}^n$ are entry-wise non-negative vectors and $1 \leq p \leq 2$, then $\sum_{i=1}^m \|X_i\|_p^p \leq \|\sum_{i=1}^m X_i\|_p^p$.

► **Lemma 6.** Fix $1 \leq p \leq q \leq 2$, and let $Z = (Z_1, Z_2, \dots, Z_n) \sim D_p^m$. Suppose $X_1, \dots, X_m \in \mathbb{R}^n$ are non-negative vectors, with $\mathcal{X} = \sum_j X_j$. Then for any $\lambda \geq 1$, if either $q - p \geq c > 0$ for some constant c independent of m , or if $p = 2$, we have

$$\Pr \left[\sum_{j=1}^m |\langle Z, X_j \rangle|^q \geq C \lambda^q \|\mathcal{X}\|_p^q \right] \leq \frac{1}{\lambda^p}$$

Otherwise, we have $\Pr[\sum_{j=1}^m |\langle Z, X_j \rangle|^q \geq C \log(\lambda m) \lambda^q \|\mathcal{X}\|_p^q] \leq \frac{1}{\lambda^p}$, where C is some constant (depending only on c in the first case).

► **Corollary 7.** Suppose $Z = (Z_1, \dots, Z_m)$ where the Z_i 's are uniform over $\{1, -1\}$ and pairwise independent, and let X_1, \dots, X_m be non-negative vectors with $\mathcal{X} = \sum_j X_j$. Then for any $\lambda \geq 1$, we have $\Pr[\sum_{j=1}^m |\langle Z, X_j \rangle|^2 \geq \lambda \|\mathcal{X}\|_2^2] \leq \frac{1}{\lambda}$

► **Corollary 8.** Let $Z = (Z_1, Z_2, \dots, Z_n) \sim D_2^m$ be i.i.d. Gaussian. Suppose $X_1, \dots, X_m \in \mathbb{R}^n$ are non-negative vectors, with $\mathcal{X} = \sum_j X_j$. Then for any $\lambda \geq c \log(m)$ for some sufficiently large constant c , we have $\Pr[\sum_{j=1}^m |\langle Z, X_j \rangle| \geq \lambda \|\mathcal{X}\|_2] \leq \exp(-C\lambda)$, where C is some universal constant.

3.1 Randomized Rounding of Sketches

We now introduce our randomized rounding protocol. Consider non-negative integral vectors $X_1, X_2, \dots, X_m \in \mathbb{Z}_{\geq 0}^n$, with $\mathcal{X} = \sum_{i=1}^m X_i$. Fix a message passing topology $G = (V, E)$, where each player $i \in V$ is given as input X_i . Fix any vertex \mathcal{C} that is a center of G , and let T be a shortest path spanning tree of G rooted at \mathcal{C} as described at the beginning of the section. Let d be the depth of T . The players use shared randomness to choose a random vector $Z \in \mathbb{R}^n$, and their goal is to approximately compute $\langle Z, \mathcal{X} \rangle = \langle Z, \sum_{i=1}^m X_i \rangle$. The goal of this section is to develop a d -round randomized rounding protocol, so that at the end of the protocol the approximation to $\langle Z, \mathcal{X} \rangle$ is stored at the vertex \mathcal{C} .

We begin by introducing the rounding primitive which we use in the protocol. Fix $\epsilon > 0$, and let $\gamma = (\epsilon \delta / \log(nm))^C$, for a sufficiently large constant $C > 1$. For any real value $r \in \mathbb{R}$, let $i_r \in \mathbb{Z}$ and $\alpha_i \in \{1, -1\}$ be such that $(1 + \gamma)^{i_r} \leq \alpha_i r \leq (1 + \gamma)^{i_r + 1}$. Now fix p_r such that $\alpha_i r = p_r (1 + \gamma)^{i_r + 1} + (1 - p_r) (1 + \gamma)^{i_r}$. We then define the rounding random variable $\Gamma(r)$ by

$$\Gamma(r) = \begin{cases} 0 & \text{if } r = 0 \\ \alpha_i (1 + \gamma)^{i_r + 1} & \text{with probability } p_r \\ \alpha_i (1 + \gamma)^{i_r} & \text{with probability } 1 - p_r \end{cases}$$

The following proposition is clear from the construction of p_r and the fact that the error is deterministically bounded by $\gamma|r|$.

► **Proposition 9.** For any $r \in \mathbb{R}$, We have $\mathbb{E}[\Gamma(r)] = r$ and $\mathbf{Var}[\Gamma(r)] \leq r^2 \gamma^2$

We partition T into d layers, so that all nodes at distance $d - t$ from \mathcal{C} in T are put in layer t . Define $L_t \subset [n]$ to be the set of players at layer t in the tree. For any vertex $u \in G$, let T_u be the subtree of T rooted at u (including the vertex u). For any player i , let $C_i \subset [n]$ be the set of children of i in the tree T . The procedure for all players $j \in V$ is then given as Algorithm 1.

■ **Algorithm 1** Recursive Randomized Rounding.

Procedure for node j in layer i :

1. Choose random vector $Z \in \mathbb{R}^n$ using shared randomness.
2. Receive rounded sketches $r_{j_1}, r_{j_2}, \dots, r_{j_{t_j}} \in \mathbb{R}$ from the t_j children of node j in the prior layer (if any such children exist).
3. Compute $x_j = \langle X_j, Z \rangle + r_{j_1} + r_{j_2} + \dots + r_{j_{t_j}} \in \mathbb{R}$.
4. Compute $r_j = \Gamma(x_j)$. If player $j \neq \mathcal{C}$, then send r_j to the parent node of j in T . If $j = \mathcal{C}$, then output r_j as the approximation to $\langle Z, \mathcal{X} \rangle$.

For each player i in layer 0, they take their input X_i , and compute $\langle Z, X_i \rangle$. They then round their values as $r_i = \Gamma(\langle Z, X_i \rangle)$, where the randomness used for the rounding function Γ is drawn independently for each call to Γ . Then player i sends r_i to their parent in T . In general, consider any player i at depth $j > 0$ of T . At the end of the j -th round, player i will receive a rounded value r_ℓ for every child vertex $\ell \in C_i$. They then compute $x_i = \langle Z, X_i \rangle + \sum_{\ell \in C_i} r_\ell$, and $r_i = \Gamma(x_i)$, and send r_i to their parent in T . This continues until, on round d , the center vertex \mathcal{C} receives r_ℓ for all children $\ell \in C_{\mathcal{C}}$. The center \mathcal{C} then outputs $r_{\mathcal{C}} = \langle Z, X_{\mathcal{C}} \rangle + \sum_{\ell \in C_{\mathcal{C}}} r_\ell$ as the approximation.

For any player i , let $Q_i = \sum_{u \in T_i} X_u$, and $y_i = \langle Z, Q_i \rangle$. Then define the error e_i at player i as $e_i = y_i - r_i$. We first prove a proposition that states the expectation of the error e_i for any player i is zero, and then the main lemma which bounds the variance of e_i . The error bound of the protocol at \mathcal{C} then results from an application of Chebyshev's inequality.

► **Proposition 10.** *For any player i , we have $\mathbb{E}[e_i] = 0$. Moreover, for any players i, j such that $i \notin T_j$ and $j \notin T_i$, the variables e_i and e_j are statistically independent.*

► **Lemma 11.** *Fix $p \in [1, 2]$, and let $Z = (Z_1, Z_2, \dots, Z_n) \sim D_p^n$. Then the above procedure when run on $\gamma = (\epsilon\delta/(d \log(nm)))^{\mathcal{C}}$ for a sufficiently large constant \mathcal{C} , produces an estimate $r_{\mathcal{C}}$ of $\langle Z, \mathcal{X} \rangle$, held at the center vertex \mathcal{C} , such that $\mathbb{E}[r_{\mathcal{C}}] = \langle Z, \mathcal{X} \rangle$. Moreover, over the randomness used to draw Z , with probability $1 - \delta$ for $p < 2$, and with probability $1 - e^{-1/\delta}$ for Gaussian Z , we have $\mathbb{E}[(r_{\mathcal{C}} - \langle Z, \mathcal{X} \rangle)^2] \leq (\epsilon/\delta)^2 \|\mathcal{X}\|_p$. Thus, with probability at least $1 - O(\delta)$, we have $|r_{\mathcal{C}} - \langle Z, \mathcal{X} \rangle| \leq \epsilon \|\mathcal{X}\|_p$. Moreover, if $Z = (Z_1, Z_2, \dots, Z_n) \in \mathbb{R}^n$ where each $Z_i \in \{1, -1\}$ is a 4-wise independent Rademacher variable, then the above bound holds with $p = 2$ (and with probability $1 - \delta$).*

► **Theorem 12.** *For $p \in (1, 2]$, there is a protocol for F_p estimation which succeeds with probability $3/4$ in the message passing model, which uses a total of $O(\frac{m}{\epsilon^2}(\log(\log(n)) + \log(d) + \log(1/\epsilon)))$ communication, and a max communication of $O(\frac{1}{\epsilon^2}(\log(\log(n)) + \log(d) + \log(1/\epsilon)))$, where d is the diameter of the communication network.*

3.2 Heavy Hitters and Point Estimation

In this section, we show how our randomized rounding protocol can be used to solve the L_2 heavy hitters problem. For a vector $\mathcal{X} \in \mathbb{R}^n$, let $\mathcal{X}_{\text{tail}(k)}$ be \mathcal{X} with the k largest (in absolute value) entries set equal to 0. Formally, given a vector $\mathcal{X} \in \mathbb{R}^n$, the heavy hitters problem is to output a set of coordinates $H \subset [n]$ of size at most $|H| = O(\epsilon^{-2})$ that contains all $i \in [n]$ with $|\mathcal{X}_i| \geq \epsilon \|\mathcal{X}_{\text{tail}(1/\epsilon^2)}\|_2$. Our protocols solve the strictly harder problem of *point-estimation*. The point estimation problem is to output a $\tilde{\mathcal{X}} \in \mathbb{R}^n$ such that $\|\tilde{\mathcal{X}} - \mathcal{X}\|_\infty \leq \epsilon \|\mathcal{X}_{\text{tail}(1/\epsilon^2)}\|_2$. Our protocol uses the well-known *count-sketch* matrix S [18], which we now introduce.

► **Definition 13.** Given a precision parameter ϵ and an input vector $\mathcal{X} \in \mathbb{R}^n$, count-sketch stores a table $A \in \mathbb{R}^{\ell \times 6/\epsilon^2}$, where $\ell = \Theta(\log(n))$. Count-sketch first selects pairwise independent hash functions $h_j : [n] \rightarrow [6/\epsilon^2]$ and 4-wise independent $g_j : [n] \rightarrow \{1, -1\}$, for $j = 1, 2, \dots, \ell$. Then for all $i \in [\ell]$, $j \in [6/\epsilon^2]$, it computes the following linear function $A_{i,j} = \sum_{k \in [n], h_i(k)=j} g_i(k)\mathcal{X}_k$, and outputs an approximation $\tilde{\mathcal{X}}$ of \mathcal{X} given by $\tilde{\mathcal{X}}_k = \text{median}_{i \in [\ell]} \{g_i(k)A_{i,h_i(k)}\}$

Observe that the table $A \in \mathbb{R}^{\ell \times 6/\epsilon^2}$ can be flattened into a vector $A \in \mathbb{R}^{6\ell/\epsilon^2}$. Given this, A can be represented as $A = S\mathcal{X}$ for a matrix $S \in \mathbb{R}^{6\ell/\epsilon^2 \times n}$. For any $i \in [\ell]$, $j \in [6/\epsilon^2]$, and $\ell \in [n]$, the matrix S is given by $S_{(i-1)(6/\epsilon^2)+j,\ell} = \delta_{i,j,\ell}g_j(\ell)$, where $\delta_{i,j,\ell}$ indicates the event that $h_i(\ell) = j$. Given $S\mathcal{X}$, one can solve the point-estimation problem as described in Definition 13 [18]. In order to reduce the communication from sending each coordinate of $S\mathcal{X}$ exactly, we can use our rounding procedure to approximately compute the sketch $S\mathcal{X}$, which will give us the following theorem.

► **Theorem 14.** Consider a message passing topology $G = (V, E)$ with diameter d , where the i -th player is given as input $X_i \in \mathbb{Z}_{\geq 0}^n$ and $\mathcal{X} = \sum_{i=1}^m X_i$. Then there is a communication protocol which outputs an estimate $\tilde{\mathcal{X}} \in \mathbb{R}^n$ of \mathcal{X} such that $\|\tilde{\mathcal{X}} - \mathcal{X}\|_\infty \leq \epsilon \|\mathcal{X}_{\text{tail}(1/\epsilon^2)}\|_2$ with probability $1 - 1/n^c$ for any constant $c \geq 1$. The protocol uses $O(\frac{m}{\epsilon^2} \log(n)(\log(\log(n)) + \log(d) + \log(1/\epsilon)))$ total communication, and a max communication of $O(\frac{1}{\epsilon^2} \log(n)(\log(\log(n)) + \log(d) + \log(1/\epsilon)))$.

