so that $\frac{2^{\text{poly}(n,m)}(C)^\delta}{L^{1-\delta}} = 2\epsilon$. Note that the number of bits to specify L is polynomial in $\langle c \rangle, \langle \epsilon \rangle, n, m$, where $\langle c \rangle, \langle \epsilon \rangle$ denote the number of bits required to represent these quantities. Thus, $OPT \leq \beta/L \leq OPT + 2\epsilon$. Now if $\gamma + \epsilon \leq \beta/L$ then for the optimal solution $x^* \in K$, $c^T x^* = OPT \geq \frac{\beta}{L} - 2\epsilon \geq \gamma - \epsilon$. If $\gamma + \epsilon \geq \beta/L$ then for all x in K (and hence $S(K, -\epsilon)$), we have $c^T x \leq OPT \leq \beta/L \leq \gamma + \epsilon$. Since at least one of these two conditions must hold, the conditions of weak validity problem can be correctly asserted.

Proof of Lemma 24

In the proof, for any vector y , recall that we use $\|y\|_\infty$ for $\max_i |y_i|$ and $\|\hat{y} - y\|$ for the Euclidean distance between \hat{y} and y . We will frequently use the fact that the distance of a point x_0 from the hyperplane $w^T x + b = 0$ is equal to $\frac{|w^T x_0 + b|}{\|w\|}$.

Recall the definitions of Span Weak Membership, Cut Weak Membership and Densest Cut:

1. Given a weighted graph $G = (V, E)$ with weights \hat{y}_e on the edges and $\delta > 0$,
 - a. The goal in Span Weak Membership is to assert either $\hat{y} = (\hat{y}_e)_{e \in E}$ is in $S(K_s, \delta)$ or \hat{y} is not in $S(K_s, -\delta)$ where

$$K_s = \left\{ \sum_{e \in E^+(S)} y_e \leq 0 \quad \forall S \in 2^V \setminus \emptyset, \|y\|_\infty \leq 1 \right\},$$

- b. The goal in Cut Weak Membership is to assert either $\hat{y} = (\hat{y}_e)_{e \in E}$ is in $S(K_c, \delta)$ or \hat{y} is not in $S(K_c, -\delta)$ where

$$K_c = \left\{ \sum_{e \in \delta(S)} y_e \leq 0 \quad \forall S \in 2^V \setminus \emptyset, \|y\|_\infty \leq 1 \right\}.$$

Note that in the Cut Weak membership, we have constraints $\sum_{e \in \delta(S)} y_e \leq 0$ instead of $\sum_{e \in E^+(S)} y_e \leq 0$ for all S .

2. In the Densest-Cut problem, given a graph $G = (V, E)$ and a positive rational M , the goal is to decide if there exist a set $S \subset V$ s.t. $\frac{|\delta(S)|}{|S||V \setminus S|} \geq M$.

■ **Figure 2** Reduction from Cut-Weak-Membership to Span-Weak-Membership. The number shown on the edges in E is the weight y_e , while on edges in E' is product of $L = 48$ and weight y'_e .

The Densest-Cut is known to be NP-Hard [7]. Note that $\frac{|\delta(S)|}{|S||V \setminus S|}$ called the density of cut $(S, V \setminus S)$ can take values only from $\left\{ \frac{r}{s(|V|-s)} \mid 1 \leq r \leq |E|, 1 \leq s \leq |V| - 1, r, s \in \mathbb{Z}_+ \right\}$. Thus there are only polynomially many possible values of cut densities. We will use this fact in our proof.

► **Lemma 26.** *There is a reduction from Cut Weak Membership to Span Weak Membership.*

Proof. Our goal in Cut Weak Membership, given a graph a $G = (V, E)$ with weights \hat{y}_e on edges and $\delta > 0$, is to assert either $\hat{y} = (\hat{y}_e)_{e \in E}$ is in $S(K_c, \delta)$ or \hat{y} is not in $S(K_c, -\delta)$. If the point \hat{y} violates the constraint $\|\hat{y}\|_\infty \leq 1$ of K_c then it can be asserted that \hat{y} is not in $S(K_c, -\delta)$. So we assume $\|\hat{y}\|_\infty \leq 1$. Given this assumption, we have $w(\delta_G(v)) \leq |E|$.

We construct an instance of Span-Weak-Membership (see Figure 2), i.e., graph $G' = (V', E')$, \hat{y}'_e and δ' as follows (the values of B and L will be set later):

$$\begin{aligned} V' &= V \cup \{s, t\} \\ E' &= E \cup \{\{s, t\}\} \cup \{\{v, s\}\} \quad \forall v \in V', v \neq \{s, t\} \\ \hat{y}'_e &= \begin{cases} \frac{y_e}{L} & \text{if } e \in E \\ -\frac{\frac{1}{2}w(\delta_G(v))}{L} & \text{if } e = \{v, s\}, v \neq t \\ -\frac{B}{L} & \text{if } e = \{s, t\}. \end{cases} \end{aligned}$$

The value of B is set to $2|E| + |V||E|$ so that $\sum_{e \in E_{G'}^+(S)} \hat{y}'_e \leq \frac{-B+|E|+1/2|V||E|}{L} \leq 0$ for all S containing either s or t . Further, $L = 2B$ so that $\|\hat{y}'\|_\infty = 1/2$ where $\hat{y}' = (\hat{y}'_e)_{e \in E'}$. Finally we choose $\delta' = \frac{1}{2} \min \left\{ \frac{\sqrt{|E|}\delta}{2L\sqrt{|E'|}}, \frac{|E|+1/2|V||E|}{\sqrt{|E'|}L}, \frac{1}{2} \right\}$.

▷ **Claim 27.** For all $S \subseteq V$, $w(E_{G'}^+(S)) = \frac{w(\delta_G(S))}{2L}$.

Proof. This is because

$$L w(E_{G'}^+(S)) = L \sum_{e \in E_{G'}^+(S)} w'_e = w(E_G(S)) + w(\delta_G(S)) + \sum_{v \in S} -\frac{1}{2} w(\delta_G(v)),$$

and since $w(\delta_G(v))$ counts edges in $E_G(S)$ twice and edges in $\delta_G(S)$ once,

$$L w(E_{G'}^+(S)) = w(E_G(S)) + w(\delta_G(S)) - \frac{1}{2} \cdot (2w(E_G(S)) + w(\delta_G(S))) = \frac{w(\delta_G(S))}{2}. \quad \triangleleft$$

Suppose the algorithm for Span Weak Membership asserts that the point \hat{y}' is in $S(K_s, \delta')$. If \hat{y}' satisfies all the constraints $\sum_{e \in E_{G'}^+(S)} y_e \leq 0$ for all $S \in 2^V \setminus \emptyset$ then the point \hat{y} must satisfy all the constraints $\sum_{e \in \delta_G(S)} y_e \leq 0$ for all $S \in 2^V \setminus \emptyset$ (because by the Claim 27

$w(\delta_G(S)) = 2L \cdot w(E_{G'}^+(S))$ and hence $\hat{y} \in K_c$. Thus $\hat{y} \in S(K_c, \delta)$. Now suppose \hat{y}' violates a constraint $\sum_{e \in E_{G'}^+(R)} y_e \leq 0$ for some $R \in 2^V \setminus \emptyset$. Since $\hat{y}' \in S(K_s, \delta')$, it is at most δ' distance away from the hyperplanes corresponding to the violated constraints. Therefore, we have $w(E_{G'}^+(R)) = \sum_{e \in E_{G'}^+(R)} \hat{y}'_e \leq \delta' \sqrt{|E'|}$. By Claim 27, $w(\delta_G(R)) \leq 2L\delta' \sqrt{|E'|}$.

Therefore, the point \hat{y} is at most $\frac{2L\delta' \sqrt{|E'|}}{\sqrt{|E|}}$ distance from K_c . Since $\delta' < \frac{\sqrt{|E|}\delta}{2L\sqrt{|E'|}}$, so $\hat{y} \in S(K_c, \delta)$.

Suppose the algorithm for Span Weak Membership problem asserts that the point \hat{y}' is not in $S(K_s, -\delta')$. If \hat{y}' violates a constraint $\sum_{e \in E_{G'}^+(S)} y_e \leq 0$ for some $S \in 2^V \setminus \emptyset$ then the point \hat{y} also violates $\sum_{e \in \delta_G(S)} y_e \leq 0$ for S (by Claim 27). Hence, it can be asserted that \hat{y} is not in $S(K_c, -\delta)$. So now assume that \hat{y}' satisfies all the constraints $\sum_{e \in E_{G'}^+(S)} y_e \leq 0$ for all $S \in 2^V \setminus \emptyset$. Also, as shown earlier, \hat{y}' satisfies the other constraints of K_s . Since \hat{y}' is in K_s but not in $S(K_s, -\delta')$, some $y \in S(\hat{y}', \delta')$ must have distance $< \delta'$ from some hyperplane of K_s . The distance of \hat{y}' from the hyperplane $\sum_{e \in E_{G'}^+(S)} y_e = 0$ for S containing s or t is at least $\frac{|-B+|E|+1/2|V||E'|}{\sqrt{|E'|L}} = \frac{|E|+1/2|V||E'|}{\sqrt{|E'|L}} > \delta'$. Also for any $y \in S(\hat{y}', \delta')$, we have $\|y\|_\infty - \|\hat{y}'\|_\infty \leq \|y - \hat{y}'\|_\infty \leq \|y - \hat{y}\|_\infty \leq \|y - \hat{y}'\|_\infty$. So $\|y\|_\infty \leq \delta + 1/2 \leq 1$ for all $y \in S(\hat{y}', \delta')$. Therefore, it must be the case that distance of \hat{y}' from the hyperplane $\sum_{e \in E_{G'}^+(S)} y_e = 0$ for some $S \in 2^V \setminus \emptyset$ is $< \delta'$. By Claim 27, the distance of the point \hat{y} from the hyperplane $\sum_{e \in \delta_G(S)} y_e = 0$ is at most $\frac{2L\sqrt{|E'|}\delta'}{\sqrt{|E|}} < \delta$. Hence, \hat{y} is not in $S(K_c, -\delta)$. ◀

Now we finish the proof by giving reduction from Densest-Cut to Cut Weak Membership.

► **Lemma 28.** *There is a reduction from Densest-Cut to Cut Weak Membership.*

Proof. In the Densest Cut problem, a graph $G = (V, E)$ and a positive rational M are given and the goal is to determine if there exists a set $S \subset V$ s.t. the density of the cut $(S, V \setminus S)$ is at least M , i.e., $\frac{|\delta_G(S)|}{|S||V \setminus S|} \geq M$. Let $M = \frac{p}{q}$ for positive integers p, q . We set L to $2 \max\{M, |1 - M|\}$ (so that later, $\|\hat{y}\|_\infty = 1/2$) and t to $\frac{1}{qL}$.

Given the graph $G = (V, E)$ and M , the instance of Cut Weak Membership is a complete graph $G' = (V, E')$ (so $|E'| = \frac{|V|(|V|-1)}{2}$), weight \hat{y}_e on each edge $e \in E'$ such that \hat{y}_e is $\frac{1-M}{L}$ if it existed in E and $\frac{-M}{L}$ otherwise, and $\delta = \frac{1}{2} \min\{\frac{1}{2}, \frac{t}{\sqrt{|E'|}}\}$. Let $\hat{y} = (\hat{y}_e)_{e \in E'}$. This defines the polytope K_c as in (10) for the instance of Cut Weak Membership.

It is easy to see that $w(\delta_{G'}(S)) = \frac{1}{L}(|\delta_G(S)| - M|S||V \setminus S|)$. Therefore, $\exists S \subset V$ s.t. $w(\delta_{G'}(S)) \geq 0 \Leftrightarrow \exists S \subset V$ s.t. $\frac{|\delta_G(S)|}{|S||V \setminus S|} \geq M$.

Since M is equal to $\frac{p}{q}$ for some $p, q \in \mathbb{Z}_+$, therefore the weight of an edge is either $\frac{q-p}{qL}$ or $\frac{-p}{qL}$. So if a cut value $w(\delta_{G'}(S))$ is strictly positive for any S then $w(\delta_{G'}(S))$ must be at least $\frac{1}{qL} = t$. Similarly, if $w(\delta_{G'}(S)) < 0$ then we have $w(\delta_{G'}(S)) \leq -t$.

Now suppose an algorithm for Cut Weak Membership asserts \hat{y} is in $S(K_c, \delta)$. Thus for all S , $w(\delta_{G'}(S)) = \sum_{e \in \delta_{G'}(S)} \hat{y}_e \leq \sqrt{|E'|}\delta$. Since $\delta < \frac{t}{\sqrt{|E'|}}$, so it must be the case that for all S , $w(\delta_{G'}(S)) \leq 0$. This implies that for all S , the cut density $\frac{|\delta_G(S)|}{|S||V \setminus S|} \leq M$.

Suppose the algorithm for Cut Weak Membership asserts that \hat{y} is not in $S(K_c, -\delta)$. If $\hat{y} \notin K_c$ (and since $\|\hat{y}\|_\infty \leq 1$) then clearly there exists a set S such that $w(\delta_{G'}(S)) > 0$. This implies there is a cut $(S, V \setminus S)$ with density $\frac{|\delta_G(S)|}{|S||V \setminus S|} > M$. Now assume \hat{y} is in K_c . Now for any $y \in S(\hat{y}, \delta)$, we have $\|y\|_\infty - \|\hat{y}\|_\infty \leq \|y - \hat{y}\|_\infty \leq \|y - \hat{y}\|_\infty \leq \delta$. So $\|y\|_\infty \leq \delta + 1/2 < 1$. So there must exist a hyperplane $\sum_{e \in \delta_{G'}(S)} y_e = 0$ for some S with at most δ distance from \hat{y} . Therefore, there exist a set S with $0 \geq w(\delta_{G'}(S)) \geq -\sqrt{|E'}\delta$. Since $\delta < \frac{t}{\sqrt{|E'|}}$, this

means $w(\delta_{G'}(S)) = 0$ and hence density of cut $(S, V \setminus S)$ is M . Thus, if an algorithm for Cut Weak Membership asserts that \hat{y} is not in $S(K_c, -\delta)$ then there exists a cut with density at least M .

Therefore, assuming an efficient algorithm for Cut Weak Membership, it can be determined if there exists a cut with density at least M or all cuts have density at most M . However, the goal in Densest Cut is to determine if there is a cut with density $\geq M$ or all cuts have density strictly less than M . But since the density can take only polynomial number of values $\left\{ \frac{r}{s(|V|-s)} \mid 1 \leq r \leq |E|, 1 \leq s \leq |V| - 1, r, s \in \mathbb{Z}_+ \right\}$ (as noted before), by using at most two oracle calls to the Cut-Weak-Membership problem we can solve the original problem. ◀

Almost Optimal Classical Approximation Algorithms for a Quantum Generalization of Max-Cut

Abstract

Approximation algorithms for constraint satisfaction problems (CSPs) are a central direction of study in theoretical computer science. In this work, we study classical product state approximation algorithms for a physically motivated quantum generalization of Max-Cut, known as the quantum Heisenberg model. This model is notoriously difficult to solve exactly, even on bipartite graphs, in stark contrast to the classical setting of Max-Cut. Here we show, for any interaction graph, how to classically and efficiently obtain approximation ratios 0.649 (anti-ferromagnetic XY model) and 0.498 (anti-ferromagnetic Heisenberg XYZ model). These are almost optimal; we show that the best possible ratios achievable by a product state for these models is $2/3$ and $1/2$, respectively.

1 Introduction

The study of approximation algorithms for NP-complete problems is a central area of research in theoretical computer science (see, e.g., [20, 30]). Indeed, the field has seen breakthroughs such as the celebrated Goemans-Williamson [19] 0.878-approximation algorithm for Max-Cut, and the PCP theorem [4, 3], which yielded a general framework for showing hardness of approximation results. Here, an approximation algorithm A with ratio $0 < r < 1$ is defined as follows: Given an instance Π of a maximization problem with optimal value OPT , A runs in polynomial time and outputs a value $\widetilde{\text{OPT}}$ satisfying $r\text{OPT} \leq \widetilde{\text{OPT}} \leq \text{OPT}$. of study in approximation algorithms are Boolean constraint satisfaction problems (CSPs) such as Max-SAT and Max-Cut, in which one is roughly given a set of local constraints acting on $k \in O(1)$ bits each (out of a total of n bits), and asked to compute the largest number of constraints which are simultaneously satisfiable.

In the quantum setting, CSPs are naturally generalized by the k -local Hamiltonian problem (k -LH) [24]. In the latter, one is given as input an exponentially large (in the number of qubits, n) Hermitian matrix H known as a *local Hamiltonian*, which has a succinct description in terms of local “quantum clauses.” The goal is to estimate the smallest eigenvalue of H , $\lambda_{\min}(H)$, i.e. the *ground state energy* of H . Slightly more formally, a k -local Hamiltonian $H = \sum_{S \subseteq [n]} H_S$ acts on n qubits in total, with each local quantum “clause” H_S acting on a constant number k of qubits denoted by subset $S \subseteq [n]$ with $|S| = k$. (Thus, each H_S is a $2^k \times 2^k$ Hermitian matrix. Note that formally, H_S implicitly denotes operator $I_{[n] \setminus S} \otimes H_S$; this ensures dimensions match in the sum over clauses.) Quantum CSPs in which the matrices H_S are diagonal correspond to classical CSPs.

The problem k -LH is not only physically motivated (it is the problem of estimating the energy of a quantum many-body system when cooled to near absolute zero), but also complexity theoretically – it was the first known QMA-complete problem [24], where Quantum Merlin Arthur (QMA) is the quantum analogue of NP. As such, k -LH has been a central problem of study in the field of Quantum Hamiltonian Complexity (see, e.g. [28, 18] for surveys), which (among other aims) uses tools from complexity theory to uncover the limits and structure of physical systems in nature. In recent years, this interdisciplinary research has led to a growing body of work on classical *approximation algorithms* for k -LH. It is this direction which we pursue in this paper.

1.1 Product state algorithms and previous work

We begin by reviewing previous work on approximation algorithms for k -LH.

Mean-field or product-state algorithms

All known classical approximation algorithms for k -LH fall under the category of *mean-field* or *product-state* algorithms. Here, the issue is that the optimal solution to a k -LH instance may be an exponentially large quantum state $|\psi\rangle \in \mathbb{C}^{2^n}$ (which would be the *ground state* or eigenvector of H corresponding to its ground state energy, $\lambda_{\min}(H)$). Any classical algorithm for approximating k -LH must hence presumably pick a reasonable succinctly representable class of quantum states to optimize over; the simplest such class is the set of n -qubit *product states*. A product state is the quantum analogue of a product distribution – the entire 2^n -dimensional vector $|\psi\rangle$ is fully specified by locally giving an assignment $|\psi_i\rangle \in \mathbb{C}^2$ to each qubit i , i.e. $|\psi\rangle = |\psi_1\rangle \otimes \cdots \otimes |\psi_n\rangle$.

► **Remark.** It is crucial to note that even though product states are not entangled, they nevertheless generalize classical bit string assignments, and are thus *NP-hard to optimize over* in the worst case. Thus, even with this simplest ansatz of product states, approximating k -LH is highly non-trivial.

Previous work for QMA-complete models

We now outline the known approximation algorithms for k -LH, which are all mean-field algorithms. The first such work was due to Bansal, Bravyi, and Terhal [5], who gave a classical polynomial-time approximation scheme (PTAS) for k -LH on bounded degree planar

graphs. Next, Gharibian and Kempe [17] gave a PTAS for computing product-state solutions to dense CSPs, and showed their algorithm yielded a d^{1-k} approximation for dense k -LH on local d -dimensional systems. Brandão and Harrow [7] then gave PTAS-es for k -LH in three settings: Planar, dense, and low threshold rank graphs. Most recently, Bravyi, Gosset, König, and Temme [9] gave a $O(\log n)$ -approximation algorithm for traceless 2-local Hamiltonians. As we shall see, this last work may be viewed as complementary to ours (and indeed, the techniques used are similar, although independently developed) – the algorithm of [9] is more general than ours (applies to all traceless Hamiltonians) but has a non-constant approximation ratio ($O(\log n)$ ratio). We take the complementary route: We study a more specific model, the central quantum Heisenberg model, but in return are able to achieve substantially stronger *constant* approximation ratios. Finally, Lee and Hallgren [25] obtain a non-trivial constant-factor approximation algorithm for 2-LH when each clause is positive semi-definite. We remark that with the exception of [5], all of these works are based on semidefinite programs (SDP).

Previous work for Hamiltonians of “intermediate” complexity

For completeness, we also note that Bravyi [8] and Bravyi and Gosset [11] showed fully polynomial randomized approximation schemes (FPRAS) for approximating the partition function¹ of certain ferromagnetic models, such as the ferromagnetic transverse field Ising model (ferromagnetic TIM). In general, the TIM problem is StoqMA-complete, as shown by Bravyi and Hastings [10]. Here, $\text{MA} \subseteq \text{StoqMA} \subseteq \text{QMA}$, and it is generally believed StoqMA is strictly smaller than QMA (the former is in the Polynomial-time Hierarchy, whereas the latter is believed not to be). Thus, such models may be thought of as being of “intermediate” complexity.

Brief note on the quantum PCP theorem

An advantage of any mean-field classical approximation algorithm for k -LH is that it yields negative progress on the central open question: Does a quantum PCP theorem² hold [1, 2]? This is because such algorithms show that a *classical* (i.e. NP) witness suffices to attain certain approximation ratios for k -LH. Thus, unless $\text{NP} = \text{QMA}$ (which is believed highly unlikely), a quantum PCP theorem for k -LH with the same approximation ratios cannot hold.

1.2 Our results

We give classical approximation algorithms for a maximization version of the fundamental *quantum Heisenberg model*, which can be thought of as a family of Hamiltonians generalizing the NP-complete Max-Cut problem.

Maximization versus minimization

For clarity, we study the natural *maximization* variant of k -LH, in which one is given H and asked to estimate its *largest* eigenvalue $\lambda_{\max}(H)$. We study this variant for two reasons (see also [16]): First, in the minimization setting, if $\lambda_{\min}(H) = 0$, the notion of an approximation

¹ The ability to compute the partition function allows one in turn to solve k -LH.

² Recently, the “entangled non-local games” version of the PCP theorem has been established under randomized reductions [26]. The “hardness of approximation” version involving approximating ground state energies of local Hamiltonians, however, which is relevant to this work, remains open.

ratio is not well-defined, and second, the maximization setting allows us to naturally align with classical approximation algorithms for CSPs such as Max-Cut. We remark that in the exact setting, computing $\lambda_{\min}(H)$ is equivalent in complexity to computing $\lambda_{\max}(H)$ since $\lambda_{\min}(H) = \lambda_{\max}(-H)$ – thus, both maximization and minimization variants of k -LH are QMA-complete. More precisely, if H is a Hamiltonian corresponding to an instance of the (anti-ferromagnetic) quantum Heisenberg model, then we approximate the instance $\lambda_{\max}(mI - H)$, where m is the number of clauses. In terms of approximability, the complexity of both models need not coincide. An appropriate classical analogy is the relationship of the Ising problem on graphs, $\min_{z_i \in \{-1,1\}} \sum_{ij \in E} z_i z_j$, for which an $O(\log n)$ -approximation is the best known (see, e.g., [13]) and the Max-Cut problem, $\max_{z_i \in \{-1,1\}} \sum_{ij \in E} (1 - z_i z_j)/2$, for which the Goemans-Williamson 0.878-approximation is known. These problems are equivalent from an exact optimization perspective. From an approximation perspective, the standard quantum Heisenberg model is a generalization of the Ising problem, while the problem we study is a generalization of Max-Cut (see Appendix A for details). We note that Bravyi et al.’s $O(\log n)$ -approximation for traceless 2-local Hamiltonians [9] includes the standard quantum Heisenberg model as a special case.

The quantum Heisenberg model

The Heisenberg model is fundamental to the study of magnetism, and has received attention for at least almost a century now (e.g. the well-known Bethe ansatz of 1931 [6]). It is a family of 2-local Hamiltonians, defined in this paper as having constraints H_{ij} acting on qubits i and j of the form (see Section 2 for formal definitions):

$$H_{ij} = I - \alpha X_i \otimes X_j - \beta Y_i \otimes Y_j - \gamma Z_i \otimes Z_j,$$

for Pauli matrices X, Y, Z , and where X_i indicates X acts on qubits i . (Recall we study *maximization*, i.e. estimating $\lambda_{\max}(H)$.) Three important well-known special cases of this model are: (1) the Max-Cut problem ($\alpha = \beta = 0, \gamma = 1$) (in Appendix A, we sketch why this case indeed captures Max-Cut), (2) the (anti-ferromagnetic) XY model ($\alpha = \beta = 1, \gamma = 0$), and (3) the (anti-ferromagnetic) Heisenberg model ($\alpha = \beta = \gamma = 1$), which we also refer to as the anti-ferromagnet. The latter, for example, is notoriously difficult to solve *even on bipartite graphs*, in contrast to Max-Cut. The only solutions for the anti-ferromagnet we are aware of is on the 1D chain [6] and on the complete graph (see, e.g., [14]). This notoriety is well-deserved – when non-negative polynomial-size weights are allowed on each constraint, both the XY model and anti-ferromagnet are QMA-hard [14, 29].

In this paper, we first show (Section 4) how to approximate the XY model and anti-ferromagnet almost optimally. The following is an informal statement (see Theorem 6 for a formal statement).

► **Theorem 1.** *Let $\alpha, \beta, \gamma \in \{0, 1\}$. Then, there exists a randomized, polynomial time classical algorithm for the quantum Heisenberg model which outputs a product state solution with ratio at least:*

- 0.878 if $\alpha + \beta + \gamma = 1$ (equivalent to Max-Cut),
- 0.649 if $\alpha + \beta + \gamma = 2$ (equivalent to the XY model),
- 0.498 if $\alpha + \beta + \gamma = 3$ (anti-ferromagnet).

We then show in Corollary 5 that these ratios are almost optimal, in the sense that the *best* approximation ratios possible for a product state solution (whether efficiently attainable or not) to the XY model and anti-ferromagnet are at most $2/3$ and $1/2$, respectively. It

should be noted that, in contrast, the naive “random assignment” strategy (i.e. choose the maximally mixed state $I/2^n$ as the assignment) yields ratios of only $1/3$ and $1/4$ for the XY model and anti-ferromagnet, respectively.

Next, in Section 4.1 we give two ways in which our algorithm (or a variant of it) can be applied to a broader class of Hamiltonians:

- Section 4.1.1 shows how to relax the constraint that $\alpha, \beta, \gamma \in \{0, 1\}$. Specifically, we allow a different set of parameters $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in [-1, 1]$ for each edge $(i, j) \in E$. In return for this generality, the approximation ratios we obtain are slightly weaker.
- Section 4.1.2 uses a trick from entanglement theory [22, 23] to characterize the class of models which can be reduced to the Heisenberg model via application of local unitaries, and hence to which our algorithms apply.

1.3 Techniques

Our algorithms are based on semidefinite programming (SDP), and in particular use the first level of a non-commutative generalization of the Lasserre SDP hierarchy. Similar generalizations have been used previously in [7, 9]. Note that a key difference between our approach and the previous SDP-based works of [16, 7] is that the SDPs we derive are relaxations not just of the best attainable *product state* objective function value, but rather of the true optimal value $\lambda_{\max}(H)$ itself. This is why the ratios we obtain in Theorem 6 can be close to optimal for a product state ansatz. We note that a simple modification of our SDP relaxation does give an upper bound on the NP-hard problem of finding the best product-state solution; our techniques can be used to yield classical approximation algorithms for this problem as well.

1.4 Open questions

Many questions in the study of approximability in the quantum setting remain open. For example, what are the best achievable approximation ratios classically for the Heisenberg model, and do hardness of approximation results based on the unique games conjecture yield tight bounds as they do for Max-Cut and related classical CSPs? Can tight ratios of $2/3$ and $1/2$ be obtained for the XY model and anti-ferromagnet, respectively? Are there constant-factor approximation algorithms for general k -LH (recall [9] give $O(\log n)$ approximations for traceless 2-local Hamiltonians)? How well can one approximate “intermediate” Hamiltonian models such as the *anti-ferromagnetic* TIM (recall [8, 11] approximate the ferromagnetic TIM)? Can one optimize approximately over more general ansatzes than mean-field/product states, such as tensor network states? Can quantum approximation algorithms *provably* outperform the best classical approximation algorithms? Finally, does a quantum PCP theorem (in the sense of “hardness of approximation for quantum CSPs”) hold? It is hoped that the current paper will act as a step towards resolutions for some of these problems.

1.5 Organization

In Section 2, we give definitions and preliminaries. Section 3 gives upper bounds on the power of the mean-field ansatz. Section 4 gives our approximation algorithms. Certain technical proofs are deferred to Appendix B. Some background in basic quantum information is assumed; see, for example, Nielsen and Chuang [27] for a standard reference.

2 Preliminaries

2.1 Notation

Let $[n] := \{1, \dots, n\}$. The sets $\mathcal{H}(\mathcal{X})$ and $\mathcal{D}(\mathcal{X})$ denote the sets of Hermitian and density operators acting on complex Euclidean space \mathcal{X} . For $A, B \in \mathcal{H}(\mathcal{X})$, we say $A \succeq B$ if $A - B$ is positive semidefinite, i.e. $A - B \succeq 0$. The spectral/operator norm of A is denoted $\|A\|_\infty = \text{tr}(\sqrt{A^\dagger A})$.

2.2 Physically motivated 2-local Hamiltonians

Let $G = (V, E)$ be a simple, undirected graph with $|V| = n$ and $|E| = m$. In this section, we study physically motivated 2-local Hamiltonians H based on the quantum Heisenberg model, $H = \sum_{(i,j) \in E} w_{ij} H_{ij}$ for $H_{ij} = \alpha X_i X_j + \beta Y_i Y_j + \gamma Z_i Z_j$ (more accurately, since we are in the setting of maximization, we use local terms as given in Equation (1)), where we consider $\alpha, \beta, \gamma \in \{0, 1\}$ and $w_{ij} \geq 0$. This includes QMA-hard special cases such as the quantum Heisenberg anti-ferromagnet [14, 29]. Here, X, Y, Z are the Pauli matrices

$$X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad Y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix},$$

and X_i, Y_i, Z_i refer to the Pauli matrices acting on the i th qubit (i.e., tensored with identity on all other qubits).

Specifically, we consider the equivalent (in the setting of exact computation) maximization variant where each local term is defined

$$H_{ij} = I - \alpha X_i X_j - \beta Y_i Y_j - \gamma Z_i Z_j, \quad (1)$$

and our goal is to estimate the *largest* eigenvalue of $H = \sum_{(i,j) \in E} w_{ij} H_{ij}$ with $w_{ij} \geq 0$. This variant is clearly still QMA-hard, and includes as a special case, for example, the canonical NP-complete problem Max-Cut, obtained up to scaling by a constant factor of 2) by setting $\alpha = 0, \beta = 0, \gamma = 1$.

We now set definitions for the rest of this paper. Let $F_{\alpha, \beta, \gamma}$ denote the set of all H with (non-negative weighted) constraints of the form of Equation (1), with parameters α, β, γ and on all interaction graphs G (for all $n \geq 0$). For example, $F_{0,0,1}$ denotes the set of all possible Max-Cut instances with non-negative edge weights. In this paper, we refer to the family $F = \bigcup_{\alpha, \beta, \gamma \in \{0,1\}} F_{\alpha, \beta, \gamma}$ as “the Heisenberg model”. Let $\text{SEP} = \text{conv}(\bigotimes_{i=1}^n \rho_i \mid \rho_i \in \mathcal{D}(\mathbb{C}^2))$ for $\text{conv}(S)$ the convex hull of set S , i.e. SEP is the set of fully separable quantum states on n qubits.

3 Upper bounds on product state ratios

As quantum states on n qubits generally require exponential space to represent, a classical approximation algorithm for estimating ground state energies must generally optimize over a restricted class of quantum states, or an *ansatz*. Our ansatz in this section will be to optimize over SEP. To formalize this, we first define the notion of a product state ratio.

Product state ratio

Let $H \in \mathcal{H}((\mathbb{C}^2)^{\otimes n})$ be a Hermitian operator with largest eigenvalue $\text{OPT}(H) = \lambda_{\max}(H)$, and let

$$\text{OPT}_{\text{prod}}(H) := \max_{\rho \in \text{SEP}} \text{tr}(H\rho).$$

By convexity, the optimal ρ here is a (pure) product state. The *product state ratio* is defined as $\text{OPT}_{\text{prod}}(H)/\text{OPT}(H)$. For the Heisenberg model in particular, for any fixed $\alpha, \beta, \gamma \in \{0, 1\}$, define

$$\Gamma_{\alpha, \beta, \gamma} = \min_{H \in F_{\alpha, \beta, \gamma}} \frac{\text{OPT}_{\text{prod}}(H)}{\text{OPT}(H)},$$

the worst-case product state ratio over all Hamiltonians in $F_{\alpha, \beta, \gamma}$.