4 F_p Estimation for $p < 1$

In this section, we develop algorithms for F_p estimation for $p < 1$ in the message passing model, and in the process obtain improved algorithms for entropy estimation. We begin by reviewing the fundamental sketching procedure used in our estimation protocol. The algorithm is known as a Morris counter [51, 26]. The algorithm first picks a base $1 < b \leq 2$, and initializes a counter $C \leftarrow 0$. Then, every time it sees an insertion, it increments the counter $C \leftarrow C + \delta$, where $\delta = 1$ with probability b^{-C} , and $\delta = 0$ otherwise (in which case the counter remains unchanged). After n insertions, the value n can be estimated by $\tilde{n} = (b^C - b)/(b - 1) + 1$.

► **Definition 15.** The approximate counting problem is defined as follows. Each player i is given a positive integer value $x_i \in \mathbb{Z}_{\geq 0}$, and the goal is for some player at the end to hold an estimate of $x = \sum_i x_i$.

► **Proposition 16** (Proposition 5 [26]). If C_n is the value of the Morris counter after n updates, then $\mathbb{E}[\tilde{n}] = n$, and $\text{Var}[\tilde{n}] = (b - 1)n(n + 1)/2$.

► **Corollary 17.** If C_n is the value of a Morris counter run on a stream of n insertions with base $b = (1 + (\epsilon\delta)^2)$, then with probability at least $1 - \delta$, we have $\tilde{n} = (1 \pm \epsilon)n$ with probability at least $1 - \delta$. Moreover, with probability at least $1 - \delta$, the counter C_n requires $O(\log \log(n) + \log(1/\epsilon) + \log(1/\delta))$ -bits to store.

► **Lemma 18.** Given Morris counters X, Y run on streams of length n_1, n_2 respectively, There is a merging procedure that produces a Morris counter Z which is distributed identically to a Morris counter that was run on a stream of $n_1 + n_2$ insertions.

► **Corollary 19.** There is a protocol for F_1 estimation of non-negative vectors, equivalently for the approximate counting problem, in the message passing model which succeeds with probability $1 - \delta$ and uses a max-communication of $O((\log \log(n) + \log(1/\epsilon) + \log(1/\delta))$ -bits.

We now note that Morris counters can easily be used as approximate counters for streams with both insertions and deletions (positive and negative updates), by just storing a separate Morris counter for the insertions and deletions, and subtracting the estimate given by one from the other at the end.

► **Corollary 20.** *Using two Morris counters separately for insertions and deletions, on a stream of I insertions and D deletions, there is an algorithm, called a signed Morris counter, which produces \tilde{n} with $|\tilde{n} - n| \leq \epsilon(I + D)$, where $n = I - D$, with probability $1 - \delta$, using space $O(\log \log(I + D) + \log(1/\epsilon) + \log(1/\delta))$.*

Hereafter, when we refer to a Morris counter that is run on a stream which contains both positive and negative updates as a *signed* Morris counter. Therefore, the guarantee of Corollary 20 apply to such signed Morris counters, and moreover such signed Morris counters can be Merged as in Lemma 18 with the same guarantee.

■ **Algorithm 2** Multi-party F_p estimation protocol, $p < 1$.

Procedure for player j

$k \leftarrow \Theta(1/\epsilon^2)$, $\epsilon' \leftarrow \Theta(\epsilon \frac{\delta^{1/p}}{\log(n/\delta)})$, $\delta \leftarrow 1/(200k)$

1. Using shared randomness, choose sketching matrix $S \in \mathbb{R}^{k \times n}$ of i.i.d. p -stable random variables, with $k = \Theta(1/\epsilon)$. Generate S up to precision $\eta = \text{poly}(1/(n, m, M))$, so that $\eta^{-1}S$ has integral entries.
2. For each $i \in [k]$, receive signed Morris counters $y_{j_1, i}, y_{j_2, i}, \dots, y_{j_t, i}$ from the $t \in \{0, \dots, m\}$ children of node j in the prior layer.
3. Compute $\eta^{-1}\langle S_i, X_j \rangle \in \mathbb{Z}$, where S_i is the i -th row of S , and run a new signed Morris counter C on $\eta^{-1}\langle S_i, X_j \rangle$ with parameters (ϵ', δ') .
4. Merge the signed Morris counters $y_{j_1, i}, y_{j_2, i}, \dots, y_{j_t, i}, C$ into a counter $y_{j, i}$.
5. Send the merged signed Morris counter $y_{j, i}$ to the parent of player j . If player j is the root node \mathcal{C} , then set C_i to be the estimate of the signed Morris counter $y_{j, i}$, and return the estimate $\eta \cdot \text{median} \left\{ \frac{|C_1|}{\theta_p}, \dots, \frac{|C_k|}{\theta_p} \right\}$, where θ_p is the median of the distribution \mathcal{D}_p .

We now provide our algorithm for F_p estimation in the message passing model with $p \leq 1$. Our protocol is similar to our algorithm for $p \geq 1$. We fix a vertex \mathcal{C} which is a center of the communication topology. We then consider the shortest path tree T rooted at \mathcal{C} , which has depth at most d , where d is the diameter of G . The players then choose random vectors $S_i \in \mathbb{R}^n$ for $i \in [k]$, and the j -th player computes $\langle S_i, X_j \rangle$, and adds this value to a Morris counter. Each player receives Morris counters from their children in T , and thereafter merges these Morris counters with its own. Finally, it sends this merged Morris counter, containing updates from all players in the subtree rooted at j , to the parent of j in T . At the end, the center \mathcal{C} holds a Morris counter C_i which approximates $\sum_j \langle S_i, X_j \rangle$. The main algorithm for each player j is given formally as Algorithm 2.

► **Theorem 21.** *For $p \in (0, 1)$, there is a protocol for F_p estimation in the message passing model which succeeds with probability $2/3$ and uses a total communication of $O(\frac{m}{\epsilon^2}(\log \log(n) + \log(1/\epsilon))$ -bits, and a max-communication of $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon))$ -bits. The protocol requires a total of at most d rounds, where d is the diameter of the communication topology G .*

4.1 The Streaming Algorithm for F_p Estimation, $p < 1$

As discussed earlier, the insertion-only streaming model of computation is a special case of the above communication setting, where the graph in question is the line graph, and each player receives vector $X_i \in \mathbb{R}^n$ which is the standard basis vector $e_j \in \mathbb{R}^n$ for some $j \in [n]$. The only step remaining to fully generalize the result to the streaming setting is an adequate derandomization of the randomness required to generate the matrix S . Our derandomization will follow from the results of [45], which demonstrate that, using a slightly different estimator known as the log-cosine estimator, the entries of each row S_i can be generated with only $\Theta(\log(1/\epsilon)/\log \log(1/\epsilon))$ -wise independence, and the seeds used to generate separate rows of S_i need only be pairwise independent. Thus, storing the randomness used to generate S requires only $O(\frac{\log(1/\epsilon)}{\log \log(1/\epsilon)} \log(n))$ -bits of space.

We now discuss the estimator of [45] precisely. The algorithm generates a matrix $S \in \mathbb{R}^{k \times n}$ and $S' \in \mathbb{R}^{k' \times n}$ with $k = \Theta(1/\epsilon^2)$ and $k' = \Theta(1)$, where each entry of S, S' is drawn from \mathcal{D}_p . For a given row i of S , the entries $S_{i,j}$ are $\Theta(\log(1/\epsilon)/\log \log(1/\epsilon))$ -wise independent, and for $i \neq i'$, the seeds used to generate $\{S_{i,j}\}_{j=1}^n$ and $\{S_{i',j}\}_{j=1}^n$ are pairwise independent. S' is generated with only $\Theta(1)$ -wise independence between the entries in a given row in S' , and pairwise independence between rows. The algorithm then maintains the vectors $y = S\mathcal{X}$ and $y' = S'\mathcal{X}$ throughout the stream, where $\mathcal{X} \in \mathbb{Z}_{\geq 0}^n$ is the stream vector. Define $y'_{med} = \text{median}\{|y'_i|\}_{i=1}^{k'}/\theta_p$, where θ_p is the median of the distribution \mathcal{D}_p ([45] discusses how this can be approximated to $(1 \pm \epsilon)$ efficiently). The log-cosine estimator R of $\|\mathcal{X}\|_p$ is then given by $R = y'_{med} \cdot \left(-\ln \left(\frac{1}{k} \sum_{i=1}^k \cos \left(\frac{y_i}{y'_{med}} \right) \right) \right)$

► **Theorem 22.** *There is a streaming algorithm for insertion only F_p estimation, $p \in (0, 1)$, outputs a value \tilde{R} such that with probability at least $2/3$, we have that $|\tilde{R} - \|\mathcal{X}\|_p| \leq \epsilon \|\mathcal{X}\|_p$ where $\mathcal{X} \in \mathbb{R}^n$ is the state of the stream vector at the end of the stream. The algorithm uses $O((\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon)) + \frac{\log(1/\epsilon)}{\log \log(1/\epsilon)} \log(n))$ -bits of space.*

5 Entropy Estimation

In this section, we show how our results imply improved algorithms for entropy estimation in the message-passing model. Here, for a vector $\mathcal{X} \in \mathbb{R}^n$, the Shannon entropy is given by $H = \sum_{i=1}^n \frac{|\mathcal{X}_i|}{\|\mathcal{X}\|_1} \log \left(\frac{\|\mathcal{X}\|_1}{|\mathcal{X}_i|} \right)$. We follow the approach taken by [21, 47, 31, 32] for entropy estimation in data streams, which is to use sketched of independent *maximally-skewed stable random variables*. While we introduced p -stable random variables in Definition 3 as the distribution with characteristic function $\mathbb{E}[e^{itZ}] = e^{-|t|^p}$, we remark now that the p -stable distribution is also parameterized by an additional *skewness* parameter $\beta \in [-1, 1]$. Up until this point, we have assumed $\beta = 0$. In this section, however, we will be using maximally skewed, meaning $\beta = -1$, $p = 1$ -stable random variables. We introduce these now

► **Definition 23 (Stable distribution, general).** *There is a distribution $F(p, \beta, \gamma, \delta)$ called the p -stable distribution with skewness parameter $\beta \in [-1, 1]$, scale γ , and position δ . The characteristic function of a $Z \sim F(p, \beta, \gamma, \delta)$ variable Z is given by:*

$$\mathbb{E}[e^{-itZ}] = \begin{cases} \exp(-\gamma^p |t|^p [1 - i\beta \tan(\frac{\pi p}{2}) \text{sign}(t)] + i\delta t) & \text{if } p \in (0, 2] \setminus \{1\} \\ \exp(-\gamma |t| [1 + i\beta \frac{2}{\pi} \text{sign}(t) \log(|t|)] + i\delta t) & \text{if } p = 1 \end{cases}$$

where $\text{sign}(t) \in \{1, -1\}$ is the sign of a real $t \in \mathbb{R}$. Moreover, if $Z \sim F(p, \beta, \gamma, 0)$ for any $\beta \in [-1, 1]$ and $0 < p < 2$, for any $\lambda > 0$ we have $\Pr[|Z| > C\lambda] \leq (\frac{\gamma}{\lambda})^p$, where C is some universal constant. We refer the reader to [54] for a further discussion on the parameterization and behavior of p -stable distributions with varying rates.

■ **Algorithm 3** Entropy Estimation algorithm of [21].

Sketching algorithm for Entropy Estimation

Input: $\mathcal{X} \in \mathbb{R}^n$

1. Generate $S \in \mathbb{R}^{k \times n}$ for $k = \Theta(1/\epsilon^2)$ of i.i.d. $F(1, -1, \pi/2, 0)$ random variables to precision $\eta = 1/\text{poly}(M, n)$.
2. Compute $S\mathcal{X} \in \mathbb{R}^k$.
3. Set $y_i \leftarrow (S\mathcal{X})_i / \|\mathcal{X}\|_1$ for $i \in [k]$
4. Return $\tilde{H} = -\log\left(\frac{1}{k} \sum_{i=1}^k e^{y_i}\right)$

The algorithm of [21] is given formally as Algorithm 3. The guarantee of the algorithm is given in Theorem 24.

► **Theorem 24** ([21]). *The above estimate \tilde{H} satisfies $|\tilde{H} - H| < \epsilon$ with probability at least $9/10$.*

► **Lemma 25.** *Fix $0 < \epsilon_0 < \epsilon$. Let $S \in \mathbb{R}^{k \times n}$ with $k = \Theta(1/\epsilon^2)$ be a matrix of i.i.d. $F(1, -1, \pi/2, 0)$ random variables to precision $\eta = 1/\text{poly}(M, n)$. Then there is a protocol in the message passing model that outputs $Y \in \mathbb{R}^k$ at a centralized vertex with $\|Y - S\mathcal{X}\|_\infty \leq \epsilon_0 \|\mathcal{X}\|_1$ with probability $9/10$. The protocol uses a total communication of $O(\frac{m}{\epsilon^2}(\log \log(n) + \log(1/\epsilon_0)))$ -bits, and a max-communication of $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon_0)))$ -bits.*

► **Theorem 26.** *There is a multi-party communication protocol in the message passing model that outputs a ϵ -additive error of the Shannon entropy H . The protocol uses a max-communication of $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon)))$ -bits.*

Since our protocol does not depend on the topology of G , a direct corollary is that we obtain a $\tilde{O}(\epsilon^{-2})$ -bits of space *streaming* algorithm for entropy estimation in the random oracle model. Recall that the random oracle model allows the streaming algorithm query access to an arbitrarily long tape of random bits. This fact is used to store the random sketching matrix S .

► **Theorem 27.** *There is a streaming algorithm for ϵ -additive approximation of the empirical Shannon entropy of an insertion only stream in the random oracle model, which succeeds with probability $3/4$. The space required by the algorithm is $O(\frac{1}{\epsilon^2}(\log \log(n) + \log(1/\epsilon)))$ bits.*

6 Approximate Matrix Product in the Message Passing Model

In this section, we consider the approximate regression problem in the message passing model over a topology $G = (V, E)$. Here, instead of vector valued inputs, each player is given as input two integral matrices $X_i \in \{0, 1, 2, \dots, M\}^{n \times t_1}$, $Y_i \in \{0, 1, 2, \dots, M\}^{n \times t_2}$. It is generally assumed that $n \gg t_1, t_2$, so the matrices X_i, Y_i are rectangular. Let $\mathcal{X} = \sum_{i=1}^m X_i$ and $\mathcal{Y} = \sum_i Y_i$. The goal of the players is to approximate the matrix product $\mathcal{X}^T \mathcal{Y} \in \mathbb{R}^{t_1 \times t_2}$. Specifically, at the end of the protocol one player must output a matrix $R \in \mathbb{R}^{t_1 \times t_2}$ such that $\|R - \mathcal{X}^T \mathcal{Y}\|_F \leq \epsilon \|\mathcal{X}\|_F \|\mathcal{Y}\|_F$, where for a matrix A , $\|A\|_F = (\sum_{i,j} A_{i,j}^2)^{1/2}$ is the Frobenius norm of A .

We now describe a classic sketching algorithm which can be used to solve the approximate regression problem. The algorithm picks a $S \in \mathbb{R}^{k \times n}$ of i.i.d. Gaussian variables with variance $1/k$. It then computes $S\mathcal{X}$ and $S\mathcal{Y}$, and outputs $(S\mathcal{X})^T S\mathcal{Y}$. The following fact about such sketches will demonstrate correctness.

► **Lemma 28** ([43]). Fix matrices $\mathcal{X} \in \mathbb{R}^{n \times t_1}$, $\mathcal{Y} \in \mathbb{R}^{n \times t_2}$ and $0 < \epsilon_0$. Let $S \in \mathbb{R}^{k \times n}$ be a matrix of i.i.d. Gaussian random variables with variance $1/k$, for $k = \Theta(1/(\delta\epsilon_0^2))$. Then we have $\Pr[\|\mathcal{X}^T S^T S \mathcal{Y} - \mathcal{X}^T \mathcal{Y}\|_F \leq \epsilon_0 \|\mathcal{X}\|_F \|\mathcal{Y}\|_F] \geq 1 - \delta$. Moreover, with the same probability we have $\|S\mathcal{X}\|_F = (1 \pm \epsilon_0)\|\mathcal{X}\|_F$ and $\|S\mathcal{Y}\|_F = (1 \pm \epsilon_0)\|\mathcal{Y}\|_F$.

Now by Lemma 11, the central vertex \mathcal{C} can recover a value $r_{\mathcal{C}}^{i,j}$ such that $\mathbb{E}[r_{\mathcal{C}}^{i,j}] = (S\mathcal{X})_{i,j}$ and $\mathbf{Var}[r_{\mathcal{C}}^{i,j}] \leq \epsilon^2 \|\mathcal{X}_{*,j}\|_2$ (after setting δ sufficiently small), where $\mathcal{X}_{*,j}$ is the j -th column of \mathcal{X} . Thus, the central vertex can obtain a random matrix $R^{\mathcal{X}} \in \mathbb{R}^{k \times t_1}$ such that $\mathbb{E}[R^{\mathcal{X}}] = (S\mathcal{X})$ and $\mathbb{E}[\|R^{\mathcal{X}} - S\mathcal{X}\|_F^2] \leq k\epsilon^2 \sum_{j=1}^{t_1} \|\mathcal{X}_{*,j}\|_2$. Setting $\epsilon = \text{poly}(1/k) = \text{poly}(1/\epsilon_0)$ small enough, we obtain $\mathbb{E}[\|R^{\mathcal{X}} - S\mathcal{X}\|_F^2] \leq \epsilon_0^2 \|\mathcal{X}\|_F$. Similarly, we can obtain a $R^{\mathcal{Y}}$ at the central vertex \mathcal{C} , and output the estimate $R = (R^{\mathcal{X}})^T R^{\mathcal{Y}}$. Utilizing the error guarantees of Lemma 11 as well as Lemma 28, we obtain the following theorem.

► **Theorem 29.** Given inputs $\mathcal{X} = \sum_{i=1}^m X_i$, $\mathcal{Y} = \sum_{i=1}^m Y_i$ as described above, there is a protocol which outputs, at the central vertex \mathcal{C} , a matrix $R \in \mathbb{R}^{t_1 \times t_2}$ such that with probability $3/4$ we have $\|R - \mathcal{X}^T \mathcal{Y}\|_F \leq \epsilon \|\mathcal{X}\|_F \|\mathcal{Y}\|_F$. The max communication required by the protocol is $O(\epsilon^{-2}(t_1 + t_2)(\log \log n + \log 1/\epsilon + \log d))$, where d is the diameter of the communication topology G .

A Proof Sketch of $\Omega(m/\epsilon^2)$ Lower Bound for F_p estimation in the One-Way Coordinator Model

We now sketch the proof of the $\Omega(m/\epsilon^2)$ lower bound that was remarked upon in the introduction. First, consider the following problem Alice is given a vector $x \in \mathbb{R}^t$, and bob $y \in \mathbb{R}^t$, such that $x_i \geq 0, y_i \geq 0$ for all $i \in [t]$. Alice and Bob both send a message to Eve, who must then output a $(1 \pm \epsilon)$ approximation to $\|x + y\|_p$, for $p \in (0, 2] \setminus \{1\}$. Via a reduction from the Gap-Hamming communication problem, there is a $\Omega(1/\epsilon^2)$ -bit communication lower bound for this problem [58]. More specifically, there is a distribution \mathcal{D} over inputs $(x, y) \in \mathbb{R}^t \times \mathbb{R}^t$, such that any communication protocol that solves the above problem on these inputs correctly with probability $3/4$ must send $\Omega(1/\epsilon^2)$ bits.

Now consider the one-way coordinator model, where there are m players connected via an edge to a central coordinator. They are given inputs x_1, \dots, x_m , and must each send a single message to the coordinator, who then must estimate $\|x\|_p = \|x_1 + x_2 + \dots + x_m\|_p$. Consider

two distribution, P_1, P_2 over the inputs (x_1, \dots, x_m) . In the first, two players i, j are chosen uniformly at random, and given as inputs $(x, y) \sim \mathcal{D}$, and the rest of the players are given the 0 vector. In P_2 , we draw $(x, y) \sim \mathcal{D}$, and every player is given either x or y at random. The players are then either given input from P_1 or P_2 , with probability $1/2$ for each. In the first case, if the two players with the input do not send $\Omega(1/\epsilon^2)$ bits, then they will not be able to solve the estimation problem via the 2-party lower bound. However, given only their input, the distributions P_1 and P_2 are indistinguishable to a given player. So the players cannot tell if the input is from P_1 or P_2 , so any player that gets a non-zero input must assume they are in case P_1 if they want to solve the communication problem with sufficiently high constant probability, and send $\Omega(1/\epsilon^2)$ bits of communication. This results in $\Omega(m/\epsilon^2)$ total communication when the input is from P_2 , which is the desired lower bound.

B $\Omega(1/\epsilon^2)$ Lower Bound for additive approximation of Entropy in Insertion-Only Streams

We now prove the $\Omega(1/\epsilon^2)$ -bits of space lower bound for any streaming algorithm that produces an approximation \tilde{H} such that $|\tilde{H} - H| < \epsilon$ with probability $3/4$. Here H is the empirical entropy of the stream vector \mathcal{X} , namely $H = H(\mathcal{X}) = -\sum_{i=1}^n \frac{|x_i|}{F_1} \log \frac{|x_i|}{F_1}$. To prove the lower bound, we must first introduce the GAP-HAMDIST problem. Here, there are two players, Alice and Bob. Alice is given $x \in \{0, 1\}^t$ and Bob receives $y \in \{0, 1\}^t$. Let $\Delta(x, y) = |\{i \mid x_i \neq y_i\}|$ be the Hamming distance between two binary strings x, y . Bob is promised that either $\Delta(x, y) \leq t/2 - \sqrt{t}$ (NO instance) or $\Delta(x, y) \geq t/2 + \sqrt{t}$ (YES instance), and must decide which holds. Alice must send a single message to Bob, from which he must decide which case the inputs are in. It is known that any protocol which solves this problem with constant probability must send $\Omega(t)$ -bits in the worst case (i.e. the maximum number of bits sent, taken over all inputs and random bits used by the protocol).

► **Proposition 30** ([58, 39]). *Any protocol which solves the GAP-HAMDIST problem with probability at least $2/3$ must send $\Omega(t)$ -bits of communication in the worst case.*

We remark that while a $\Omega(1/\epsilon^2)$ lower bound is known for *multiplicative-approximation* of the entropy, to the best of our knowledge there is no similar lower bound written in the literature for additive approximation.

► **Theorem 31.** *Any algorithm for ϵ -additive approximation of the entropy H of a stream, in the insertion-only model, which succeeds with probability at least $2/3$, requires space $\Omega(\epsilon^{-2})$*

Proof. Given a $x, y \in \{0, 1\}^t$ instance of GAP-HAMDIST, for $t = \Theta(1/\epsilon^2)$, Alice constructs a stream on $2t$ items. Let x' be the result of flipping all the bits of x , and let $x'' = x \circ 0^t + 0^t \circ x' \in \{0, 1\}^{2t}$ where \circ denotes concatenation. Define y', y'' similarly. Alice then inserts updates so that the stream vector $\mathcal{X} = x''$, and then sends the state of the streaming algorithm to Bob, who inserts his vector, so that now $\mathcal{X} = x'' + y''$. We demonstrate that the entropy of H differs by an additive term of at least ϵ between the two cases. In all cases case, we have

$$\begin{aligned} H &= \frac{t - \Delta}{t} \log(t) + \frac{\Delta}{2t} \log(2t) \\ &= \log(t) + \Delta \left(\frac{2 \log(t) - \log 2t}{2t} \right) \end{aligned} \tag{1}$$

We can assume $t \geq 4$, and then $2\log(t) - \log(2t) = C > 0$, where C is some fixed value known to both players that is bounded away from 0. So as Δ increases, the entropy increases. Thus in a YES instance, the entropy is at least

$$\begin{aligned} H &\geq \log(t) + (t/2 + \sqrt{t}) \frac{C}{2t} \\ &= \log(t) + (1/4 + 1/2\sqrt{t})C \\ &= \log(t) + C/4 + \Theta(\epsilon) \end{aligned} \tag{2}$$

In addition, in the NO instance, the entropy is maximized when $\Delta = t/2 - \sqrt{t}$. so we have

$$\begin{aligned} H &\leq \log(t) + (t/2 - \sqrt{t}) \frac{C}{2t} \\ &= \log(t) + C/4 - \Theta(\epsilon) \end{aligned} \tag{3}$$

Therefore, the entropy differs between YES and NO instances by at least an additive $\Theta(\epsilon)$ term. After sufficient rescaling of ϵ by a constant, we obtain our $\Omega(t) = \Omega(1/\epsilon^2)$ lower bound for additive entropy estimation via the linear lower bound for GAP-HAMDIST from Proposition 30. \blacktriangleleft

The Complexity of Partial Function Extension for Coverage Functions

Abstract

Coverage functions are an important subclass of submodular functions, finding applications in machine learning, game theory, social networks, and facility location. We study the complexity of partial function extension to coverage functions. That is, given a partial function consisting of a family of subsets of $[m]$ and a value at each point, does there exist a coverage function defined on all subsets of $[m]$ that extends this partial function? Partial function extension is previously studied for other function classes, including boolean functions and convex functions, and is useful in many fields, such as obtaining bounds on learning these function classes.

We show that determining extendibility of a partial function to a coverage function is NP-complete, establishing in the process that there is a polynomial-sized certificate of extendibility. The hardness also gives us a lower bound for learning coverage functions. We then study two natural notions of approximate extension, to account for errors in the data set. The two notions correspond roughly to multiplicative point-wise approximation and additive L_1 approximation. We show upper and lower bounds for both notions of approximation. In the second case we obtain nearly tight bounds.