By definition, $\Gamma_{\alpha, \beta, \gamma}$ yields an upper bound on the best approximation ratio achievable by any approximation algorithm using a product state ansatz. It is thus crucial to understand $\Gamma_{\alpha, \beta, \gamma}$, which we now do for the Heisenberg model. For this, we first give two lemmas which fully characterize the optimal product state ratio on a *single* (unit weight) edge. Note the characterization we give is more general than how we defined the Heisenberg model here, in that it applies for any $\alpha, \beta, \gamma \in \mathbb{R}$. (For clarity, the term proportional to the identity is omitted in Lemmas 2 and 3 below, but is accounted for in the subsequent statement of Corollary 4.) The proofs of both lemmas are deferred to Appendix B.

► **Lemma 2.** *Let $H = \alpha X \otimes X + \beta Y \otimes Y + \gamma Z \otimes Z$ for $\alpha, \beta, \gamma \in \mathbb{R}$. Then $\text{OPT}_{\text{prod}}(H) = \|(\alpha, \beta, \gamma)\|_{\infty}$.*

► **Lemma 3.** *Let $H = \alpha X \otimes X + \beta Y \otimes Y + \gamma Z \otimes Z$ for $\alpha, \beta, \gamma \in \mathbb{R}$. Then*

$$\text{OPT}(H) = \max(|\alpha - \beta| + \gamma, |\alpha + \beta| - \gamma).$$

The following corollary now follows essentially immediately by applying Lemmas 2 and 3 to a single unit weight edge of the form in Equation 1 (i.e. with an identity term).

► **Corollary 4.** *For any $\alpha, \beta, \gamma \in \mathbb{R}$,*

$$\Gamma_{\alpha, \beta, \gamma} \leq \frac{1 + \max(|\alpha|, |\beta|, |\gamma|)}{1 + \max(|\alpha - \beta| - \gamma, |\alpha + \beta| + \gamma)}.$$

Proof. Combine Lemmas 2 and 3 with the following additional observation: The values α, β, γ , as defined for $F_{\alpha, \beta, \gamma}$, should be interpreted as $-\alpha, -\beta, -\gamma$ for Lemmas 2 and 3 due to how Equation 1 is stated. As a result, the positions of the γ and $-\gamma$ terms are swapped in the result of Lemma 3. ◀

We thus have the following for the special case of the Heisenberg model we consider here (i.e. $\alpha, \beta, \gamma \in \{0, 1\}$).

► **Corollary 5.** *For any $\alpha, \beta, \gamma \in \{0, 1\}$, if:*

- $\alpha + \beta + \gamma = 1$, then $\Gamma_{\alpha, \beta, \gamma} = 1$.
- $\alpha + \beta + \gamma = 2$, then $\Gamma_{\alpha, \beta, \gamma} \leq 2/3$.
- $\alpha + \beta + \gamma = 3$, then $\Gamma_{\alpha, \beta, \gamma} \leq 1/2$.

Proof. When $\alpha, \beta, \gamma \in \{0, 1\}$, the bound of Corollary 4 simplifies to

$$\Gamma_{\alpha, \beta, \gamma} \leq \frac{2}{1 + \alpha + \beta + \gamma},$$

from which the upper bounds claimed follow. The matching lower bound for $\alpha + \beta + \gamma = 1$ is obtained since H can be mapped via local Pauli gates to $H' \in F_{0,0,1}$, i.e. H' is diagonal in the standard basis. Thus, product states are optimal in this case. For example, applying local Hadamard gates to each qubit maps any $H \in F_{1,0,0}$ to $H' \in F_{0,0,1}$. (A matching lower bound can also be obtained for $\alpha + \beta + \gamma = 3$ by observing that $H_{ij} \geq 0$, and using the general result that any local Hamiltonian H' (not necessarily from the Heisenberg model) with positive semidefinite constraints satisfies $\text{OPT}_{\text{prod}}(H')/\text{OPT}(H') \geq 1/2$ [16]. However, unlike Theorem 6, the lower bound of [16] is not known to be efficiently achievable.) ◀

4 Almost optimal product-state approximation algorithms

In Section 3, we gave upper bounds on $\Gamma_{\alpha,\beta,\gamma}$ for the Heisenberg model. In this section, we give almost matching algorithmic lower bounds on $\Gamma_{\alpha,\beta,\gamma}$ when $\alpha + \beta + \gamma \in \{2, 3\}$ (recall $\alpha + \beta + \gamma = 1$ is equivalent to Max-Cut, and so $\Gamma_{\alpha,\beta,\gamma} = 1$). Specifically, we give an approximation algorithm which is almost optimal in the following sense: Given $H \in F_{\alpha,\beta,\gamma}$, it outputs a product state ρ_{prod} with approximation ratio at least 0.649 and 0.498 when $\alpha + \beta + \gamma$ equals 2 and 3, respectively, which by Corollary 5 almost matches the best possible mean-field ratios of $2/3$ and $1/2$, respectively.

► **Theorem 6.** *Let $H \in F_{\alpha,\beta,\gamma}$ for $\alpha, \beta, \gamma \in \{0, 1\}$. There exists a randomized, polynomial-time algorithm which obtains approximation ratios at least 0.878, 0.649 or 0.498, when $\alpha + \beta + \gamma$ equals 1, 2 or 3, respectively.*

Proof. Suppose H has interaction graph $G = (V, E)$ for $|V| = n$ and edge weights $w_{ij} \geq 0$ for $(i, j) \in E$. We first define a semidefinite programming (SDP) relaxation of $\text{OPT}(H)$ via the first level of the Lasserre hierarchy (see, e.g., [7] for a similar exposition for the setting of low threshold rank graphs). We then show that applying a generalization of the Goemans-Williamson (GW) [19, 12] rounding scheme yields the desired result.

The SDP. Each solution of the SDP relaxation will be a “moment matrix” $M \in \mathbb{R}^{3n \times 3n}$, whose rows (resp., columns) are indexed by 2-tuples $(i, k) \in [n] \times [3]$ (resp., $(j, l) \in [n] \times [3]$) such that ideally, i, j denote qubits, and k, l a choice of Pauli matrix from sequence $(\sigma_1, \sigma_2, \sigma_3) = (X, Y, Z)$. Under this interpretation, an ideal solution M corresponds to a density matrix $\rho \in \mathcal{D}((\mathbb{C}^2)^{\otimes n})$, such that

$$M(ik, jl) = \text{tr}(\rho \sigma_k^i \sigma_l^j), \quad (2)$$

where σ_k^i corresponds to Pauli operator σ_k applied to qubit i , i.e. implicitly we have $\sigma_k^i \otimes I_{[n] \setminus \{i\}}$.

Let us remark about the assumption that M is real. Note that for an ideal solution (i.e. as in Equation (2)), M is Hermitian. Indeed, for $i \neq j$, $M(ik, jl) = M(jl, ik) \in \mathbb{R}$, since the Pauli terms act on different qubits and hence commute. (A similar argument holds for $i = j$ and $k = l$.) If, however, $i = j$ and $k \neq l$, then since the Pauli matrices anti-commute, we have $M(ik, jl) = -M(jl, ik)$, and indeed $M(ik, jl), M(jl, ik) \in \mathbb{C} \setminus \mathbb{R}$ (since, e.g., $XY = iZ$), implying $M(ik, jl)^* = M(jl, ik)$ (thus M is Hermitian; here, $*$ denotes complex conjugate). Note, however, that the case of $i = j$ and $k \neq l$ corresponds to *linear* local terms, i.e. those of the form σ_k^i , and these are the only non-real entries of M . Since our objective function involves only quadratic local terms (i.e. $\sigma_k^i \sigma_l^j$ for $i \neq j$), we can hence eliminate entries of M with $i = j$ and $k \neq l$ by replacing M with moment matrix $M' = (M + M^*)/2$, which is real and matches M on all entries with $i \neq j$ (as well as on $i = j$ and $k = l$). The real symmetric matrix M' is positive semidefinite if the Hermitian M is, and M' results in an equal objective value to that of M , hence the restriction to real moment matrices is without loss of generality.

We have thus far described the ideal solutions, M . Next, we add constraints to the SDP to help enforce this ideal interpretation of M :

1. For all $i \in [n], k \in [3]$, set $M(ik, ik) = 1$, since ideally $M(ik, ik) = \text{tr}(\rho \sigma_k^i \sigma_k^i) = \text{tr}(\rho) = 1$.
2. For all $i \in [n], k \neq l \in [3]$, set $M(ik, il) = -M(il, ik)$, since distinct Pauli matrices anti-commute.

3. Set $M \succeq 0$. This is since, ideally, for all $s \in \mathbb{R}^{3n}$, we have

$$s^T M s = \sum_{ijkl} s_{ik} s_{jl} M(ik, jl) = \text{tr} \left(\rho \left(\sum_{ik} s_{ik} \sigma_k^i \right) \left(\sum_{jl} s_{jl} \sigma_l^j \right) \right) = \text{tr}(\rho S^2) \geq 0, \quad (3)$$

where $S := \sum_{ik} s_{ik} \sigma_k^i$, and since $\rho, S^2 \succeq 0$.

Finally, the relaxed objective function is obtained by replacing each term $\text{tr}(\rho \sigma_k^i \sigma_l^j)$ with $M(ik, jl)$. For example, the relaxed objective function for $F_{1,1,1}$ becomes $\sum_{(i,j) \in E} w_{ij} (1 - M(i1, j1) - M(i2, j2) - M(i3, j3))$.

Let us remark that our formulation is essentially the first level $s = 1$ of the Lasserre SDP hierarchy. Higher levels $s > 1$ are obtained by considering s -local terms for the moment matrices, i.e. $M(i_1 k_1, \dots, i_s k_s) = \text{tr}(\rho \sigma_{k_1}^{i_1} \cdots \sigma_{k_s}^{i_s})$.

Rounding solutions to the SDP. Given any solution M to the SDP, we take the Cholesky decomposition of M to obtain a set of vectors $v_{ik} \in \mathbb{R}^{3n}$ for $i \in [n]$ and $k \in [3]$, such that $M(ik, jl) = v_{ik}^T v_{jl}$. Since $M(ik, ik) = 1$, each v_{ik} is a unit vector. Now, our aim is to round M to a product state solution $\rho_{\text{prod}} = \rho_1 \otimes \cdots \otimes \rho_n$ on n qubits. Thus, writing ρ_i in terms of its Bloch vector $\rho_i = (I + r_{i1}X + r_{i2}Y + r_{i3}Z)/2$ each v_{ik} should be thought of as a $3n$ -dimensional relaxation of $r_{ik} \in \mathbb{R}$. For any $v \in \mathbb{R}^p$, $w \in \mathbb{R}^q$, define operation

$$v \circ w = \begin{cases} 0 & \text{if } v = 0 \text{ and } w = 0 \\ v & \text{if } v \neq 0 \text{ and } w = 0 \\ w & \text{if } w \neq 0 \text{ and } v = 0 \\ (v^T, w^T)^T & \text{otherwise,} \end{cases}$$

where $(v^T, w^T)^T \in \mathbb{R}^{p+q}$ denotes the concatenation of v and w . Recalling that $H \in F_{\alpha, \beta, \gamma}$ for $\alpha, \beta, \gamma \in \{0, 1\}$, we now set

$$u_i := (\alpha v_{i1}) \circ (\beta v_{i2}) \circ (\gamma v_{i3}) \in \mathbb{R}^{(\alpha+\beta+\gamma)3n}.$$

This yields first that $w_{ij}(1 - u_i^T u_j)$ equals the term in the relaxed SDP objective function for H corresponding to edge $(i, j) \in E$. For example, if $H \in F_{1,1,0}$ (i.e. the local terms are $w_{ij}(I - X_i X_j - Y_i Y_j)$), then $u_i \in \mathbb{R}^{6n}$ and for edge $(i, j) \in E$ we have $M(i1, j1) + M(i2, j2) = u_i^T u_j$. Second, we have $\|u_i\|_2 = \sqrt{\alpha + \beta + \gamma}$.

To obtain the desired claim, define now $x_i = u_i / \|u_i\|_2$. We use a generalization of the Goemans-Williamson (GW) [19] rounding procedure due to Briët, de Oliveira Filho and Vallentin [12]. Specifically, we randomly round each $x_i \in \mathbb{R}^{(\alpha+\beta+\gamma)3n}$ to a Bloch vector $y_i \in \mathbb{R}^{\alpha+\beta+\gamma}$ as follows. Let R be a random $(\alpha + \beta + \gamma) \times (\alpha + \beta + \gamma)3n$ matrix, each of whose entries is chosen independently from a standard normal distribution with mean 0 and variance 1. Then, for each i , set

$$y_i = R x_i / \|R x_i\|_2 \in \mathbb{R}^{\alpha+\beta+\gamma}.$$

We map this to a (pure) single-qubit state ρ_i as follows. Let $I(k)$ be the index in sequence (α, β, γ) of the k th non-zero entry (if it exists), for $k \in \{1, 2, 3\}$. Then, set the $I(k)$ -th Bloch vector entry of ρ_i to $y_{i,k}$. For example, if $\alpha = \beta = \gamma = 1$, this yields $\rho_i = (I + y_{i,1}X + y_{i,2}Y + y_{i,3}Z)/2$, if $\alpha = \beta = 1$ and $\gamma = 0$, this yields $\rho_i = (I + y_{i,1}X + y_{i,2}Y)/2$, and if $\alpha = \beta = 0$ and $\gamma = 1$, this yields $\rho_i = (I + y_{i,1}Z)/2$ (note the subscript 1 in $y_{i,1}$). For ease of exposition, henceforth we refer to the Bloch vector for ρ_i as $\mathbf{r}_i = (r_1, r_2, r_3)$, where the entries of \mathbf{r}_i which are not set in the rounding scheme above being implicitly set to 0. For example, $\mathbf{r}_i = (y_{i,1}, y_{i,2}, y_{i,3})$, $\mathbf{r}_i = (y_{i,1}, y_{i,2}, 0)$, and $\mathbf{r}_i = (0, 0, y_{i,1})$, respectively, in the examples above.

31:10 Approximation Algorithms for a Quantum Generalization of Max-Cut

Approximation ratio. To analyze the approximation ratio obtained, note that for edge $(i, j) \in E$, we have

$$\begin{aligned}
 w_{ij} \operatorname{tr}(H_{ij} \rho_{\text{prod}}) &= \frac{w_{ij}}{4} \operatorname{tr}(H_{ij}(I + r_{i,1}X_i + r_{i,2}Y_i + r_{i,3}Z_i)(I + r_{j,1}X_j + r_{j,2}Y_j + r_{j,3}Z_j)) \\
 &= \frac{w_{ij}}{4} \operatorname{tr}((I - \alpha X_i X_j - \beta Y_i Y_j - \gamma Z_i Z_j) \cdot \\
 &\quad (I + r_{i,1}X_i + r_{i,2}Y_i + r_{i,3}Z_i)(I + r_{j,1}X_j + r_{j,2}Y_j + r_{j,3}Z_j)) \\
 &= w_{ij}(1 - \alpha r_{i,1}r_{j,1} - \beta r_{i,2}r_{j,2} - \gamma r_{i,3}r_{j,3}) \\
 &= w_{ij}(1 - y_i^T y_j).
 \end{aligned}$$

On the other hand, recall the SDP obtains value $w_{ij}(1 - u_i^T u_j)$ on edge $(i, j) \in E$. For brevity, let $F[r, u^T v]$ denote the right hand side of Equation 12 (Lemma 10 in Appendix C). A direct application of Lemma 10 yields $\mathbb{E}[y_i^T y_j] = F[\alpha + \beta + \gamma, x_i^T x_j]$. Then, by linearity of expectation, the expected approximation ratio is given by the expected ratio attained on each edge, which is

$$\frac{1 - \mathbb{E}[y_i^T y_j]}{1 - u_i^T u_j} = \frac{1 - F[\alpha + \beta + \gamma, x_i^T x_j]}{1 - u_i^T u_j} = \frac{1 - F[\alpha + \beta + \gamma, t]}{1 - (\alpha + \beta + \gamma)t},$$

where we defined $t = x_i^T x_j$ (note the value of F only depends on t ; see Appendix C). Numerically evaluating via Mathematica (see Appendix C for Mathematica code)

$$\min_{t \in [-1, 1/(\alpha + \beta + \gamma))} \frac{1 - F[t]}{1 - (\alpha + \beta + \gamma)t},$$

we obtain ratios of 0.878 (for $\alpha + \beta + \gamma = 1$), 0.649 (for $\alpha + \beta + \gamma = 2$), and 0.498 (for $\alpha + \beta + \gamma = 3$), respectively. Note we minimize over $t \in [-1, 1/(\alpha + \beta + \gamma))$, since for $t \in [1/(\alpha + \beta + \gamma), 1]$ the ratio can only be negative (the denominator is negative, and the numerator is in range $[0, 2]$). This completes the proof. \blacktriangleleft

4.1 Generalizations beyond the Heisenberg model

We defined the Heisenberg model $F_{\alpha, \beta, \gamma}$ in Section 2 as having all constraints identical with some fixed $(\alpha, \beta, \gamma) \in \{0, 1\}^3$. We now show how to extend the algorithm to two more general settings: The first will allow different choices of $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in [1, -1]$ on each edge (note the use of $[1, -1]$ instead of $\{0, 1\}$), and the second will require that all constraints remain identical but in exchange allows new interaction terms beyond XX, YY, ZZ .

4.1.1 Approximating Heisenberg models with varying Pauli weights

The approximation algorithm developed in the previous section made critical use of the fact that $\alpha, \beta, \gamma \in \{0, 1\}$ for our Heisenberg model $F_{\alpha, \beta, \gamma}$. Here, we generalize by allowing two relaxations, captured below in the form of constraints now allowed:

$$H_{ij} = w_{ij}(I - \alpha_{ij}X_i X_j - \beta_{ij}Y_i Y_j - \gamma_{ij}Z_i Z_j),$$

where $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in [-1, 1]$. The two relaxations to note are (1) $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in [-1, 1]$ instead of in $\{0, 1\}$, and (2) each edge $(i, j) \in E$ may have a different choice of $\alpha_{ij}, \beta_{ij}, \gamma_{ij}$. In this setting, we shall use the same relaxation as Section 4, but utilize another rounding strategy. In exchange for the added generality, the approximation ratios obtained are slightly weaker than those of Section 4.

In the theorem below, for brevity we call the sets $\{\alpha_{ij}\}, \{\beta_{ij}\}, \{\gamma_{ij}\}$ *parameter families*. We say a parameter family is *non-zero* if at least one parameter in the family is non-zero, e.g. there exists $(i, j) \in E$ such that $\alpha_{ij} \neq 0$ for family $\{\alpha_{ij}\}$.

► **Theorem 7.** *Let $H = \sum_{(i,j) \in E} H_{ij}$ be a 2-local Hamiltonian on qubits with constraints*

$$H_{ij} = w_{ij}(I - \alpha_{ij}X_iX_j - \beta_{ij}Y_iY_j - \gamma_{ij}Z_iZ_j),$$

where $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in [-1, 1]$ and $w_{ij} \in \mathbb{R}^+$. There exists a randomized, polynomial-time algorithm which obtains approximation ratio at least 0.878 (if precisely one parameter family is non-zero), 0.609 (if precisely two parameter families are non-zero), and 0.462 (if all three parameter families are non-zero).

Proof. We begin by mapping H to a “canonical” form.

Setup in “canonical” form. For now, assume $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \neq 0$ (later we will get improved ratios when some of these values are 0 for every $(i, j) \in E$). Our first observation is that we may assume $\alpha_{ij}, \beta_{ij}, \gamma_{ij} \in \{-1, 1\}$. This is because any vector $(\alpha_{ij}, \beta_{ij}, \gamma_{ij}) \in [-1, 1]^3$ is a convex combination of vectors with coordinates in $\{-1, +1\}$ (i.e. the former lies in the convex hull of discrete points $(x, y, z) \in \{-1, 1\}^3$). Thus any H_{ij} of the above form may be expressed as convex combination,

$$H_{ij} = \sum_{k=1}^4 w_{ij} \lambda_k (I - \alpha_{ij,k} X_i X_j - \beta_{ij,k} Y_i Y_j - \gamma_{ij,k} Z_i Z_j), \quad (4)$$

with $\alpha_{ij,k}, \beta_{ij,k}, \gamma_{ij,k} \in \{-1, 1\}$, and $\lambda_k \geq 0$ with $\sum_{k=1}^4 \lambda_k = 1$. Notes: (1) Since we allow multiple edges between i and j , we may include an edge for each term of the convex combination. (2) That we require at most 4 terms λ_k follows from Carathéodory’s theorem, which says that a point in \mathbb{R}^d in the convex hull of some set P requires at most $d + 1$ points of P to express as a convex combination. (3) Our approximation ratio analysis below will again be via expectation per edge, which by linearity of expectation yields that no loss in approximation is incurred by writing our constraints as in Equation (4).

Rounding algorithm. We employ the same moment SDP relaxation as in Section 4, and continue to use the terminology therein. Consider the vectors $v_{i1}, v_{i2}, v_{i3} \in \mathbb{R}^{3n}$ corresponding to an optimal solution of the SDP relaxation. The objective value of the relaxation is $w_{\text{SDP}} := \sum_{(i,j) \in E} w_{ij} (1 - \alpha_{ij} v_{i1}^T v_{j1} - \beta_{ij} v_{i2}^T v_{j2} - \gamma_{ij} v_{i3}^T v_{j3})$. Now suppose, without loss of generality (any other ordering is handled analogously):

$$- \sum_{(i,j) \in E} w_{ij} \gamma_{ij} v_{i3}^T v_{j3} \geq - \sum_{(i,j) \in E} w_{ij} \beta_{ij} v_{i2}^T v_{j2} \geq - \sum_{(i,j) \in E} w_{ij} \alpha_{ij} v_{i1}^T v_{j1},$$

so that

$$\sum_{(i,j) \in E} w_{ij} (1 - 3\gamma_{ij} v_{i3}^T v_{j3}) \geq w_{\text{SDP}}. \quad (5)$$

Recall that the v_{i3} are unit vectors (since our SDP had constraint $M(ik, ik) = 1$ for all i, k). Hence, we may view the v_{i3} as a feasible solution for the Max-Cut SDP relaxation of Goemans and Williamson and consequently, use the same rounding algorithm [19]:

31:12 Approximation Algorithms for a Quantum Generalization of Max-Cut

1. Select a random vector $r \in \mathbb{R}^{3n}$ with each entry independently and normally distributed with mean 0 and variance 1.
2. Let $r_i = r^T v_{i3} / |r^T v_{i3}| \in \{-1, 1\}$.
3. Output the product state, $\prod_i \frac{1}{2}(I + r_i Z_i)$.

Note that since the assignment above is diagonal in the Z basis (i.e. is a standard basis state), it lies in the null space of each XX and YY term of our Hamiltonian. Consequently, our expected objective value for this assignment on our Hamiltonian is

$$w_{\text{EXP}} := \sum_{(i,j) \in E} \mathbb{E}[w_{ij}(1 - \gamma_{ij} r_i r_j)] = \sum_{(i,j) \in E} w_{ij}(1 - \gamma_{ij} 2 \arcsin(v_{i3}^T v_{j3}) / \pi),$$

where the second equality follows by (1) linearity of expectation and (2) the standard analysis of the Goemans-Williamson algorithm [19], which states that $E[r_i r_j] = 2 \arcsin(v_{i3}^T v_{j3}) / \pi$.

Approximation ratio. We conclude by bounding the expected approximation ratio, $w_{\text{EXP}}/w_{\text{SDP}}$. As for the analysis of the algorithm from the previous section, we need only consider the worst-case behavior on any edge. Using (5), this is:

$$\min_{\gamma \in \{-1, 1\}, t \in [-1, 1]: 3\gamma t < 1} \frac{1 - \gamma 2 \arcsin(t) / \pi}{1 - 3\gamma t},$$

where γ represents γ_{ij} , and t represents $v_{i3}^T v_{j3}$. Numerically, this yields a ratio of 0.462. A similar analysis produces an approximation ratio of 0.609 for the case when either $\alpha_{ij} = 0$ for all $(i, j) \in E$, $\beta_{ij} = 0$ for all $(i, j) \in E$, or $\gamma_{ij} = 0$ for all $(i, j) \in E$. We recover the Goemans-Williamson 0.878-approximation in the case when two of these parameters are 0 for all $(i, j) \in E$. ◀

4.1.2 Reductions via local unitaries

We now generalize the algorithm of Section 4 in a different manner. Specifically, using a standard trick from entanglement theory (used also in [14] in a somewhat different manner), we may give an approximation-preserving reduction to the Heisenberg model in certain cases. Namely, recall that any two-qubit Hermitian operator H_{ij} can be expanded in the Pauli basis as follows (sometimes known as the *Fano form* [15]), given by:

$$H_{ij} = \kappa I + \sum_{a=1}^3 \sum_{b=1}^3 M_{ab} \sigma_a \otimes \sigma_b + \sum_{a=1}^3 r_a \sigma_a \otimes I + \sum_{b=1}^3 s_b I \otimes \sigma_b, \quad (6)$$

where $\kappa, M_{ab}, r_a, s_b \in \mathbb{R}$. The 3×3 real matrix M , which has no particular structure in general (for example, it need not be diagonalizable), is called the *correlation matrix* in entanglement theory.

► **Theorem 8.** *Let H be a 2-local Hamiltonian on n qubits, and with directed interaction graph $G = (V, E)$, where $H = \sum_{(i,j) \in E} w_{ij} H_{ij}$ for non-negative real weights w_{ij} . Assume*

1. *all H_{ij} are identical with $\kappa = r_1 = r_2 = r_3 = s_1 = s_2 = s_3 = 0$, and*
2. *the correlation matrix M of H_{ij} is an orthogonal projection (i.e. M is symmetric with $M^2 = M$).*

Then, there exists a randomized, polynomial-time algorithm which obtains approximation ratios at least 0.878, 0.649 or 0.498, when the rank of M equals 1, 2 or 3, respectively. Conversely, the best possible product-state ratio (not necessarily efficiently attainable) in each case is 1, 2/3, and 1/2, respectively.

Proof. We use the approach of [22, 23] of simulating orthogonal rotations on M via local unitary operations on H_{ij} . Namely, due to the surjective homomorphism from $SU(2)$ to $SO(3)$, if one wishes to map M to $O_1MO_2^T$ for orthogonal matrices O_1 and O_2 , there exist single-qubit unitaries U and V such that $U_i \otimes V_j H_{ij} U_i^\dagger \otimes V_j^\dagger$ has correlation matrix $O_1MO_2^T$. Since M is symmetric, it is diagonalizable by an orthogonal matrix $O \in \mathbb{R}^{3 \times 3}$ (Corollary 2.5.14 of [21]). Thus, there exists a single-qubit unitary U such that $U_i \otimes U_j H_{ij} U_i^\dagger \otimes U_j^\dagger$ has a diagonal correlation matrix with eigenvalues from set $\{0, 1\}$. Since all constraints H_{ij} are identical, it follows that $U^{\otimes n} H (U^\dagger)^{\otimes n}$ is a Hamiltonian in family $F_{\alpha, \beta, \gamma}$ for some $\alpha, \beta, \gamma \in \{0, 1\}$. The algorithm of Theorem 6 now yields the claimed lower bound on approximation. The claimed upper bound on approximation follows from Corollary 5. In both cases, we are leveraging the fact that our reduction applies only single-qubit unitary operations, and hence perfectly preserves approximation ratios attained by product states. ◀

Note that Theorem 8 uses the algorithm of Section 4. If we are willing to obtain slightly worse approximation ratios, we can relax the second requirement of Theorem 8 by instead applying the algorithm of Section 4.1.1.

► **Theorem 9.** *Let H be a 2-local Hamiltonian on n qubits, and with directed interaction graph $G = (V, E)$, where $H = \sum_{(i,j) \in E} w_{ij} H_{ij}$ for non-negative real weights w_{ij} . Assume*

1. *all H_{ij} are identical with $\kappa = r_1 = r_2 = r_3 = s_1 = s_2 = s_3 = 0$, and*
2. *the correlation matrix M of H_{ij} is symmetric.*

Then, there exists a randomized, polynomial-time algorithm which obtains approximation ratios at least 0.878, 0.609 or 0.462, when the rank of M equals 1, 2 or 3, respectively. Conversely, the best possible product-state ratio (not necessarily efficiently attainable) in each case is 1, 2/3, and 1/2, respectively.

The proof is identical to that of Theorem 8, except we use the rounding algorithm of Section 4.1.1 instead; we hence omit the proof.

A Max Cut as a special case of the Heisenberg model

We briefly sketch why local constraints $H_{ij} = I - Z_i \otimes Z_j$ in the Heisenberg model yield the NP-complete problem Max Cut. Namely, the Pauli Z operator

$$Z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}$$

is diagonal in the standard basis with eigenvalues 1 for eigenvector $|0\rangle$ and -1 for eigenvector $|1\rangle$. It follows that $Z \otimes Z$ also diagonalizes in the standard basis, with eigenvectors $|00\rangle$ and $|11\rangle$ attaining eigenvalue 1 and $|01\rangle$ and $|10\rangle$ attaining eigenvalue -1 . As a result, operator $I - Z_i \otimes Z_j$ has eigenvalues 0 (with eigenspace spanned by $|00\rangle$ and $|11\rangle$) and 2 (with eigenspace spanned by $|01\rangle$ and $|10\rangle$). But this means that on each edge $(i, j) \in E$,

$$\begin{aligned} \langle 00|I - Z_i \otimes Z_j|00\rangle &= \langle 11|I - Z_i \otimes Z_j|11\rangle = 0, \text{ and} \\ \langle 01|I - Z_i \otimes Z_j|01\rangle &= \langle 10|I - Z_i \otimes Z_j|10\rangle = 2. \end{aligned}$$

In other words, if neighboring qubits are set to opposing standard basis states (e.g. $|01\rangle$), then we obtain value 2 from an edge, and if the qubits are set to identical standard basis states (e.g. $|00\rangle$), we obtain value 0 from this edge. Finally, since all local terms are diagonal in the standard basis, the entire Hamiltonian $H = \sum_{(i,j) \in E} H_{ij}$ will also be diagonal in the standard basis. The largest eigenvalue of H will hence be the sum of the values obtained on each edge by the best standard basis state, which will correspond to a maximum cut in the graph. The actual largest eigenvalue will equal twice the maximum cut on the underlying graph (since we obtain value 2 on each cut edge, rather than 1 as for the standard Max Cut problem).

B Proofs for Section 2

Proof of Lemma 2. Observe that for standard basis vectors $|i\rangle, |j\rangle, |k\rangle, |l\rangle \in \mathbb{C}^2$, we have

$$\langle ij|X \otimes X|kl\rangle = (i \oplus k)(j \oplus l), \quad (7)$$

$$\langle ij|Y \otimes Y|kl\rangle = (-1)^{\delta_{kl}}(i \oplus k)(j \oplus l), \quad (8)$$

$$\langle ij|Z \otimes Z|kl\rangle = (-1)^{k \oplus l} \delta_{ik} \delta_{jl}, \quad (9)$$

where δ_{ij} is the usual Kronecker delta. Denoting an arbitrary product state as $|\psi\rangle = ac|00\rangle + ad|01\rangle + bc|10\rangle + bd|11\rangle$ for $|a|^2 + |b|^2 = |c|^2 + |d|^2 = 1$, we have

$$\begin{aligned} \langle \psi|H|\psi\rangle &= \alpha(a^*c^*bd + acb^*d^* + a^*d^*bc + adb^*c^*) + \\ &\quad \beta(-a^*c^*bd - acb^*d^* + a^*d^*bc + adb^*c^*) + \\ &\quad \gamma(|a|^2|c|^2 + |b|^2|d|^2 - |a|^2|d|^2 - |b|^2|c|^2) \\ &= 2\operatorname{Re}[acb^*d^*](\alpha - \beta) + 2\operatorname{Re}[adb^*c^*](\alpha + \beta) + \\ &\quad \gamma(|a|^2|c|^2 + |b|^2|d|^2 - |a|^2|d|^2 - |b|^2|c|^2) \\ &\leq 2|a||b||c||d|(|\alpha + \beta| + |\alpha - \beta|) + \\ &\quad |\gamma| \left| (|a|^2 - |b|^2)(|c|^2 - |d|^2) \right|. \end{aligned} \quad (10)$$

where the last inequality follows from the triangle inequality. Let us simplify the notation above by assuming without loss of generality $a, b, c, d \in \mathbb{R}^+$. We may also assume without loss of generality that $a \geq b$ and $c \geq d$ (since this maximizes the upper bound). Thus:

$$\langle \psi|H|\psi\rangle \leq 2abcd(|\alpha + \beta| + |\alpha - \beta|) + |\gamma|(a^2 - b^2)(c^2 - d^2).$$

31:16 Approximation Algorithms for a Quantum Generalization of Max-Cut

Note now for any $\alpha, \beta \in \mathbb{R}$, $|\alpha + \beta| + |\alpha - \beta| = \|\alpha\| + \|\beta\| + \|\alpha\| - \|\beta\|$. Assume first $|\alpha| \geq |\beta|$. Then

$$\langle \psi | H | \psi \rangle \leq 4abcd|\alpha| + |\gamma|(a^2 - b^2)(c^2 - d^2). \quad (11)$$

Let $p = 4abcd$ and $q = (a^2 - b^2)(c^2 - d^2)$. Note $p, q \geq 0$. Also, we claim $p + q \leq 1$; this will imply $\langle \psi | H | \psi \rangle \leq \max(|\alpha|, |\gamma|)$. To see this claim, note

$$p + q = (ac + bd)^2 - (ad - bc)^2 \leq (ac + bd)^2 \leq 1,$$

where the last inequality follows from the Cauchy-Schwarz inequality. The case of $|\beta| \geq |\alpha|$ follows analogously with $|\alpha|$ in Equation (11) replaced with $|\beta|$. We hence have $\langle \psi | H | \psi \rangle \leq \max(|\alpha|, |\beta|, |\gamma|) = \|(|\alpha|, |\beta|, |\gamma|)\|_\infty$.