1 Introduction

When can a *partial function* – given as a set of points from a domain, and a value at each point – be extended to a *total function* on the domain, that lies in some particular class of functions? This is the basic question of *partial function extension*, and is studied both independently (such as in convex analysis) and as a recurring subproblem in many areas in combinatorial optimization, including computational learning and property testing.

In this paper we study the computational complexity of partial function extension for *coverage functions*. Coverage functions are a natural and widely-studied subclass of submodular functions that find many applications, including in machine learning [18], auctions [6, 19], influence maximization [8, 22], and plant location [11]. For a natural number m , let $[m]$ denote the set $\{1, 2, \dots, m\}$. A set function $f : 2^{[m]} \rightarrow \mathbb{R}_+$ is a coverage function if there exists a universe U of elements with non-negative weights and m sets $A_1, \dots, A_m \subseteq U$ such that for all $S \subseteq [m]$, $f(S)$ is the total weight of elements in $\cup_{j \in S} A_j$. A coverage function is succinct if $|U|$ is at most a fixed polynomial in m .

The complexity of partial function extension has been studied earlier for other function classes, with a number of important applications shown. For boolean functions, Boros et al. present complexity results for extension to a large number of boolean function classes, as well as results on approximate extension [9]. Pitt and Valiant show a direct relation between the complexity of partial function extension problem and proper PAC-learning. Informally, a class \mathcal{F} of (boolean) functions on $2^{[m]}$ is said to be properly PAC-learnable if for any distribution μ on $2^{[m]}$ and any small enough $\epsilon > 0$, any function $f^* \in \mathcal{F}$ can be learned by a polynomial-time algorithm that returns a function $f \in \mathcal{F}$ with a polynomial number of samples that differs from f^* with probability at most ϵ . Pitt and Valiant show that if partial function extension for a class \mathcal{F} of functions is NP-hard, then the class \mathcal{F} cannot be PAC-learned unless $\text{NP} = \text{RP}$ [21].¹ They show computational lower bounds for various classes of boolean functions, thereby obtaining lower bounds on the complexity for learning these classes. In this paper, we show lower bounds on partial function extension for coverage functions, which by this relation give lower bounds on proper PAC learning as well. In separate work, we present results on the computational complexity of partial function extension for submodular, subadditive, and convex functions, and show further connections with learning and property testing [5].

Characterizing partial functions extendible to convex functions is widely studied in convex analysis. Here a partial function is given defined on a non-convex set of points, and is required to be extended to a convex function on the convex hull or some other convex domain. Characterizations for extendible partial functions are given in various papers, such as [12, 26]. This finds many applications, including mechanism design [14], decision making under risk [20], and quantum computation [25].

Another example of the ubiquity of partial function extension is in property testing. Given oracle access to a function f , the goal of property testing is to determine by querying the oracle if the function f lies in some class \mathcal{F} of functions of interest, or is far from it, i.e., differs from any function in \mathcal{F} at a large number of points. Partial function extension is a natural step in property testing, since at any time the query algorithm has a partial function consisting of the points queried and the values at those points. If at any time the partial function thus obtained is not extendible to a function in \mathcal{F} , the algorithm should reject, and should accept otherwise. Partial function extension is used to give both upper and lower bounds for property testing [5, 23]. Partial function extension is thus a basic problem that finds application in a wide variety of different fields.

Our Contribution

Our input is a partial function $H = \{(T_1, f_1), \dots, (T_n, f_n)\}$ with $T_i \subseteq [m]$ and $f_i \geq 0$, and the goal is to determine if there exists a coverage function $f : 2^{[m]} \rightarrow \mathbb{R}_{\geq 0}$ such that $f(T_i) = f_i$ for all $i \in [n]$. This is the Coverage Extension problem. Throughout the paper we use $[m]$ for the ground set, n for the number of defined sets in the partial function, and \mathcal{D} for the set of defined sets $\{T_1, \dots, T_n\}$. We also use $d = \max_{i \in [n]} |T_i|$ to denote the maximum size of sets in \mathcal{D} , and $F := \sum_{i \in [n]} f_i$.

Our first result shows that Coverage Extension is NP-hard. Interestingly, we show if there exists a coverage function extending the given partial function then there is an extension by a coverage function for which the size of the universe $|U|$ is at most n . This shows that Coverage

¹ Randomized Polynomial (RP) is the class of problems for which a randomized algorithm runs in polynomial time, always answers correctly if the input is a “no” instance, and answers correctly with probability at least $1/2$ if the input is a “yes” instance.

Extension is in NP. In contrast, it is known that minimal certificates for non-extendibility may be of exponential size [10]. Also, unlike property testing, this shows that Coverage Extension does not become easier when restricted to succinct coverage functions.

► **Theorem 1.** *Coverage Extension is NP-complete.*

For the hardness, we show a reduction from fractional graph colouring, a problem studied in fractional graph theory. Our hardness for extension also shows the following result for proper learning of succinct coverage functions.

► **Theorem 2.** *Unless $RP = NP$, the class of succinct coverage functions cannot be PAC-learned (i.e., cannot be PMAC-learned with approximation factor $\alpha = 1$).*

These are the first hardness results for learning coverage functions based on standard complexity assumptions. Earlier results showed a reduction from learning disjoint DNF formulas to learning coverage functions [13], however as far as we are aware, there are no known lower bounds for learning disjoint DNF formulas. The following theorem is shown in the appendix.

Given the hardness result for Coverage Extension, we study approximation algorithms for two natural optimization versions of the extension problem. In both of these problems, the goal is to determine the distance between the given partial function and the class of coverage functions. Based on the notion of the distance, we study the following two problems.

In *Coverage Approximate Extension*, the goal is to determine minimum value of $\alpha \geq 1$ such that there exists a coverage function $f : 2^{[m]} \rightarrow \mathbb{R}_{\geq 0}$ satisfying $f_i \leq f(T_i) \leq \alpha f_i$ for all $i \in [n]$.

In *Coverage Norm Extension*, the goal is to determine the minimum L_1 distance from a coverage function, i.e., minimize $\sum_{i \in [n]} |\epsilon_i|$ where $\epsilon_i = f(T_i) - f_i$ for all $i \in [n]$ for some coverage function f .

The two notions of approximation we study thus roughly correspond to the two prevalent notions of learning real-valued functions. Coverage Approximate Extension corresponds to PMAC learning, where we look for point-wise multiplicative approximations. Coverage Norm Extension corresponds to minimizing the L_1 distance in PAC learning.

Throughout this paper, the minimum value of α in Coverage Approximate Extension will be denoted by α^* and minimum value of $\sum_{i \in [n]} |\epsilon_i|$ in Norm Extension will be denoted by OPT . As both of these problems are generalisations of Coverage Extension, they are NP-hard. We give upper and lower bounds for approximation for both of these problem.

► **Theorem 3.** *There is a $(\min\{d, m^{2/3}\} \log d)$ -approximation algorithm for Coverage Approximate Extension. If d is a constant then there is a d -approximation algorithm.*

In Coverage Norm Extension, $OPT = 0$ iff the partial function is extendible and hence no multiplicative approximation is possible for OPT unless $P = NP$ (because of Theorem 1). We hence consider additive approximations for Coverage Norm Extension. An algorithm for Coverage Norm Extension is called an α -approximation algorithm if for all instances (partial functions), the value β returned by the algorithm satisfies $OPT \leq \beta \leq OPT + \alpha$. We show nearly tight upper and lower bounds on the hardness of approximation. As defined before $F = \sum_{i \in [n]} f_i$. Note that an F -approximation algorithm is trivial, since the function $f = 0$ is coverage and satisfies $\sum_{i \in [n]} |f(T_i) - f_i| \leq F$.

► **Theorem 4.** *There is a $(1 - 1/d)F$ -approximation algorithm for Coverage Norm Extension. Moreover, a coverage function f can be efficiently computed such that $\sum_{i \in [n]} |f(T_i) - f_i| \leq OPT + (1 - 1/d)F$.*

► **Theorem 5.** *It is NP-hard to approximate Coverage Norm Extension by a factor $\alpha = 2^{\text{poly}(n,m)} F^\delta$ for any fixed $0 \leq \delta < 1$. This holds even when $d = 2$.*

Our lower bound is roughly based on the equivalence of *validity* and *membership*, where given a convex, compact set K , the validity problem is to determine the optimal value of $c^T x$ given a vector c over all $x \in K$, while the membership problem seeks to determine if a given point x is in K or not. The equivalence of optimization and separation is a widely used tool. The reduction from optimization to separation is particularly useful for, e.g., solving linear programs with exponential constraints. Our work is unusual in both the use of validity and membership rather than optimization and separation, and because of the direction – we use the equivalence to show hardness of the validity problem. We hope that our techniques may be useful in future work as well.

Related Work

We focus here on work related to partial function extension and coverage functions. In a separate paper, we study partial function extension to submodular, subadditive, and convex functions, showing results on the complexity as well as applications to learning and property testing [5]. Previously, Seshadri and Vondrak [23] introduce the problem of extending partial functions to a submodular function, and note its usefulness in analyzing property testing algorithms. For submodular functions, partial function extension is also useful in optimization [24]. The problem of extending a partial function to a convex function is also studied in convex analysis [26, 12]. As mentioned earlier, both characterizing extendible partial functions, and the complexity of partial function extension has been studied for large classes of Boolean functions [9, 21].

Chakrabarty and Huang study property testing for coverage functions [10]. Here, the goal is to determine whether the input function (given by an oracle) is coverage or far from coverage by querying an oracle, where distance is measured by the number of points at which the function must be changed for it to be coverage. They show that succinct coverage functions can be reconstructed with a polynomial number of queries and hence can be efficiently tested. However, they conjecture that testing general coverage functions requires $2^{\Omega(m)}$ queries, and prove this lower bound under a different notion of distance. They present a particular characterization of coverage functions in terms of the W -transform that we use as well.

There has also been interest in sketching and learning coverage functions. Badanidiyuru et al. [1] showed that coverage functions admit a $(1 + \epsilon)$ -sketch, i.e., given any coverage function, there exists a succinct coverage function (of size polynomial in m and $1/\epsilon$) that approximates the original function within $(1 + \epsilon)$ factor with high probability. Feldman and Kothari [13] gave a fully polynomial time algorithm for learning succinct coverage functions in the PMAC model if the distribution is uniform. However, if the distribution is unknown, they show learning coverage functions is as hard as learning polynomial size DNF formulas for which no efficient algorithm is known.

Balkanski et al [3] study whether coverage functions can be optimized from samples. They consider a scenario where random samples $\{(S_i, f(S_i))\}$ of an unknown coverage function f are provided and ask if it is possible to optimize f under a cardinality constraint, i.e., solve $\max_{S: |S| \leq k} f(S)$. They prove a negative result: no algorithm can achieve approximation ratio better than $2^{\Omega(\sqrt{\log m})}$ with a polynomial number of sampled points.

2 Preliminaries

As earlier, for $m \in \mathbb{Z}_+$, define $[m] := \{1, 2, \dots, m\}$. A set function f over a ground set $[m]$ is a coverage function if there exists a universe U of elements with non-negative weights and m sets $A_1, \dots, A_m \subseteq U$, such that for all $S \subseteq [m]$, $f(S)$ is the total weight of elements in $\cup_{j \in S} A_j$. A coverage function is *succinct* if $|U|$ is at most a fixed polynomial in m .

Chakrabarty and Huang [10] characterize coverage functions in terms of their W -transform, which we use as well. For a set function $f : 2^{[m]} \rightarrow \mathbb{R}_{\geq 0}$, the W -transform $w : 2^{[m]} \setminus \emptyset \rightarrow \mathbb{R}$ is defined as

$$\forall S \in 2^{[m]} \setminus \emptyset, \quad w(S) = \sum_{T: S \cup T = [m]} (-1)^{|S \cap T|+1} f(T). \quad (1)$$

The set $\{w(S) | S \in 2^{[m]} \setminus \emptyset\}$ is called the set of W -coefficients of f . We can also recover the function f from its W -coefficients.

$$\forall T \subseteq [m], \quad f(T) = \sum_{S \subseteq [m]: S \cap T \neq \emptyset} w(S). \quad (2)$$

If f is a coverage function induced by the universe U and sets A_1, \dots, A_m , then the W -transform $w(S)$ is precisely the weight of the set $\{(\cap_{i \in S} A_i) \setminus \cup_{j \notin S} A_j\}$, and is hence non-negative. The converse is also true. The set $\{S | w(S) > 0\}$ is called the *support* of the coverage function, and the elements are exactly the elements of the universe U .

► **Theorem 6** ([10]). *A set function $f : 2^{[m]} \rightarrow \mathbb{R}_{\geq 0}$ is a coverage function iff all of its W -coefficients are non-negative.*

From Theorem 6, given a partial function H , there exists a coverage function f satisfying $f(T_i) = f_i$ for all $i \in [n]$ iff the following linear program is feasible, where the variables are the W -coefficients $w(S)$ for all $S \in 2^{[m]} \setminus \emptyset$.

$$\text{Extension-P:} \quad \sum_{S: S \cap T_i \neq \emptyset} w(S) = f_i \quad \forall i \in [n], \quad w(S) \geq 0 \quad \forall S \in 2^{[m]} \setminus \emptyset.$$

All missing proofs are in the appendix.

3 Coverage Extension and PAC-Learning

Our first observation is that there is a polynomial-sized certificate of extendibility to a coverage function. This is obtained by observing that at a vertex of the feasible set in Extension-P, at most n of the variables are non-zero. It is interesting to compare this with Chakrabarty and Huang [10], who give an example to show that minimal certificates of nonextendibility may be of exponential size.

► **Proposition 7.** *If a partial function is extendible to a coverage function, then it is also extendible to a coverage function with support size $\leq n$. Hence, Coverage Extension is in NP.*

We show the NP-hardness of Coverage Extension by reduction from *fractional chromatic number*, defined as follows. Given a graph $G = (V, E)$, a set $I \subseteq V$ is called an *independent set* if no two vertices in I are adjacent. Let \mathcal{I} be the set of all independent sets. The fractional chromatic number $\chi^*(G)$ of a graph G is the optimal value of the following linear program.

$$\chi^*(G) := \left\{ \min \sum_{I \in \mathcal{I}} x_I : \sum_{I \in \mathcal{I}: v \in I} x_I \geq 1 \quad \forall v \in V(G), 0 \leq x_I \leq 1 \quad \forall I \in \mathcal{I} \right\}$$

Note that if $x_I \in \{0, 1\}$ then the optimal value is just the chromatic number of the graph.²

► **Theorem 8** ([15]). *For graph $G = (V, E)$, there exist nonnegative weights $\{x_I\}_{I \in \mathcal{I}}$ on independent sets such that $\chi^*(G) = \sum_{I \in \mathcal{I}} x_I$ and $\sum_{I \in \mathcal{I}: v \in I} x_I = 1 \quad \forall v \in V$.*

► **Corollary 9**. *For graph $G = (V, E)$ and for any value of t such that $\chi^*(G) \leq t \leq |V|$, there exist nonnegative weights $\{z_I\}_{I \in \mathcal{I}}$ on independent sets such that $\sum_{I \in \mathcal{I}} z_I = t$ and $\sum_{I \in \mathcal{I}: v \in I} z_I = 1 \quad \forall v \in V$.*

► **Theorem 10** ([17]). *Given graph $G = (V, E)$ and $1 \leq k \leq |V|$, it is NP-hard to determine if $\chi^*(G) \leq k$.*

We now show the NP-hardness of Coverage Extension.

Proof of Theorem 1. Since membership in NP was shown earlier, we give the reduction from fractional chromatic number. The input is a graph $G = (V, E)$ and $1 \leq k \leq |V|$.

We identify $[n']$ with the set of vertices V , and therefore $E(G) \subseteq \{\{i, j\} \mid i, j \in [n']\}$, and any set $S \subseteq [n']$ can be viewed as a set of vertices. The partial function construction is as follows. The ground set is $[n']$ and therefore $m = n'$. The partial function is defined at all vertices, all edges, and the set consisting of all vertices. Hence \mathcal{D} , the set of defined points for the partial function, is $\{\{i\} \mid i \in [n']\} \cup E(G) \cup \{[n']\}$ and $|\mathcal{D}| = n' + |E(G)| + 1$. The value of the partial function h at these defined sets is given by

$$h(S) = \begin{cases} 1 & \text{if } S = \{i\}, i \in [n'], \\ 2 & \text{if } S \in E(G), \\ k & \text{if } S = \{[n']\}. \end{cases}$$

Intuitively, the function $h(S)$ can be interpreted as the (fractional) number of colours used to colour the subset S .

We claim that $\chi^*(G) \leq k$ iff the above partial function is extendible. Suppose $\chi^*(G) \leq k$. Therefore by Corollary 9, there exist nonnegative weights $\{x_I\}_{I \in \mathcal{I}}$ such that $\sum_{I \in \mathcal{I}} x_I = k$ and $\sum_{I \in \mathcal{I}: v \in I} x_I = 1 \quad \forall v \in V(G)$. For all $S \in 2^{[m]} \setminus \emptyset$, define the function $w(S)$ as x_S if $S \in \mathcal{I}$ and 0 otherwise. Since $w(S) \geq 0$, this defines the W -transform for a coverage function g . We have, for any $i \in [n']$,

$$g(\{i\}) = \sum_{S: S \cap \{i\} \neq \emptyset} w(S) = \sum_{I \in \mathcal{I}: i \in I} x_I = 1,$$

for any $\{i, j\} \in E(G)$,

$$g(\{i, j\}) = \sum_{S: S \cap \{i, j\} \neq \emptyset} w(S) = \sum_{I \in \mathcal{I}: i \in I} x_I + \sum_{I \in \mathcal{I}: j \in I} x_I = 2$$

as no independent set I can contain both i and j ; and finally $g(\{[n']\}) = \sum_{S: S \cap \{[n']\} \neq \emptyset} w(S) = \sum_{I \in \mathcal{I}} x_I = k$. Therefore g is an extension of the above partial function h .

² The chromatic number of a graph is the minimum number of colours required to colour the vertices so that no two adjacent vertices get the same colour.

Now suppose there is an extension, i.e., there exists $w(S) \geq 0$ for all $S \in 2^{[m]} \setminus \emptyset$ such that for any $i \in [n']$, $\sum_{S: S \cap \{i\} \neq \emptyset} w(S) = 1$; for any $\{i, j\} \in E(G)$, $\sum_{S: S \cap \{i, j\} \neq \emptyset} w(S) = 2$; and finally $\sum_{S: S \cap [n'] \neq \emptyset} w(S) = k$. For any $\{i, j\} \in E(G)$, we have

$$\sum_{S: S \cap \{i, j\} \neq \emptyset} w(S) = \sum_{S: S \cap \{i\} \neq \emptyset} w(S) + \sum_{S: S \cap \{j\} \neq \emptyset} w(S) - \sum_{S: S \supseteq \{i, j\}} w(S).$$

Therefore, $\sum_{S: S \supseteq \{i, j\}} w(S) = 0$, i.e., if $w(S) > 0$ then S must be an independent set. It now follows that $\chi^*(G) \leq \sum_{S: S \cap [n'] \neq \emptyset} w(S) = k$. \blacktriangleleft

Proper PAC-learning of Coverage functions

We now prove Theorem 2. We first recall the definition of proper PAC-learning.

► **Definition 11** ([2]). *An algorithm \mathcal{A} properly PAC-learns a family of functions \mathcal{F} , if for any distribution μ (on $2^{[m]}$) and any target function $f^* \in \mathcal{F}$, and for any sufficiently small $\epsilon, \delta > 0$:*

1. \mathcal{A} takes the sequence $\{(S_i, f^*(S_i))\}_{1 \leq i \leq l}$ as input where l is $\text{poly}(m, 1/\delta, 1/\epsilon)$ and the sequence $\{S_i\}_{1 \leq i \leq l}$ is drawn i.i.d. from the distribution μ ,
2. \mathcal{A} runs in $\text{poly}(m, 1/\delta, 1/\epsilon)$ time, and
3. \mathcal{A} returns a function $f : 2^{[m]} \rightarrow \mathbb{R} \in \mathcal{F}$ such that

$$\Pr_{S_1, \dots, S_l \sim \mu} [\Pr_{S \sim \mu} [f(S) = f^*(S)] \geq 1 - \epsilon] \geq 1 - \delta$$

We use the reconstruction algorithm for coverage functions given by Chakrabarty and Huang [10] in our proof. Given a coverage function f as an input, this reconstruction algorithm terminates in $O(ms)$ steps where s is the support size of f , i.e., the number of non-zero W -coefficients of f , and returns these non-zero W -coefficients.

Recall the reduction from fractional chromatic number to Coverage Extension (Theorem 1). Given an instance of fractional chromatic number (graph $G = (V, E)$ and rational k' with $|V| = n'$), the instance of Coverage Extension is a set of defined points $\mathcal{D} = \{\{i\} | i \in [n']\} \cup E(G) \cup \{[n']\}$ and a function h on \mathcal{D} . Let $k = |\mathcal{D}| = |V| + |E| + 1$. From Theorem 1 and Proposition 7, $\chi^*(G) \leq k'$ iff h is extendible to a coverage function with support size at most k .

Let \mathcal{F} be a family of coverage functions with support size at most k . Let $\epsilon = 1/k^3$ (and hence $\epsilon < 1/|\mathcal{D}|$) and μ be a uniform distribution over $\{(S, h(S)) | S \in \mathcal{D}\}$. Now suppose a (randomized) algorithm A properly PAC-learns \mathcal{F} . We will show that in this case, we can determine efficiently if the partial function is extendible to a coverage function, and hence $\text{RP} = \text{NP}$.

Suppose the algorithm A returns a function g . If the partial function is extendible then there exists a function in \mathcal{F} that has the same value on samples seen by A . Therefore, if the partial function is extendible then $g(S)$ must be equal to $h(S)$ for all $S \in \mathcal{D}$ (since $\epsilon < 1/|\mathcal{D}|$ and A must satisfy $\Pr_{S \sim \mathcal{D}^*} [f(S) = f^*(S)] \geq 1 - \epsilon$). We run the reconstruction algorithm on input g . If the partial function is extendible then g must be in \mathcal{F} and hence the reconstruction algorithm must terminate in $O(mk)$ steps. Further, if $\{w(S)\}_{S \in \mathcal{S}}$ is the output of the algorithm then (i) $w(S) > 0$ for all $S \in \mathcal{S}$, (ii) $|\mathcal{S}| \leq k$ (iii) the coverage function f' given by the W -coefficients $w'(S) = w(S)$ if $S \in \mathcal{S}$ and 0 otherwise is an extension of the partial function h . Condition (iii) should hold because f' must be the same as g which we have shown earlier is an extension of h .

The converse is also true – if the reconstruction algorithm terminates and (i), (ii), (iii) hold then clearly h is extendible (by f'). Since all the steps require polynomial time to check, we can efficiently determine if the partial function is extendible.

4 Coverage Approximate Extension

We now build the framework for Theorem 3. We start with the following lemma.

► **Lemma 12.** *Given a partial function H and $\alpha \geq 1$, there is no coverage function f satisfying $f_i \leq f(T_i) \leq \alpha f_i$ for all $i \in [n]$ iff the following program, with variables l_i for all $i \in [n]$ is feasible:*

$$-\alpha \sum_{i:l_i < 0} f_i l_i < \sum_{i:l_i > 0} f_i l_i \quad (3)$$

$$\sum_{i:S \cap T_i \neq \emptyset} l_i \leq 0 \quad \forall S \subseteq [m] \quad (4)$$

Thus the optimal approximation ratio α^* is the minimum value of α for which (3) and (4) are not feasible together.

A natural representation of the partial function $H = \{(T_1, f_1), \dots, (T_n, f_n)\}$ is as a weighted bipartite graph $H = (A \cup [m], E)$ with $|A| = n$, and an edge between $a_i \in A$ and $j \in [m]$ if the set T_i contains element $j \in [m]$. Each vertex $a_i \in A$ also has weight f_i . Then $d = \max_i |T_i|$ is the maximum degree of any vertex in A . For the remainder of this section, we will use this representation of partial functions.

We use the following notation given a bipartite graph $H = (A \cup [m], E)$. For any $S \subseteq [m]$, let $N(S) = \{v \in A : (v, j) \in E \text{ for some } j \in S\}$ be the set of neighbours of set S . Similarly for set $R \subseteq A$, $N(R) = \{j \in [m] : (v, j) \in E \text{ for some } v \in R\}$ be the set of neighbours of set R . For any vertex v in H , we use $N(v)$ for $N(\{v\})$. In this bipartite graph representation, the inequality (4) is equivalent to $\sum_{i \in N(S)} l_i \leq 0$ for all $S \subseteq [m]$.

We now define a parameter κ called the *replacement ratio* for a partial function H .

► **Definition 13.** *Let $H = (A \cup [m], E)$ be a bipartite graph with weights f_v on each $v \in A$. For $v \in A$, let $\mathcal{F}_v = \{R \subseteq A \setminus \{v\} \mid N(R) \supseteq N(v)\}$ be the set of all subsets of $A \setminus \{v\}$ that cover all the neighbours of v . We call each $R \in \mathcal{F}_v$ a replacement for v . The replacement ratio κ is then the minimum of $\frac{\sum_{w \in R} f_w}{f_v}$ over all vertices $v \in A$ and replacements $R \in \mathcal{F}_v$.*

The proof of the upper bound in Theorem 3 will follow from the bounds on α^* shown in Lemma 14, 16 and 18.