We now show matching lower bounds, i.e. that $|\alpha|$, $|\beta|$, and $|\gamma|$ are attainable. Returning to Equation (10):

- For $|\alpha|$: If $\alpha \geq 0$, set $a = b = c = d = 1/\sqrt{2}$, and if $\alpha < 0$, set $a = b = c = 1/\sqrt{2}$ and $d = -1/\sqrt{2}$.
- For $|\beta|$: If $\beta \geq 0$, set $a = i/\sqrt{2}$, $c = i/\sqrt{2}$, $b = d = 1/\sqrt{2}$, and if $\beta < 0$, set $a = -i/\sqrt{2}$, $c = i/\sqrt{2}$, $b = d = 1/\sqrt{2}$.
- For $|\gamma|$: If $\gamma \geq 0$, set $a = c = 1$ and $b = d = 0$. and if $\gamma < 0$, set $a = d = 1$, $b = c = 0$. ◀

Proof of Lemma 3. Denoting an arbitrary two-qubit state as $|\psi\rangle = a|00\rangle + b|01\rangle + c|10\rangle + d|11\rangle$ for $|a|^2 + |b|^2 = |c|^2 + |d|^2 = 1$, we have via Equations (7)-(9) that

$$\begin{aligned} \langle \psi | X \otimes X | \psi \rangle &= a^*d + ad^* + b^*c + bc^*, \\ \langle \psi | Y \otimes Y | \psi \rangle &= -a^*d - ad^* + b^*c + bc^*, \\ \langle \psi | Z \otimes Z | \psi \rangle &= |a|^2 - |b|^2 - |c|^2 + |d|^2. \end{aligned}$$

Thus, $\langle \psi | H | \psi \rangle$ equals

$$\begin{aligned} &\alpha(2 \operatorname{Re}(ad^*) + 2 \operatorname{Re}(bc^*)) + \beta(-2 \operatorname{Re}(ad^*) + 2 \operatorname{Re}(bc^*)) + \gamma(|a|^2 + |d|^2 - |b|^2 - |c|^2) \\ &= 2 \operatorname{Re}[ad^*](\alpha - \beta) + 2 \operatorname{Re}[bc^*](\alpha + \beta) + (|a|^2 + |d|^2 - |b|^2 - |c|^2)\gamma. \end{aligned}$$

Observe that since the coefficient of γ depends on only *absolute values* of a, b, c, d , we can assume without loss of generality that the optimal assignment has $a, b, c, d \geq 0$ and satisfies

$$\langle \psi | H | \psi \rangle = 2ad|\alpha - \beta| + 2bc|\alpha + \beta| + (a^2 + d^2 - b^2 - c^2)\gamma.$$

By applying the Arithmetic-Geometric mean inequality, we hence have

$$\begin{aligned} \langle \psi | H | \psi \rangle &\leq (a^2 + d^2)|\alpha - \beta| + (b^2 + c^2)|\alpha + \beta| + (a^2 - b^2 - c^2 + d^2)\gamma \\ &= (a^2 + d^2)(|\alpha - \beta| + \gamma) + (b^2 + c^2)(|\alpha + \beta| - \gamma) \\ &\leq \max(|\alpha - \beta| + \gamma, |\alpha + \beta| - \gamma), \end{aligned}$$

where the last statement follows since $a^2 + b^2 + c^2 + d^2 = 1$. The matching lower bound is obtained as follows. To achieve $|\alpha - \beta| + \gamma$ when $\alpha \geq \beta$, set $a = d = 1/\sqrt{2}$, and when $\alpha \leq \beta$, set $a = 1/\sqrt{2}$, $d = -1/\sqrt{2}$. Similarly, to achieve $|\alpha + \beta| - \gamma$ when $\alpha \geq -\beta$, set $b = c = 1/\sqrt{2}$, and when $\alpha \leq -\beta$, set $b = 1/\sqrt{2}$, $c = -1/\sqrt{2}$. ◀

C Lemmas and Mathematica code

In Section 4 we use the following lemma, which is stated as given in [12]. Below, ${}_2F_1(a, b; c; z)$ is the hypergeometric function, defined for $|z| < 1$ as

$${}_2F_1(a, b; c; z) = \sum_{n=0}^{\infty} \frac{(a)_n (b)_n}{(c)_n} \frac{z^n}{n!},$$

where for $n \geq 0$, we have Pochhammer symbol $(x)_n = \Gamma(x+n)/\Gamma(x) = x(x+1)\cdots(x+n-1)$ for Γ the Gamma function.

► **Lemma 10** (Briët, de Oliveira Filho and Vallentin [12]). *Let u, v be unit vectors in \mathbb{R}^n and let $Z \in \mathbb{R}^{r \times n}$ be a random matrix whose entries are distributed independently according to the standard normal distribution with mean 0 and variance 1. Then,*

$$\mathbb{E} \left[\frac{Zu}{\|Zu\|_2} \cdot \frac{Zv}{\|Zv\|_2} \right] = \frac{2}{r} \left(\frac{\Gamma((r+1)/2)}{\Gamma(r/2)} \right)^2 (u \cdot v) {}_2F_1(1/2, 1/2; r/2 + 1; (u \cdot v)^2). \quad (12)$$

Mathematica code

Below, we give the Mathematica code used to numerically calculate the approximation ratios of Theorem 6:

```
g[r_] := 2/r (Gamma[(r + 1)/2]/Gamma[r/2])^2
F[r_, t_] := g[r] t Hypergeometric2F1[1/2, 1/2, r/2 + 1, t^2]
ApproxRatio[r_] := Min[Select[ Table[(1 - F[r, t])/(1 - r t),
                                     {t, -1, 1/r, 0.01}], # > 0 &]]

ApproxRatio[1]
ApproxRatio[2]
ApproxRatio[3]
```

The code for the approximation ratios in Section 4.1.1 is:

```
ApproxRatio[r_] :=
Min[Select[ Flatten[Table[(1 - g 2 ArcSin[t]/Pi)/(1 - r g t),
                          {g, -1, 1}, {t, -1, 1, 0.01}]], # > 0 &]]

ApproxRatio[1]
ApproxRatio[2]
ApproxRatio[3]

Abstract

Given a set \mathcal{D} of n unit disks in the plane and an integer $k \leq n$, the maximum area connected subset problem asks for a set $\mathcal{D}' \subseteq \mathcal{D}$ of size k that maximizes the area of the union of disks, under the constraint that this union is connected. This problem is motivated by wireless router deployment and is a special case of maximizing a submodular function under a connectivity constraint.

We prove that the problem is NP-hard and analyze a greedy algorithm, proving that it is a $\frac{1}{2}$ -approximation. We then give a polynomial-time approximation scheme (PTAS) for this problem with resource augmentation, i.e., allowing an additional set of εk disks that are not drawn from the input. Additionally, for two special cases of the problem we design a PTAS without resource augmentation.

1 Introduction

Maximizing a submodular function¹ under constraints is a classical problem in computer science and operations research [8, 23]; the most commonly studied constraints are cardinality, knapsack and matroids constraints. A natural constraint that has received little attention is

¹ Given a set X , a function $f : 2^X \rightarrow \mathbb{R}$ is *submodular* if given any two subsets $A, B \subseteq X$, $f(A) + f(B) \geq f(A \cap B) + f(A \cup B)$.

the *connectivity* constraint. In this paper, we study the following problem: given a set of n unit disks in the plane, select a subset of k disks that maximize the area of their union, under the constraint that this union is connected. We call this problem the *Maximum Area Connected Subset* problem (MACS). Notice that the area covered by a set of disks is a monotone submodular function.

The problem is motivated by wireless router deployment, first introduced in [14], where the goal is to install a given number of routers to maximize the number of clients covered. When the clients are uniformly spread in the plane, the number of clients in a region can be approximated by the area of that region, leading to our problem.

Our Contributions

We first analyze a variant of the greedy algorithm and show that it computes a $\frac{1}{2}$ -approximation to MACS (Theorem 3); further, the analysis is tight. In contrast, the natural algorithm that greedily adds one disk at a time can end up with a solution with area a factor of $\Omega(k)$ worse than the optimal solution.

To improve upon the $\frac{1}{2}$ -approximation ratio, we turn to the resource augmentation setting in which the algorithm is allowed to add a few additional disks that need not be drawn from the input. We design a PTAS for the resource augmentation version of the problem using Arora's shifted quadtree technique (Theorem 4)². The proof hinges on the existence of a near-optimal solution with $O(\varepsilon k)$ additional disks and with additional structure that allows its computation by dynamic programming.

As a corollary, we show that for two special cases of MACS we can in fact design a PTAS without resource augmentation: *i*) when the Euclidean distances between centers of the input disks are well-approximated by shortest paths in their intersection graph (Corollary 6), and *ii*) when every point of the relevant region of the Euclidean plane is covered by at least one input disk (Corollary 9).

On the other hand, via a reduction from the Rectilinear Steiner Tree problem, we show that MACS is NP-hard (Theorem 3). We also show that MACS for the input of a set of quadrilaterals instead of disks, the problem is APX-hard (Theorem 12). We leave open the question whether MACS is APX-hard or admits a PTAS without resource augmentation.

Related work

Maximising a monotone submodular function under constraint(s) is a subject that has received a large amount of attention over the years. We refer the readers to [2, 5, 6, 8, 13, 15, 23] and the references therein. Our problem can be regarded as maximising a submodular function under a cardinality (knapsack) constraint and a connectivity constraint. Notice that the connectivity constraint is central to the difficulty of our problem: without connectivity constraints, MACS admits a PTAS even in the more general case of convex pseudodisks [4]. However even without the connectivity constraint the problem remains NP-hard³.

Another motivation for studying the connectivity constraint is related to cancer genome studies. Suppose that a vertex represents an individual protein (and associated gene), an edge represents pairwise interactions, and each vertex has an associated set. Finding the connected subgraph of k genes that is mutated in the largest number of samples is equivalent to the problem of finding the connected subgraph with k nodes that maximizes the cardinality of the union of the associated sets (see [21]).

² We also develop an alternative algorithm using Mitchell's m -guillotine dissection technique. See the full version for details.

³ The reduction is from Maximum independent set problem that is NP-hard in unit-disk graphs.

In the general (non-geometric) setting, there exists a $O\left(\frac{1}{\sqrt{k}}\right)$ -approximation algorithm for maximizing a monotone submodular function [14]. Our results show that when the submodular function and the connectivity are induced by a geometric configuration, the approximation ratio can be significantly improved.

We next consider several related problems where the connectivity constraint plays an important role. The goal of the node-cost budget problem [20] is to find a connected set of vertices in a general graph to collect the maximum profit on the vertices while guaranteeing the total cost does not exceed a certain budget. Notice that in this setting the submodular function is a simple additive function of the profits. Another related problem [3] is to assign radii to a given set of points in the plane so that the resulting set of disks is connected and the objective is to minimize the sum of radii.

Khuller et al. [12] study the budgeted connected dominating set problem where given a general undirected graph, the goal is to select k vertices whose induced subgraph is connected and that maximizes the number of dominated vertices. It was pointed out to us that their algorithm can be used to give a $\frac{1}{13}\left(1 - \frac{1}{e}\right)$ -approximate solution for MACS. The authors of [10] consider the problem of selecting k nodes of an input node-weighted graph to form a connected subgraph, with the aim of maximizing or minimizing the selected weight.

We now turn to the geometric setting. A logarithmic-factor approximation algorithm is known [9] for the connected sensor coverage problem in which one must select at most k sensors in the plane forming a connected communication network and covering the desired region, where the region covered by each sensor is convex [7, 11]. A $(1 - \varepsilon)$ -approximation algorithm in time $n^{O(1/\varepsilon)}$ for the maximum independent set problem on unit disk graphs is known [17]. The authors of [16] present a constant-factor approximation algorithm for several problems on unit disk graphs, including maximum independent set. For the geometric set cover problem where the goal is to cover a given set of input points with a minimum number of given disks, a PTAS is possible [18].

2 Our results

The Euclidean distance between two points x and y is denoted by $\|x - y\|$. When there is no confusion, we will refer to a point x in the plane and the unit disk centered at x interchangeably.

► **Definition 1.** *Given a finite set S in the plane, the unit disk intersection graph $\text{UDG}(S)$ is a graph on S where $\{x, y\} \subseteq S$ is an edge of $\text{UDG}(S)$ if and only if $\|x - y\| \leq 2$.*

A set S of points in the plane are *connected* if $\text{UDG}(S)$ is a connected graph.

► **Definition 2.** *The Maximum Area Connected Subset (MACS) problem is as follows.*

Input: *a finite set of points $X \subseteq \mathbb{R}^2$ and a non-negative integer k , where $k \leq |X|$.*

Output: *a subset $S \subseteq X$ of size at most k such that the unit-disk graph $\text{UDG}(S)$ of S is connected.*

Goal: *maximize the area of the union of the unit disks centered at the points of S .*

The optimal solution of MACS on input (X, k) is denoted by $\text{OPT}(X, k)$.

When the context is clear, we refer to $\text{OPT}(X, k)$ as OPT , which is also used to denote the area covered by the optimal solution; observe that OPT is trivially upper-bounded by πk . Any $S \subseteq X$ with $|S| \leq k$ for which $\text{UDG}(S)$ is connected is called a *feasible solution*.

We state our main results below. All omitted proofs and figures can be found in the appendix or in the full version.

► **Theorem 3** (Approximation). *There exists a polynomial-time algorithm that computes a $\frac{1}{2}$ -approximation for MACS (Algorithm 1).*

With resource augmentation, we obtain a $(1 - \varepsilon)$ -approximation.

► **Theorem 4** (Resource augmentation). *Let $\varepsilon > 0$ be a given parameter. Given a set of points $X \subseteq \mathbb{R}^2$ and a non-negative integer k , there is an algorithm (Algorithm 2) that computes, in time $n^{\mathcal{O}(\varepsilon^{-3})}$, a subset $S \subseteq X$ of size at most k and a set $S_{add} \subseteq \mathbb{R}^2$ of at most εk points, such that $\text{UDG}(S \cup S_{add})$ is connected and the area of the union of the unit disks centered at S is at least $(1 - \varepsilon)\text{OPT}(X, k)$.*

Theorem 5 can be obtained alternatively by a (deterministic) guillotine cut approach with a faster running time. We leave that for the full version of the paper.

Let $d_G(x, y)$ denote the distance between two vertices x and y of G . A set X of points in the plane is called α -well-distributed if $\text{UDG}(X)$ is an α -spanner for X [19]:

► **Definition 5.** *Given $\alpha > 0$, a finite set X of points in the plane is called α -well-distributed if for all $x, y \in X$, $d_{\text{UDG}(X)}(x, y) \leq \lceil \alpha \cdot \|x - y\| \rceil$.*

► **Corollary 6.** *There exists a PTAS for MACS on α -well-distributed inputs, where α is a fixed constant (Algorithm 3).*

► **Definition 7.** *A set X is called pseudo-convex if the convex-hull of X is covered by the union of the unit disks centered at points of X .*

► **Lemma 8.** *A pseudo-convex set X is 3.82-well-distributed.*

► **Corollary 9.** *MACS on pseudo-convex inputs admits a polynomial-time approximation scheme.*

We next turn to the hardness of MACS.

► **Theorem 10** (Hardness). *MACS is NP-hard.*

► **Definition 11.** *The QUAD-CONNECTED-COVER is defined as follows.*

Input: *a set \mathcal{T} of n convex quadrilaterals in the plane, and an integer k .*

Output: *a subset T of \mathcal{T} of size k such that the intersection graph of T is connected.*

Goal: *Maximise the area covered by the union of quadrilaterals in T .*

► **Theorem 12.** *QUAD-CONNECTED-COVER is APX-hard.*

3 Proof of Theorem 3: the Two-by-two algorithm

In the section we present a simple $\frac{1}{2}$ -approximation for MACS based on a greedy approach: we iteratively add two unit disks that maximize the area covered while maintaining feasibility. Interestingly, the algorithm that adds disks one at a time is not a constant approximation algorithm. See Figure 1 for an example. Moreover, trying all possible sets of s disks, for any $s \geq 3$, in the neighborhood of the current solution does not improve the approximation ratio. This can be seen on Figure 2 where the first disk chosen by the algorithm is not x , but x_s .

Let B_x denote the unit disk centered at $x \in \mathbb{R}^2$ and $B(S) = \bigcup_{x \in S} B_x$ denote their union. The area covered by a set $C \subset \mathbb{R}^2$ is denoted by $\mathcal{A}(C)$. When $C = B(S)$, its area is simply written as $\mathcal{A}(S)$. Given a graph G , $G[S]$ denotes the subgraph induced by a subset S of vertices. A subset of the vertices of a graph is a *dominating set* if every vertex belongs to the set or is adjacent to some vertex of it.

■ **Figure 1** The greedy algorithm that adds only one connected disk maximising the marginal area covered is not a constant factor algorithm. For any $k \geq 0$ and $\varepsilon > 0$, consider the above input where $O = (0, 0)$, and $y_i = (2(i - 1) + \varepsilon, 0)$ for all i . Then, put all x_1, \dots, x_k evenly spaced (by an angle α) on a circle of radius 2 around O so that none of them intersect y_2 . Each light grey regions are covered by only one disk x_i so the marginal gain of adding x_i to any solution is at least the area of one of these regions, say $a > 0$. If ε is chosen such that $\mathcal{A}(B_{y_1} \setminus B_O) < a$, then if the algorithm starts by picking disk O , it will then choose all x_j , so that the area covered by the solution is upper-bounded by the area of a radius 3 disk, 9π , while the optimal solution (disks y_i) has area πk .

One can find an example similar to Figure 2 to show that optimising the initial choice of the first disk(s) does not improve the approximation ratio.

► **Theorem 3 (Approximation).** *There exists a polynomial-time algorithm that computes a $\frac{1}{2}$ -approximation for MACS (Algorithm 1).*

We can assume w.l.o.g. that $\text{UDG}(X)$ is connected; otherwise we return the maximum value over all connected components. The execution of Algorithm 1 is divided in two phases. An iteration belongs to the first phase as long as the current solution S is not a dominating set in the graph $\text{UDG}(X)$.

During the first phase, in each iteration the area covered increases by at least π . During the second phase, since the current solution is a dominating set, any disk can be added while keeping the solution feasible. Therefore the algorithm reduces to a standard greedy algorithm to maximize a submodular function, and the analysis is similar to the proof that Nemhauser's algorithm is a $(1 - \frac{1}{e})$ -approximation for classic submodular functions.

■ **Algorithm 1** The Two-by-two algorithm for MACS.

Input: $X \subseteq \mathbb{R}^2, k \geq 0$, where X is finite and $k \leq |X|$.

Output: a feasible set of size k .