► **Lemma 14.** *For any partial function H , $\alpha^* \geq \frac{1}{\kappa}$.*

Proof. By definition of κ , there exists a vertex $v \in A$ and a replacement R for v such that $\sum_{w \in R} f_w = c f_v$. Note that setting $l_w = -1 \quad \forall w \in R$, $l_v = 1$ and all other l_w 's to be zero results in feasibility of the inequalities $\sum_{w \in N(S)} l_w \leq 0$ for all $S \in 2^{[m]} \setminus \emptyset$. From the definition of α^* and Lemma 12, $\alpha^* \sum_{w \in R} f_w \geq f_v$, and hence $\alpha^* \geq 1/\kappa$. ◀

Let $\beta = \frac{\min\{d, m^{2/3}\}}{\kappa}$. Given values $\{l_v\}_{v \in A}$ on the vertices in A such that $\sum_{v \in N(S)} l_v \leq 0$ for all $S \subseteq [m]$, we will show that $\beta \sum_{v:l_v < 0} f_v l_v \geq \sum_{v:l_v > 0} f_v l_v$ and hence $\alpha^* \leq \beta$. If $l_v = 0$ for any vertex, we simply ignore such a vertex, since it does not affect either (4) or (3).

By scaling, we can assume that $l_v \in \mathbb{Z}$ for all $v \in A$. At some point, we will use Hall's theorem to show a perfect matching. To simplify exposition, we replace each $v \in A$ with $|l_v|$ identical copies, each of which is adjacent to the same vertices as v . Each such new vertex v' has $l_{v'} = 1$ if $l_v > 0$ and $l_{v'} = -1$ if $l_v < 0$, and $f_{v'} = f_v$. Let the new bipartite graph be $H' = (A' \cup [m], E')$. It is easy to check that in the new bipartite graph, the degree of vertices in A' and the values κ , $\sum_{v \in A': l_v > 0} f_v l_v$, $\sum_{v \in A': l_v < 0} f_v l_v$ and $\sum_{v \in N(S)} l_v$ remain unchanged for all $S \subseteq [m]$.

Let $\mathcal{N} = \{v \in A' | l_v = -1\}$ and $\mathcal{P} = \{v \in A' | l_v = 1\}$, and let E^- be the set of edges with one end-point in \mathcal{N} , while E^+ are the edges with one end-point in \mathcal{P} . For any $S \subseteq [m]$, let $N^-(S) = N(S) \cap \mathcal{N}$ and $N^+(S) = N(S) \cap \mathcal{P}$ (so $N(S) = N^+(S) \cup N^-(S)$). Finally, define $E^+(S)$ ($E^-(S)$) as the set of edges with one end-point in S and the other end-point in \mathcal{P} (\mathcal{N}). If $S = \{j\}$, we abuse notation slightly and use $N^-(j)$, $N^+(j)$, $E^-(j)$ and $E^+(j)$. Note that $|N^-(S)| \geq |N^+(S)|$ for all $S \subseteq [m]$ in H' , since in H , $\sum_{v \in N(S)} l_v \leq 0$ for all $S \subseteq [m]$. Our goal is to show $\beta \sum_{v \in \mathcal{N}} f_v \geq \sum_{v \in \mathcal{P}} f_v$.

► **Lemma 15.** *Suppose for some $\beta' \geq 1$, $\beta' |N^-(S)| \geq \sum_{j \in S} |N^+(j)|$ for all $S \subseteq [m]$. Then for each vertex $v \in \mathcal{P}$, there exists a replacement $F_v \subseteq \mathcal{N}$ such that each vertex in \mathcal{N} is contained in F_v for at most β' vertices $v \in \mathcal{P}$. Hence, $\beta' \sum_{v \in \mathcal{N}} f_v \geq \kappa \sum_{v \in \mathcal{P}} f_v$ and so $\alpha^* \leq \frac{\beta'}{\kappa}$.*

Proof. By Hall's theorem, there exists a set of edges $M \subseteq E^-$ such that (i) the degree in M of each vertex $j \in [m]$ is at least $|N^+(j)|$, and (ii) the degree in M of each vertex $v \in \mathcal{N}$ is at most β' . Because of (i), for each $j \in [m]$ there is an injection h_j from edges in $E^+(j)$ to edges in $E^-(j) \cap M$, i.e., each edge in $E^+(j)$ maps to a distinct edge in $E^-(j) \cap M$. Now for a vertex $v \in \mathcal{P}$, consider a neighbouring vertex $j \in N(v)$. Each such edge (v, j) is in $E^+(j)$, and is hence mapped by h_j to an edge in $E^-(j) \cap M$. Let F_v be the end-points in \mathcal{N} of these mapped edges. That is, $w \in F_v$ iff there exists $j \in N(v)$ such that $(w, j) = h_j(v, j)$. Then F_v is a replacement for v , and hence, $\sum_{w \in F_v} f_w \geq \kappa f_v$. Further, because of (ii), and since each h_j is an injection, each vertex in \mathcal{N} is contained in F_v for at most β' vertices $v \in \mathcal{P}$. Then summing the inequality $\sum_{w \in F_v} f_w \geq \kappa f_v$ over all $v \in \mathcal{P}$, we get that $\beta' \sum_{v \in \mathcal{N}} f_v \geq \kappa \sum_{v \in \mathcal{P}} f_v$ as required. ◀

► **Lemma 16.** *For any partial function H , $\alpha^* \leq \frac{d}{\kappa}$.*

Proof. Fix $S \subseteq [m]$. Since $|N^-(j)| \geq |N^+(j)|$ for all $j \in [m]$, $\sum_{j \in S} |N^-(j)| \geq \sum_{j \in S} |N^+(j)|$, and since d is the maximum degree of any vertex in A' , $d|N^-(S)| \geq \sum_{j \in S} |N^-(j)|$. The proof follows from Lemma 15. ◀

If we can show $m^{2/3}|N^-(S)| \geq \sum_{j \in S} |N^+(j)|$ for all $S \subseteq [m]$ then by Lemma 15, $\alpha^* \leq \frac{m^{2/3}}{\kappa}$. Unfortunately this may not be true. Let $\mathcal{N} = \{v_1\}$, $\mathcal{P} = \{v_2\}$, $E^- = \{(v_1, j) | j \in [m]\}$ and $E^+ = \{(v_2, j) | j \in [m]\}$. Note that $\sum_{j \in [m]} |N^+(j)| = m$ whereas $|N^-([m])| = 1$. Notice that in this bad example, the bipartite graph contains a 4-cycle v_1, j_1, v_2, j_2, v_1 where $v_1 \in \mathcal{N}$ and $v_2 \in \mathcal{P}$. We now define a subgraph called a *diamond* which generalises such a 4-cycle. A diamond (v_p, v_n, J) of size k is a subgraph of H' where $v_p \in \mathcal{P}$, $v_n \in \mathcal{N}$, $J \subseteq [m]$ ($|J| = k$) such that for all $j \in J$, both (v_p, j) and (v_n, j) are contained in E' . Note that a 4-cycle is a diamond of size two (and the bad example considered above is a diamond of size m).

Let $k_{max} = m^a$ ($0 \leq a \leq 1$) be the maximum size of any diamond in H' .

► **Lemma 17.** *For all $S \subseteq [m]$, $m^{\frac{1+a}{2}} |N^-(S)| \geq \sum_{j \in S} |N^+(j)|$, where m^a is the size of the largest diamond in H' .*

Proof. Recall that for all $j \in [m]$, $|N^+(j)| \leq |N^-(j)|$, hence there is an injection h_j from $N^+(j)$ to $N^-(j)$, i.e, h_j maps each vertex in $N^+(j)$ to a unique vertex in $N^-(j)$. Fix $S \subseteq [m]$ and vertex $v \in \mathcal{P}$, and let $S_v := N(v) \cap S$ be the neighbourhood of v in S . We will consider $N^+(S_v)$ and $N^-(S_v)$, the negative and positive neighbourhoods of S_v . Note that since all vertices in S_v are adjacent to $v \in \mathcal{P}$, a vertex in $N^-(S_v)$ is adjacent to at most m^a vertices in S_v , by definition of a . Thus for a vertex $v' \in N^-(S_v)$, there are at most m^a different vertices $j \in S_v$ for which h_j maps a vertex in $N^+(j)$ to v' , and hence $m^a |N^-(S_v)| \geq \sum_{j \in S_v} |N^+(j)|$.

30:10 The Complexity of Partial Function Extension for Coverage Functions

Now if there is a vertex $v \in \mathcal{P}$ such that $m^{\frac{1-a}{2}} \sum_{j \in S_v} |N^+(j)| \geq \sum_{j \in S} |N^+(j)|$ then we are done, since

$$|N^-(S)| \geq |N^-(S_v)| \geq \frac{\sum_{j \in S_v} |N^+(j)|}{m^a} \geq \frac{\sum_{j \in S} |N^+(j)|}{m^{\frac{1+a}{2}}}.$$

So assume that for all $v \in \mathcal{P}$, $\sum_{j \in S_v} |N^+(j)| \leq \frac{\sum_{j \in S} |N^+(j)|}{m^{\frac{1-a}{2}}}$. In this case, note that by reversing the order of summation,

$$\sum_{j \in S} |N^+(j)|^2 = \sum_{j \in S} \sum_{v \in N^+(j)} |N^+(j)| = \sum_{v \in N^+(S)} \sum_{j \in S_v} |N^+(j)| \leq |N^+(S)| \frac{\sum_{j \in S} |N^+(j)|}{m^{\frac{1-a}{2}}}.$$

Therefore, using the above inequality for $|N^+(S)|$,

$$|N^-(S)| \geq |N^+(S)| \geq m^{\frac{1-a}{2}} \frac{\sum_{j \in S} |N^+(j)|^2}{\sum_{j \in S} |N^+(j)|} \geq \frac{m^{\frac{1-a}{2}} \left(\sum_{j \in S} |N^+(j)| \right)^2}{|S| \sum_{j \in S} |N^+(j)|} \geq \frac{\sum_{j \in S} |N^+(j)|}{m^{\frac{1+a}{2}}}$$

as required by the lemma. The third inequality follows from Cauchy-Schwarz. \blacktriangleleft

From Lemmas 15 and 17, if $a \leq 1/3$ then $\alpha^* \leq \frac{m^{2/3}}{\kappa}$. Next we show this is true in general.

► **Lemma 18.** *For any partial function H , $\alpha^* \leq \frac{m^{2/3}}{\kappa}$.*

Proof. If $k_{max} \leq m^{1/3}$ then by Lemma 17 and 15, $\alpha^* \leq \frac{m^{2/3}}{\kappa}$. So we assume $k_{max} > m^{1/3}$. In this case, we pick a diamond (v_p, v_n, J) of size $> m^{1/3}$. We remove, for all $j \in J$, the edges (v_p, j) and (v_n, j) . We repeat the above procedure (in the new graph) until we are left with a bipartite graph where all diamonds are of size at most $m^{1/3}$. Note that if a diamond (v_p, v_n, J) of size k is removed then the degree of v_n decreases by k . Hence, for a fixed vertex v_n , number of removed diamonds is at most $m^{2/3}$ (as at any step we remove diamonds of size at least $m^{1/3}$). It is easy to see that after every step, $|N^-(S)| \geq |N^+(S)|$ (for all $S \in 2^{[m]} \setminus \emptyset$) still holds in the bipartite graph. Let H^* be the bipartite graph at the end (all diamonds of size at most $m^{1/3}$).

Note that we do not remove any vertex in the above procedure. Fix vertex $v \in \mathcal{P}$. By Lemmas 17 and 15 with $a = 1/3$, there exists $F_v \subseteq \mathcal{N}$ such that F_v covers all neighbours of v in H^* and each vertex in \mathcal{N} is contained in F_v for at most $m^{2/3}$ vertices $v \in \mathcal{P}$. Since we have removed edges, F_v may not cover all the neighbours of v in H' . Let $v^1, \dots, v^s \in \mathcal{N}$ be the set of all vertices such that for each $i \in [s]$, a diamond (v, v^i, J^i) was removed in a removal step. Clearly $\{v^1, \dots, v^s\} \cup F_v$ cover all the neighbour of v in H' . Therefore, we have $\sum_{i=1}^s f_{v^i} + \sum_{w \in F_v} f_w \geq \kappa f_v$. Since any v^i ($1 \leq i \leq s$) is a part of at most $m^{2/3}$ removed diamonds and each vertex in \mathcal{N} is contained in F_v for at most $m^{2/3}$ vertices $v \in \mathcal{P}$, summing the above inequality for each $v \in \mathcal{P}$, we get $m^{2/3} \sum_{v \in \mathcal{N}} f_v \geq \kappa \sum_{v \in \mathcal{P}} f_v$ as required. \blacktriangleleft

It follows from Lemmas 14, 16 and 18 that an algorithm that returns $\frac{\min\{d, m^{2/3}\}}{\kappa}$ is a $\min\{d, m^{2/3}\}$ -approximation algorithm. However, computing κ corresponds to solving a general set cover instance, and is NP-hard. This connection however allows us to show the following result.

► **Lemma 19.** *Given a partial function, the replacement ratio κ can be efficiently approximated by κ' such that $\kappa \leq \kappa' \leq \kappa \log d$. If d is a constant, the replacement ratio κ can be determined efficiently.*

This completes the proof of the upper bound in Theorem 3. In the full version of the paper, we show there exist partial functions such that (i) $\alpha^* = 1/\kappa$ for any value of κ , and (ii) with $d = \sqrt{m}$ and $\alpha^* = \Omega(\frac{\sqrt{m}}{\kappa \log m})$. The bounds shown on α^* thus cannot be substantially improved.

5 Coverage Norm Extension

From Theorem 6, the Norm Extension problem can be stated as the convex program Norm-P. It can be equivalently transformed to a linear program whose dual is Norm-D.

$$\begin{array}{l} \text{Norm-P:} \quad \min \sum_{i=1}^n |\epsilon_i| \\ \quad \sum_{S: S \cap T_i \neq \emptyset} w(S) = f_i + \epsilon_i \quad \forall i \in [n] \\ \quad w(S) \geq 0 \quad \forall S \in 2^{[m]} \setminus \emptyset \end{array} \quad \left| \quad \begin{array}{l} \text{Norm-D:} \quad \max \sum_{i=1}^n f_i y_i \\ \quad \sum_{i: S \cap T_i \neq \emptyset} y_i \leq 0 \quad \forall S \in 2^{[m]} \setminus \emptyset \\ \quad -1 \leq y_i \leq 1 \quad \forall i \in [n] \end{array} \right. \quad (5)$$

Both Norm-P and Norm-D are clearly feasible. We use OPT for the optimal value of Norm-P (and Norm-D). As stated earlier, no multiplicative approximation is possible for OPT unless $P = NP$. Therefore, we consider additive approximations for Norm Extension.

An algorithm for Norm Extension is called an α -approximation algorithm if for all instances (partial functions), the value β returned by the algorithm satisfies $OPT \leq \beta \leq OPT + \alpha$. First we prove our upper bound in Theorem 4. Recall that $d = \max_{i \in [n]} |T_i|$ and $F = \sum_{i \in [n]} f_i$. As noted earlier, the function $f(\cdot) = 0$ is trivially an F -approximation algorithm for Norm Extension, since $\sum_{i \in [n]} |f(T_i) - f_i| = F$.

Proof of Theorem 4. Consider the linear programs obtained by restricting Norm-P to variables $w(S)$ for $S \in [m]$, and similarly restricting the constraints (5) in Norm-D to sets $S \in [m]$ only. They are clearly the primal and dual of each other. The optimal values of these modified problems (say OPT^R , w^R and y^R) can be computed in polynomial time. We will show that $OPT \leq OPT^R \leq OPT + (1 - 1/d)F$ for the proof of the theorem. The first inequality is obvious, since OPT^R is the optimal solution to a relaxed (dual) linear program.

For the second inequality, define $y^A = (y_1^A, \dots, y_n^A)$ as the vector such that for all $i \in [n]$, $y_i^A = y_i^R$ if $y_i^R \leq 0$ and y_i^R/d otherwise. Then note that

$$OPT^R = \sum_{i \in [n]} f_i y_i^R = \sum_{i \in [n]} f_i y_i^A + (1 - 1/d) \sum_{i: y_i^R \geq 0} f_i y_i^R \leq \sum_{i \in [n]} f_i y_i^A + (1 - 1/d)F, \quad (7)$$

where the last inequality is because each $y_i^R \leq 1$. We now show that y^A is a feasible solution for Norm-D, and hence $\sum_{i \in [n]} f_i y_i^A \leq OPT$. Together with (7) this completes the proof.

Clearly y^A satisfies the constraints (6). We will show that y^A also satisfies the constraints (5) for all $S \in 2^{[m]} \setminus \emptyset$. Consider any $S \in 2^{[m]} \setminus \emptyset$. Let $P = \{i \in [n] | S \cap T_i \neq \emptyset \text{ and } y_i^R > 0\}$ and $N = \{i \in [n] | S \cap T_i \neq \emptyset \text{ and } y_i^R \leq 0\}$. Thus $P \cup N$ are all sets in \mathcal{D} that have nonempty intersection with S . We have for any $j \in S$ that $\sum_{i: j \in T_i} y_i^R \leq 0$. Summing these inequalities over $j \in S$, we obtain $\sum_{i \in P \cup N} |T_i \cap S| y_i^R \leq 0$. Thus $\sum_{i \in P} y_i^R + d \sum_{i \in N} y_i^R \leq 0$. From the definition of y_i^A , we get $\sum_{i: S \cap T_i \neq \emptyset} y_i^A \leq 0$, as required. \blacktriangleleft

We now prove the lower bound in Theorem 4. We start with an outline of the proof. In a nutshell, the proof shows the following reductions (for brevity, WM stands for Weak Membership and WV for Weak Validity):

30:12 The Complexity of Partial Function Extension for Coverage Functions

$$\text{Densest-Cut} \leq_p \text{Cut WM} \leq_p \text{Span WM} \equiv \text{Coverage WM} \leq_p \text{Coverage WV} \\ \leq_p \text{Norm Extension}.$$

Given a graph $G = (V, E)$ and a positive rational M , the *Densest-Cut* problem asks if there is a cut $S \subset V$ such that $\frac{\delta(S)}{|S||V \setminus S|} > M$. The Densest-Cut problem is known to be NP-hard [7], and ultimately we reduce the Densest-Cut problem to the problem of approximating the optimal value for Norm-P. We formally define the other problems later. However, to show this reduction, we need to utilize the equivalence of optimization (or validity) over a polytope and membership in the polytope. Typically optimization algorithms use the equivalence of optimization and separation to show upper bounds, e.g., that a linear program with an exponential number of constraints can be optimized. Our work is unique in that we use the less-utilized equivalence of validity and membership; and secondly, we use it to show hardness. In fact, since we are looking for hardness of approximation algorithms, our work is complicated further by the need to use *weak* versions of this equivalence.

Given a convex and compact set K and a vector c , the *Strong Validity* problem, given a vector c , is to find the maximum value of $c^T x$ such that $x \in K$ (the x which obtains this maximum is not required). In the *Strong Membership* problem, the goal is to determine if a given vector y is in K or not. The *Weak Validity* and *Weak Membership* problems are weaker versions of the Strong Validity and Strong Membership problems respectively, formally defined later. Then Theorem 4.4.4 in [16] says that for a convex and compact body K , there is an oracle polynomial time reduction from the Weak Membership problem for K to the Weak Validity problem for K .

To formally state Theorem 4.4.4 from [16], which will form the basis of our reduction, we need the following notations and definitions.

We use $\|\cdot\|$ for the Euclidean norm. Let $K \subseteq \mathbb{R}^{n'}$ be a convex and compact set. A ball of radius $\epsilon > 0$ around K is defined as

$$S(K, \epsilon) := \{x \in \mathbb{R}^{n'} \mid \|x - y\| \leq \epsilon \text{ for some } y \in K\}.$$

Thus, for $x \in \mathbb{R}^{n'}$, $S(x, \epsilon)$ is the ball of radius ϵ around x . The interior ϵ -ball of K is defined as

$$S(K, -\epsilon) := \{x \in K \mid S(x, \epsilon) \subseteq K\}$$

Thus $S(K, -\epsilon)$ can be seen as points deep inside K .

► **Definition 20** ([16]). *Given a vector $c \in \mathbb{Q}^{n'}$, a rational number γ and a rational number $\epsilon > 0$, the Weak Validity problem is to assert either (1) $c^T x \leq \gamma + \epsilon$ for all $x \in S(K, -\epsilon)$, or (2) $c^T x \geq \gamma - \epsilon$ for some $x \in S(K, \epsilon)$. Note that the vector x satisfying the second inequality is not required.*

► **Definition 21** ([16]). *Given a vector $y \in \mathbb{R}^{n'}$ and $\delta > 0$, the Weak Membership problem is to assert either (1) $y \in S(K, \delta)$, or (2) $y \notin S(K, -\delta)$.*

Intuitively, in the Weak Membership problem, it is required to distinguish between the cases when the given point y is far from the polyhedron K (in which case, the algorithm should return $y \notin S(K, -\delta)$) and y is deep inside K (which case the algorithm should return $y \in S(K, \delta)$). If y is near the boundary of K , then either output can be returned. Our reduction crucially uses the following result.

► **Theorem 22** (Theorem 4.4.4 of [16]). *Given a weak validity oracle for $K \subseteq \mathbb{R}^n$ that runs in polynomial time and a positive R such that $K \subseteq S(0, R)$, the Weak Membership problem for the polyhedron K can be solved in polynomial time.*

For our problem K is the polytope of linear program Norm-D.

$$K := \left\{ y \in \mathbb{R}^n : \sum_{i: S \cap T_i \neq \emptyset} y_i \leq 0 \quad \forall S \subseteq [m], \quad \|y\|_\infty \leq 1 \right\}. \quad (8)$$

Coverage WM \leq_p Coverage WV \leq_p Coverage Norm Extension

Coverage Weak Membership is the Weak Membership problem for polytope K (8). Given a set $\mathcal{D} = \{T_1, \dots, T_n\}$ (where $T_i \subseteq [m]$) with weights \hat{y}_i ($\hat{y}_i \in \mathbb{R}$) associated with T_i for all $i \in [n]$ and a $\delta > 0$, the goal in this problem is to assert either $(\hat{y}_1, \dots, \hat{y}_n) \in S(K, \delta)$ or $(\hat{y}_1, \dots, \hat{y}_n) \notin S(K, -\delta)$.

Note that Coverage Norm Extension is the Strong Validity problem for K with $c_i = f_i$. We show the following lemma (Coverage WV \leq_p Coverage Norm Extension).

► **Lemma 23.** *If there is an $\alpha = 2^{\text{poly}(n, m)} F^\delta$ efficient approximation algorithm (for any fixed $0 \leq \delta < 1$) for Coverage Norm Extension then there is an efficient algorithm for Weak Validity problem for K .*

Theorem 22 immediately gives Coverage WM \leq_p Coverage WV.

Span WM \equiv Coverage WM

In fact, we show that Coverage Weak Membership is NP-hard even for the case when $|T_i| = 2$ for all $i \in [n]$.³ The restriction $|T_i| = 2$ gives us a graphical representation of the membership problems. We first introduce some notations, which will be used in the remainder. Given a weighted graph $G = (V, E)$ and a set $S \subseteq V$, the span $E_G^+(S)$ and cut $\delta_G(S)$ of set S are the set of edges with at least one endpoint and exactly one endpoint in S respectively. We use $w(E_G^+(S))$, $w(\delta_G(S))$ and $w(E_G(S))$ for the sum of weight of edges with at least one endpoint, exactly one endpoint and both endpoints in S respectively. If the set S is a single vertex v then we use v instead of $\{v\}$. If the graph G is understood from the context we drop the subscript G .

Given a set $\mathcal{D} = \{T_1, \dots, T_n\}$ ($T_i \subseteq [m]$) with the property that $|T_i| = 2$ for all $i \in [n]$, we construct a weighted graph $G = (V, E)$ as follows: vertex set $V = [m]$ and $\{i, j\} \in E$ ($i, j \in [m]$) iff there exists a $T_k \in \mathcal{D}$ such that $T_k = \{i, j\}$. The weight \hat{y}_k associated with $T_k = \{i, j\}$ is now associated to the edge $\{i, j\}$. Now the constraint $\sum_{i: T_i \cap S \neq \emptyset} y_i \leq 0$ (in the polyhedron K) translates to $\sum_{e \in E^+(S)} y_e \leq 0$ for all $S \subseteq V$. Thus Coverage-Weak-Membership for $|T_i| = 2$ case is equivalent to following problem, which we call *Span Weak Membership*.

Given a weighted graph $G = (V, E)$ with weights \hat{y}_e on the edges and $\delta > 0$, assert either $\hat{y} = (\hat{y}_e)_{e \in E}$ is in $S(K_s, \delta)$ or \hat{y} is not in $S(K_s, -\delta)$, where

$$K_s = \left\{ \sum_{e \in E^+(S)} y_e \leq 0 \quad \forall S \subseteq V, \quad \|y\|_\infty \leq 1 \right\}. \quad (9)$$

³ There is a relatively easier proof for unrestricted d by reduction from Set Cover, which we show in the full version.

■ **Figure 1** Reduction from Cut Strong Membership to Span Strong Membership. The number shown on the edges in E is the weight y_e , while on edges in E' is the product of $L = 24$ and weight y'_e .

Densest-Cut \leq_p Cut WM \leq_p Span WM

We now show that the Span Weak Membership is NP-Hard thereby showing Coverage Weak Membership is also NP-Hard for the restricted setting with $|T_i| = 2$ for all $i \in [n]$. We first define Cut Weak Membership.