```

1 if  $k$  is even then
2    $S \leftarrow$  any two intersecting disks of  $X$ ;
3 else
4    $S \leftarrow$  any one disk of  $X$ ;
5 while  $|S| \leq k - 2$  do
6    $\{x, x'\} \leftarrow \arg \max \{\mathcal{A}(S \cup \{x, x'\}) : x, x' \in X, S \cup \{x, x'\} \text{ is feasible}\}$ ;
7    $S \leftarrow S \cup \{x, x'\}$ ;
8 return  $S$ ;
```

32:6 Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint

Proof. We first analyze the even case where $k = 2\kappa$, and then we reduce the odd case to the even one. Let $S_\kappa = \{x_1, x_2, \dots, x_{2\kappa}\}$ be the solution returned by the algorithm. Let $S_i = \{x_1, \dots, x_{2i}\}$ be the set right before the i -th iteration and let d be the smallest integer such that S_d is a dominating set in $\text{UDG}(X)$. If such an integer does not exist, i.e., S_κ is not a dominating set, then set $d = \kappa$.

▷ **Claim 13.** The area $\mathcal{A}(S_d)$ is at least πd .

Proof. For $i < d$, S_i is not a dominating set. Then there exist two disks y, y' such that $B(S_i) \cap B_y = \emptyset$ and $S \cup \{y, y'\}$ is connected. Adding such a pair increases the area covered by at least $\mathcal{A}(B_y) = \pi$. Since (x_{2i+1}, x_{2i+2}) is chosen to maximize $\mathcal{A}(S_i \cup \{x, x'\})$ among all feasible pairs, $\mathcal{A}(S_{i+1}) \geq \mathcal{A}(S_i \cup \{y, y'\}) \geq \mathcal{A}(S_i) + \pi$. By induction, $\mathcal{A}(S_d) \geq \pi d$. ◁

Note that when $d = \kappa$, Claim 13 immediately implies that $\mathcal{A}(S_\kappa) \geq \frac{\text{OPT}}{2}$. Also regardless of the initial choice, the area covered by the first two disks is at least π . This observation will be useful when we prove the case where k is odd.

▷ **Claim 14.** For all $d \leq i \leq \kappa$, $\mathcal{A}(\text{OPT}) \leq \mathcal{A}(S_i) + \kappa \cdot (\mathcal{A}(S_{i+1}) - \mathcal{A}(S_i))$.

Proof. It is easy to check that the function $\mathcal{A}(\cdot)$ satisfies the following properties for all $H \subseteq H' \subseteq X$:

positivity: $\mathcal{A}(H) \geq 0$.

monotonicity: $\mathcal{A}(H) \leq \mathcal{A}(H')$.

submodularity: $\forall H'' \subseteq X, \mathcal{A}(H' \cup H'') \leq \mathcal{A}(H \cup H'') - \mathcal{A}(H) + \mathcal{A}(H')$.

Let $\text{OPT} = \{y_1, \dots, y_{2\kappa}\}$. We have for all $d \leq i \leq \kappa$:

$$\begin{aligned} \mathcal{A}(\text{OPT}) &\leq \mathcal{A}(S_i \cup \text{OPT}) \\ &= \mathcal{A}(S_i) + (\mathcal{A}(S_i \cup \{y_1, y_2\}) - \mathcal{A}(S_i)) + \dots \\ &\quad + (\mathcal{A}(S_i \cup \{y_1, \dots, y_{2\kappa}\}) - \mathcal{A}(S_i \cup \{y_1, \dots, y_{2\kappa-2}\})) \\ &\leq \mathcal{A}(S_i) + (\mathcal{A}(S_i \cup \{y_1, y_2\}) - \mathcal{A}(S_i)) + \dots + (\mathcal{A}(S_i \cup \{y_{2\kappa-1}, y_{2\kappa}\}) - \mathcal{A}(S_i)) \\ &\leq \mathcal{A}(S_i) + \kappa \cdot (\mathcal{A}(S_i \cup \{x_{2i+1}, x_{2i+2}\}) - \mathcal{A}(S_i)) \\ &= \mathcal{A}(S_i) + \kappa \cdot (\mathcal{A}(S_{i+1}) - \mathcal{A}(S_i)). \end{aligned}$$

The first and the second inequality respectively come from *monotonicity* and *submodularity*, while the third one follows from the fact that for $i \geq d$, (x_{2i+1}, x_{2i+2}) is the pair of disks maximizing $\mathcal{A}(S_i \cup \{x, x'\})$ among **all pairs** (x, x') in X . As S_d is a connected dominating set in X , all pairs (y_{2j-1}, y_{2j}) for $1 \leq i \leq \kappa$ are considered. ◁

We can now re-write Claim 14 as

$$\text{For all } d \leq i \leq \kappa : \mathcal{A}(S_{i+1}) \geq \left(1 - \frac{1}{\kappa}\right) \mathcal{A}(S_i) + \frac{\text{OPT}}{\kappa}.$$

Combined with Claim 13, simple algebra yields that for $d \leq i \leq \kappa$, we have

$$\mathcal{A}(S_i) \geq \left[1 - \left(1 - \frac{d}{2\kappa}\right) \left(1 - \frac{1}{\kappa}\right)^{i-d}\right] \text{OPT}.$$

Therefore, for $i = \kappa$ we have

$$\mathcal{A}(S) = \mathcal{A}(S_\kappa) \geq \left[1 - \left(1 - \frac{d}{2\kappa}\right) \left(1 - \frac{1}{\kappa}\right)^{\kappa-d}\right] \text{OPT} = \left[1 - \frac{1}{2} (1+t) \left(1 - \frac{1}{\kappa}\right)^{\kappa t}\right] \text{OPT}$$

■ **Figure 2** A tight example for Algorithm 1. For any $\varepsilon > 0$, X contains $x = (0, 0)$ (stripe-shaded), $x_i = (2(i - 1) + i\varepsilon, 0)$ and $x'_i = ((2 + \varepsilon)i, 0)$ for $1 \leq i \leq k$ (blue) and $y_i = (-2i - \varepsilon/2, 0)$ for $0 \leq i \leq k$ (orange). Suppose that $k = 1 + 2\kappa$ is odd and the algorithm starts with $S_0 := \{x, x\}$. Then the algorithm will add $\{x_i, x'_i\}$ in iteration i since it covers more additional area than $\{y_0, y_1\}$. The solution returned (blue disks) covers an area of $\pi + \kappa(\pi + f(\varepsilon)) \approx \frac{k}{2}\pi$, for some function $f(\cdot)$ with $\lim_{\varepsilon \rightarrow 0} f(\varepsilon) = 0$, while **OPT** (orange disks) covers an area $k\pi$.

where $t = \frac{\kappa - d}{\kappa} \in [0, 1]$. As $1 + x \leq e^x$ for all $x \in \mathbb{R}$, we get

$$\mathcal{A}(S) \geq \left(1 - \frac{1}{2}(1 + t)e^{-t}\right) \mathbf{OPT} \geq \left(1 - \frac{1}{2}e^t e^{-t}\right) \mathbf{OPT} = \frac{1}{2} \mathbf{OPT},$$

concluding the proof of the case when k is an even number.

For the odd case $k = 2\kappa - 1$: in the first iteration, instead of adding two disks to S_1 , we add a single disk of X to S_1 . This is equivalent to adding two copies of the same disk. This iteration belongs to the first phase, and the only properties we used in the first phase is that each iteration adds an area of π , and keeps the solution feasible; these are clearly true for the first iteration even with one disk. ◀

Figure 2 shows a tight example.

4 Proof of Theorem 4: PTAS with resource augmentation

► **Theorem 4** (Resource augmentation). *Let $\varepsilon > 0$ be a given parameter. Given a set of points $X \subseteq \mathbb{R}^2$ and a non-negative integer k , there is an algorithm (Algorithm 2) that computes, in time $n^{\mathcal{O}(\varepsilon^{-3})}$, a subset $S \subseteq X$ of size at most k and a set $S_{add} \subseteq \mathbb{R}^2$ of at most εk points, such that $\text{UDG}(S \cup S_{add})$ is connected and the area of the union of the unit disks centered at S is at least $(1 - \varepsilon) \mathbf{OPT}(X, k)$.*

We first summarise the high level ideas; the details are then presented in subsequent sections. Let (X, k) denote an input of MACS and **OPT** be the optimal solution of MACS on input (X, k) . When the context is clear **OPT** can also denote the total area covered by the union of the unit disks centered in points of **OPT**.

We start by guessing a bounding box of size $\Theta(k) \times \Theta(k)$ that contains **OPT**. Next, another square of size $L \times L$, where $L = \Theta(k)$, is randomly shifted so that it always contains the bounding box. We remove all disks that are outside the square. That square is then recursively partitioned into smaller squares until they have (large) constant size. This hierarchical dissection induces a grid.

We remove all disks that intersect the lines of the grid. In contrast, we deploy some new disks (X_{add}) in some strategic *portal* positions along the lines and near the boundary of all the smallest squares.

Next, we use dynamic programming to build a solution from the smallest squares upwards. The difficulty lies in having to guarantee the connectivity when combining solutions from smaller squares into larger squares using additional disks, while controlling the time complexity and the number of disks added.

The key of our approach lies in Lemma 20, in which we argue that with constant probability, there exists a well-structured near-optimal solution that uses at most εk additional disks.

4.1 The grid

The first step is to reduce significantly the size of the input by guessing the position of the optimal solution.

► **Lemma 15.** *There exists a point $c \in X$ such that **OPT** is contained in an axis-parallel square of side length $4k$ and centered in c .*

Proof. For c , take any disk in **OPT** and recall that **OPT** is connected and has at most k disks, so all the disks in **OPT** are contained in the square centered at c and with side length $4k$. ◀

Given the randomly shifted hierarchical dissection, we use the same terminology as Vazirani [22, Chapter 11] to define the *root square*, the *shift* of the dissection, the *horizontal* and *vertical lines*, the *levels* of squares and of lines of the dissection, and the *portals*. The recursive dissection stops when a square has side length $L_0 = \Theta(\varepsilon^{-1})$ (*leaf square*). Portals are either at the intersection of grid lines or distributed along the grid lines (with varying density). We make some observations here (all details and proofs are in the following section and the appendix). First, the distance between two consecutive portals on a line at level ℓ is $\mathcal{O}(L/(m2^\ell))$, where m represents the density of portals on the grid. The greater this parameter, the greater the accuracy of the solution and higher the running time. Choosing $m = \Theta(\varepsilon^{-1} \log(L/L_0)) = \mathcal{O}(\varepsilon^{-1} \log(\varepsilon k))$ allows us to compute a near-optimal solution in polynomial time.

► **Observation 16.** *If an horizontal line of level ℓ crosses a vertical line of level greater than or equal to ℓ then the intersection point is a horizontal portal.*

We define a set \mathcal{P} of *portal disks* which we position at or near the portals. If a portal (i, j) is on exactly one line of the grid then we add the portal disk (i, j) to \mathcal{P} . If a portal (i, j) is at the intersection of two lines of the grid, then *i*) if it is a horizontal portal then we add to \mathcal{P} two portal disks $(i, j + 2)$ and $(i, j - 2)$, and *ii*) if it is a vertical portal then we add to \mathcal{P} two portal disks $(i - 2, j)$ and $(i + 2, j)$.

Given a square C of the dissection, the *potential portal disks* of C , denoted by \mathcal{P}_C , are the portal disks on the boundary of C .

► **Observation 17.** *For any square, the number of potential portal disks is $\mathcal{O}(m) = \mathcal{O}(\varepsilon^{-1} \log(\varepsilon k))$.*

The *border* of a leaf square C , denoted as ∂C , is the set of points in C within distance 1 from C 's boundary. The remaining points of C are called the *core* of C , written as $\text{core}(C)$. A unit disk with its center in C intersects the boundary if and only if its center lies in the border. If two disks are in the core of two different leaf squares, then they do not intersect. We refer to the union of the core of all *leaf squares* as the *core*. In a leaf square $C = [a, b] \times [c, d]$, the set of points formed by the boundary of the square $[a + 2, b - 2] \times [c + 2, d - 2]$ is called the *fence*. We cover the fence of C by *fence disks*, aligned such that each corner of this square is the center of a fence disk. See Figure 4. We denote by \mathcal{F} the set of all fence disks for all leaf squares. The set of portal disks and fence disks form the set of *additional disks* $X_{\text{add}} = \mathcal{P} \cup \mathcal{F}$.

4.2 Detailed construction of the grid

Let L' be the sidelength of the box given by the Lemma 15, and set X' be the set of points of X lying inside this box. Let L be the smallest power of 2 greater than $2L'$. The *root square* is defined to be the axis-parallel $L \times L$ square with the same left-bottom corner as the bounding-box.

A *shift* is an non-negative integer a smaller than or equal to $L/2$. We say that the root square is *shifted* by a if it is translated by the vector $(-a, -a)$. Notice that any shifted root square contains the bounding-box.

Given a shifted root square, we can define its *dissection* as a recursive partitioning into smaller squares. The $L \times L$ root square is divided into four squares of size $L/2 \times L/2$. Each of these squares is again divided into four $L/4 \times L/4$ squares, so forth. The process stops when the side length of a square is equal to $L_0 = \Theta(\epsilon^{-1})$. Let $d = \log(L/L_0) = \mathcal{O}(\log(\epsilon k))$. We can think of this partitioning as 4-ary tree, where each node at level ℓ corresponds to a $L_0 2^\ell \times L_0 2^\ell$ square and has four children corresponding to four $L_0 2^{\ell-1} \times L_0 2^{\ell-1}$ squares. The root square is at level 0 and the *leaf squares* are at level d . Given two squares of level ℓ and level ℓ' , $\ell > \ell'$, we say the former is of higher level than the latter. So the leaf square is the one with the highest level.

This dissection defines a *grid* composed of $2 \cdot (2^d - 1)$ horizontal and vertical lines of length L . We say that a line is at *level* $\ell \in \{1, \dots, d\}$ if it was added on the grid to divide a square at level $\ell - 1$ into four squares at level ℓ . There are 2^ℓ horizontal (*resp.* vertical) lines at level ℓ . See figure 3.

Figure 3 An illustration of the grid with $d = 3$. Numbers on the top and the right are the level of the corresponding lines and the red, orange and yellow are respectively the example of square of the dissection at level 1, 2 and 3.

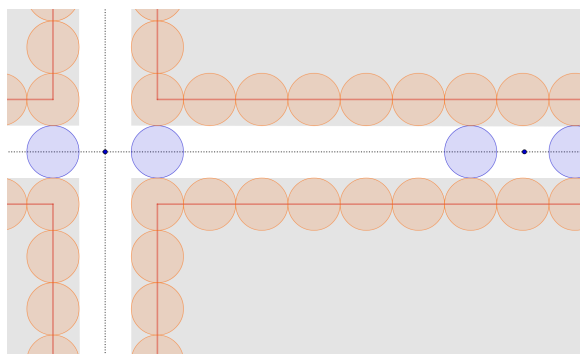

Figure 4 The grey and white area are respectively the *core* and the *border*. Dotted lines are from the grid while the orange lines represent the *fence* and orange disks are the *fence disks*. Blue points are (*vertical*) *portals* and blue disks are *portal disks*.

On each horizontal line of level $\ell \geq 1$, we will place a set of *vertical* – notice the naming asymmetry – *portals* of level ℓ , near which (not exactly on which) we will deploy the portal disks to facilitate the connection of disks on both sides of this line. We define a set of horizontal portals for each vertical line in an analogous manner. Notice that it is possible that a point is both a vertical portal and a horizontal portal. Let $m = \mathcal{O}(\epsilon^{-1}d)$ be a power of two. Along a line of level ℓ , there are $m2^\ell + 1$ portals evenly spaced so that the distance between two neighboring portals have distance exactly $\frac{L}{m2^\ell}$.

4.3 Dynamic program

The algorithm uses dynamic programming. The dynamic programming table is indexed by *configurations*.

- **Definition 18.** A configuration is a 5-tuple $\mathcal{C} = [C, t, t_{add}, P, \sim]$, where:
- C is a square of the dissection.
 - $0 \leq t \leq k$ is an integer, denoting the number of disks of S used by the solution inside C .
 - $0 \leq t_{add} \leq \varepsilon k$ is an integer, denoting the number of additional disks used by the solution inside C .
 - $P \subseteq \mathcal{P}_C$ is a subset of potential portal disks of C , those that are used by the solution.
 - \sim is a planar connectivity relation on P (described below), representing the connectivity achieved so far by the part of the solution inside C .

In the following, to facilitate discussion, we will refer to portals disks as simply portals. An equivalence relation \sim on P is a *planar connectivity relation* if each equivalence class has an associated tree with the portals at the leaves, and there exists a planar embedding of those trees inside the square, such that the trees do not intersect.

The content of the dynamic programming table, the *value* of a configuration $\mathcal{C} = [C, t, t_{add}, P, \sim]$, denoted by $\mathcal{A}(\mathcal{C})$, is the maximum area that can be covered by a set $S \subseteq X$ of t disks in $C \cap \text{core}^4$, such that there is a set $S_{add} \subseteq X_{add}$ of t_{add} additional disks such that any $p, p' \in P$ with $p \sim p'$ are in the same connected component induced by $S \cup S_{add} \cup P$. We say that p and p' are *connected in \mathcal{C}* . If such sets $\{S, S_{add}, P\}$ do not exist for configuration \mathcal{C} , the value $\mathcal{A}(\mathcal{C})$ is set to $-\infty$.

4.4 Computing leaf entries of the dynamic programming

We first explain how to fill the entries of the table corresponding to the leaf squares. For each leaf square C , we enumerate

1. all possible subsets $S \subseteq X' \cap \text{core}(C)$ of at most k_0 disks, for a parameter $k_0 = \mathcal{O}(\varepsilon^{-3})$ (see Lemma 20).
2. all possible subsets $S_f \subseteq \mathcal{F} \cap C$,
3. all possible subsets $P \subseteq \mathcal{P}_C$, and
4. all possible planar connectivity relations \sim on P .

We say that (S, S_f, P, \sim) is a *guess* in C and that it is *usable* if one of the following two conditions holds:

Case 1. if $P = \emptyset$, then $S \cup S_f$ is connected, otherwise

Case 2. every connected component of $S \cup S_f \cup P$ contains at least one portal disk in P .

Each usable guess (S, S_f, P) in C corresponds to a configuration $\mathcal{C} := [C, |S|, |S_f|, P, \sim]$, where \sim is the planar connectivity relation on P induced by the connected components of $S \cup S_f \cup P$.

Several usable guesses (S, S_f, P) can potentially correspond to the same configuration \mathcal{C} . The value of \mathcal{C} is computed⁵ as the maximum value $\mathcal{A}(S)$ over all such guesses S .

⁴ Recall that *core* is the union of the *core*(C) of all leaf squares C .

⁵ The area covered by the union of a set of disks is a real number that can be computed exactly. When the desired accuracy is a fixed constant (for instance ε), one can give an approximation of this area with the desired precision in polynomial time.

■ **Figure 5** Illustration of cases (a)-(b)-(c) of point 6. in Definition 19.

4.5 Computing all entries

It remains to show how to compute the solution of a configuration, say $\mathcal{C} = [C, t, t_{add}, P, \sim]$, for a square C at level ℓ , by combining the solutions $[C^i, t^i, t_{add}^i, P^i, \sim^i]$ of the four child squares C^i , $i = 1, 2, 3, 4$, at level $\ell + 1$. Recall that connectivity relations \sim^i capture the information about connectivity in the squares C^i . Let $P = \{p_0, \dots, p_s\}$ be the subset of potential portal disks. We define \sim' as the *transitive closure* of all \sim^i : $p \sim' p'$ if and only if there exists a sequence of squares $i_1, \dots, i_s \in \{1, 2, 3, 4\}$ and a sequence of portals $p = p_0, \dots, p_s = p'$ such that for all $1 \leq j \leq s$, p_j is a common portal of $P^{i_{j-1}}$ and P^{i_j} . Further, p_{j-1} and p_j must be connected in C^{i_j} . We call \mathcal{C} *empty* if $P = \emptyset$ and $t = 0$, and *closed* if $P = \emptyset$ and $t > 0$.

We now define the notion of compatibility of configurations.

► **Definition 19.** Five configurations $(\mathcal{C}, \mathcal{C}^1, \mathcal{C}^2, \mathcal{C}^3, \mathcal{C}^4)$ with $\mathcal{C} = [C, t, t_{add}, P, \sim]$ and $\mathcal{C}^i = [C^i, t^i, t_{add}^i, P^i, \sim^i]$ are compatible if all the following properties are satisfied.

1. all \mathcal{C}^i have the same level and their union is the square C .
2. $P = \bigcup_{i=1}^4 P^i \cap \partial C$.
3. \sim is the restriction of the transitive closure \sim' of $(\sim^i)_{1 \leq i \leq 4}$ to P .
4. $t = t^1 + t^2 + t^3 + t^4$ and $t \leq k$.
5. $t_{add} = t_{add}^1 + t_{add}^2 + t_{add}^3 + t_{add}^4 + |\bigcup_{i=1}^4 P^i \setminus P|$ and $t_{add} \leq \varepsilon k$.
6. exactly one of following three conditions holds.
 - (a) \mathcal{C}^i , $i \in \{1, 2, 3, 4\}$, is closed and all \mathcal{C}^j , $j \neq i$ are empty.
 - (b) \mathcal{C} is closed and there is exactly one equivalence class for \sim' .
 - (c) all equivalence classes of \sim' contain a portal in P .

► **Remark.** By condition 2, the set P of portals used by \mathcal{C} is obtained by removing from $\bigcup_{i=1}^4 P^i$ the portals not on the border of C . Notice that these removed portals in $\bigcup_{i=1}^4 P^i \setminus P$ are now counted as additional disks (in condition 5). Condition 6 attempts to capture all possible situations – either we have a single connected component not connected to the “outside world”, which is a feasible solution by itself, (see Condition (6a) and Condition (6b)), or we have several connected components, each of which must be further connected to the outside world in a later stage (see Condition (6c)). See Figure 5. Finally, it is easy to see that if all \sim^i satisfy the connectivity relation, then so does \sim .

Let a be a shift chosen uniformly at random in $\{0, \frac{L}{2}\}$. We consider the grid associated to this shift and the set of additional disks on this grid as defined in the previous section. The following lemma is essential to our main theorem. Recall that \mathcal{P} denotes the set of portal disks and \mathcal{F} the set of fence disks.

32:12 Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint

► **Lemma 20** (Structural Lemma). *Given a fixed parameter $\varepsilon > 0$, there exists a subset $S \subseteq \text{core}$ of input disks and a set $S_{\text{add}} \subseteq \mathcal{P} \cup \mathcal{F}$ of additional disks, such that with probability at least $1/3$,*

- (i) (feasibility) $|S| \leq k$ and $S \cup S_{\text{add}}$ is connected,
- (ii) (bounded resource augmentation) $|S_{\text{add}}| \leq \varepsilon k$,
- (iii) (near-optimality) $\mathcal{A}(S) \geq (1 - \varepsilon)\mathbf{OPT}$,
- (iv) (bounded local size) For each leaf square C , $|C \cap S| = \mathcal{O}(\varepsilon^{-3})$.

Our dynamic programming aims at finding a solution satisfying all conditions of this Structural Lemma. We show that such a solution can be computed in time $n^{\mathcal{O}(\varepsilon^{-3})}$. The *bounded local size* property ensures that we can try all possible configurations in the leaf squares in polynomial time. We also prove that for any square, the number of different planar connectivity relations is upper-bounded by the *Catalan number* of the number of potential portal disks of the square. It follows from Observation 17 that this number is polynomially bounded.

4.6 Proof of the structural Lemma

We construct S and S_{add} from **OPT** in two steps. In the first step, we build sets S' and S_{add} that satisfy properties (i)-(iii); and in the second step, we construct $S \subseteq S'$ by removing some disks from S' so as to satisfy property (iv) while maintaining the validity of the three first properties.

4.6.1 Part 1: Construction of the set of additional disks

Fix any shift, consider its associated grid and dissection and the corresponding set of additional disks $X_{\text{add}} = \mathcal{P} \cup \mathcal{F}$. Let S' be the union of disks in **OPT** that are located in the core of a leaf square of the dissection, namely

$$S' = \mathbf{OPT} \cap \text{core}.$$

Observe that S' might be disconnected since we have removed from **OPT** all the disks that were intersecting the grid. Letting *border* denote $\bigcup_{C \text{ is leaf}} \partial(C)$, we show how to replace the set of input disks $\mathbf{OPT} \cap \text{border}$ by a subset $S_{\text{add}} \subseteq \mathcal{F} \cup \mathcal{P}$ of additional disks.

Each leaf square $[a, b] \times [c, d]$ has an associated fence that is the boundary of the square $[a + 2, b - 2] \times [c + 2, d - 2]$. For each vertical (*resp.* horizontal) portal disk (x, y) , we define a *connection line*, which is $\{x\} \times [y - 2, y + 2]$ (*resp.* $[x - 2, x + 2] \times \{y\}$). The set of fences and connection lines naturally partition the set of points which are at distance at most 2 from the lines of the grid into a set of *rectangles* \mathcal{R} . See Figure 6. Notice that all connections and fences are covered by the union of additional disks. Given a rectangle $R \in \mathcal{R}$, we define $\text{disk}(R) \subseteq X_{\text{add}}$ as the minimal set of additional disks that contain R .

We construct S_{add} as the union of $\text{disk}(R)$, over all rectangles R that intersect a disk $x \in \mathbf{OPT} \cap \text{border}$.

$$S_{\text{add}} = \bigcup \{ \text{disk}(R) : R \in \mathcal{R}, \exists x \in \mathbf{OPT} \cap \text{border} \text{ such that } B_x \cap R \neq \emptyset \}$$

Notice that each disk $x \in \mathbf{OPT} \cap \text{border}$ intersects at most two rectangles. Furthermore, such a disk does not intersect with any fence and can intersect at most one connection line.

► **Claim 21.** Sets S' and S_{add} are such that $S' \cup S_{\text{add}}$ is connected, S' has size at most k and with probability at least $1/3$: $|S_{\text{add}}| \leq \mathcal{O}(\varepsilon k)$ and $\mathcal{A}(S') \geq (1 - \mathcal{O}(\varepsilon))\mathbf{OPT}$.

■ **Figure 6** Dotted lines are the grid lines. The bottom and top horizontal lines have respectively level 8 and 10, and the vertical lines from left to right have level 5, 10 and 9. Grey continuous line are the *fence*, and the red ones, the *connection lines*. Points and blue disks are *portals* and *portal disks*. Striped orange areas illustrate some rectangles $R \in \mathcal{R}$, and other disks are *fence disks* of the corresponding sets $\text{disk}(R)$.

The proof is in the appendix (the argument is similar to the one of Arora [1]). We first upper-bound the expectation of $|S_{add}|$ and $\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S')$, and then use Markov's inequality. To bound the expectation of $|S_{add}|$, we observe that the number of additional disks added in S_{add} for each disk in \mathbf{OPT} intersecting a line at level ℓ is $\mathcal{O}(L/(m2^\ell))$ while the probability that a disk intersects a line at level ℓ is $\mathcal{O}(2^\ell/L)$.

4.6.2 Part 2: Sparsification of S'

The sets $S' \cup S_{add}$ obtained so far may not satisfy the last property (*bounded local size*). In this section, we show how to remove some disks from S' to guarantee this property while still maintaining the other required properties in Lemma 20.

Suppose that there exists a leaf square C such that $S'_C := S' \cap C$ has size greater than $k_0 := (1 + \beta^{-1})L_0^2 = \mathcal{O}(\varepsilon^{-3})$, where $\beta = \min\{\varepsilon/12, 1\}$. Then the core of C is “overcrowded” and we show how to construct a non-overcrowded subset maintaining connectivity while losing only an $\varepsilon/2$ -th fraction of the covered area.

Define a set S to be initially equal to S' . Consider each overcrowded leaf square C one by one, and define $S_C = S \cap C$. Start with an empty set H and for each disk $x \in S_C$, add x in H if $\mathcal{A}(H \cup \{x\}) - \mathcal{A}(H) \geq \beta$. Define $\bar{H} = S_C \setminus H$ as the complement of H and then apply Claim 22 to $G = \text{UDG}(S \cup S_{add})$ and $D = S \cup S_{add} \setminus \bar{H}$ to define $D' \subseteq \bar{H}$. Finally update S to $(S \setminus \bar{H}) \cup D'$.

▷ **Claim 22.** Let $G = (V, E)$ be a connected graph and D a dominating set with μ connected components. There exists a subset $D' \subseteq V \setminus D$ of size at most $2(\mu - 1)$ such that $G[D \cup D']$ is connected.

Proof. Let H and H' be two connected components in D that minimize $d_G(H, H')$. Then, $d_G(H, H') \leq 3$. Indeed, if $d_G(H, H') \geq 4$, then there exists a vertex x on a shortest path from H to H' that is not dominated by D . This implies that we can find two vertices that connect H and H' . We repeat this operation until there is only one connected component. This requires at most $2(\mu - 1)$ vertices. ◁

32:14 Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint

The following claim, together with Claim 21 ensures that sets S and S_{add} built in Part 1 and Part 2 satisfy the expected properties of our structural Lemma.

▷ **Claim 23.** The constructed sets S and S_{add} satisfy

- (i) $S \cup S_{add}$ is connected,
- (ii) for each leaf square C , $|S \cap C| \leq k_0$, and
- (iii) $\mathcal{A}(S) \geq (1 - \varepsilon/2)\mathcal{A}(S')$.

This Claim might not be true if the radius of disks considered are arbitrary. The proof of this fact follows from geometrical observations about unit disks.

■ **Algorithm 2** PTAS for MACS with resource augmentation.

Input: X, k, ε .
Output: a real number $maxi \geq (1 - \varepsilon)\mathbf{OPT}$.

```

1 forall  $c \in X$  do
2   let  $\mathcal{B}'$  be the  $4k \times 4k$  square centered at  $c$ ;
3    $X' \leftarrow X \cap \mathcal{B}'$ ;
4    $L \leftarrow$  the smallest power of 2 such that  $L \geq 8k$ ;
5   forall  $shift\ a \in \{0, \dots, L/2\}$  do
6     Create a table  $tab$ ;
7     foreach  $configuration\ \mathcal{C}$  do
8        $tab[\mathcal{C}] \leftarrow -\infty$ ;
9       /* Initialization */
10      foreach  $\mathcal{C}$  at level  $d$  (leaf square) do
11         $tab[\mathcal{C}] \leftarrow \max\{\mathcal{A}(S) : (S, S_f, P) \text{ is usable and corresponds to } \mathcal{C}\}$ ;
12      /* Fusion */
13      foreach level  $0 \leq i \leq d - 1$  in decreasing order do
14        foreach  $configuration\ \mathcal{C}$  at level  $i$  do
15           $tab[\mathcal{C}] \leftarrow \max\left\{\sum_{i=1}^4 tab[\mathcal{C}^i] : (\mathcal{C}, \mathcal{C}^1, \mathcal{C}^2, \mathcal{C}^3, \mathcal{C}^4) \text{ are compatible}\right\}$ ;
16 return  $maxi = \max_{\substack{\text{configuration } \mathcal{C} \\ \text{for root square}}} tab[\mathcal{C}]$ ;
```

Notice that since the root square has no potential portals (portals are only placed on lines at level at least 1), any configuration that corresponds to the root square has only one connected component. We can easily add information in the table so that the algorithm also outputs the corresponding sets S and S_{add} .

Notice that Algorithm 2 tries all possible shift a . Our structural Lemma 20 ensures that there exists at least one shift such that the output satisfies all expected properties of Theorem 4.

► **Theorem 24.** Algorithm 2 has a running time $n^{\mathcal{O}(\varepsilon^{-3})}$.

The key ingredient in order to prove that our algorithm is polynomial follows from Observation 17. We show that the number of connectivity relations of a set of $\mathcal{O}(m)$ portals corresponds to its *Catalan number* which is polynomial when $m = \mathcal{O}(\varepsilon^{-1} \log(\varepsilon k))$.

■ **Algorithm 3** PTAS for MACS for well-distributed inputs.

Input: X an α -well-distributed input, $k \geq 0$, $\varepsilon > 0$.

Output: A feasible solution to $\text{MACS}(X, k)$.

- 1 Choose $\varepsilon' > 0$ and $k' \leq k$ such that $(1 - \varepsilon')(1 - 10(22\alpha + 4)\varepsilon') \geq (1 - \varepsilon)$ and $k'(1 + (22\alpha + 4)\varepsilon') = k$;
 - 2 Let S, S_{add} be the solution of Algorithm 2 on input (X, k', ε') ;
 - 3 Let S' be the set obtained from S_{add} by Lemma 25;
 - 4 **return** $S \cup S'$;
-

5 A PTAS for well-distributed inputs

Let us recall the definition of well-distributed input.

► **Definition 5.** Given $\alpha > 0$, a finite set X of points in the plane is called α -well-distributed if for all $x, y \in X$, $d_{UDG(X)}(x, y) \leq \lceil \alpha \cdot \|x - y\| \rceil$.

Here $\lceil \cdot \rceil$ is the ceiling function. This ensures that the right-hand side is always at least one. Notice that a well-distributed set is necessarily connected.

One intuitive view of a well-distributed input is to look at the shape of the “holes” of the input, that are the different connected components of the complement of the union of the input disks in the plane. The assumption of well-distribution means that these holes are roughly *fat*.

One particular interesting case arises when there is no hole at all. We call these sets *pseudo-convex*, and we prove that this is a particular case of well-distributed inputs.

► **Definition 7.** A set X is called pseudo-convex if the convex-hull of X is covered by the union of the unit disks centered at points of X .

► **Lemma 8.** A pseudo-convex set X is 3.82 -well-distributed.

Our Corollary 6 states that the restriction of MACS to well-distributed inputs admits a PTAS. The algorithm works as follows. Given a parameter $0 < \varepsilon \leq 1/2$, and an input (X, k) of MACS, we run Algorithm 2 on input (X, k', ε') for suitable values k' and ε' specified below. Next, we transform the set of additional disks obtained into a set of input disks that has roughly the same size while maintaining the connectivity of the solution. See Lemma 25 and Algorithm 3 for details. This algorithm naturally applies to pseudo-convex inputs (Corollary 9).

► **Lemma 25.** Given an α -well-distributed input X and two finite sets $S \subseteq X$ and $S_{add} \subseteq \mathbb{R}^2$ such that $UDG(S \cup S_{add})$ is connected, there exists a set $S' \subseteq X$ of size at most $(22\alpha + 4)|S_{add}|$ such that $UDG(S \cup S')$ is connected. Moreover, such a set can be computed in polynomial time.

In the previous lemma, the set S_{add} is not supposed to be a set of additional disks as defined in Section 4.

Since $\varepsilon' = \Theta(\varepsilon/\alpha)$, the previous algorithm runs in polynomial time when ε and α are fixed constants.

▷ **Claim 26.** The solution returned by Algorithm 3 on input (X, k, ε) is a feasible solution to $\text{MACS}(X, k)$ and covers an area at least $(1 - \varepsilon)\text{OPT}(X, k)$.

In order to prove this result we need to state the following “stability” property over optimal solutions.

► **Lemma 27.** Let $\eta < \frac{1}{2}$. Then $\text{OPT}(X, k) \geq (1 - 10\eta) \cdot \text{OPT}(X, k(1 + \eta))$.

A Omitted proofs

Proof of Claim 21. Clearly $|S'| \leq |\mathbf{OPT}| \leq k$. We now prove that $S' \cup S_{add}$ is connected. Suppose that there exists a disk $x \in \mathbf{OPT} \cap \text{border}$ such that $\mathbf{OPT} \setminus \{x\}$ is split into several connected components. We know that x intersects only one rectangle $R_1 \in \mathcal{R}$ or two rectangles $R_1, R_2 \in \mathcal{R}$. Since \mathbf{OPT} is connected, and B_x is contained in the set $U = R_1$ or $U = R_1 \cup R_2$, each connected component intersects the boundary of U . Then, B_x intersects a disk in $\text{disk}(R_1)$ or $\text{disk}(R_2)$. Therefore, $\mathbf{OPT} \setminus \{x\} \cup \text{disk}(R_1) \cup \text{disk}(R_2)$ is connected. By doing so for each $x \in \mathbf{OPT} \cap \text{border}$, it follows that $S' \cup S_{add}$ is connected.

It remains to show that, under a uniform random shift a , with probability at least one third we have $|S_{add}| \leq \mathcal{O}(\varepsilon k)$ and $\mathcal{A}(S') = \mathcal{A}(\mathbf{OPT} \cap \text{core}) \geq (1 - \mathcal{O}(\varepsilon))|\mathbf{OPT}|$. The proof is very similar to Arora’s approach, we first upper-bound the expectation of $|S_{add}|$ and $\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S')$, and then use *Markov inequality* to conclude.

We first upper-bound the expected number of additional disks. For each $x \in \mathbf{OPT}$ intersecting a line at level ℓ , we have added at most two sets of additional disks associated to rectangles with side length smaller than the distance between two consecutive portals of this line. It follows that $\mathcal{O}(L/(m2^\ell))$ additional disks have been added to S_{add} for each disk in \mathbf{OPT} intersecting a line of level ℓ . This can be observed in Figure 7. Moreover, the probability that a disk intersects a line at level ℓ is $\mathcal{O}(2^\ell/L)$. Then,

$$\begin{aligned} \mathbb{E}(|S_{add}|) &\leq \sum_{x \in \mathbf{OPT}} \sum_{\ell=0}^{d-1} P(x \text{ intersects exactly one line at level } \ell) \mathcal{O}\left(\frac{L}{m2^\ell}\right) \\ &= \sum_{x \in \mathbf{OPT}} \sum_{\ell=0}^{d-1} \mathcal{O}\left(\frac{2^\ell}{L} \cdot \frac{L}{m2^\ell}\right) = \mathcal{O}\left(\frac{dk}{m}\right) = \mathcal{O}(\varepsilon k) \end{aligned}$$

■ **Figure 7** \mathbf{OPT} is represented by orange disks. Disks of \mathbf{OPT} that intersect the grid (dotted line) are replaced by additional disks (striped blue disks). This operation maintains the connectivity of the set.

32:18 Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint

We now upper-bound the expectation of $\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S')$. First we have $\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S') \leq \mathcal{A}(\mathbf{OPT} \cap \textit{border})$, and the probability that a point $p \in B(\mathbf{OPT})$ is in $B(\mathbf{OPT} \cap \textit{border})$ is smaller than that p is at distance 2 from the lines of the grid. Therefore

$$\begin{aligned} \mathbb{E}(\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S')) &\leq \mathbb{E}(\mathcal{A}(\mathbf{OPT} \cap \textit{border})) \\ &\leq \int_{p \in B(\mathbf{OPT})} P(p \text{ is at distance at most 4 from the grid}) dp \\ &\leq \int_{p \in B(\mathbf{OPT})} 2 \cdot \frac{4}{L_0} dp \\ &\leq \frac{8 \cdot \mathbf{OPT}}{L_0} = \mathcal{O}(\varepsilon \mathbf{OPT}) \end{aligned}$$

By choosing the constant properly in the big O notation and using the Markov inequality, we can show that the probability of $|S_{\textit{add}}| > O(\varepsilon k)$ and the probability of $\mathcal{A}(\mathbf{OPT}) - \mathcal{A}(S) > O(\varepsilon \mathbf{OPT})$ are both upper bounded by $\frac{1}{3}$. Thus, by a union bound, we conclude the proof. \triangleleft

Proof of Claim 23. For (i), we just need to argue that for each leaf square C , after \overline{H} is defined, $S \cup S_{\textit{add}} \setminus \overline{H}$ is a dominating set in $UDG(S \cup S_{\textit{add}})$ (then the proof follows from Claim 22). Indeed if a disk x is in \overline{H} then it means that $\mathcal{A}(H \cup \{x\}) - \mathcal{A}(H) < \beta \leq 1$. In particular, it implies that there exists a disk in $H \subseteq S \cup S_{\textit{add}} \setminus \overline{H}$ that intersects x .

For (ii), observe that the size of $S \cap C$ is the sum of the size of the corresponding sets H and D' built during the “sparsification” of C . Since all disks in H increases the area covered by at least β and are contained in a square of area L_0^2 , the number of disks in H is upper-bounded by $\beta^{-1}L_0^2$. Moreover, each connected component of $S \cup S_{\textit{add}} \setminus \overline{H}$ had a disk contained in C so that the number μ of connected component is upper-bounded by $L_0^2/\pi < L_0^2/2$. Therefore $|D'| < L_0^2$. Finally $|H \cup D'| < (1 + \beta^{-1})L_0^2 = k_0$.

For (iii), we start by observing that the union $B(S')$ of disks in S' is contained in the set $B^+(S)$, which is defined as

$$B^+(S) := \{z \in \mathbb{R}^2 \mid \exists x \in S \text{ such that } \|z - x\| \leq 1 + \beta\}$$

Indeed, if there exists a point p covered by a disk x in S' but at distance at least $1 + \beta$ from any disk of S then adding x to S would increase the area covered by S by more than β .

■ **Figure 8** S consists of grey disks. The boundary of $B^+(S)$ is the dotted curve. Circular sectors are in orange while the red one represents a circular sector in $B^+(S)$.

Therefore, we have the following inclusion

$$B(S) \subseteq B(S') \subseteq B^+(S), \tag{1}$$

and if the following geometrical claim holds, our proof of (iii) will be complete.

▷ **Claim 28.** $\mathcal{A}(B(S)) \geq (1 - \varepsilon/2)\mathcal{A}(B^+(S))$

The result follows from the fact that $B(S)$ is a union of unit-disks. See Figure 8. The boundary of $B(S)$ is made of *circular arcs* and each of these arcs is associated with a *circular sector* θ_i . Circular sectors intersect with other circular sectors only on the extreme points of their corresponding arcs, thus $\mathcal{A}(\cup_i \theta_i) = \sum_i \mathcal{A}(\theta_i)$.

We can associate with each circular sector θ_i (of a disk of radius 1) its “dilation” θ_i^+ which corresponds to the same circular sector in a disk of radius $1+\beta$. We have $\mathcal{A}(\theta_i^+) = (1+\beta)^2 \mathcal{A}(\theta_i)$ and can see that $B^+(S) \setminus B(S) \subseteq \cup_i (\theta_i^+ \setminus \theta_i)$. Then

$$\begin{aligned} \mathcal{A}(B^+(S)) - \mathcal{A}(B(S)) &= \mathcal{A}(B^+(S) \setminus B(S)) = \mathcal{A}\left(\bigcup_i (\theta_i^+ \setminus \theta_i)\right) \\ &\leq \sum_i \mathcal{A}(\theta_i^+ \setminus \theta_i) = \sum_i \mathcal{A}(\theta_i^+) - \mathcal{A}(\theta_i) \\ &\leq \sum_i (1 + \beta)^2 \mathcal{A}(\theta_i) - \mathcal{A}(\theta_i) \\ &\leq \sum_i 3\beta \mathcal{A}(\theta_i) = 3\beta \mathcal{A}\left(\bigcup_i \theta_i\right) \leq 3\beta \mathcal{A}(B(S)) \end{aligned}$$

Therefore, $\mathcal{A}(B(S)) \geq \frac{\mathcal{A}(B^+(S))}{1 + 3\beta} \geq (1 - \varepsilon/2)\mathcal{A}(B^+(S))$. This concludes the proofs of Claims 28 and 23. ◁

Proof of Theorem 24.

Size of *tab*. There exists 4^i squares at level i so the total of squares is $\sum_{i=0}^d 4^i = \mathcal{O}(4^{d+1})$.

For any square C , the number of potential portal disks is at most $4m$. To see this, observe that if C is of level i , it is of size $L/2^i \times L/2^i$. Furthermore, it is surrounded by lines of level at most i and two adjacent portals on such a line has distance $\Omega(L/(m2^i))$.

Therefore, the number of possible sets $P \subseteq \mathcal{P}_C$ is 2^{4m} , and for each set P of size r the total number of planar connectivity relations is equal to the r -th *Catalan number*

: $P(r) = \frac{1}{r-1} \binom{2r}{r} = \mathcal{O}\left(\frac{1}{m-1} \binom{8m}{m}\right)$ and then by Stirling formula we get $P(r) = \mathcal{O}(4^{4m})$. To see that $P(r)$ is the r -th Catalan number, we check that it satisfies the same recurrence relation :

$$P(r) = \sum_{k=1}^r P(k-1) \cdot P(r-k) \tag{2}$$

with $P(0) = 1$. Indeed, if k denotes the index of the first portal p_k that is on the connected component of the r -th portal disk p_r , then the portal disk p_i with $1 \leq i \leq k-1$ cannot be equivalent to a portal p_j disk with $k \leq j \leq n$, and then the equivalence relation can be restricted to the set $\{p_i, 1 \leq i \leq k-1\}$ and there are $P(k-1)$ possible distinct choices. Next observe that since p_n and p_k are connected (i.e. $p_n \sim p_k$), it is enough to count the number of different equivalence relations in $\{p_j, k+1 \leq j \leq r\}$, which is $P(r-k)$.

32:20 Maximizing Covered Area in the Euclidean Plane with Connectivity Constraint

Finally, observe that k can be from 1 to r ($k = r$ means that p_r is alone in its connected component.) We thus concludes (2). Therefore, creating tab in line 6 can be done in time $\mathcal{O}(4^{d+1}\varepsilon k^2 8^{4m}) = k^{\mathcal{O}(1/\varepsilon)}$.

Initialization. There exists 4^d leaf squares and for each of them, we try all possible guesses. This can be done in time $n^{\mathcal{O}(\varepsilon^{-3})}$.

Fusion. Trying all possible combinations can be done in time $k^{\mathcal{O}(1/\varepsilon)}$ ◀

Proof of Lemma 27. Let X be a set of points of the plane, k a positive integer and $\eta \leq 1/2$ a parameter. We prove a stronger result. Given any solution feasible solution S to $\text{MACS}(X, k(1 + \eta))$, there exists a subset S' of S that is a feasible solution to $\text{MACS}(X, k)$ with value at least $(1 - 10\eta)\mathcal{A}(S)$. Obviously Lemma 27 follows when S is optimal. If $\mathcal{A}(S) \geq k/3$, then remove ηk disks from S without disconnecting S . For instance, consider a spanning tree on $UDG(S)$ and remove the nodes from the leaves to the root until you reach the desired size. Let S' denote the subset obtained.

$$\mathcal{A}(S') \geq \mathcal{A}(S) - \eta\pi k \geq (1 - 3\pi\eta)\mathcal{A}(S) \geq (1 - 10\eta)\mathcal{A}(S)$$

If $\mathcal{A}(S) < k/3$, let I be a maximal independent set in S . We have $|I|\pi = \mathcal{A}(I) \leq \mathcal{A}(S) < \frac{k}{3}$. According to claim 22, there exists a connected dominating set $I \subseteq D \subseteq S$ in S of size at most $3|I| - 2 < k/\pi < \frac{k}{3}$. Consider a set $H \subseteq S \setminus D$ of size $k - |D| > \frac{2}{3}k$ built by greedily adding a disk $h \in S \setminus (D \cup H)$ maximising the marginal area $\mathcal{A}(D \cup H \cup \{h\}) - \mathcal{A}(D \cup H)$. Since D is a connected dominating set, the set $S' := D \cup H$ is connected. Since all disk where added greedily in H , for all $H \in S \setminus S'$, we have

$$\mathcal{A}(S' \cup \{h\}) - \mathcal{A}(S') \leq \frac{\mathcal{A}(S) - \mathcal{A}(D)}{|H|} \leq \frac{2\mathcal{A}(S)}{k}$$

By submodularity, we deduce that $\mathcal{A}(S) - \mathcal{A}(S') \leq \eta k \cdot \frac{2\mathcal{A}(S)}{3k}$. That implies $\mathcal{A}(S') \geq (1 - \frac{2}{3}\eta)\mathcal{A}(S)$. This concludes the proof of lemma 27. ◀

Remark that this proof is constructive and it is easy to check that finding S' from any given set S can be done in polynomial time.

Proof of Lemma 25. Let us use the same notation as in the statement of Lemma 25. We prove how to build S' from S_{add} such that $|S'| \leq (22\alpha + 4)|S_{add}|$ while preserving connectivity.

Let Y be a connected component of S_{add} . We prove that we can find a set $Y' \subseteq X$ of input disks such that $|Y'| \leq (4 + 22\alpha)|Y|$ and $(S_{add} \setminus Y) \cup (S \cup Y')$ is connected. Removing Y might split the solution into several connected components F_1, \dots, F_s . For each connected component F_i , pick one disk x_i in $F_i \cap X$ that intersects Y .

Step 1. Each additional disk y in Y is adjacent to at most 6 disks x_i . We can connect the corresponding connected component by using 20α disks of the input. Indeed, any two x_i and x_j adjacent to y has a Euclidean distance at most 4. Since X is well-distributed their distance in $UDG(X)$ is at most 4α . Then, we can find $\lceil 4\alpha - 1 \rceil$ disks in X which connect x_i and x_j . In order to connect all the x_i that are adjacent to y , it is sufficient to repeat this operation 5 times, which asks at most 20α disks. We can perform this operation for each additional disk that was not already considered. Then, in total for this first step we need to use at most $20\alpha|Y|$ disks.

Step 2. During step 1, we may have connected some disks x_i , so that the number of connected components has decreased. The number of connected components is $s' \leq s$, each of them corresponds to a disk x_i , and without loss of generality we can assume that the corresponding indexes are such that $1 \leq i \leq s'$. Let T be a spanning tree on $UDG(Y)$. Without loss of generality, we can suppose that indexes i are such that the sequence $(x_1, \dots, x_{s'})$ correspond to a T transversal. Note that after step 1, each x_i can be associated to a different y in Y . Then, we reconnect each x_i to x_{i+1} for $1 \leq i \leq s-1$. If x_i and x_{i+1} are respectively associated to y_i and y_{i+1} , then $\|x_i - x_{i+1}\| \leq 2 + 2d_T(y_i, y_{i+1})$ and thus $d_{UDG(X)}(x_i, x_{i+1}) \leq \lceil \alpha(2 + 2d_T(y_i, y_{i+1})) \rceil$. Then, we can find $\lceil \alpha(2 + 2d_T(y_i, y_{i+1})) \rceil - 1$ disks in X to connect x_i and x_{i+1} . In order to connect all x_i we need to use at most

$$\sum_{i=1}^{s'-1} \lceil \alpha(2 + 2d_T(y_i, y_{i+1})) \rceil - 1 \leq 2(s' - 1)\alpha + 2 \sum_{i=1}^{s'-1} d_T(y_i, y_{i+1})$$

input disks. Since the order corresponds to a T transversal, each edge is visited at most twice and then $\sum_{i=1}^{s'-1} d_T(y_i, y_{i+1}) \leq 2(|Y| - 1)$. Therefore the total number of disks that were added during this second step is bounded by $|Y|(4 + 2\alpha)$.

We proved that there exists a subset $Y' \subseteq X$ of size at most $(4 + 22\alpha)|Y|$ such that $(S \cup S_{add} \setminus Y) \cup Y'$ is connected. By doing so for each connected component of S_{add} , we get the result claimed. \blacktriangleleft

Proof of Lemma 8. Let X be a pseudo-convex set, G its unit-disk-graph, and x and y be any two disks in X at distance $L = \|x - y\|$. We show that $d_G(x, y) \leq \lceil \alpha L \rceil$ where $\alpha = 12/\pi < 3.82$.

If $L < 2$ then the two unit disks associated to x and y overlap so that $d_G(x, y) = 1 \leq \lceil \alpha L \rceil$. Otherwise suppose that $L \geq 2$. Since X is pseudo-convex, it is connected and any point in the line segment $[x, y]$ is covered by a disk in X . Let $S = \{z \in X \mid B_z \cap [x, y] \neq \emptyset, \|x - z\| > 2 \text{ and } \|y - z\| > 2\}$ and let I be any maximal independent set in $S \cup \{x, y\}$. Since S is at distance at least 2 from x and y , we deduce that $x, y \in I$ and all disks in $I \setminus \{x, y\}$ are inside a $L \times 4$ rectangle and then $|I| \leq 4L/\pi$. Since I is maximal, it is a dominating set in S . Therefore, claim 22 implies that there exists a connected subset $D \subseteq X$ such that $I \subseteq D$ and $|D| \leq 3|I| - 2 \leq 12L/\pi - 2$. We deduce that $d_G(x, y) \leq (12L/\pi - 2) + 1 \leq \lceil \alpha L \rceil$. \blacktriangleleft

Proof of Claim 26. The solution output by Algorithm 2 on input (X, k', ε') verifies the following properties: $S \cup S_{add}$ is connected, the size of S and S_{add} are respectively upper-bounded by k' and $\varepsilon'k'$ and $\mathcal{A}(S) \geq (1 - \varepsilon')\mathbf{OPT}(X, k')$. Therefore, the set S' given by Lemma 25 has size at most $(22\alpha + 4)|S_{add}| \leq (22\alpha + 4)\varepsilon'k'$, and then $|S \cup S'| \leq k' + (22\alpha + 4)\varepsilon'k' \leq (1 + (22\alpha + 4)\varepsilon')k' = k$. Since $S \cup S'$ is connected, this set is a feasible solution to $\text{MACS}(X, k)$.

Finally, from Lemma 27 with parameter $\eta = (22\alpha + 4)\varepsilon'$, we get that the area covered by this solution is

$$\begin{aligned} \mathcal{A}(S \cup S') &\geq \mathcal{A}(S) \geq (1 - \varepsilon')\mathbf{OPT}(X, k') \geq (1 - \varepsilon')(1 - 10\eta)\mathbf{OPT}(X, k'(1 + \eta)) \\ &\geq (1 - \varepsilon')(1 - 10(22\alpha + 4)\varepsilon')\mathbf{OPT}(X, k'(1 + (22\alpha + 4)\varepsilon')) \\ &\geq (1 - \varepsilon)\mathbf{OPT}(X, k) \end{aligned}$$

which concludes the proof. \blacktriangleleft

Robust Correlation Clustering

Abstract

In this paper, we introduce and study the ROBUST-CORRELATION-CLUSTERING problem: given a graph $G = (V, E)$ where every edge is either labeled $+$ or $-$ (denoting similar or dissimilar pairs of vertices), and a parameter m , the goal is to delete a set D of m vertices, and partition the remaining vertices $V \setminus D$ into clusters to minimize the cost of the clustering, which is the sum of the number of $+$ edges with end-points in different clusters and the number of $-$ edges with end-points in the same cluster. This generalizes the classical CORRELATION-CLUSTERING problem which is the special case when $m = 0$. Correlation clustering is useful when we have (only) qualitative information about the similarity or dissimilarity of pairs of points, and ROBUST-CORRELATION-CLUSTERING equips this model with the capability to handle noise in datasets.

In this work, we present a *constant-factor* bi-criteria algorithm for ROBUST-CORRELATION-CLUSTERING on complete graphs (where our solution is $O(1)$ -approximate w.r.t the cost while however discarding $O(1)m$ points as outliers), and also complement this by showing that no finite approximation is possible if we do not violate the outlier budget. Our algorithm is very simple in that it first does a simple LP-based *pre-processing* to delete $O(m)$ vertices, and subsequently runs a particular CORRELATION-CLUSTERING algorithm ACNAlg [2] on the residual instance. We then consider general graphs, and show $(O(\log n), O(\log^2 n))$ bi-criteria algorithms while also showing a hardness of α_{MC} on both the cost and the outlier violation, where α_{MC} is the lower bound for the MINIMUM-MULTICUT problem.

1 Introduction

Clustering is one of the most widely used tools in various scientific disciplines (such as biology, computer science, machine learning and operations research to name a few) due to its wide applicability in these domains. Broadly speaking, the goal of clustering is to partition a given dataset into a number of clusters such that data items in the same cluster are more alike each other than data items in different clusters. In many application domains, the data items are naturally represented as points in a metric space, and the distance between the corresponding vectors is used as a measure of (dis)similarity. In such cases, clustering formulations such as k -median or k -means are the de-facto standards to utilize. However, there are also quite a few application domains where the information available to us is simply

whether different pairs of data items are similar or dissimilar to each other. Examples of such settings where there is only qualitative information include data items being web-pages on the internet, a collection of people on a social network or even a group of proteins. Motivated by such settings, Bansal et al. [3] formulated a problem known as *correlation clustering* (in fact, a similar problem was implicitly studied by Ben-Dor et al. [4] as ‘Cluster Editing’).

► **Problem 1** (CORRELATION-CLUSTERING). *We are given a complete graph $G = (V, \binom{V}{2})$, and a labelling of each edge as either positive or negative, denoting whether the end vertices of the edge are similar to each other or dissimilar. In other words, the edge set $\binom{V}{2}$ is partitioned into $E_+ \dot{\cup} E_-$ where E_+ denotes the similar pairs and E_- denotes dissimilar pairs. The goal is to compute a partition $\mathcal{C} = \{C_1, C_2, \dots, C_r\}$ of V (so $V = \dot{\cup}_{1 \leq i \leq r} C_i$ is a disjoint union of the C_i ’s) to minimize the cost of the clustering, which is the total number of E_+ edges with end-points in different clusters and E_- edges with end-points in the same cluster.*

A nice modeling aspect of this problem is that the number of clusters is not specified as part of the input, and rather, left to the algorithm. This makes it a compelling problem when we do not have a priori knowledge of the number of clusters we seek in the final partitioning.

Since being introduced formally as an optimization problem, there have been numerous works trying to understand the computational complexity of the problem. Bansal et al. [3] show that the problem is APX-hard (ruling out the design of PTASes unless $P=NP$) and obtain a constant-factor *approximation algorithm* for this problem. Subsequently, there have been a series of works (see, e.g., the survey by Wirth [23]) getting better factors, with the current best bound being a factor of 2.06 due to Chawla et al. [8].

Despite the simplicity and elegance of the various clustering formulations described thus far, a significant shortcoming of most of them is that they are not robust to noisy points. For example, the presence of a few outliers in the data set can completely change the *cost* and *structure* of solutions obtained by running clustering algorithms for k -median, k -means, etc. Indeed, this has prompted much recent study in the CS, ML and statistics communities of *robust* versions of these problems [6, 10, 17]. Motivated by this observation, and the fact that real-world data sets are often noisy, we investigate the *robustness* of correlation clustering.

► **Problem 2** (ROBUST-CORRELATION-CLUSTERING). *The input to this problem is identical to the correlation clustering instance as in Problem 1. Additionally, we are also given a parameter m , which denotes the number of points we can discard while clustering. The goal is to identify a set $D \subseteq V$ of outliers of size m , and cluster the remaining points $V \setminus D$ to minimize the cost of the resulting clustering, i.e., the total number of E_+ edges (resp. E_- edges) in $V \setminus D$ with end-points in different clusters (resp. same cluster).*

We note that CORRELATION-CLUSTERING problem also makes sense when the edge set $E_+ \cup E_-$ is not the complete graph, since we often do not have complete information about the (dis)similarity of each pair of points (it could be expensive or even impossible to obtain such information like in the case of protein-protein interactions). Now the problem becomes much harder, and the current best known algorithms have approximation guarantees of a factor of $O(\log n)$. Moreover, there is an approximation-preserving reduction from the MINIMUM-MULTICUT problem, for which the best known approximation is an $O(\log n)$ factor [5]. In this paper, we also consider the ROBUST-CORRELATION-CLUSTERING problem on general graphs, analogous to the study of CORRELATION-CLUSTERING in general graphs [5].

► **Problem 3** (ROBUST-CORRELATION-CLUSTERING on General Graphs). *The problem is identical to Problem 2, with the exception that the union of E_+ and E_- need not be $\binom{V}{2}$.*

1.1 Our Results

Having introduced the problem, the first question we address is whether the CORRELATION-CLUSTERING objective is indeed susceptible to outliers in the dataset. That is, we seek to understand whether the solution cost and/or structure can change a lot by the removal of a few points in the dataset. Classical objectives such as k -median and k -means suffer from this drawback *even in the simplest of settings* when we are promised that after removing some m data-points, *the optimal clustering of the remaining points would have 0 cost*. In such cases, solving k -means objective on the original instance could yield very different solutions than the intended solution, which is the 0 cost (or perfect clustering).

Somewhat surprisingly, our first simple observation is that the correlation clustering objective is inherently robust to an extent, at least in the case when the cost of the clustering after removing m outliers becomes 0. We show that in this case, the optimal correlation clustering solution and the optimal robust correlation clustering solution are structurally identical upto $O(m)$ points.

► **Theorem 4.** *Consider an instance \mathcal{I} of ROBUST-CORRELATION-CLUSTERING on complete graphs such that $\text{Opt}(\mathcal{I}) = 0$, i.e., there exists a set $D^* \subseteq V$ of m vertices deleting which, the subgraph induced by $V \setminus D^*$ admits a perfect clustering \mathcal{C}^* . Then, consider any optimal solution $\tilde{\mathcal{C}}$ to CORRELATION-CLUSTERING (Problem 1). There exists a set \tilde{D} of $O(m)$ vertices s.t. the cost of $\tilde{\mathcal{C}} \setminus \tilde{D}^1$ has objective function value 0.*

This theorem in fact sets apart the correlation clustering objective from other clustering objectives such as k -means and k -median where an analogous statement to Theorem 4 does not hold. Moreover, we believe that a similar result is true even when $\text{Opt}(\mathcal{I}) \neq 0$ when comparing the optimal solutions of the robust and non-robust problems.

Now, while this exhibits the robustness of correlation clustering w.r.t. *optimal solutions*, the problem is APX-hard and hence we typically do not deal with optimal solutions. Hence, we next consider the same question, but for approximation algorithms.

► **Theorem 5.** *There exists an instance \mathcal{I} of ROBUST-CORRELATION-CLUSTERING on complete graphs which satisfies the following properties: (a) $\text{Opt}(\mathcal{I}) = 0$, i.e., there exists a set $D \subseteq V$ of $m = O(\sqrt{n})$ vertices deleting which, the subgraph induced by $V \setminus D$ admits a perfect clustering, and (b) there exists a constant-factor approximately optimal solution \mathcal{C} to the CORRELATION-CLUSTERING objective function (1), such that, for any set S of $< n - 1$ vertices, the cost of the clustering $\mathcal{C} \setminus S$ is still non-zero.*

This then provides sufficient motivation for undertaking this study, with the main focus of whether we can design efficient approximation algorithms for ROBUST-CORRELATION-CLUSTERING. Our first result in this direction is a negative result, which says that it is in fact NP-hard to obtain any finite approximation algorithm for ROBUST-CORRELATION-CLUSTERING, even on complete graphs. This is in stark contrast to Problem 1, where we know very good constant-factor approximations.

► **Theorem 6.** *It is NP-hard to obtain any finite approximation factor for ROBUST-CORRELATION-CLUSTERING on complete graphs, unless we violate the budget on the number of outliers.*

¹ We somewhat abuse notation to let $\mathcal{C} \setminus D$ to denote the clustering obtained by removing the points in D from the clustering \mathcal{C} .

We therefore seek to obtain *bi-criteria approximation algorithms*: an (a, b) bi-criteria approximation for ROBUST-CORRELATION-CLUSTERING is one where the solution's cost is at most a times the optimal cost, and the number of outliers in our solution is at most $b \cdot m$.

► **Theorem 7.** *There is an efficient bi-criteria $(6, 6)$ -approximation algorithm for ROBUST-CORRELATION-CLUSTERING on complete graphs.*

Our algorithm is extremely simple: it essentially does a simple LP-based *pre-processing* step to prune out a set of $O(m)$ outliers, and then executes a classical algorithm for CORRELATION-CLUSTERING [2] (henceforth called ACNAlg) on the remaining vertices. This approach works because the LP relaxation which [2] uses for solving CORRELATION-CLUSTERING is a purely covering LP (as opposed to the more natural metric LP relaxation for CORRELATION-CLUSTERING), and can easily be adapted to incorporating outliers. We remark that, owing to the pre-processing step, our overall algorithm requires solving an LP: it would be very interesting to develop a purely combinatorial algorithm for ROBUST-CORRELATION-CLUSTERING on complete graphs. It might even be possible for a simple adaptation of the ACNAlg algorithm to be a constant-factor bi-criteria approximation. We leave this as an important avenue of future research.

Finally, we turn our attention to ROBUST-CORRELATION-CLUSTERING on general graphs, where we show poly-logarithmic bi-criteria algorithms and logarithmic hardness results on both the cost as well as the outlier budget. While the CORRELATION-CLUSTERING problem is equivalent to MINIMUM-MULTICUT [14] and we can use any MINIMUM-MULTICUT algorithm to solve the problem, we show that one specific technique based on *padded decompositions* of metric spaces naturally lends itself to solving the robust problem.

► **Theorem 8.** *There is an efficient bi-criteria $(O(\log n), O(\log^2 n))$ -approximation algorithm for ROBUST-CORRELATION-CLUSTERING on general graphs.*

► **Theorem 9.** *It is NP-hard to obtain any bi-criteria (a, b) -approximation algorithm for ROBUST-CORRELATION-CLUSTERING on general graphs for $b < \alpha_{\text{MC}}$ or $a < \alpha_{\text{MC}}$ where α_{MC} is the inapproximability factor for the MINIMUM-MULTICUT problem.*

It would be interesting to resolve the gap between the $O(\log^2 n)$ upper bound and the $\Omega(\log n)$ lower bound for the outlier budget violation.

1.2 Related Work

Since its introduction, CORRELATION-CLUSTERING has received much attention with focus on designing better algorithms (see the survey of [23]), faster algorithms in the parallel and distributed [11] and streaming settings [1], stochastic/average-case settings [19], and applications [12, 13, 20]. There is also work on a related objective function of *maximizing* the number of classified edges [3]. Being a maximization objective, it is easier to design simple constant-factor approximation algorithms like random partitions, etc. There are however, better SDP-based approximation algorithms [5, 22].

Recently there has also been a large body of work on the crucial problem of noise-resilient or *robust* clustering for distance-based clustering objectives such as k -means [10, 17], and designing faster algorithms [7, 21, 16], and parallel and distributed algorithms in this model [9, 18]. To the best of our knowledge, this is the first work to study the CORRELATION-CLUSTERING problem from robustness point of view.

1.3 Paper Outline

We first describe the inherent robustness to outliers of *optimal solutions* for CORRELATION-CLUSTERING in Section 2. We then consider ROBUST-CORRELATION-CLUSTERING for complete graphs, and show our hardness of approximation in Section 3, followed by the bi-criteria algorithm in Section 4. Finally, in Section 5 and Appendix A, we turn our attention to the case of general graphs and present our algorithm and hardness.

2 Robustness of the Correlation-Clustering Objective

In this section, we show two simple but illuminating results. The first result explains how, in contrast to problems like k -median and k -means, the vanilla correlation clustering objective is in fact *inherently robust* to an extent, *when solved optimally*. The second result then shows this not to be true when considering solutions which are only approximately optimal. We remark that the second result and that fact that correlation clustering is APX-hard [3] serves as a strong motivation for studying the ROBUST-CORRELATION-CLUSTERING problem.

2.1 Optimal Correlation-Clustering Solutions are Robust

In this section, we exhibit the inherent robustness of the correlation clustering objective (1) in a specialized scenario. Indeed, consider an instance \mathcal{I} of ROBUST-CORRELATION-CLUSTERING such that $\text{Opt}(\mathcal{I}) = 0$, i.e., there exists a set of m points deleting which the remaining points are perfectly clusterable, i.e., have 0 cost. Now, imagine we obtain an optimal CORRELATION-CLUSTERING solution (Problem 1) to instance \mathcal{I} . We show that there exist $O(m)$ points, deleting which, the cost indeed becomes 0 for this solution. This tells us that the optimal solutions to 2 and 1 are nearly identical to each other (upto $O(m)$ points), and hence, that the correlation clustering objective is inherently robust!

Proof of Theorem 4. We begin by recalling the theorem statement and setting up notation. Let \mathcal{I} be an instance of ROBUST-CORRELATION-CLUSTERING such that $\text{Opt}(\mathcal{I}) = 0$, i.e., there exists a set $D^* \subseteq V$ of m vertices deleting which, the subgraph induced by $V \setminus D^*$ admits a perfect clustering \mathcal{C}^* . And consider any optimal solution $\tilde{\mathcal{C}}$ to instance \mathcal{I} w.r.t the CORRELATION-CLUSTERING objective function (1). We would like to claim that there exists a set \tilde{D} of $O(m)$ vertices such that $\tilde{\mathcal{C}} \setminus \tilde{D}$ is identical to $\mathcal{C}^* \setminus \tilde{D}$. We show this by showing that the cost of the clustering $\tilde{\mathcal{C}} \setminus \tilde{D}$ is 0, and hence it must be the same as $\mathcal{C}^* \setminus \tilde{D}$.

To this end, let $\mathcal{C}^* = \{C_1^*, C_2^*, \dots, C_r^*\}$ denote the optimal ROBUST-CORRELATION-CLUSTERING clustering over vertices $V \setminus D^*$, and let $\tilde{\mathcal{C}} = \{\tilde{C}_1, \tilde{C}_2, \dots, \tilde{C}_s\}$ denote the optimal CORRELATION-CLUSTERING clustering over all vertices V . We divide the clusters in $\tilde{\mathcal{C}}$ into two types:

- (a) A cluster $\tilde{C} \in \tilde{\mathcal{C}}$ is a *mixed cluster* if it contains points from more than one cluster in \mathcal{C}^* , i.e., there exists i_1, i_2 s.t $|\tilde{C} \cap C_{i_1}^*| > 0$ and $|\tilde{C} \cap C_{i_2}^*| > 0$, and
- (b) A cluster $\tilde{C} \in \tilde{\mathcal{C}}$ is an *isolated cluster* if it contains points from only one cluster in \mathcal{C}^* .

We then show that the total number of points in mixed clusters is $O(m)$, and can simply add all such points to \tilde{D} . At this point, we would only be left with isolated clusters. Subsequently, we show that two isolated clusters composed of points from the same cluster in \mathcal{C}^* can contain at most $O(m)$ points. Therefore, we once again add these points to \tilde{D} . Finally, we add all the remaining set of at most m outliers to \tilde{D} . It is easy to see that the resulting clustering $\tilde{\mathcal{C}} \setminus \tilde{D} = \mathcal{C}^* \setminus D^*$. These results are established in Lemmas 10 and 11. ◀

► **Lemma 10.** *Let \tilde{C} be a mixed cluster, and let $X = \tilde{C} \cap D^*$ denote its overlap with the outlier set R^* in the optimal ROBUST-CORRELATION-CLUSTERING clustering. Then we have $|\tilde{C}| \leq O(1)|X|$.*

Proof. Since $\tilde{C} \in \tilde{\mathcal{C}}$ is a mixed cluster, there exists $i_1 \neq i_2$ s.t. $|\tilde{C} \cap C_{i_1}^*| > 0$ and $|\tilde{C} \cap C_{i_2}^*| > 0$. Now, since $\tilde{\mathcal{C}}$ is an optimal solution for CORRELATION-CLUSTERING, we have that the cost of the clustering must increase when we consider the following clustering $\tilde{\mathcal{C}}_1 = (\tilde{\mathcal{C}} \setminus \tilde{C}) \cup (\tilde{C} \cap C_{i_1}^*) \cup (\tilde{C} \setminus C_{i_1}^*)$ formed by replacing \tilde{C} with $(\tilde{C} \cap C_{i_1}^*)$ and $(\tilde{C} \setminus C_{i_1}^*)$. since \mathcal{C}^* is an optimal clustering with cost 0, we know that all the edges between $C_{i_1}^*$ and C_i^* for $i \neq i_1$ belong to E_- . This, combined with the fact that the cost of this new clustering is more than that of $\tilde{\mathcal{C}}$ gives us the following inequality:

$$\begin{aligned} |\tilde{C} \cap C_{i_1}^*| \left(\sum_{i \neq i_1} |\tilde{C} \cap C_i^*| \right) &\leq |X| |\tilde{C} \cap C_{i_1}^*| \\ \implies \sum_{i \neq i_1} |\tilde{C} \cap C_i^*| &\leq |X| \end{aligned} \quad (1)$$

A similar argument by replacing \tilde{C} with $(\tilde{C} \cap C_{i_2}^*)$ and $(\tilde{C} \setminus C_{i_2}^*)$ would yield $\sum_{i \neq i_2} |\tilde{C} \cap C_i^*| \leq |X|$. Summing the two inequalities, we get that $|\tilde{C} \setminus X| \leq 2|X|$, and so $|\tilde{C}| \leq 3|X|$, completing the proof. ◀

► **Lemma 11.** *Let \tilde{C}_1, \tilde{C}_2 be two isolated clusters containing points from the same cluster $C^* \in \mathcal{C}^*$, and let $X_1 = \tilde{C}_1 \cap D^*$ and $X_2 = \tilde{C}_2 \cap D^*$ denote their intersections with the outlier set R^* in the optimal ROBUST-CORRELATION-CLUSTERING clustering. Then we have $|\tilde{C}_1 \cup \tilde{C}_2| \leq O(1)|X_1 \cup X_2|$.*

Proof. Since $\tilde{\mathcal{C}}$ is an optimal solution w.r.t the CORRELATION-CLUSTERING objective, we know that if we modify $\tilde{\mathcal{C}}$ by moving the points $\tilde{C}_1 \cap C^*$ to cluster \tilde{C}_2 , the cost does not decrease. This gives us the following inequality, which uses the fact that all edges within C^* belong to E_+ due to the fact that cost of C^* is 0:

$$\begin{aligned} |\tilde{C}_1 \cap C^*| |\tilde{C}_2 \cap C^*| &\leq (|X_1| + |X_2|) |\tilde{C}_1 \cap C^*| \\ \implies |\tilde{C}_2 \cap C^*| &\leq |X_1| + |X_2| \end{aligned}$$

A similar argument would also give us $|\tilde{C}_1 \cap C^*| \leq |X_1| + |X_2|$. Adding these inequalities gives us $|\tilde{C}_1 \cap C^*| + |\tilde{C}_2 \cap C^*| \leq 2(|X_1| + |X_2|)$, and adding back X_1 and X_2 will incur an additional cost of $|X_1| + |X_2|$, hence completing the proof. ◀

2.2 Approximate Solutions may not be Robust

We next focus on *approximation algorithms* to CORRELATION-CLUSTERING, and show that they need not be robust to outliers (Theorem 5). Indeed, consider the following instance $\mathcal{I} = (V, E)$ of ROBUST-CORRELATION-CLUSTERING with $n + \sqrt{n}$ points. Consider a $\sqrt{n} \times \sqrt{n}$ grid, such that all points lying on the same row are pairwise similar, i.e., belong to E_+ while any two points lying on different rows are dissimilar and belong to E_- . To this arrangement, \sqrt{n} bad points are added, which are pairwise dissimilar to one another, but share a + edge with each of the n points in the original $\sqrt{n} \times \sqrt{n}$ grid.

We first note that the optimal CORRELATION-CLUSTERING solution to \mathcal{I} has cost $\Omega(n\sqrt{n})$. Indeed, consider any triangle u, v, w where u is a bad point, and v and w belong to different rows. Note that there must at least be one mis-classified edge in this triangle in the optimal

solution. So, if we let \mathcal{B} denote the set of all such bad triangles, the following is a valid lower bound on OPT: $\min \sum_{e \in t, t \in \mathcal{B}} z_e$ s.t. $\sum_{e \in t} z_e \geq 1, \forall t \in \mathcal{B}$. The dual of this is $\max \sum_{t \in \mathcal{B}} y_t$ s.t. $\sum_{t: e \in t, t \in \mathcal{B}} y_t \leq 1, \forall e \in E$. It is easy to see that the optimal value of the dual LP is at least $\Omega(n\sqrt{n})$ by setting $y_t = 1/n$ for all bad triangles in \mathcal{B} . Now consider a clustering \mathcal{C} which clusters each column of the grid into a cluster, and puts the bad points in another cluster. The overall cost of the clustering is $O(n\sqrt{n})$, which is a constant-factor approximation. Moreover, note that the only way to get a 0 cost clustering from \mathcal{C} (without altering the structure of \mathcal{C}) is by deleting all the n grid points.

3 Robust-Correlation-Clustering on Complete Graphs: Hardness

In this section, we give the proof of Theorem 6. The proof follows by an approximation preserving reduction from vertex cover. Consider an instance \mathcal{I}_{vc} of vertex cover, given by a graph, $G = (V, E)$ on n vertices. We construct the ROBUST-CORRELATION-CLUSTERING instance \mathcal{I} as follows: for each vertex $v \in V$, we create two points v_1 and v_2 , giving us a total of $2n$ vertices in \mathcal{I} . For every vertex $v \in V$, we make the edge $(v_1, v_2) \in E_+$. Similarly, for any pair of vertices $u, v \in V$ the edges (u_2, v_2) , (u_1, v_2) and (u_2, v_1) all belong to E_- . Finally, we place edge $(u_1, v_1) \in E_+$ if the edge $(u, v) \in E$, and in E_- otherwise. The outlier budget is some parameter m , unrelated to the number of edges in G .

► **Lemma 12.** *There exists a solution of cost 0 for \mathcal{I} if G has a vertex cover of size m .*

Proof. Let $S \subseteq V$ denote a vertex cover of size m for G , and let $S_1 = \{v_1 : v \in S\}$. Then, consider the natural clustering $\mathcal{C} = \{\{v_1, v_2\} : v \in V\}$ comprising of the pairs of vertices. The only mis-classified edges in this clustering are of the form (u_1, v_1) corresponding to edges (u, v) of G . But now, suppose we declare the points in S_1 as outliers, then it follows that the resulting clustering $\mathcal{C} \setminus S_1$ has 0 cost, since S is a vertex cover for G . ◀

► **Lemma 13.** *If there is a set S of m outliers such that the remaining points has a 0 cost clustering \mathcal{C} in instance \mathcal{I} , then G has a vertex cover of size at most m in instance \mathcal{I}_{vc} .*

Proof. We construct a candidate vertex cover S' for G from the outlier-set S as follows: for each $v \in V$, include $v \in S'$ if either v_1 or v_2 is in S . We claim then that S' is a valid vertex cover for G . To the contrary, suppose an edge (u, v) is not covered by S' . Then, none of the four points u_1, u_2, v_1, v_2 are included in the outlier-set S in the robust clustering solution. Now, since clustering \mathcal{C} has 0 cost, it must be that the four points u_1, u_2, v_1 and v_2 must belong to the same cluster in \mathcal{C} , or else, one of the edges in (u_1, u_2) , (u_2, v_2) , and (v_2, v_1) , all of which belong to E_+ , would be mis-classified. But now the edges (u_1, v_2) and (v_1, u_2) belong to E_- and would be mis-classified in \mathcal{C} , which contradicts the fact that \mathcal{C} has 0 cost. ◀

Theorem 6 then follows from Lemmas 12 and 13.

4 Robust-Correlation-Clustering on Complete Graphs: Algorithms

In this section, we design a simple LP-rounding based bi-criteria approximation algorithm for ROBUST-CORRELATION-CLUSTERING (Problem 2) and prove Theorem 7. We begin by recalling the problem setup: we are given an instance \mathcal{I} consisting of a graph (V, E_+, E_-) on n points with $E_+ \cup E_- = \binom{V}{2}$. The goal is to identify a set of vertices D such that $|D| = m$, and a clustering \mathcal{C} over $V \setminus D$ such that the total cost is minimized. We start with the following definition crucial to the design and analysis of our algorithm.

► **Definition 14** (Bad Triangles). A triplet (u, v, w) of points is said to be a bad triangle if exactly two of the three edges among (u, v) , (v, w) , (u, w) belong to E_+ and one to E_- .

Note a bad triangle captures the *smallest unit of inconsistency* in the similarity information among the points: either we delete one of the vertices as an outlier, or at least one of the edges must be mis-classified. In what follows, let \mathcal{B} denote the set of all bad triangles in \mathcal{I} .

4.1 Recap of ACNAIlg for Correlation-Clustering [2]

Since the crux of our algorithm is the ACNAIlg for correlation clustering, we begin with a quick recap of ACNAIlg. Essentially, the algorithm iteratively picks a *random* un-clustered vertex v as a new cluster center, and includes all other un-clustered vertices similar to v .

■ **Algorithm 1** ACNAIlg(V, E_+, E_-).