Given a weighted graph $G = (V, E)$ with weights \hat{y}_e on the edges and $\delta > 0$, the goal in Cut Weak Membership is to assert either $\hat{y} = (\hat{y}_e)_{e \in E}$ is in $S(K_c, \delta)$ or \hat{y} is not in $S(K_c, -\delta)$ where

$$K_c = \left\{ \sum_{e \in \delta(S)} y_e \leq 0 \quad \forall S \in 2^V \setminus \emptyset, \|y\|_\infty \leq 1 \right\}. \quad (10)$$

Note that in the Cut Weak membership problem, we have constraints $\sum_{e \in \delta(S)} y_e \leq 0$ instead of $\sum_{e \in E^+(S)} y_e \leq 0$ for all S .

► **Lemma 24.** *There is a reduction from Densest-Cut to Cut Weak Membership and from Cut Weak Membership to Span Weak Membership. Therefore, Coverage Weak Membership is NP-hard even when $d = 2$.*

We can now complete the proof of Theorem 5.

Proof of Theorem 5. Suppose there is an efficient α -approximation algorithm for Coverage Norm Extension. Then by Lemma 23 there is an efficient algorithm for Weak Validity problem for polytope K (8) and then by Theorem 22 we have an efficient algorithm for Coverage Weak Membership. But by Lemma 24, this is not possible unless $P = NP$. ◀

We here prove Lemma 25, which is a weaker statement than Lemma 24 to convey the main ideas. Recall that in Strong Membership problem, the goal is to decide if given vector y is in polyhedron K . Following our nomenclature, we define the following Strong Membership problems.

An instance of Span Strong Membership and Cut Strong Membership is given by a weighted graph $G = (V, E)$ with weights \hat{y}_e on the edges, and the goal is to decide if vector $y = (y_e)_{e \in E}$ is in K_s and K_c respectively, with K_s and K_c as defined in (9), (10).

► **Lemma 25.** *There is a reduction from Densest-Cut to Cut Strong Membership, and from Cut Strong Membership to Span Strong Membership.*

Proof. For the second reduction, the instance of Cut Strong Membership is weighted graph $G = (V, E)$ with weights y_e on the edges. We assume $\|y\|_\infty \leq 1$ as otherwise clearly $y \notin K_c$.

Let $L = 2|E| + |V||E|$. We construct an instance of Span Strong Membership (see Figure 1), i.e., graph $G' = (V', E')$ and weights y'_e as follows:

$$V' = V \cup \{s, t\}, E' = E \cup \{s, t\} \cup \{v, s\} \quad \forall v \in V, y'_e = \begin{cases} \frac{y_e}{L} & \text{if } e \in E(G) \\ -\frac{1}{2L}w(\delta_G(v)) & \text{if } e = \{v, s\}, v \neq t \\ -1 & \text{if } e = \{s, t\}. \end{cases}$$

Then $\|y'\|_\infty \leq 1$.

Assume $y \notin K_c$, i.e., there exists $S \subseteq V$ s.t. $w(\delta_G(S)) > 0$. We need to show there exists $S' \subseteq V'$ s.t. $\sum_{e \in E^+(S')} y'_e > 0$. For $S' = S$, $L \sum_{e \in E^+(S')} y'_e = w(E_G(S)) + w(\delta_G(S)) + \sum_{v \in S} -\frac{1}{2} \cdot w(\delta_G(v)) = w(E_G(S)) + w(\delta_G(S)) - \frac{1}{2} \cdot (2w(E_G(S)) + w(\delta_G(S))) = \frac{w(\delta_G(S))}{2} > 0$.

Now assume $y \in K_c$, i.e., $\forall S \subseteq V, w(\delta_G(S)) \leq 0$. We need to show $\forall S' \subseteq V'$, $\sum_{e \in E^+(S')} y'_e \leq 0$. Since $y'_{\{s, t\}} = -1$ (and L is sufficiently large), we need to consider only those S' which do not contain either s or t . But we have shown that for such S' , $\sum_{e \in E^+(S')} y'_e = \frac{w(\delta_G(S'))}{2L} \leq 0$.

Now we finish the proof by giving a reduction from Densest-Cut to Cut Strong Membership. Given an undirected graph $G = (V, E)$ and rational M , we want to know if there exists $S \subset V$ s.t. $\frac{\delta_G(S)}{|S||V \setminus S|} > M$. Consider the complete graph $G' = (V, E')$ where the weight of an edge is $\frac{1-M}{L}$ if it existed in E , and is $-\frac{M}{L}$ otherwise (note that edges may now have positive, negative, or zero weight). Let $L' = 2 \max\{M, |1 - M|\}$ be a sufficiently large quantity so that $\|\hat{y}\|_\infty < 1$. It is easy to see that $L' w(\delta_{G'}(S)) = |\delta_G(S)| - M|S||V \setminus S|$. Therefore, $\exists S \subset V$ s.t. $w(\delta_{G'}(S)) > 0 \Leftrightarrow \exists S \subset V$ s.t. $\frac{|\delta_G(S)|}{|S||V \setminus S|} > M$. \blacktriangleleft

A Appendix

Proof of Proposition 7

Consider the polyhedron Extension-P. If the partial function is extendible, then Extension-P is nonempty. Since the variables are non-negative, the polyhedron must have a vertex [4], and in particular there is a vertex in which at most n variables $w(S)$ are non-zero. This is because the dimension of the problem is 2^m , hence at a vertex at least 2^m constraints must be tight. But then at least $2^m - n$ of constraints $w(S) \geq 0$ must be tight.

Proof of Corollary 9

Consider the polytope $P = \{\sum_{I \in \mathcal{I}: v \in I} x_I = 1 \quad \forall v \in V(G), 0 \leq x_I \leq 1 \quad \forall I \in \mathcal{I}\}$. By the Theorem 8, there exists $x = \{x_I\}_{I \in \mathcal{I}}$ in P such that $\chi^*(G) = \sum_{I \in \mathcal{I}} x_I$. Consider $y = \{y_I\}_{I \in \mathcal{I}}$ given by $y_{\{v\}} = 1$ for all $v \in V(G)$ and 0 otherwise. Therefore, $y \in P$ and $|V(G)| = \sum_{I \in \mathcal{I}} y_I$. Consider $z = \lambda x + (1 - \lambda)y$ where $\lambda = \frac{|V(G)| - t}{|V(G)| - \chi^*(G)}$. Therefore, $z \in P$ and $\sum_{I \in \mathcal{I}} z_I = \lambda \sum_{I \in \mathcal{I}} x_I + (1 - \lambda) \sum_{I \in \mathcal{I}} y_I = t$.

Proof of Lemma 12

From Theorem 6, given a partial function H and $\alpha \geq 1$, there exists a coverage function f satisfying $f_i \leq f(T_i) \leq \alpha f_i$ for all $i \in [n]$ iff the following linear program is feasible, where the variables are the W -coefficients $w(S)$ for all $S \in 2^{[m]} \setminus \emptyset$:

$$f_i \leq \sum_{S: S \cap T_i \neq \emptyset} w(S) \leq \alpha f_i \quad \forall i \in [n]$$

$$w(S) \geq 0 \quad \forall S \in 2^{[m]} \setminus \emptyset.$$

By Farkas' Lemma, it follows that the above linear program is feasible iff the following linear program is infeasible, with variables y_i and z_i for all $i \in [n]$:

$$\alpha \sum_{i=1}^n f_i y_i < \sum_{i=1}^n f_i z_i \tag{11}$$

$$\sum_{i: S \cap T_i \neq \emptyset} y_i \geq \sum_{i: S \cap T_i \neq \emptyset} z_i \quad \forall S \in 2^{[m]} \setminus \emptyset \tag{12}$$

$$y_i, z_i \geq 0.$$

Now we proceed towards proving the claim. Suppose l_i 's satisfy (4) and (3). Set y_i and z_i as follows: If $l_i \leq 0$ then let $y_i = -l_i$ and $z_i = 0$. Else if $l_i > 0$ then let $y_i = 0$ and $z_i = l_i$. It is easy to see that $y_i, z_i \geq 0$ and $l_i = z_i - y_i$ and hence (12) is satisfied by y_i 's and z_i 's. Further, $\alpha \sum_{i=1}^n f_i y_i = \alpha (\sum_{i: l_i \leq 0} f_i y_i + \sum_{i: l_i > 0} f_i y_i) = -\alpha \sum_{i: l_i \leq 0} f_i l_i$ and similarly $\sum_{i=1}^n f_i z_i = \sum_{i: l_i > 0} f_i l_i$. Thus (11) is also satisfied by y_i 's and z_i 's.

For the other direction observe that if the vector $y = (y_1, \dots, y_n), z = (z_1, \dots, z_n) \geq 0$ satisfy (11) and (12) then wlog we can assume for any i , the minimum of y_i and z_i is 0 (otherwise we can decrease both y_i and z_i by the minimum of y_i and z_i , and $\alpha \geq 1$ allows (11) to remain true). Note that $\sum_i f_i y_i = \sum_{i: y_i \leq z_i} f_i y_i + \sum_{i: y_i > z_i} f_i y_i = \sum_{i: y_i > z_i} f_i y_i$, since $\min\{y_i, z_i\} = 0$ by the previous observation. Now suppose $y, z \geq 0$ satisfy (11) and (12). We thus have $\alpha \sum_{i=1}^n f_i y_i < \sum_{i=1}^n f_i z_i \Leftrightarrow \alpha \sum_{y_i > z_i} f_i y_i < \sum_{z_i > y_i} f_i z_i$. Now let $l_i = z_i - y_i$. This makes both (4) and (3) true.

Proof of Lemma 19

Suppose we are given a weighted bipartite graph $G = (A \cup [m], E)$ with weight f_v on each $v \in A$. Recall that κ is the minimum of $\frac{\sum_{w \in R} f_w}{f_v}$ over vertices $v \in A$ and $R \in \mathcal{F}_v$ where $\mathcal{F}_v = \{R \subseteq A \setminus \{v\} | N(R) \supseteq N(v)\}$ is the set of all $R \subseteq A \setminus \{v\}$ that covers all the neighbours of v .

We will use $f(R)$ ($R \subseteq A$) to denote the summation $\sum_{v \in R} f_v$. If d is a constant then for each $v \in A$, we can find minimum of $f(R)$ over all $R \subseteq \mathcal{F}_v$ in $O(n^d)$ time where $n = |A|$. Therefore, by taking the minimum of the above minimum value over all vertices $v \in A$, we get the value of κ . For general d , we use an approximation algorithm for **Set-Cover** to find, for each vertex $v \in A$, a set $R'_v \in \mathcal{F}_v$ such that $f(R'_v) \leq f(R_v) \log d$ where R_v is the optimal set. It can be seen that $\kappa' = \min_{v \in A} \frac{f(R'_v)}{f_v}$ has the property $\kappa' \leq \kappa \log d$.

Proof of Lemma 23

The instance of weak validity problem is given by a vector $c \in \mathbb{Q}^n$ and rational numbers γ and $\epsilon > 0$. We show that there is a reduction from general Weak Validity to Weak Validity with instances satisfying $c_i \geq 0$ for all $i \in [n]$.

Let $N = \{i \in [n] \mid c_i \leq 0\}$. Consider a vector c' such that $c'_i = 0$ for $i \in N$ and c_i otherwise and $\gamma' = \gamma - \sum_{i \in N} |c_i|$. If x is in $S(K, \epsilon)$ then clearly \bar{x} defined as $\bar{x}_i = -1$ if $i \in N$ and x_i otherwise, is also in $S(K, \epsilon)$. If for some x in $S(K, \epsilon)$, we have $(c')^T x \geq \gamma' - \epsilon$ then for $\bar{x} \in S(K, \epsilon)$, we have $c^T \bar{x} = \sum_{i \in N} |c_i| + (c')^T x \geq \gamma - \epsilon$. Also if for all $x \in S(K, -\epsilon)$, we have $(c')^T x \leq \gamma' + \epsilon$ then $c^T x \leq \sum_{i \in N} |c_i| + (c')^T x \leq \gamma + \epsilon$. This shows the reduction and hence we assume $c_i \geq 0$ in the instance of Weak Validity problem.

Let OPT and OPT' be the optimal value of Norm-P for $(f_1, \dots, f_n) = (c_1, \dots, c_n)$ and $(f_1, \dots, f_n) = (Lc_1, \dots, Lc_n)$ respectively (L will be chosen later). Obviously $OPT' = L \cdot OPT$. Let the approximation algorithm for Norm-P return β for instance $(f_1, \dots, f_n) = (Lc_1, \dots, Lc_n)$. Let $C = \sum_i c_i$. Therefore, $OPT' \leq \beta \leq OPT' + 2^{\text{poly}(n,m)}(LC)^\delta = L \cdot OPT + 2^{\text{poly}(n,m)}(LC)^\delta$ and hence $\beta/L \leq OPT + \frac{2^{\text{poly}(n,m)}(C)^\delta}{L^{1-\delta}}$. We set $L := \left(\frac{2^{\text{poly}(n,m)}(C)^\delta}{2\epsilon}\right)^{1/1-\delta}$