```

set  $U = V$  and  $C = \emptyset$       ▷ initialize set of un-clustered points and set of cluster centers
while  $U \neq \emptyset$  do
  sample  $v \sim \text{Unif}(U)$ 
  update  $C \leftarrow C \cup \{v\}$       ▷ random  $v$  is sampled as a cluster center
  let  $C_v = \{u \in U : (u, v) \in E_+\} \cup \{v\}$       ▷ un-clustered vertices similar to  $v$ 
  update  $U \leftarrow U \setminus C_v$ 
end while
return:  $\mathcal{C} = \{C_v : v \in C\}$ 

```

► **Theorem 15** ([2]). ACNAIlg(V, E_+, E_-) is a 3 approximation for CORRELATION-CLUSTERING.

In what follows, we outline the proof in [2] of ACNAIlg, and describe a couple of definitions and lemmas which will be useful in understanding our overall analysis.

► **Definition 16.** A bad triangle $(u, v, w) \in \mathcal{B}$ is said to be touched, denoted by $\text{touched}(t) = 1$, if there exists a point in the algorithm execution when all three vertices u, v, w belong to the un-clustered set U and one of u, v, w gets sampled as a cluster center.

► **Lemma 17.** At the end of Algorithm 1, every mis-classified edge (i.e., an E_- edge which is in a single cluster, or an E_+ edge which goes across clusters) is associated with a unique bad triangle which is touched. Moreover, the opposite vertex to the mis-classified edge must be sampled as the cluster center.

Proof. Consider a stage of the algorithm when a vertex u gets chosen as a cluster center. Then any newly mis-classified edge (v, w) can be of two types: (i) $(v, w) \in E_-$ is mis-classified due to both (u, v) and (u, w) belonging to E_+ ; (ii) (v, w) belonging to E_+ , with $(u, v) \in E_+$ and $(u, w) \in E_-$. In both cases we can associate the newly mis-classified edge (v, w) with the unique bad triangle (u, v, w) which gets touched. ◀

Proof of Theorem 15. The first step is the following LP-based lower bound on $\text{Opt}(\mathcal{I})$. Indeed, we know that each bad triangle must have at least one mis-classified edge, and so the LP is simply a linear relaxation for finding a maximal set of disjoint bad triangles.

$$\begin{aligned}
 \text{maximize} \quad & \sum_{t \in \mathcal{B}} w_t, & \text{s.t.}, & & (\text{LP1}) \\
 & \sum_{t \in \mathcal{B}: u, v \in t} w_t \leq 1, & \forall e = (u, v) \in E, & \\
 & w_t \in [0, 1], & \forall t \in \mathcal{B}. &
 \end{aligned}$$

Since it will be useful in the next section, we state the dual program, which is a relaxation for the hitting set for all bad triangles.

$$\begin{aligned} & \text{minimize} && \sum_{u,v} z_{u,v}, && \text{s.t.}, && \text{(LP2)} \\ & z_{u,v} + z_{v,w} + z_{u,w} \geq 1, && \forall t \in \mathcal{B}, \\ & z_{u,v} \in [0, 1], && \forall u, v \in \mathcal{B}. \end{aligned}$$

Now, let $p_t = \mathbb{E}[\text{touched}(t)]$, where $\text{touched}(t)$ is the indicator random variable for whether a bad triangle t is touched in the algorithm. The crux of the proof is the following lemma.

► **Lemma 18.** *The values $\{\mathbb{E}[\text{touched}(t)]/3 : t \in \mathcal{B}\}$ form a feasible solution to LP1.*

Proof. To this end, consider any edge $e = (u, v)$ and the set of bad triangles $\mathcal{B}_{u,v} = \{(u, v, w) \in \mathcal{B}\}$ it is part of. Lemma 17 tells us that (u, v) will be mis-classified if and only if one of these bad triangles $t \equiv (u, v, w) \in \mathcal{B}_{u,v}$ is touched, and the third vertex w must be picked as a cluster center when the triangle is touched. Finally note that, for any triangle $t \equiv (u, v, w)$, the probability that w is picked as the cluster center conditioned on $\text{touched}(t)$ is exactly $1/3$, since the algorithm selects the new cluster center uniformly at random from the un-clustered vertices. Thus we have that: $1 \geq \mathbb{P}((u, v) \text{ is mis-classified}) = \sum_{t \in \mathcal{B}_{u,v}} p_t/3$, thereby showing the LP feasibility of $\{p_t/3\}$. ◀

Also note that by Lemma 17, we have that $\mathbb{E}[\text{cost}(\mathcal{C})] = \sum_{t \in \mathcal{B}} p_t$, where $\text{cost}(\mathcal{C})$ is the objective value of the clustering \mathcal{C} . Lemma 18 coupled with this inequality bounding the cost completes the proof of Theorem 15. ◀

4.2 LP-rounding algorithm for Robust-Correlation-Clustering

We now present our constant-factor bi-criteria approximation for ROBUST-CORRELATION-CLUSTERING which uses ACNAIlg as a sub-routine. Since the ACNAIlg algorithm analysis bounds the expected cost of the clustering in terms of the LP relaxation LP1, by duality, we can also infer that the expected cost of ACNAIlg is bounded by the LP relaxation LP2. We use this intuition as our starting point: indeed, we can extend this covering LP to handle outliers in the following natural manner. Let $z_{u,v}$ denote whether an edge (u, v) is mis-classified, and y_u denote whether a vertex is deleted or not. Then the following LP3 is a valid LP relaxation for ROBUST-CORRELATION-CLUSTERING on complete graphs.

$$\begin{aligned} & \text{minimize} && \sum_{(u,v) \in \binom{V}{2}} z_{u,v}, && \text{s.t.} && \text{(LP3)} \\ & y_u + y_v + y_w + z_{u,v} + z_{v,w} + z_{u,w} \geq 1, && \forall t = (u, v, w) \in \mathcal{B}, && \text{(2)} \\ & \sum_u y_u \leq m, \\ & z_{u,v} \geq 0, && \forall (u, v) \in \binom{V}{2}, \\ & y_u \geq 0, && \forall u \in V. \end{aligned}$$

Equation (2) of LP3 states that at least a unit cost is incurred for any bad triangle in \mathcal{B} if no vertices from this triangle are deleted. Let $\{y_u^* : u \in V\}, \{z_{u,v}^* : (u, v) \in \binom{V}{2}\}$ denote the optimal solution to LP3.

► **Lemma 19.** $\text{Opt}(\mathcal{I}) \geq \sum_{(u,v) \in \binom{V}{2}} z_{u,v}^* = \text{Opt}(LP3)$.

33:10 Robust Correlation Clustering

Proof. Indeed, consider any optimal solution to the ROBUST-CORRELATION-CLUSTERING instance, and set $z_{u,v} = 1$ if (u, v) is mis-classified, and $y_u = 1$ if u is deleted. For any bad triangle $(u, v, w) \in \mathcal{B}$, note that either one of u, v or w must be deleted as an outlier in the optimal solution, or one of the three edges must be mis-classified. Hence the first LP constraint is satisfied. The second is true since the optimal solution deletes at most m outliers. Finally, the objective function captures the number of mis-classified edges. ◀

■ **Algorithm 2** $\text{RCCA}(\text{g}(V, E_+, E_-, m))$.

-
- 1: **Initialization:** $V_{\text{del}} \leftarrow \emptyset$ ▷ Set of deleted vertices
 - 2: Let the optimal solution of LP3 be denoted as $\{y_u^* : u \in V\} \cup \{z_{uv}^* : (u, v) \in \binom{V}{2}\}$
 - 3: $V_{\text{del}} \leftarrow \{v \in V : y_v^* \geq 1/6\}$ ▷ Delete vertices having $y_v^* \geq 1/6$
 - 4: $V' \leftarrow V \setminus V_{\text{del}}$
 - 5: **return:** $\text{ACNA}(\text{g}(V', E'_+, E'_-))$ ▷ E'_+, E'_- : edges in $\binom{V}{2}$ not incident on V_{del}
-

4.3 Analysis

► **Theorem 20.** $\text{RCCA}(\text{g}(V, E_+, E_-, m))$ is a bi-criteria $(6, 6)$ -approximation for ROBUST-CORRELATION-CLUSTERING.

Proof. The proof of this result follows from Lemmas 21 and 22. ◀

► **Lemma 21.** At most $6m$ vertices are deleted by $\text{RCCA}(\text{g}(V, E_+, E_-, m))$.

Proof. Recall that $\text{RCCA}(\text{g}(V, E_+, E_-, m))$ deletes those vertices having $y_u^* \geq 1/6$ in the optimal solution to LP3. Let the set of vertices deleted by $\text{RCCA}(\text{g}(V, E_+, E_-, m))$ be denoted V_{del} . Then,

$$|V_{\text{del}}| = \sum_{u \in V} \mathbb{1}(y_u^* \geq 1/6) \leq \sum_{u \in V} 6y_u^* \leq 6m.$$

Therefore, the budget of vertices to remove is not exceeded by more than a factor of 6. ◀

We next bound the cost incurred by the clustering output by $\text{RCCA}(\text{g}(V, E_+, E_-, m))$.

► **Lemma 22.** The cost of the clustering output by $\text{RCCA}(\text{g}(V, E_+, E_-, m))$ is at most 6 times the cost of the optimal clustering to \mathcal{I} .

Proof. Since the first step deletes vertices in $V_{\text{del}} = \{v \in V : y_v^* \geq 1/6\}$, it suffices to consider the remaining vertices $V' = V \setminus V_{\text{del}}$ and show that $\text{ACNA}(\text{g})$ has cost at most 6Opt on the residual instance. The proof is again very simple: indeed, each vertex $v' \in V'$ has $y_{v'}^* \leq 1/6$, we get that the optimal LP solution to LP3 satisfies $z_{u,v}^* + z_{v,w}^* + z_{u,w}^* \geq 1/2$ for all $(u, v, w) \in \mathcal{B}'$, where \mathcal{B}' denotes the set of all bad triangles induced in the vertex set V' . Then by simply considering the scaled variables $2z_{u,v}^*$, we get that there exists a feasible solution to LP2 for the CORRELATION-CLUSTERING instance induced in (V', E'_+, E'_-) , of cost at most 2Opt . Hence, since the 3-approximation of $\text{ACNA}(\text{g})$ guarantee holds against the dual LP LP1, we can use weak duality to complete the proof. ◀

5 Algorithms for Robust-Correlation-Clustering on General Graphs

In this section, we consider ROBUST-CORRELATION-CLUSTERING on general graphs and prove Theorem 8. Given an instance \mathcal{I} , comprising of graph $G = (V, E_+ \cup E_-)$ and outlier budget m , we begin with the following LP relaxation:

$$\text{Minimize} \quad \sum_{(u,v) \in E_+ \cup E_-} z_{u,v}, \quad \text{s.t.}, \quad (\text{LP6})$$

$$x_{u,v} + x_{v,w} \geq x_{u,w}, \quad \forall u \neq v \neq w \quad (3)$$

$$y_u + y_v + z_{u,v} \geq 1 - x_{u,v}, \quad \forall (u,v) \in E_- \quad (4)$$

$$y_u + y_v + z_{u,v} \geq x_{u,v}, \quad \forall (u,v) \in E_+ \quad (5)$$

$$\sum_u y_u \leq m, \quad (6)$$

$$x_{u,v}, z_{u,v}, y_u \in [0, 1]$$

In simple terms, on imposing integer constraints, LP6 asks to find a clustering s.t. $x_{u,v} = 1$ if u and v belong to different clusters, and 0 otherwise. It is easy to check that such an assignment of $x_{u,v}$ satisfies the triangle inequality constraint Equation (3). The objective function charges a unit cost ($z_{u,v} = 1$) for dissimilar (resp. similar) pairs of points (u, v) placed in the same (resp. different) clusters, only if neither u nor v is deleted, i.e. if $y_u = y_v = 0$. In addition, Equation (6) ensures that at most m vertices are deleted in the intended solution. The following lemma is then an immediate consequence of the fact that the optimal integral solution to ROBUST-CORRELATION-CLUSTERING instance \mathcal{I} is feasible for Equation (LP6).

► **Lemma 23.** *The optimal solution $\{x^*, y^*, z^*\}$ to the LP above has objective value at most $\text{Opt}(\mathcal{I})$, the cost of an optimal ROBUST-CORRELATION-CLUSTERING solution. Moreover, we may slightly perturb this solution to ensure that (a) $\min_{(u,v): x_{u,v}^* \neq 0} x_{u,v}^* \geq 1/n^2$ and $\min_{u: y_u^* \neq 0} y_u^* \geq 1/n^2$, i.e., the smallest non-zero values among x^* and y^* variables is at least $1/n^2$, and (b) the perturbed solution has same objective value and satisfies all the LP inequalities except Equation (6), which is satisfied up to $\sum_u y_u^* \leq (m + 1/n)$.*

We require the lower bound on the x^* and y^* variables for technical reasons which will become clear as the proof proceeds. However, for all practical purposes, the reader may assume that it is just the optimal solution to the LP. We begin by observing that the one of the techniques of solving the CORRELATION-CLUSTERING problem is by reducing it to MINIMUM-MULTICUT problem (in fact, up to constant factors, the CORRELATION-CLUSTERING problem on general graphs is *equivalent* to MINIMUM-MULTICUT on general graphs in [14]), and running the best known approximation to MINIMUM-MULTICUT to get $O(\log n)$ approximations to CORRELATION-CLUSTERING. In our case, for ROBUST-CORRELATION-CLUSTERING, just like how we used a specific approximation algorithm ACNA1g for CORRELATION-CLUSTERING, it turns out that the right starting point for general graphs is the following beautiful partitioning scheme (Theorem 24) for metric spaces known as *padded decompositions*. At a high level, they randomly *partition* a metric space into regions of bounded diameter, such that the probability of a *ball of radius ρ around any vertex v* being separated by the partitioning is proportional to ρ . This generalizes the standard partitioning schemes which just guarantee that the probability that any pair u, v being separated is proportional to $d(u, v)$. While any scheme which satisfies the latter suffices to get good algorithms for CORRELATION-CLUSTERING, we crucially use the stronger property in our algorithm for ROBUST-CORRELATION-CLUSTERING.

33:12 Robust Correlation Clustering

► **Theorem 24** ([15]). *For any finite metric space (X, d) and parameter $\Delta > 0$, there exists a randomized algorithm $\text{PaddedClustering}(X, d, \Delta)$ which outputs a clustering \mathcal{C} of points in X such that,*

- *Every cluster $C \in \mathcal{C}$ has diameter at most Δ ,*
- *For every $x \in X$ and $\rho \in (0, \Delta/8)$,*

$$\text{Prob}(\text{Ball}_\rho(x) \not\subseteq C(x)) \leq \alpha(x) \frac{\rho}{\Delta}, \quad (7)$$

where $\alpha(x) = \mathcal{O}(\log(\frac{|\text{Ball}_\Delta(x)|}{|\text{Ball}_{\Delta/8}(x)|})) = \mathcal{O}(\log n)$ and $C(x)$ denotes the points in the same cluster as x in \mathcal{C} .

5.1 Rounding Algorithm

Before we describe the algorithm in detail, we now provide an overview.

Step 1. We first compute a near-optimal solution $\{x^*, y^*, z^*\}$ for Equation (LP6) satisfying the conditions of Lemma 23.

Step 2. We run the padded decomposition scheme on x^* with $\Delta = 0.25$ to obtain a clustering \mathcal{C}^* of the points. Indeed, we can interpret \mathcal{C}^* as a *rounding* of the $x_{u,v}$ variables into an integral clustering: if $x_{u,v}^* \geq 0.25$, then u and v are definitely in different clusters of \mathcal{C}^* , and if $x_{u,v}^*$ is small, then they are in different clusters with probability $\propto \mathcal{O}(\log n)x_{u,v}^*$.

Step 3. If a mis-classified edge in this clustering has $z_{u,v}^*$ at least some constant, say 0.25, then we can charge such edges to the LP objective.

Step 4a. It remains to consider mis-classified edges with small $z_{u,v}^*$. If $(u, v) \in E_-$, then again this is an easy case, since we know that $x_{u,v}^* \leq 0.25$ because (u, v) is mis-classified, hence it must belong to the same cluster, and all clusters have diameter at most 0.25 w.r.t the x^* metric. Hence, if $z_{u,v}^* \leq 0.25$ for such edges, we can infer that $y_u^* + y_v^* \geq 0.5$ from Equation (4), and we can handle all such edges by *deleting all vertices* with $y_u^* \geq 0.25$.

Step 4b. We are finally left with handling the case when $(u, v) \in E_+$, and $z_{u,v}^*$ is small. Here again, we are in good shape if $x_{u,v}^*$ is at least some constant, since from Equation (5) we know that at least one of y_u^* or y_v^* or $z_{u,v}^*$ must be large, so we can either delete an end-point of (u, v) , or we can charge this mis-classified edge to the LP objective. On the other hand, if $x_{u,v}^*$ is small and (u, v) is mis-classified (and so u and v belong to different clusters since $(u, v) \in E_+$), we use the padded decomposition property that such an event occurred with very low probability, and we can actually afford to scale the variables by $x_{u,v}^*$ to get that $\frac{y_u^*}{x_{u,v}^*} + \frac{y_v^*}{x_{u,v}^*} + \frac{z_{u,v}^*}{x_{u,v}^*} \geq 1$. In expectation, the overall scaling factor would be bounded from Theorem 24, and moreover, for each mis-classified edge in E_+ , we can either charge it to the scaled $z_{u,v}^*$ variable, or delete an end-point due to the scaled y_u^* or y_v^* being large. Of course, this is a simplified view since we cannot consider different scaling factors for different edges. In our actual algorithm, we scale each y_v^* by a quantity r_v , where r_v is the radius of the *smallest ball around v* w.r.t metric s^* which gets separated by the clustering \mathcal{C}^* . This is where our proof uses the stronger properties of the padded decomposition schemes.

► **Theorem 25.** *$\text{RCC-general}(V, E_+, E_-, m)$ is a randomized $(\mathcal{O}(\log n), \mathcal{O}(\log^2 n))$ bi-criteria approximation for ROBUST-CORRELATION-CLUSTERING on general graphs.*

Proof. We begin by introducing some notation that will be useful for the analysis of the algorithm. Consider the clustering \mathcal{C}^* output by $\text{PaddedClustering}(V, x^*, 0.25)$ in $\text{RCC-general}(V, E_+, E_-, m)$. We slightly abuse notation and let $\mathcal{C}^*(v)$ denote the set of all vertices

Algorithm 3 $\text{RCC-general}(V, E_+, E_-, m)$.

- 1: Let $\{x^*, y^*, z^*\}$ denote the (perturbed) optimal solution to LP6 obtained in Lemma 23
- 2: Compute $\mathcal{C}^* = \text{PaddedClustering}(V, x^*, 0.25)$
- 3: Define $V_b^- = \{v \in V : \exists u \in \mathcal{C}^*(v) \text{ such that } (u, v) \in E_-\}$ \triangleright candidate vertices for deletion: have a $-$ edge to at least one other vertex in the same cluster
- 4: Define $V_{\text{del}}^- = \{v \in V_b^- : y_v^* \geq 1/4\}$
- 5: Set $V' \leftarrow V \setminus V_{\text{del}}^-$
- 6: Define $V_b^+ = \{v \in V' : \exists u \in V' \setminus \mathcal{C}^*(v) \text{ such that } (u, v) \in E_+\}$ \triangleright candidate vertices for deletion: have a $+$ edge to at least one vertex in a different cluster
- 7: For each $u \in V_b^+$, define

$$\hat{y}_u \stackrel{\text{def}}{=} 2^r \cdot y_u^*, \text{ where } \frac{1}{2^r} < \min_{v \in V' \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq \frac{1}{2^{r-1}}$$

- 8: Define $V_{\text{del}}^+ = \{v \in V_b^+ : \hat{y}_v \geq 1/3\}$
 - 9: **Return:** $D_{\text{alg}} = V_{\text{del}}^- \cup V_{\text{del}}^+$ as outliers and the clustering $\mathcal{C}_{\text{alg}} = \mathcal{C}^* \setminus D$
-

which are in the same cluster as v in the clustering \mathcal{C}^* . Define E_b^- as the set of $-$ edges between vertices in V in the same cluster in \mathcal{C}^* , $E_b^- \stackrel{\text{def}}{=} \{(u, v) \in E_- : u \in \mathcal{C}^*(v)\}$. In addition, define E_b^+ to be the set of $+$ edges between vertices in V' lying in different clusters in \mathcal{C}^* , i.e., $E_b^+ \stackrel{\text{def}}{=} \{(u, v) \in E_+ : u \in V' \setminus \mathcal{C}^*(v)\}$. Let $\text{cost}(\text{alg})$ denote the cost of the clustering output by $\text{RCC-general}(V, E_+, E_-, m)$ and let $V_{\text{del}} = V_{\text{del}}^- \cup V_{\text{del}}^+$ denote the set of vertices deleted. Observe that any edge that contributes to $\text{cost}(\text{alg})$ belongs to either E_b^+ or E_b^- and is not incident on any vertex in V_{del} . Therefore, $\text{cost}(\text{alg})$ can be decomposed as

$$\text{cost}(\text{alg}) \leq \text{cost}(\text{alg})^- + \text{cost}(\text{alg})^+. \quad (8)$$

where $\text{cost}(\text{alg})^-$ denotes the cost associated with edges in E_b^- that are not incident on vertices in V_{del}^- , and $\text{cost}(\text{alg})^+$ denotes the cost associated with edges in E_b^+ that are not incident on vertices in $V_{\text{del}}^- \cup V_{\text{del}}^+$.

Let Opt^* denote the cost of the optimal solution to LP6. To bound the cost of our solution, we show in Lemmas 28 and 33 respectively that $\text{cost}(\text{alg})^-$ is upper-bounded by 4Opt^* , while $\mathbb{E}[\text{cost}(\text{alg})^+]$ is upper-bounded by $O(\log n)\text{Opt}^*$.

On the other hand, to bound the number of vertices deleted by $\text{RCC-general}(V, E_+, E_-, m)$, we follow a similar strategy. Since, $|V_{\text{del}}| = |V_{\text{del}}^-| + |V_{\text{del}}^+|$, we separately upper bound V_{del}^- and $\mathbb{E}[V_{\text{del}}^+]$ in Lemmas 27 and 32 by $4m$ and $\mathcal{O}(\log^2 n)m$ respectively. \blacktriangleleft

Recall that the optimal solution of LP6 is denoted as $(\{y_u^*\}, \{x_{u,v}^*\}, \{z_{u,v}^*\})$. We begin by establishing some basic properties of the clustering \mathcal{C}^* .

\triangleright **Claim 26.** For any edge $(u, v) \in E_b^-$, $y_u^* + y_v^* + z_{u,v}^* \geq 0.75$.

Proof. Recall that E_b^- denotes the set of dissimilar points in V that are placed in the same cluster by \mathcal{C}^* . Since, $E_b^- \subseteq E_-$, the optimal solution to LP6 must satisfy the negative edge-constraint (4) for edge (u, v) , and so $y_u^* + y_v^* + z_{u,v}^* \geq 1 - x_{u,v}^*$. Now, note that $x_{u,v}^* \leq 0.25$, since u and v belong to the same cluster in \mathcal{C}^* and the diameter of any cluster in $\text{PaddedClustering}(X, d, \Delta)$ is at most Δ from Theorem 24. \triangleleft

\blacktriangleright **Lemma 27.** The set of vertices, V_{del}^- satisfies $|V_{\text{del}}^-| \leq 4 \sum_{v \in V} y_v^* \leq 4(m + 1/n)$.

Proof. Recall that V_{del}^- is the set of vertices, $v \in V_b^-$ such that $y_v^* \geq 1/4$. This, combined with the fact that $\{y_v^*\}$ satisfies $\sum_u y_u^* \leq m + 1/n$ from Lemma 23, completes the proof. \blacktriangleleft

33:14 Robust Correlation Clustering

► **Lemma 28.** *The cost of mis-classified E_- edges $\text{cost}(\text{alg})^-$ is at most $4 \sum_{(u,v) \in E^-} z_{u,v}^*$.*

Proof. Observe that $\text{cost}(\text{alg})^-$ accrues unit cost only for edges in E_b^- which are not incident on a vertex in V_{del}^- . This implies that $y_u^* \leq 0.25$ for all vertices incident on such edges. This, combined with Claim 26 completes the proof. ◀

We now move onto the analysis of $\text{cost}(\text{alg})^+$ and $|V_{\text{del}}^+|$, which are slightly more involved. In this respect, define

$$\hat{z}_{u,v} \stackrel{\text{def}}{=} \begin{cases} \frac{z_{u,v}^*}{x_{u,v}^*}, & v \notin \mathcal{C}^*(u), \\ 0 & \text{otherwise.} \end{cases} \quad (9)$$

We demonstrate some useful facts about $\hat{z}_{u,v}$ and \hat{y}_u , which recall is defined previously as,

$$\hat{y}_u = 2^r \cdot y_u^*, \quad \text{where, } r : \frac{1}{2^r} < \min_{v \in V \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq \frac{1}{2^{r-1}}$$

▷ **Claim 29.** For any edge $(u, v) \in E_b^+$, $\mathbb{E}[\hat{z}_{u,v}] \leq \mathcal{O}(\log n) z_{u,v}^*$.

Proof. Observe that if two points belong to different clusters, then we must necessarily have for $\rho = x_{u,v}^*$ that $\text{Ball}_\rho(u) \not\subseteq \mathcal{C}(u)$. Therefore, from Theorem 24,

$$\text{Prob}(u \notin \mathcal{C}^*(v)) \leq \mathcal{O}(\log n) \frac{x_{u,v}^*}{0.25}.$$

Therefore, from the definition of $\hat{z}_{u,v}$ in (9), it follows that, $\mathbb{E}[\hat{z}_{u,v}] \leq \mathcal{O}(\log n) \frac{x_{u,v}^*}{0.25} \frac{z_{u,v}^*}{x_{u,v}^*} + 0 = \mathcal{O}(\log n) z_{u,v}^*$. ◀

▷ **Claim 30.** For any vertex $v \in V_b^-$, $\mathbb{E}[\hat{y}_u] \leq \mathcal{O}(\log^2 n) \cdot y_u^*$.

Proof. Observe that $x_{u,v}^* \in [n^{-2}, 1]$. Therefore, r takes values from the set $\{0, 1, 2, \dots, 2 \log n\}$. By definition of \hat{y}_u ,

$$\begin{aligned} \mathbb{E}[\hat{y}_u] &= \sum_{r=0}^{2 \log n} 2^r (y_u^*) \text{Prob} \left(\frac{1}{2^r} < \min_{v \in V \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq \frac{1}{2^{r-1}} \right), \\ &\leq \sum_{r=0}^{2 \log n} 2^r (y_u^*) \text{Prob} \left(\min_{v \in V \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq \frac{1}{2^{r-1}} \right). \end{aligned} \quad (10)$$

Next, observe that the event $\min_{v \in V \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq 2^{-(r-1)}$ can only occur if the ball of radius $2^{-(r-1)}$ centered at u does not lie entirely within $\mathcal{C}(u)$. Therefore, from Theorem 24,

$$\text{Prob} \left(\min_{v \in V \setminus \mathcal{C}^*(u)} x_{u,v}^* \leq \frac{1}{2^{r-1}} \right) \leq \mathcal{O}(\log n) \frac{1}{2^{r-1}}.$$

Plugging this into (10) gives, $\mathbb{E}[\hat{y}_u] \leq \mathcal{O}(\log n) \sum_{r=0}^{2 \log n} y_u^* = \mathcal{O}(\log^2 n) \cdot y_u^*$. ◀

▷ **Claim 31.** For any edge $(u, v) \in E_b^+$, we have that $\hat{y}_u + \hat{y}_v + \hat{z}_{u,v} \geq 1$.

Proof. Since $E_b^+ \subseteq E_+$, every $(u, v) \in E_b^+$ must satisfy the positive edge-constraint (5) $y_u^* + y_v^* + z_{u,v}^* \geq x_{u,v}^*$. The proof then concludes by dividing both sides by $x_{u,v}^*$, and using the definitions of \hat{y}_u and $\hat{z}_{u,v}$. ◀

► **Lemma 32.** *The set of vertices V_{del}^+ satisfies, $\mathbb{E}[|V_{\text{del}}^+|] \leq \mathcal{O}(\log^2 n) m$.*

Proof. Recall that V_{del}^+ is defined as the set of vertices $v \in V_b^+$ such that $\hat{y}_v \geq 1/3$. Therefore $|V_{\text{del}}^+| = \sum_{v \in V_b^+} \mathbb{1}(\hat{y}_v \geq 1/3)$. Since $\mathbb{1}(\hat{y}_v \geq 1/3) \leq 3\hat{y}_v$, it follows that $|V_{\text{del}}^+| \leq 3 \sum_{v \in V_b^+} \hat{y}_v$. Taking expectation on both sides, and using Claim 30, $\mathbb{E}[|V_{\text{del}}^+|] \leq \mathcal{O}(\log^2 n) \sum_{v \in V_b^+} y_v^*$. The proof concludes by relaxing the summation $v \in V_b^+$ to $v \in V$, and using Lemma 23 to claim that $\sum_{v \in V} y_v^* \leq m + \frac{1}{n} \leq 2m$. ◀

► **Lemma 33.** *The expected cost of the mis-classified E_+ edges $\mathbb{E}[\text{cost}(\text{alg})^+]$ is at most $\mathcal{O}(\log n) \sum_{(u,v) \in E_+} z_{u,v}^*$.*

Proof. $\text{cost}(\text{alg})^+$ is the cost corresponding to edges in E_b^+ which are not incident on any vertex in V_{del} . Recall that a vertex $v \in V'$ belongs to V_{del} only if $\hat{y}_v \geq 1/3$. Following a similar proof as Lemma 28, we get that,

$$\text{cost}(\text{alg})^+ \leq \sum_{(u,v) \in E_b^+} \mathbb{1}(\hat{z}_{u,v} \geq 1/3) \leq 3 \sum_{(u,v) \in E_b^+} \hat{z}_{u,v},$$

Taking expectations on both sides, using Claim 29 to upper bound $\mathbb{E}[\hat{z}_{u,v}]$ by $\mathcal{O}(\log n) z_{u,v}^*$, and relaxing the summation to $(u, v) \in E_+$ completes the proof. ◀

A Hardness of Robust-Correlation-Clustering on General Graphs

Firstly, when $m = 0$, ROBUST-CORRELATION-CLUSTERING is simply CORRELATION-CLUSTERING, for which is known NP-hardness of $\Omega(\alpha_{MC})$ [5]. We show that it is NP-hard to get any (a, b) -approximation for ROBUST-CORRELATION-CLUSTERING with finite b when $a < \alpha_{MC}$, for any $m > 0$.

► **Theorem 34.** *It is NP-hard to have an (a, b) bi-criteria approximation to ROBUST-CORRELATION-CLUSTERING for any finite b and $a < \alpha_{MC}$.*

Proof. The proof is via a reduction from MINIMUM-MULTICUT, similar to the proof for CORRELATION-CLUSTERING in [5]. Consider the MINIMUM-MULTICUT instance problem $\mathcal{I} = \{G(V, E), \{(s_i, t_i), 1 \leq i \leq k\}\}$, where $(s_i, t_i), 1 \leq i \leq k$ represent k source-sink pairs. We construct the ROBUST-CORRELATION-CLUSTERING problem instance \mathcal{I}^* as follows. The edges in G become $+$ edges in \mathcal{I}^* . For each $i, 1 \leq i \leq k$, we add a negative edge between (s_i, t_i) of weight $-W$, for some large positive integer W , say $W = n^3$. We can make the instance unweighted by replacing a negative edge of weight $-W$ by W parallel length two paths; each path has a fresh intermediate vertex, with one $+$ edge and one $-$ edge. Clearly, the minimum cost clustering must have (s_i, t_i) in different clusters $\forall 1 \leq i \leq k$. In addition, introduce m more vertices which act like outliers, represented by set $U = \{u_1, u_2, \dots, u_m\}$ in \mathcal{I}^* . Connect each $u_i, 1 \leq i \leq m$ to every vertex $q, q \in V(\mathcal{I}^*) \setminus U$ with an edge of weight $-W$ and an edge of weight W . We can make the instance unweighted by replacing the negative edge as described before, and the positive edge of weight W by W parallel length two paths; each path has a fresh intermediate vertex, with both edges $+$.

Due to the above construction, the vertices $(q, u_i), q \in V(\mathcal{I}^*) \setminus U, 1 \leq i \leq m$ add a high cost irrespective of whether they lie in the same cluster or not.

Hence, the optimal solution to ROBUST-CORRELATION-CLUSTERING on the problem instance \mathcal{I}^* removes vertices u_1, u_2, \dots, u_m , and the corresponding optimal cost is same as the MINIMUM-MULTICUT optimal cost on instance \mathcal{I} . ◀

We next establish that unless the budget of vertices to be removed is violated by a certain factor, it is NP-hard to find any approximation to the cost of the optimal solution to ROBUST-CORRELATION-CLUSTERING.

► **Theorem 35.** *It is NP-hard to find an (a, b) bi-criteria approximation to ROBUST-CORRELATION-CLUSTERING for any finite a , and $b < \alpha_{MC}$.*

Proof. The proof of this result once again follows via a reduction from MINIMUM-MULTICUT. Indeed, consider the MINIMUM-MULTICUT instance problem $\mathcal{I} = \{G(V, E), \{(s_i, t_i), 1 \leq i \leq k\}\}$, where $(s_i, t_i), 1 \leq i \leq k$ represent k source-sink pairs. We now define an intermediate problem which will simplify our overall reduction. ◀

► **Definition 36** (VERTEX-MULTICUT). *Given a problem instance $\mathcal{I} = \{H, \{(s_i, t_i), 1 \leq i \leq k\}\}$, where $(s_i, t_i), 1 \leq i \leq k$ represent k source-sink pairs, the VERTEX-MULTICUT problem is to find the minimum set of vertices $S \subseteq V(H)$ such that no source-sink pair lie in the same connected component in the graph induced on $V(H) \setminus S$.*

► **Lemma 37.** *There exists an approximation preserving reduction from MINIMUM-MULTICUT to VERTEX-MULTICUT.*

33:18 Robust Correlation Clustering

Proof. The idea is to reduce the MINIMUM-MULTICUT problem instance \mathcal{I} to a VERTEX-MULTICUT problem instance $\mathcal{I}' = \{H(V', E'), \{(s'_i, t'_i), 1 \leq i \leq l\}\}$. Consider the graph $G = (V, E)$ as defined above. Reduce each vertex $v_i \in V$ into a clique of large size, say n , where $n = |V|$. Let $\text{clique}(v_i) = \{v_{i1}, v_{i2}, \dots, v_{in}\}$, where $v_i \in V, 1 \leq i \leq n$ represent the clique in H . For every $(s_i, t_i), 1 \leq i \leq k$ source-sink pair in \mathcal{I} , let each of $(s_{ia}, t_{ib}) \forall 1 \leq a, b \leq n$ be a source sink pair in instance \mathcal{I}' . Hence, instance \mathcal{I}' will contain kn^2 source-sink pairs in comparison with the k pairs in \mathcal{I} . We now define the edges in \mathcal{I}' . E' is composed of two components, $\cup_{i \leq n} E_{\text{clique}(v_i)}$ and E_{across} , where $E_{\text{clique}(v_i)} = \{(v_{ia}, v_{ib}), 1 \leq i, a, b \leq n, a \neq b\}$, and $E_{\text{across}} = \{(v_{ij}, v_{ji}) : (v_i, v_j) \in E\}$.

We now have a VERTEX-MULTICUT problem instance \mathcal{I}' . We claim that the reduction from \mathcal{I} to \mathcal{I}' is an approximation preserving reduction. Let S denote the optimal solution to problem instance \mathcal{I}' , that is, S denotes the optimal set of vertices to remove to disconnect the source-sink pairs. Let $v_{ij} \in S, 1 \leq i, j \leq n$. Removing the edge $(v_i, v_j) \in E$ in instance \mathcal{I} is equivalent to removing the vertex v_{ij} (or v_{ji}) in \mathcal{I}' where $(v_i, v_j) \in E'$. Hence solving the VERTEX-MULTICUT problem solves MINIMUM-MULTICUT problem as well. ◀

► **Lemma 38.** *There exists an approximation preserving reduction from VERTEX-MULTICUT to approximating the budget of number of vertices to remove in ROBUST-CORRELATION-CLUSTERING problem.*

Proof. Given a VERTEX-MULTICUT problem instance $\mathcal{I}' = \{H, \{(s_i, t_i) | 1 \leq i \leq k, \}\}$, we construct a ROBUST-CORRELATION-CLUSTERING problem instance \mathcal{I}'' . The edges in H becomes positive edges in \mathcal{I}'' . In addition, add a negative edge between each (s_i, t_i) pair of weight $-W$, for some large positive integer W , say $W = n^3$. The graph can be made unweighted as discussed in the proof to Theorem 34.

Consider the instance \mathcal{I}'' . The minimum set of vertices R such that the graph induced on remaining vertices has a 0 cost clustering is identical to the optimal solution to the instance \mathcal{I}' . From Lemma 37, it follows that if \mathcal{I}' can be solved optimally, the underlying MINIMUM-MULTICUT problem instance \mathcal{I} can be solved optimally. Therefore from Theorem 34 and Lemma 37, it follows that it is NP-hard to violate the budget of number of vertices to remove by a factor $< \alpha_{\text{MC}}$ such that the cost of the output clustering is a finite approximation to the optimal cost. ◀

Counting Independent Sets and Colorings on Random Regular Bipartite Graphs

Abstract

We give a fully polynomial-time approximation scheme (FPTAS) to count the number of independent sets on almost every Δ -regular bipartite graph if $\Delta \geq 53$. In the weighted case, for all sufficiently large integers Δ and weight parameters $\lambda = \tilde{\Omega}(\frac{1}{\Delta})$, we also obtain an FPTAS on almost every Δ -regular bipartite graph. Our technique is based on the recent work of Jenssen, Keevash and Perkins (SODA, 2019) and we also apply it to confirm an open question raised there: For all $q \geq 3$ and sufficiently large integers $\Delta = \Delta(q)$, there is an FPTAS to count the number of q -colorings on almost every Δ -regular bipartite graph.

1 Introduction

Counting independent sets on bipartite graphs ($\#BIS$) plays a significant role in the field of approximate counting. A wide range of counting problems in the study of counting CSPs [14, 6, 15] and spin systems [19, 20, 17, 7], have been proved to be $\#BIS$ -equivalent or $\#BIS$ -hard under approximation-preserving reductions (AP-reductions) [13]. Despite its great importance, it is still unknown whether $\#BIS$ admits a fully polynomial-time approximation scheme (FPTAS) or it is as hard as counting the number of satisfying assignments of Boolean formulas ($\#SAT$) under AP-reduction.

In this paper, we consider the problem of approximating $\#BIS$ (and its weighted version) on random regular bipartite graphs. Random regular bipartite graphs frequently appear in the analysis of hardness of counting independent sets [34, 12, 38, 39, 17]. Therefore, understanding the complexity of $\#BIS$ on such graphs is potentially useful for gaining

insights into the general case. Let $Z(G, \lambda) = \sum_{I \in \mathcal{I}(G)} \lambda^{|I|}$ where $\mathcal{I}(G)$ is the set of all independent sets of a graph G and $\lambda > 0$ is the weight parameter. This function also arises in the study of the hardcore model of lattice gas systems in statistical mechanics. Hence we usually call $Z(G, \lambda)$ the partition function of the hardcore model with fugacity λ .

In the case where input graphs are allowed to be nonbipartite, the approximability for counting the number of independent sets ($\#IS$) is well understood. Exploiting the correlation decay properties of $Z(G, \lambda)$, Weitz [41] presented an FPTAS for graphs of maximum degree Δ at fugacity $\lambda < \lambda_c(\Delta) = \frac{(\Delta-1)^{\Delta-1}}{(\Delta-2)^\Delta}$. On the hardness side, Sly [38] proved that, unless $NP = RP$, there is a constant $\varepsilon = \varepsilon(\Delta)$ that no polynomial-time approximation scheme exists for $Z(G, \lambda)$ on graphs of maximum degree Δ at fugacity $\lambda_c(\Delta) < \lambda < \lambda_c(\Delta) + \varepsilon(\Delta)$. Later, this result was improved at any fugacity $\lambda > \lambda_c(\Delta)$ [39, 16]. In particular, these results state that if $\Delta \leq 5$, there is an FPTAS for $\#IS$ on graphs of maximum degree Δ , otherwise there is no efficient approximation algorithm unless $NP = RP$.

The situation is different on bipartite graphs. No NP-hardness result is known even on graphs with unbounded degree. Surprisingly, Liu and Lu [29] designed an FPTAS for $\#BIS$ which only requires one side of the vertex partition to be of maximum degree $\Delta \leq 5$. On the other hand, it is $\#BIS$ -hard to approximate $Z(G, \lambda)$ at fugacity $\lambda > \lambda_c(\Delta)$ on bipartite graphs of maximum degree $\Delta \geq 3$ [7].

Recently, Helmuth, Perkins, and Regts [25] developed a new approach via the polymer model and gave efficient counting and sampling algorithms for the hardcore model at high fugacity on certain finite regions of the lattice \mathbb{Z}^d and on the torus $(\mathbb{Z}/n\mathbb{Z})^d$. Their approach is based on a long line of work [36, 37, 28, 1, 2, 35]. Shortly after that, Jenssen, Keevash, and Perkins [26] designed an FPTAS for the hardcore model at high fugacity on bipartite expander graphs of bounded degree. And they further extended the result to random Δ -regular bipartite graphs with $\Delta \geq 3$ at fugacity $\lambda > (2e)^{250}$. This is the first efficient algorithm for the hardcore model at fugacity $\lambda > \lambda_c(\Delta)$ on random regular bipartite graphs. A natural question is, can we design FPTAS for lower fugacity and in particular the problem $\#BIS$ on random regular bipartite graphs? Indeed, we obtain such results. Let $\mathcal{G}_{n,\Delta}^{\text{bip}}$ denote the set of all Δ -regular bipartite graphs with n vertices on both sides.

► **Theorem 1.** *For $\Delta \geq 53$ and fugacity $\lambda \geq 1$, with high probability (tending to 1 as $n \rightarrow \infty$) for a graph G chosen uniformly at random from $\mathcal{G}_{n,\Delta}^{\text{bip}}$, there is an FPTAS for the partition function $Z(G, \lambda)$.*

► **Theorem 2.** *For all sufficiently large integers Δ and fugacity $\lambda = \tilde{\Omega}(\frac{1}{\Delta})^1$, with high probability (tending to 1 as $n \rightarrow \infty$) for a graph G chosen uniformly at random from $\mathcal{G}_{n,\Delta}^{\text{bip}}$, there is an FPTAS for the partition function $Z(G, \lambda)$.*

For notational convenience, we use the term “on almost every Δ -regular bipartite graph” to denote that a property holds with high probability (tending to 1 as $n \rightarrow \infty$) for randomly chosen graphs from $\mathcal{G}_{n,\Delta}^{\text{bip}}$.

Counting proper q -colorings on a graph is another extensively studied problem in the field of approximate counting [27, 4, 5, 10, 23, 22, 33, 9, 24, 18, 11, 31, 21]. In general graphs, if the number of colors q is no more than the maximum degree Δ , there may not be any proper coloring over the graph. Therefore, approximate counting is studied in the range that $q \geq \Delta + 1$. It was conjectured that there is an FPTAS if $q \geq \Delta + 1$, but the current best result is $q \geq \alpha\Delta + 1$ with a constant α slightly below $\frac{11}{6}$ [40, 8]. The conjecture was only confirmed for the special case $\Delta = 3$ [30].

¹ This means that $\lambda \geq (c_1 \log^{c_2} \Delta)/\Delta$ for some constants $c_1, c_2 > 0$.

On bipartite graphs, the situation is quite different. For any $q \geq 2$, we know that there always exist proper q -colorings for every bipartite graph. For any $q \geq 3$, it is shown to be $\#BIS$ -hard but unknown to be $\#BIS$ -equivalent [13]. Using a technique analogous to that for $\#BIS$, we obtain an FPTAS to count the number of q -colorings on random Δ -regular bipartite graphs for all sufficiently large integers $\Delta = \Delta(q)$ for any $q \geq 3$.

► **Theorem 3.** *For $q \geq 3$ and $\Delta \geq 100\bar{q}^{10}$ where $\bar{q} = \lceil q/2 \rceil$, with high probability (tending to 1 as $n \rightarrow \infty$) for a graph chosen uniformly at random from $\mathcal{G}_{n,\Delta}^{\text{bip}}$, there is an FPTAS to count the number of q -colorings.*

This result confirms a conjecture in [26].

Our Technique

The classical approach to designing approximate counting algorithms is random sampling via Markov chain Monte Carlo (MCMC). However, it is known that the Markov chains are slowly mixing on random bipartite graphs for both independent set and coloring if the degree Δ is not too small. Taking $\#BIS$ as an example, a typical independent set of a random regular bipartite graph of degree at least 6 is unbalanced: it either chooses most of its vertices from the left side or the right side. Thus, starting from an independent set with most vertices from the left side, a Markov chain is unlikely to reach an independent set with most of its vertices from the right side in polynomial time.

Even so, a recent beautiful work exactly makes use of the above separating property to design approximate counting algorithms [26]. By making the fugacity $\lambda > (2e)^{250}$ sufficiently large, they proved that largest contribution to the partition function comes from extremely unbalanced independent sets, those which occupy almost no vertices on one side and almost all vertices on the other side. In particular, for a bipartite graph $G = (\mathcal{L}, \mathcal{R}, E)$ with n vertices on both sides, they identified two independent sets $I = \mathcal{L}$ and $I = \mathcal{R}$ as ground states as they have the largest weight λ^n among all the independent sets. They proved that one only needs to sum up the weights of states which are close to one of the ground states, for no state is close to both ground states and the contribution from the states which are far away from both ground states is exponentially small.

However, the ground state idea cannot be directly applied to counting independent sets and counting colorings since each valid configuration is of the same weight. We extend the idea of ground states to ground clusters, which is not a single configuration but a family of configurations. For example, we identify two ground clusters for independent sets, those which are entirely chosen from vertices on the left side and those which are entirely chosen entirely from vertices on the right side. If a set of vertices is entirely chosen from vertices on one side, it is obviously an independent set. Thus each cluster contains 2^n different independent sets. Similarly, we want to prove that we can count the configurations which are close to one of the ground clusters and then add them up. For counting colorings, there are multiple ground clusters indexed by a subset of colors $\emptyset \subsetneq X \subsetneq [q]$: colorings which color \mathcal{L} only with colors from X and color \mathcal{R} only with colors from $[q] \setminus X$.

Unlike the ground states in [26], our ground clusters may overlap with each other and some configurations are close to more than one ground cluster. In addition to proving that the number of configurations which are far away from all ground clusters is exponentially small, we also need to prove that the number of double counted configurations is small.

After identifying ground states and with respect to a fixed ground state, Jenssen, Keevash, and Perkins [26] defined a polymer model representing deviations from the ground state and rewrote the original partition function as a polymer partition function. We follow this

idea and define a polymer model representing deviations from a ground cluster. However, deviation from a ground cluster is much subtler than deviation from a single ground state. For example, if we define polymer as connected components from the deviated vertices in the graph, we cannot recover the original partition function from the polymer partition function. We overcome this by defining polymer as connected components in the graph G^2 , where an edge of G^2 corresponds to a path of length at most 2 in the original graph. Here, a compatible set of polymers also corresponds to a family of configurations in the original problem, while it corresponds to a single configuration in [26].

It is much more common in counting problems that most contribution is from a neighborhood of some clusters rather than a few isolated states. So, we believe that our development of the technique makes it suitable for a much broader family of problems.

Organization of the paper

In this 10-page version, we only prove Theorem 1 which already explains the key technique for proving Theorem 2 and Theorem 3. The complete proof (and the modifications necessary) for these two can be found in the full version. In Section 2 we review necessary definitions and facts. In Section 3 we prove Theorem 1, where the proof is divided into four parts. The first part deals with the property of the independent sets on certain graphs. The second part uses the polymer model to approximate the number of independent sets. The third part discusses how to approximate the partition function of the polymer model. The last part puts these things together.

Independent work

Towards the end of this project, we learned that the authors of [26] obtained similar results in their upcoming journal version submission.

2 Preliminaries

2.1 Independent sets and random regular bipartite graphs

All graphs considered in this paper are unweighted, undirected, with no loops but may have multiple edges. Let $G = (V, E)$ be a graph. We use $d_G(u, w)$ to denote the distance between two vertices u, w in the graph G . For $\emptyset \subsetneq U, W \subseteq V$, define $d_G(U, W) = \min_{u \in U, w \in W} d_G(u, w)$. Let $U \subseteq V$ be a nonempty set. Let $N_G(U) = \{v \in V : d_G(\{v\}, U) = 1\}$ to be the neighborhood of U and emphasize that $N_G(U) \cap U = \emptyset$. We use $G[U]$ to denote the induced subgraph of G on U . Let E^2 be the set of unordered pairs (u, v) such that $u \neq v$ and $d_G(u, v) \leq 2$. We define G^2 to be the graph (V, E^2) . It is clear that if the maximum degree of G is at most Δ , then the maximum degree of G^2 is at most Δ^2 . An independent set of the graph G is a subset $U \subseteq V$ such that $(u, w) \notin E$ for any $u, w \in U$. We use $\mathcal{I}(G)$ to denote the set of all independent sets of G . The weight of an independent set I is $\lambda^{|I|}$ where $\lambda > 0$ is a parameter called fugacity. We use $Z(G, \lambda) = \sum_{I \in \mathcal{I}(G)} \lambda^{|I|}$ to denote the partition function of the graph G . Clearly, $Z(G, 1)$ is the number of independent sets of G .

For two positive real numbers a and b , we say a is an ε -relative approximation to b for some $\varepsilon > 0$ if $\exp(-\varepsilon)b \leq a \leq \exp(\varepsilon)b$, or equivalently $\exp(-\varepsilon)a \leq b \leq \exp(\varepsilon)a$. A fully polynomial-time approximation scheme (FPTAS) is an algorithm that for every $\varepsilon > 0$ outputs an ε -relative approximation to $Z(G)$ in time $(|G|/\varepsilon)^C$ for some constant $C > 0$, where $Z(G)$ is some quantity, like the number of independent sets, of graphs G that we would like to compute.

We use $G \sim \mathcal{G}_{n,\Delta}^{\text{bip}}$ to denote sampling a Δ -regular bipartite graph G with n vertices on both sides uniformly at random. We say a Δ -regular bipartite graph $G = (\mathcal{L}, \mathcal{R}, E)$ with n vertices on both sides is an (α, β) -expander if for all subsets $U \subseteq \mathcal{L}$ or $U \subseteq \mathcal{R}$ with $|U| \leq \alpha n$, $|N(U)| \geq \beta|U|$. This property is called the expansion property of G . We use $\mathcal{G}_{\alpha,\beta}^\Delta$ to denote the set of all Δ -regular bipartite (α, β) -expanders. It is known that a random regular bipartite graph is an expander with high probability.

2.2 The polymer model

Let G be a graph and Ω be a finite set. A polymer $\gamma = (\bar{\gamma}, \omega_\gamma)$ consists of a support $\bar{\gamma}$ which is a connected subgraph of G and a mapping ω_γ which assigns to each vertex in $\bar{\gamma}$ some value in Ω . We use $|\bar{\gamma}|$ to denote the number of vertices of $\bar{\gamma}$. There is also a weight function $w(\gamma, \cdot) : \mathbb{C} \rightarrow \mathbb{C}$ for each polymer γ . There can be many polymers defined on the graph G and we use $\Gamma^* = \Gamma^*(G)$ to denote the set of all polymers defined on it. However, at the moment we do not give a constructive definition of polymers. Such definitions are presented when they are needed, see Section 3.2. We say two polymers γ_1 and γ_2 are compatible if $d_G(\bar{\gamma}_1, \bar{\gamma}_2) > 1$ and we use $\gamma_1 \sim \gamma_2$ to denote that they are compatible. For a subset $\Gamma \subseteq \Gamma^*$ of polymers, it is compatible if any two different polymers in this set are compatible. We define $\mathcal{S}(\Gamma^*) = \{\Gamma \subseteq \Gamma^* : \Gamma \text{ is compatible}\}$ to be the collection of all compatible subsets of polymers. For $\Gamma \in \mathcal{S}(\Gamma^*)$, we also define $|\bar{\Gamma}|$ to be the number of vertices of the subgraph $\bar{\Gamma}$ and let $\omega_{\bar{\Gamma}}$ be a mapping which assigns each vertex $v \in \bar{\Gamma}$ the value that ω_γ assigns to v where γ is the unique polymer whose support contains vertex v . We say (Γ^*, w) is a polymer model defined on the graph G and the partition function of this polymer model is $\Xi(G, z) = \sum_{\Gamma \in \mathcal{S}(\Gamma^*)} \prod_{\gamma \in \Gamma} w(\gamma, z)$, where z is a complex variable and $\prod_{\gamma \in \emptyset} w(\gamma, z) = 1$ by convention. The following theorem states conditions that $\Xi(G, z)$ can be approximated efficiently.

► **Theorem 4** ([25], Theorem 2.2). *Fix Δ and let \mathcal{G} be a set of graphs of degree at most Δ . Suppose:*

- *There is a constant C such that for all $G \in \mathcal{G}$, the degree of $\Xi(G, z)$ is at most $C|G|$.*
 - *For all $G \in \mathcal{G}$ and $\gamma \in \Gamma^*(G)$, $w(\gamma, z) = a_\gamma z^{|\bar{\gamma}|}$ where $a_\gamma \neq 0$ can be computed in time $\exp(O(|\bar{\gamma}| + \log_2 |G|))$.*
 - *For every connected subgraph G' of every $G \in \mathcal{G}$, we can list all polymers $\gamma \in \Gamma^*(G)$ with $\bar{\gamma} = G'$ in time $\exp(O(|G'|))$.*
 - *There is a constant $R > 0$ such that for all $G \in \mathcal{G}$ and $z \in \mathbb{C}$ with $|z| < R$, $\Xi(G, z) \neq 0$.*
- Then for every z with $|z| < R$, there is an FPTAS for $\Xi(G, z)$ for all $G \in \mathcal{G}$.*

The following condition by Kotecký and Preiss (KP-condition) is useful to show that $\Xi(G, z)$ is zero-free in certain regions.

► **Lemma 5** ([28]). *Suppose there is a function $a : \Gamma^* \rightarrow \mathbb{R}_{>0}$ and for every $\gamma^* \in \Gamma^*$,*

$$\sum_{\gamma: \gamma \not\sim \gamma^*} e^{a(\gamma)} |w(\gamma, z)| \leq a(\gamma^*). \text{ Then } \Xi(G, z) \neq 0.$$

To verify the KP-condition, usually we need to enumerate polymers and the following lemma is useful to bound the number of enumerated polymers.

► **Lemma 6** ([3]). *For any graph $G = (V, E)$ with maximum degree Δ and $v \in V$, the number of connected induced subgraphs of order $k \geq 2$ containing v is at most $(e\Delta)^{k-1}/2$. As a corollary, the number of connected induced subgraphs of order $k \geq 1$ containing v is at most $(e\Delta)^{k-1}$.*

2.3 Some useful lemmas

Throughout this paper, we use $H(x)$ to denote the binary entropy function

$$H(x) = -x \log_2 x - (1-x) \log_2(1-x), \quad x \in (0, 1).$$

Moreover, we extend this function to the interval $[0, 1]$ by defining $H(0) = H(1) = 0$. This is reasonable since $\lim_{x \rightarrow 0^+} H(x) = \lim_{x \rightarrow 1^-} H(x) = 0$.

► **Lemma 7.** *It holds that $H(x) \leq 2\sqrt{x(1-x)} \leq 2\sqrt{x}$ for all $0 \leq x \leq 1$.*

► **Lemma 8** ([32, Lemma 10.2]). *Suppose that n is a positive integer and $k \in [0, 1]$ is a number such that kn is an integer. Then $\frac{2^{H(k)n}}{n+1} \leq \binom{n}{kn} \leq 2^{H(k)n}$.*

► **Lemma 9.** *For $b > a > 0$, the function $f(\lambda) = \lambda^a / (\lambda + 1)^b$ is monotonically increasing on $[0, \frac{a}{b-a}]$ and monotonically decreasing on $[\frac{a}{b-a}, +\infty)$.*

3 Counting independent sets for $\lambda \geq 1$

Throughout this section, we consider integers $\Delta \geq 53$, fugacity $\lambda \geq 1$ and set parameters ζ, α, β to be $\zeta = 1.28, \alpha = \frac{2.9}{\Delta}, \beta = \frac{\Delta}{2.9\zeta}$.

► **Lemma 10.** *For $\Delta \geq 53$, $\lim_{n \rightarrow \infty} \Pr_{G \sim \mathcal{G}_{n,\Delta}^{\text{bip}}} [G \in \mathcal{G}_{\alpha,\beta}^\Delta] = 1$.*

The reader can find the detailed proof of the lemma above in the full version of the paper.

In the rest of this section, whenever possible, we will simplify notations by omitting superscripts, subscripts and brackets with the symbols between (but this will not happen in the statement of lemmas and theorems). For example, $Z(G, \lambda)$ may be written as Z if G and λ are clear from context.

3.1 Approximating $Z(G, \lambda)$

For all $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha,\beta}^\Delta, \mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$ and $\lambda \geq 1$, let $\mathcal{I}_{\mathcal{X}}(G) = \{I \in \mathcal{I}(G) : |I \cap \mathcal{X}| < \alpha n\}$ and $Z_{\mathcal{X}}(G, \lambda) = \sum_{I \in \mathcal{I}_{\mathcal{X}}(G)} \lambda^{|I|}$. The main result in this part is that we can use $Z_{\mathcal{L}}(G, \lambda) + Z_{\mathcal{R}}(G, \lambda)$ to approximate $Z(G, \lambda)$.

► **Lemma 11.** *For $\Delta \geq 53$ and $\lambda \geq 1$, there are constants $C = C(\Delta) > 1$ and $N = N(\Delta)$ so that for all $G \in \mathcal{G}_{\alpha,\beta}^\Delta$ with $n > N$ vertices on both sides, $Z_{\mathcal{L}}(G, \lambda) + Z_{\mathcal{R}}(G, \lambda)$ is a C^{-n} -relative approximation to $Z(G, \lambda)$.*

Proof. Apply Lemma 12 and Lemma 13. ◀

► **Lemma 12.** *For $\Delta \geq 3$ and $\lambda \geq 1$, there are constants $C = C(\Delta) > 1$ and $N = N(\Delta)$ so that for all $G \in \mathcal{G}_{\alpha,\beta}^\Delta$ with $n > N$ vertices on both sides, $\sum_{I \in \mathcal{I}_{\mathcal{L}}(G) \cup \mathcal{I}_{\mathcal{R}}(G)} \lambda^{|I|}$ is a C^{-n} -relative approximation to $Z(G, \lambda)$.*

Proof. Let $\mathcal{B} = \mathcal{I} \setminus (\mathcal{I}_{\mathcal{L}} \cup \mathcal{I}_{\mathcal{R}})$. For any $I \in \mathcal{B}$, it follows from the definition of \mathcal{B} that $|I \cap \mathcal{L}| \geq \alpha n$ and $|I \cap \mathcal{R}| \geq \alpha n$. Using the expansion property, we obtain $|N(I \cap \mathcal{L})| \geq \beta \lfloor \alpha n \rfloor$ and thus $|I \cap \mathcal{R}| \leq n - |N(I \cap \mathcal{L})| \leq (1 - 1/t)n$ where $1/t = \beta \lfloor \alpha n \rfloor / n \geq \alpha\beta - \beta/n$. Analogously, it holds that $|I \cap \mathcal{L}| \leq (1 - 1/t)n$. In the following, we assume $n \geq N_1$ for some $N_1 = N_1(\Delta) > 0$, such that $1 - 1/t \leq 1 - \alpha\beta + \beta/n = 1 - 1/\zeta + \beta/n \leq 0.219$. We obtain an upper bound of $\sum_{I \in \mathcal{B}} \lambda^{|I|}$ as follows:

- (a) Consider an independent set $I \in \mathcal{B}$. Recall that $\alpha n \leq |I \cap \mathcal{L}| \leq (1 - 1/t)n$. We first enumerate a subset $U \subseteq \mathcal{L}$ with $\alpha n \leq |U| \leq (1 - 1/t)n$ and then enumerate all independent sets I with $I \cap \mathcal{L} = U$. Since $1 - 1/t < 1/2$, there are at most $n^{\binom{n}{\lfloor (1-1/t)n \rfloor}} \leq n2^{H(1-1/t)n}$ ways to enumerate such a set U , where the inequality follows from Lemma 8.
- (b) Now fix a set $U \subseteq \mathcal{L}$. Recall that every independent set $I \in \mathcal{B}$ satisfies $|I \cap \mathcal{R}| \leq (1 - 1/t)n$. Therefore $\sum_{I \in \mathcal{B}: |I \cap \mathcal{L}|=U} \lambda^{|I|} = \lambda^{|U|} \sum_{I \in \mathcal{B}: |I \cap \mathcal{L}|=U} \lambda^{|I \cap \mathcal{R}|} \leq \lambda^{(1-1/t)n} (\lambda + 1)^{(1-1/t)n}$.
- (c) Combining the first two steps we obtain $\sum_{I \in \mathcal{B}} \lambda^{|I|} \leq n2^{H(1-1/t)n} \lambda^{(1-1/t)n} (\lambda + 1)^{(1-1/t)n} = n2^{H(1-1/t)n} (\lambda^2 + \lambda)^{(1-1/t)n}$.

Using $\sum_{I \in \mathcal{I}_{\mathcal{L}} \cup \mathcal{I}_{\mathcal{R}}} \lambda^{|I|} \geq (\lambda + 1)^n$ and the upper bound above, we obtain

$$\frac{\sum_{I \in \mathcal{B}} \lambda^{|I|}}{\sum_{I \in \mathcal{I}_{\mathcal{L}} \cup \mathcal{I}_{\mathcal{R}}} \lambda^{|I|}} \leq \frac{n2^{H(1-1/t)n} (\lambda^2 + \lambda)^{(1-1/t)n}}{(\lambda + 1)^n} = n(f(\lambda))^n, \tag{1}$$

where $f(\lambda) = 2^{H(1-1/t)} \cdot \frac{\lambda^{1-1/t}}{(\lambda+1)^{1/t}}$. Since $1 - 1/t < 1/t$, it follows from Lemma 9 that $f(\lambda) \leq f(1) = 2^{H(1-1/t)-1/t} < 1$ for all $\lambda \geq 1$. So there exists some constant $C > 1$ such that Equation (1) $\leq n(f(1))^n < C^{-n}$ for all $n > N \geq N_1$ where $N = N(\Delta)$ is another sufficiently large constant. \blacktriangleleft

► Lemma 13. For $\Delta \geq 53$ and $\lambda \geq 1$, there are constants $C > 1$ and N so that for all $G \in \mathcal{G}_{\alpha, \beta}^\Delta$ with $n > N$ vertices on both sides, $Z_{\mathcal{L}}(G, \lambda) + Z_{\mathcal{R}}(G, \lambda)$ is a C^{-n} -relative approximation to $\sum_{I \in \mathcal{I}_{\mathcal{L}}(G) \cup \mathcal{I}_{\mathcal{R}}(G)} \lambda^{|I|}$.

Proof. For any $I \in \mathcal{I}_{\mathcal{L}} \cap \mathcal{I}_{\mathcal{R}}$, it holds that $|I \cap \mathcal{L}| < \alpha n$ and $|I \cap \mathcal{R}| < \alpha n$. Clearly $\sum_{I \in \mathcal{I}_{\mathcal{L}} \cup \mathcal{I}_{\mathcal{R}}} \lambda^{|I|} \geq (\lambda + 1)^n$. Therefore

$$\frac{\sum_{I \in \mathcal{I}_{\mathcal{L}} \cap \mathcal{I}_{\mathcal{R}}} \lambda^{|I|}}{\sum_{I \in \mathcal{I}_{\mathcal{L}} \cup \mathcal{I}_{\mathcal{R}}} \lambda^{|I|}} \leq (\lambda + 1)^{-n} \left(\sum_{k=0}^{\lfloor \alpha n \rfloor} \binom{n}{k} \lambda^k \right)^2 \leq n^2 \left(\frac{4^{H(\alpha)} \lambda^{2\alpha}}{\lambda + 1} \right)^n, \tag{2}$$

where the last inequality follows from Lemma 8. Recall that $\alpha = 2.9/\Delta$ and $\Delta \geq 53$. Then $\left. \frac{4^{H(\alpha)} \lambda^{2\alpha}}{\lambda + 1} \right|_{\lambda=1} \leq 0.76 < 1$. It follows from Lemma 9 that $4^{H(\alpha)} \lambda^{2\alpha}/(\lambda + 1)$ is monotonically decreasing in λ on $[1, \infty)$ for all fixed $\Delta \geq 53$. Thus Equation (2) $\leq (1/(0.76n^{2/n}))^{-n} < C^{-n}$ for some constant $C > 1$ and for all $n > N$ where N is a sufficiently large constant. \blacktriangleleft

3.2 Approximating $Z_{\mathcal{X}}(G, \lambda)$

In this subsection, we discuss how to approximate $Z_{\mathcal{X}}(G, \lambda)$ for any graph $G \in \mathcal{G}_{\alpha, \beta}^\Delta$, $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$ and $\lambda \geq 1$. We will use the polymer model (see Section 2.2). First we constructively define the polymers we need. For any $I \in \mathcal{I}_{\mathcal{X}}(G)$, we can partition the graph $(G^2)[I \cap \mathcal{X}]$ into connected components U_1, U_2, \dots, U_k for some $k \geq 0$ (trivially $k = 0$ if $I \cap \mathcal{X} = \emptyset$). There are no edges in G^2 between U_i and U_j for any $1 \leq i \neq j \leq k$. If $k > 0$, let $p(I) = \{(U_1, \mathbf{1}_{U_1}), (U_2, \mathbf{1}_{U_2}), \dots, (U_k, \mathbf{1}_{U_k})\}$ where $\mathbf{1}_{U_i}$ is the unique mapping from U_i to $\{1\}$. If $k = 0$, let $p(I) = \emptyset$. We define the set of all polymers to be $\Gamma_{\mathcal{X}}^*(G) = \bigcup_{I \in \mathcal{I}_{\mathcal{X}}(G)} p(I)$ and each element in this set is called a polymer. When the graph G and \mathcal{X} are clear from the context, we simply denote by Γ^* the set of polymers. Clearly, p is a mapping from $\mathcal{I}_{\mathcal{X}}(G)$ to the set $\{\Gamma \in \mathcal{S}(\Gamma_{\mathcal{X}}^*(G)) : |\overline{\Gamma}| < \alpha n\}$ since $|\overline{p(I)}| = |I \cap \mathcal{X}| < \alpha n$ for all $I \in \mathcal{I}_{\mathcal{X}}(G)$. For each polymer γ , define its weight function $w(\gamma, \cdot)$ as $w(\gamma, z) = \lambda^{|\overline{\gamma}|} (\lambda + 1)^{-|N(\overline{\gamma})|} |z^{|\overline{\gamma}|}|$, where z is a complex variable. The weight function can be computed in polynomial time in $|\overline{\gamma}|$. The partition function of the polymer model (Γ^*, w) on the graph G^2 is the following sum: $\Xi(z) = \sum_{\Gamma \in \mathcal{S}(\Gamma^*)} \prod_{\gamma \in \Gamma} w(\gamma, z)$. Recall that two polymers γ_1 and γ_2 are compatible if $d_{G^2}(\overline{\gamma}_1, \overline{\gamma}_2) > 1$ and this condition is equivalent to $d_G(\overline{\gamma}_1, \overline{\gamma}_2) > 2$.

► **Lemma 14.** For all bipartite graphs $G = (\mathcal{L}, \mathcal{R}, E)$ with n vertices on both sides, $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$ and $\lambda \geq 0$,

$$Z_{\mathcal{X}}(G, \lambda) = (\lambda + 1)^n \sum_{\Gamma \in \mathcal{S}(\Gamma_{\mathcal{X}}^*(G)): |\bar{\Gamma}| < \alpha n} \prod_{\gamma \in \Gamma} w(\gamma, 1).$$

Proof. In the definition of polymers, p is a mapping from $\mathcal{I}_{\mathcal{X}}$ to $\{\Gamma \in \mathcal{S}(\Gamma^*) : |\bar{\Gamma}| < \alpha n\}$. Thus $Z_{\mathcal{X}}(G, \lambda) = \sum_{I \in \mathcal{I}_{\mathcal{X}}} \lambda^{|I|} = \sum_{\Gamma \in \mathcal{S}(\Gamma^*): |\bar{\Gamma}| < \alpha n} \sum_{I \in \mathcal{I}_{\mathcal{X}}: p(I) = \Gamma} \lambda^{|I|}$. Fix $\Gamma \in \mathcal{S}(\Gamma^*)$ with $|\bar{\Gamma}| < \alpha n$. It holds that

$$\sum_{I \in \mathcal{I}_{\mathcal{X}}: p(I) = \Gamma} \lambda^{|I|} = \sum_{I \in \mathcal{I}_{\mathcal{X}}: I \cap \mathcal{X} = \bar{\Gamma}} \lambda^{|I|} = \lambda^{|\bar{\Gamma}|} (\lambda + 1)^{|\mathcal{L} \sqcup \mathcal{R} \setminus (\mathcal{X} \sqcup N_G(\bar{\Gamma}))|}, \quad (3)$$

where the last equality follows from $|\bar{\Gamma}| < \alpha n$. Since Γ is compatible, $N_G(\bar{\Gamma}) = \sqcup_{\gamma \in \Gamma} N_G(\bar{\gamma})$ and $|\mathcal{L} \sqcup \mathcal{R} \setminus (\mathcal{X} \sqcup N_G(\bar{\Gamma}))| = n - \sum_{\gamma \in \Gamma} |N_G(\bar{\gamma})|$. Thus Equation (3) = $\lambda^{\sum_{\gamma \in \Gamma} |\bar{\gamma}|} (\lambda + 1)^{n - \sum_{\gamma \in \Gamma} |N_G(\bar{\gamma})|} = (\lambda + 1)^n \prod_{\gamma \in \Gamma} w(\gamma, 1)$. ◀

► **Lemma 15.** For $\Delta \geq 53$ and $\lambda \geq 1$, there are constants $C > 1$ and N so that for all $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha, \beta}^{\Delta}$ with $n > N$ vertices on both sides and $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$,

$$(\lambda + 1)^n \Xi(1) = (\lambda + 1)^n \sum_{\Gamma \in \mathcal{S}(\Gamma_{\mathcal{X}}^*(G))} \prod_{\gamma \in \Gamma} w(\gamma, 1)$$

is a C^{-n} -relative approximation to $Z_{\mathcal{X}}(G, \lambda)$.

Proof. It is clear that $Z_{\mathcal{X}}(G, \lambda) \geq (\lambda + 1)^n$. Then using Lemma 14 and Lemma 16 we obtain

$$\rho = \frac{(\lambda + 1)^n \Xi(1) - Z_{\mathcal{X}}(G, \lambda)}{Z_{\mathcal{X}}(G, \lambda)} \leq \sum_{\Gamma \in \mathcal{S}(\Gamma^*): |\bar{\Gamma}| \geq \alpha n} \prod_{\gamma \in \Gamma} w(\gamma, 1) \leq \sum_{\Gamma \in \mathcal{S}(\Gamma^*): |\bar{\Gamma}| \geq \alpha n} 2^{-\beta |\bar{\Gamma}|}. \quad (4)$$

To enumerate each $\Gamma \in \mathcal{S}(\Gamma^*)$ with $|\bar{\Gamma}| \geq \alpha n$ at least once, we first enumerate an integer $\alpha n \leq k \leq n$, then since $\bar{\Gamma} \subseteq \mathcal{X}$, we choose k vertices from \mathcal{X} . Therefore, from Equation (4) we have

$$\rho \leq \sum_{k=\lceil \alpha n \rceil}^n \binom{n}{k} 2^{-\beta k} \leq \sum_{k=\lceil \alpha n \rceil}^n 2^{H(k/n)n} 2^{-\beta k} \leq \sum_{k=\lceil \alpha n \rceil}^n \left(2^{2\sqrt{n/k} - \beta}\right)^k \leq \sum_{k=\lceil \alpha n \rceil}^n \left(2^{2\sqrt{1/\alpha} - \beta}\right)^k,$$

where the inequalities follow from Lemma 8 and Lemma 7. Recall that $\zeta = 1.28$, $\alpha = 2.9/\Delta$, $\beta = \Delta/(2.9\zeta)$ and $\Delta \geq 53$. Let $f(\Delta) = 2\sqrt{1/\alpha} - \beta = 2\sqrt{\Delta/2.9} - \Delta/(2.9\zeta)$. We

obtain $\rho \leq \frac{2^{f(\Delta)\alpha n}}{1 - 2^{f(\Delta)}} = \frac{\left(2^{2\sqrt{2.9/\Delta} - 1/\zeta}\right)^n}{1 - 2^{f(\Delta)}}$. Since $f(\Delta)$ is monotonically decreasing in Δ on $[53, +\infty)$, $\rho \leq \frac{\left(2^{2\sqrt{2.9/53} - 1/1.28}\right)^n}{1 - 2^{2\sqrt{53/2.9} - 53/(2.9 \times 1.28)}} \leq 0.81^n / 0.98 < C^{-n}$ for some constant $C > 1$ and for all $n > N$ where N is a sufficiently large constant. ◀

► **Lemma 16.** For all polymers $\gamma \in \Gamma^*$ defined by $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha, \beta}^{\Delta}$, $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$ and $\lambda \geq 1$, $|w(\gamma, z)| \leq (2^{-\beta}|z|)^{|\bar{\gamma}|}$. As a corollary, $w(\gamma, 1) \leq 2^{-\beta|\bar{\gamma}|}$ and for all compatible $\Gamma \subseteq \Gamma^*(G)$, $\prod_{\gamma \in \Gamma} w(\gamma, 1) \leq 2^{-\beta|\bar{\Gamma}|}$.

Proof. Let $n = |\mathcal{L}| = |\mathcal{R}|$ and let γ be any polymer. It follows from the definition of polymers that $|\bar{\gamma}| \leq \alpha n$ and by the expansion property, $|N(\bar{\gamma})| \geq \beta|\bar{\gamma}|$. Thus we have $|w(\gamma, z)| = \lambda^{|\bar{\gamma}|} (\lambda + 1)^{-|N(\bar{\gamma})|} |z|^{|\bar{\gamma}|} \leq (\lambda(\lambda + 1)^{-\beta})^{|\bar{\gamma}|} |z|^{|\bar{\gamma}|} \leq (2^{-\beta}|z|)^{|\bar{\gamma}|}$ where the last inequality follows from Lemma 9 since $\beta > 1$ and $\lambda \geq 1$. In particular, $w(\gamma, 1) \leq 2^{-\beta|\bar{\gamma}|}$. For any compatible Γ , it holds that $|\bar{\Gamma}| = \sum_{\gamma \in \Gamma} |\bar{\gamma}|$. Thus $\prod_{\gamma \in \Gamma} w(\gamma, 1) \leq \prod_{\gamma \in \Gamma} 2^{-\beta|\bar{\gamma}|} = 2^{-\beta|\bar{\Gamma}|}$. ◀

3.3 Approximating the partition function of the polymer model

► **Lemma 17.** *For $\Delta \geq 53$ and $\lambda \geq 1$, there is an FPTAS for $\Xi(1)$ for all $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha, \beta}^{\Delta}$ and $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$.*

Proof. Apply the FPTAS in Theorem 4. ◀

To apply Theorem 4, we need to show that for the parameters in Lemma 17, the partition function has no zeros in the entire unit disk centered at 0.

► **Lemma 18.** *There is a constant $R > 1$ so that for $\Delta \geq 53$ and $\lambda \geq 1$, $\Xi(z) \neq 0$ for all $G \in \mathcal{G}_{\alpha, \beta}^{\Delta}$, $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$ and $z \in \mathbb{C}$ with $|z| < R$.*

Proof. Set $R = 1.001$. For any $\gamma \in \Gamma^*$, let $a(\gamma) = t|\bar{\gamma}|$ where $t = (-1 + \sqrt{1 + 8e}) / (4e) \approx 0.346$. We will verify that the KP-condition $\sum_{\gamma: \gamma \not\sim \gamma^*} e^{t|\bar{\gamma}|} |w(\gamma, z)| \leq t|\bar{\gamma}^*|$ holds for any $\gamma^* \in \Gamma^*$ and any $|z| < R$. It then follows from Lemma 5 that $\Xi(z) \neq 0$ for any $|z| < R$. Recall that $d_{G^2}(\bar{\gamma}, \bar{\gamma}^*) \leq 1$ for all $\gamma \not\sim \gamma^*$. Thus there is always a vertex $v \in \bar{\gamma} \subseteq \mathcal{X}$ such that $v \in \bar{\gamma}^* \sqcup N_{G^2}(\bar{\gamma}^*)$. The number of such vertices v is at most $\Delta^2|\bar{\gamma}^*|$. So to enumerate each $\gamma \not\sim \gamma^*$ at least once, we can: a) first enumerate a vertex v in $\mathcal{X} \cap (\bar{\gamma}^* \cup N_{G^2}(\bar{\gamma}^*))$; b) then enumerate an integer k from 1 to $\lfloor \alpha n \rfloor$; c) finally enumerate γ with $v \in \bar{\gamma}$ and $|\bar{\gamma}| = k$. Since $\bar{\gamma}$ is connected in G^2 , applying Lemma 6 and using Lemma 16 to bound $|w(\gamma, z)|$ we obtain $\sum_{\gamma: \gamma \not\sim \gamma^*} e^{t|\bar{\gamma}|} |w(\gamma, z)| \leq \Delta^2|\bar{\gamma}^*| \left(e^{t2^{-\beta}}|z| + \sum_{k=2}^{\lfloor \alpha n \rfloor} (e\Delta^2)^{k-1} 2^{-1} e^{tk} 2^{-\beta k} |z|^k \right)$. Let $x = e^{t+1} \Delta^2 2^{-\beta} R$. Since $|z| < R$, we obtain $\sum_{\gamma: \gamma \not\sim \gamma^*} e^{t|\bar{\gamma}|} |w(\gamma, z)| \leq \frac{x}{e} |\bar{\gamma}^*| \left(1 + \frac{1}{2} \sum_{k=2}^{\infty} x^{k-1} \right) = \frac{x(2-x)}{2e(1-x)} \cdot |\bar{\gamma}^*|$. Recall that $\zeta = 1.28$, $\beta = \Delta / (2.9\zeta)$ and $\Delta \geq 53$. Since $\Delta^2 2^{-\beta}$ is monotonically decreasing in Δ on $[53, +\infty)$, it holds that $x = e^{t+1} \Delta^2 2^{-\beta} R \leq (e^{t+1} \Delta^2 2^{-\beta} R) \big|_{\Delta=53} \leq 0.545$, and hence $\frac{x(2-x)}{2e(1-x)} < 0.33 < t$. ◀

3.4 Putting things together

Using the results from previous parts, we obtain our main result for counting independent sets.

► **Theorem 1.** *For $\Delta \geq 53$ and fugacity $\lambda \geq 1$, with high probability (tending to 1 as $n \rightarrow \infty$) for a graph G chosen uniformly at random from $\mathcal{G}_{n, \Delta}^{\text{bip}}$, there is an FPTAS for the partition function $Z(G, \lambda)$.*

Proof. This theorem follows from Lemma 10 and Lemma 19. ◀

► **Lemma 19.** *For $\Delta \geq 53$ and $\lambda \geq 1$, there is an FPTAS for $Z(G, \lambda)$ for all $G \in \mathcal{G}_{\alpha, \beta}^{\Delta}$.*

Proof. First we state our algorithm. See Algorithm 1 for a pseudocode description. The input is a graph $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha, \beta}^{\Delta}$ and an approximation parameter $\varepsilon > 0$. The output is a number \widehat{Z} to approximate $Z(G, \lambda)$. We use $\Xi_{\mathcal{X}}(z)$ to denote the partition function of the polymer model $(\Gamma_{\mathcal{X}}^*(G), w)$ for $\mathcal{X} \in \{\mathcal{L}, \mathcal{R}\}$. Let N_1, C_2, N_2, C_2 be the constants in Lemma 11 and Lemma 15, respectively. These two lemmas show that $(\lambda + 1)^n (\Xi_{\mathcal{L}}(1) + \Xi_{\mathcal{R}}(1))$ is a $C_1^{-n} + C_2^{-n} \leq 2 \min(C_1, C_2)^{-n} \leq C^{-n}$ -relative approximation to $Z(G, \lambda)$ for another constant $C > 1$ and all $n > N \geq \max(N_1, N_2)$ where N is another sufficiently large constant. If $n \leq N$ or $\varepsilon \leq 2C^{-n}$, we use the brute-force algorithm to compute $Z(G, \lambda)$. If $\varepsilon > 2C^{-n}$, we apply the FPTAS in Lemma 17 with approximation parameter $\varepsilon' = \varepsilon - C^{-n}$ to obtain outputs $\widehat{Z}_{\mathcal{L}}$ and $\widehat{Z}_{\mathcal{R}}$ which approximate $\Xi_{\mathcal{L}}(1)$ and $\Xi_{\mathcal{R}}(1)$, respectively. Let $\widehat{Z} = (\lambda + 1)^n (\widehat{Z}_{\mathcal{L}} + \widehat{Z}_{\mathcal{R}})$ be the output. It is clear that $\exp(-\varepsilon)\widehat{Z} \leq Z(G, \lambda) \leq \exp(\varepsilon)\widehat{Z}$.

■ **Algorithm 1** Counting independent sets at fugacity $\lambda \geq 1$ for $\Delta \geq 53$.

-
- 1: **Input:** A graph $G = (\mathcal{L}, \mathcal{R}, E) \in \mathcal{G}_{\alpha, \beta}^{\Delta}$ with n vertices on both sides and $\varepsilon > 0$
 - 2: **Output:** \widehat{Z} such that $\exp(-\varepsilon)\widehat{Z} \leq Z(G, \lambda) \leq \exp(\varepsilon)\widehat{Z}$
 - 3: **if** $n \leq N$ or $\varepsilon \leq 2C^{-n}$ **then**
 - 4: Use the brute-force algorithm to compute $\widehat{Z} \leftarrow Z(G, \lambda)$;
 - 5: Exit;
 - 6: **end if**
 - 7: $\varepsilon' \leftarrow \varepsilon - C^{-n}$;
 - 8: Use the FPTAS in Lemma 17 to obtain $\widehat{Z}_{\mathcal{L}}$, an ε' -relative approximation to the partition function $\Xi(z)$ at $z = 1$ of the polymer model $(\Gamma_{\mathcal{L}}^*(G), w)$.
 - 9: Use the FPTAS in Lemma 17 to obtain $\widehat{Z}_{\mathcal{R}}$, an ε' -relative approximation to the partition function $\Xi(z)$ at $z = 1$ of the polymer model $(\Gamma_{\mathcal{R}}^*(G), w)$.
 - 10: $\widehat{Z} \leftarrow (\lambda + 1)^n (\widehat{Z}_{\mathcal{L}} + \widehat{Z}_{\mathcal{R}})$;
-

Then we show that Algorithm 1 is indeed an FPTAS. It is required that the running time of our algorithm is bounded by $(n/\varepsilon)^{C_3}$ for some constant C_3 and for all $n > N_3$ where N_3 is a constant. Let $N_3 = N$. If $\varepsilon \leq 2C^{-n}$, the running time of the algorithm would be $2.1^n \leq (nC^n/2)^{C_3} \leq (n/\varepsilon)^{C_3}$ for sufficient large C_3 . If $\varepsilon > 2C^{-n}$, the running time of the algorithm would be $(n/\varepsilon')^{C_4} = (n/(\varepsilon - C^{-n}))^{C_4} \leq (2n/\varepsilon)^{C_4} \leq (n/\varepsilon)^{C_3}$ for sufficient large C_3 , where C_4 is a constant from the FPTAS in Lemma 17. ◀

Abstract

The *Maximal* points in a set S are those that are not *dominated* by any other point in S . Such points arise in multiple application settings and are called by a variety of different names, e.g., maxima, Pareto optimums, skylines. Their ubiquity has inspired a large literature on the *expected* number of maxima in a set S of n points chosen IID from some distribution. Most such results assume that the underlying distribution is uniform over some spatial region and strongly use this uniformity in their analysis.

This research was initially motivated by the question of how this expected number changes if the input distribution is perturbed by random noise. More specifically, let \mathbf{B}_p denote the uniform distribution from the 2-dimensional unit ball in the metric L_p . Let $\delta\mathbf{B}_q$ denote the 2-dimensional L_q -ball, of radius δ and $\mathbf{B}_p + \delta\mathbf{B}_q$ be the convolution of the two distributions, i.e., a point $v \in \mathbf{B}_p$ is reported with an error chosen from $\delta\mathbf{B}_q$. The question is how the expected number of maxima change as a function of δ . Although the original motivation is for small δ , the problem is well defined for any δ and our analysis treats the general case.

More specifically, we study, as a function of n, δ , the expected number of maximal points when the n points in S are chosen IID from distributions of the type $\mathbf{B}_p + \delta\mathbf{B}_q$ where $p, q \in \{1, 2, \infty\}$ for $\delta > 0$ and also of the type $\mathbf{B}_\infty + \delta\mathbf{B}_q$ where $q \in [1, \infty)$ for $\delta > 0$.

For fixed p, q we show that this function changes “smoothly” as a function of δ but that this smooth behavior sometimes transitions unexpectedly between different growth behaviors.

1 Introduction

Let S be a set of 2-dimensional points. The “largest” points in S are the *maximal points* of S and are a well-studied object. More formally

► **Definition 1.** For $u \in \mathbb{R}^2$ let $u.x$ ($u.y$) denote the x (y) coordinate of u . For $u, v \in \mathbb{R}^2$, u is dominated by v if $u \neq v$, $u.x \leq v.x$ and $u.y \leq v.y$. If $S \subset \mathbb{R}^2$ then

$$\text{MAX}(S) = \{u \in S : u \text{ is not dominated by any point in } S \setminus \{u\}\}.$$

$\text{MAX}(S)$ are the maximal points of S . See Fig. 1.

■ **Figure 1** The diagram shows $\text{MAX}(S_n)$ for two point sets S_n . In both (a) and (b) the circles denote the points in S_n and the (red) filled circles are $\text{MAX}(S_n)$. If the points are considered as being drawn from region D , $P(v)$, as introduced in Def. 2, denotes the region in D that dominates v . In (a), D is the dotted square; in (b), D is the dotted circle.

The problems of finding and estimating the number of maximal points of a set in \mathbb{R}^2 appear very often in many fields under different names: *maximal vectors*, *skylines*, *Pareto frontier/points* and others, see e.g. [5, 12, 15, 17, 18] for a more exhaustive history of the problems, uses in Computer Science and further references, Sections 1 and 2 in [7].

Let S_n denote a set of n points chosen Independently Identically Distributed (IID) from some 2-D distribution \mathbf{D} and $M_n = |\text{MAX}(S_n)|$ be the random variable counting the number of maximal points in S_n . Because maxima are so ubiquitous, understanding the expected number of maxima has been important in different areas and many properties of M_n have been studied. More specifically, if \mathbf{D} is the uniform distribution drawn from an L_p ball with $p \geq 1$, then it is well known [2, 6, 12, 14], that

- If $p = \infty$, then $\mathbf{E}[M_n] = H_n \sim \ln n$.
 The same result holds if the points are drawn from some distribution $\mathbf{D} = (\mathbf{X}, \mathbf{Y})$ where \mathbf{X} and \mathbf{Y} are any two 1-dimensional distributions that are independent of each other.
- If $p \geq 1$, then $\lim_{n \rightarrow \infty} \frac{\mathbf{E}[M_n]}{\sqrt{n}} = C_p$, where C_p is a constant dependent only upon p .
- Similar upper bounds to the above, i.e., that $\mathbf{E}[M_n] = O(\sqrt{n})$, derived using similar techniques, are known if \mathbf{D} is a *uniform* distribution from ANY convex region [11].

It is also known [16] that if the n points are chosen IID from a 2-D Gaussian distribution then $\mathbf{E}[M_n] \sim \ln n$. There are also generalizations of these results (both the \mathbf{B}_p ones and the Gaussian one) to higher dimensions. See [14] for a table containing most known results.

Surprisingly, given the importance of the problem, not much is known for other distributions. The motivation for this work is to extend the family of distributions for which $\mathbf{E}[M_n]$ can be derived.

Consider a point u originally generated from a uniform distribution over a unit L_p ball but measured or reported with an error, in the L_q metric, of at most δ . The actual reported point can be equivalently considered as being chosen from a new distribution which we denote by $\mathbf{B}_p + \delta\mathbf{B}_q$ (the next section provides formal definitions). The support of this distribution is the Minkowski sum of the two balls but the distribution is not uniform over this support. Fig. 2 shows the support of $\mathbf{B}_p + \delta\mathbf{B}_q$, for different values of p and q .

Although the problem described above originally assumed small δ , it is well defined for all $\delta > 0$, which is the problem analyzed in this paper. More specifically, the motivation for the present work is twofold:

- Explain how $\mathbf{E}[M_n]$ changes when the distribution is perturbed.
(Note: the perturbation size δ may be specified as a function of the sample size n .)
- Increase the families of distributions for which $\mathbf{E}[M_n]$ is understood.

The idea of analyzing how quantities change under perturbations could also be considered from the perspective of *smoothed analysis* [20, 21]. In the classic setting, smoothed analysis of the number of maxima would mean analyzing how, given a *fixed* set S_n , $\mathbf{E}[M_n]$ would change under small perturbations (as a function of the original set S_n). This was the approach in [9, 8] (see similar work for convex hulls in [10]). This paper differs in that it is the *Distribution* that is being smoothed (or convoluted) and not the point set. This paper also differs from recent work [22, 1] on the *most-likely* skyline and convex hull problems. Those papers assume each point has a given probability distribution and are attempting to find the subset of points that has the highest probability of being the skyline (or convex hull).

Outline of the paper. The next section defines the problem and states and explains our results. Sec. 3 describes key technical and conceptual ideas and tools used to achieve the main result. Sec. 4 describes how these tools are used to derive the result. Sec. 5 provides a review and a collection of open problems and possible extensions.

Due to space limitations, the proofs of many of the lemmas and theorems are not included. For the full proofs, please see the extended version of this paper [13] posted on Arxiv.

2 Definitions and Results

Let “ $p \in [1, \infty)$ ” and “ $p \geq 1$ ” both denote that p is a finite real number ≥ 1 . $p = \infty$ also being permitted will be denoted by $p \in [1, \infty]$.

Recall: Let $\delta \geq 0$.

For $u \in \mathbb{R}^2$, $\delta u = (\delta \cdot u.x, \delta \cdot u.y)$. For $u, v \in \mathbb{R}^2$, $u + v = (u.x + v.x, u.y + v.y)$.

If $D \subseteq \mathbb{R}^2$, $\delta D = \{\delta u : u \in D\}$.

For $D_1, D_2 \subseteq \mathbb{R}^2$, $D_1 + D_2 = \{u_1 + u_2 : u_1 \in D_1, u_2 \in D_2\}$ will denote the *Minkowski sum* of D_1 and D_2 .

For $u \in \mathbb{R}^2$, $u + D$ will denote $\{u\} + D$.

Balls and Unit Balls: Let $u \in \mathbb{R}^2$, $r > 0$ and $p \in [1, \infty)$. Define:

- The L_p ball of radius r around u as $B_p(u, r) = \{(x, y) : |x - u.x|^p + |y - u.y|^p \leq r^p\}$.
- The L_∞ ball of radius r around u as $B_\infty(u, r) = \{(x, y) : \max(|x - u.x|, |y - u.y|) \leq r\}$.
- The respective *unit balls* as $B_p = B_p((0, 0), 1)$ and $B_\infty = B_\infty((0, 0), 1)$.

Set $a_p = \text{Area}(B_p)$ to be the area of the L_p unit ball. Then $a_\infty = 4, a_1 = 2, a_2 = \pi$. We use the fact that $a_p = \Theta(1)$.

Generation of a probability distribution: Let \mathbf{D} be a distribution with support $D \subset \mathbb{R}^2$. Then

- If $\delta \geq 0$, the distribution $\delta \mathbf{D}$ is generated by choosing a point u using \mathbf{D} and then returning the point δu .
- Let $\mathbf{D}_1, \mathbf{D}_2$ be two distributions over \mathbb{R}^2 . Generate the *convolution* $\mathbf{D}_1 + \mathbf{D}_2$ by choosing a point u_1 from \mathbf{D}_1 and a point u_2 from \mathbf{D}_2 and returning $u_1 + u_2$.
- A set $S_n = \{u_1, \dots, u_n\}$ is said to be *chosen from \mathbf{D}* if each u_i is generated *independently and identically distributed* (IID) using the distribution \mathbf{D} .

35:4 Maximal Points of the Convolution of Two 2-D Distributions

Uniform distribution on unit balls: For all $p \in [1, \infty]$, \mathbf{B}_p will denote the uniform distribution that selects a point uniformly from B_p . This distribution has support B_p with uniform density $1/a_p$ within B_p .

Convolution of two distributions: Let $\mathbf{B}_p + \delta\mathbf{B}_q$ be the convolution of distributions \mathbf{B}_p and $\delta\mathbf{B}_q$.

$(\mathbf{B}_p + \delta\mathbf{B}_q)$'s support of this distribution is the Minkowski sum $B_p + \delta B_q$. Observe that the density of $\mathbf{B}_p + \delta\mathbf{B}_q$ is **not** uniform in $B_p + \delta B_q$. It is this non-uniformity that will cause complications in calculating $\mathbf{E}[M_n]$. The main result of this paper is

► **Theorem 1.** Fix p, q so that either $p, q \in \{1, 2, \infty\}$ or $p = \infty$ and $q \geq 1$.

Let S_n be n points chosen from the distribution $\mathbf{B}_p + \delta\mathbf{B}_q$ and $M_n = |\text{MAX}(S_n)|$.

Let $\delta \geq 0$ be a function of n . Then $\mathbf{E}[M_n]$ behaves as below:

	(a)	(b)	(c)	(d)	(e)	(f)
	$\mathbf{D} =$	$0 \leq \delta$				$\delta = 1$
(i)	$\mathbf{B}_\infty + \delta\mathbf{B}_\infty$	$\Theta(\ln n)$				$\Theta(\ln n)$
		$\delta \leq \frac{1}{\sqrt{n}}$	$\frac{1}{\sqrt{n}} \leq \delta \leq 1$	$1 \leq \delta \leq \sqrt{n}$	$\sqrt{n} \leq \delta$	
(ii)	$\mathbf{B}_1 + \delta\mathbf{B}_1$	$\Theta(\sqrt{n})$	$\Theta\left(\frac{n^{1/3}}{\delta^{1/3}}\right)$	$\Theta(\delta^{1/3}n^{1/3})$	$\Theta(\sqrt{n})$	$\Theta(n^{1/3})$
(iii)	$\mathbf{B}_2 + \delta\mathbf{B}_2$	$\Theta(\sqrt{n})$	$\Theta\left(\frac{n^{2/7}}{\delta^{3/7}}\right)$	$\Theta(\delta^{3/7}n^{2/7})$	$\Theta(\sqrt{n})$	$\Theta(n^{2/7})$
		$\delta \leq \frac{1}{\sqrt{n}}$	$\frac{1}{\sqrt{n}} \leq \delta \leq \sqrt{n}$		$\sqrt{n} \leq \delta$	
(iv)	$\mathbf{B}_\infty + \delta\mathbf{B}_q$	$\Theta(\ln n)$	$\Theta(\ln n + \sqrt{\delta}n^{1/4})$		$\Theta(\sqrt{n})$	$\Theta(n^{1/4})$
		$\delta \leq \frac{1}{\sqrt{n}}$	$\frac{1}{\sqrt{n}} \leq \delta \leq n^{1/26}$	$n^{1/26} \leq \delta \leq \sqrt{n}$	$\sqrt{n} \leq \delta$	
(v)	$\mathbf{B}_1 + \delta\mathbf{B}_2$	$\Theta(\sqrt{n})$	$\Theta\left(\frac{n^{2/7}}{\delta^{3/7}}\right)$	$\Theta(\sqrt{\delta}n^{1/4})$	$\Theta(\sqrt{n})$	$\Theta(n^{2/7})$

Interpretation of the table:

- When $p = q = \infty$, M_n has exactly the same distribution as if S_n were chosen from \mathbf{B}_∞ , so row (i) is an uninteresting case, only included for completeness.
- When δ is small enough ($\leq 1/\sqrt{n}$), $\mathbf{E}[M_n]$ behaves almost as if S_n were chosen from \mathbf{B}_p and when δ is large enough ($\geq \sqrt{n}$) $\mathbf{E}[M_n]$ behaves almost as if S_n were chosen from \mathbf{B}_q . This is reflected in columns (b) and (e).
- Lemma 8 states that M_n has the same distribution for S_n chosen from both $\mathbf{B}_p + \delta\mathbf{B}_q$ and $\mathbf{B}_q + \frac{1}{\delta}\mathbf{B}_p$. Thus row (iv) gives the behavior for $\mathbf{B}_q + \delta\mathbf{B}_\infty$ for any $q \geq 1$ and row (v) the behavior for $\mathbf{B}_2 + \delta\mathbf{B}_1$.
- When $p = q \in \{1, 2\}$, $\mathbf{E}[M_n]$ starts at $\Theta(\sqrt{n})$, smoothly decreases until reaching $\delta = 1$ and then increases again until reaching $\Theta(\sqrt{n})$. The behavior at $\delta = 1$ is different for $p = q = 1$ and $p = q = 2$. In both cases there is symmetry between δ and $1/\delta$ (from Lemma 8).
- When $p = 1, q = 2$ there is no symmetry. The behavior starts at $\Theta(\sqrt{n})$, decreases to $\Theta(n^{7/26})$ at $\delta = n^{1/26}$ and then increases again at a different rate to $\Theta(\sqrt{n})$.
- When $p = \infty$, the behavior is asymptotically equivalent for all $q \in [1, \infty)$, not just $q = 1, 2$. The only difference is in the value of the constant hidden by the Θ . The behavior starts at $\Theta(\ln n)$, stays there for a short while and then smoothly increases to $\Theta(\sqrt{n})$.

■ **Figure 2** Illustrations of the supports of some of the different distributions in the form $\mathbf{B}_p + \delta \mathbf{B}_q$ examined in Theorem 1. The dotted lines denote the B_p and δB_q balls centred at 0. Note that in all cases the density is uniform near the centre of the support but then decreases to 0 as the boundary is approached. The grey areas denote, approximately, where the maxima of S_n are concentrated.

■ **Figure 3** Illustration of definitions of $P(v)$ and $P'(v)$ for $B_p + \delta B_q$. Left side is $B_\infty + \delta B_2$; right is $B_1 + \delta B_1$. In both diagrams the interior ball (heavy boundary) is the B_p ball centered at the origin a . $P(v)$ is the set of points in $B_p + \delta B_q$ that dominate v and $P'(v)$ is the preimage of v in B_p .

3 Basic Lemmas

The following collection of Lemmas comprise the basic toolkit used to derive Theorem 1.

Recall: Let \mathbf{D} be a distribution over \mathfrak{R}^2 , $x \in \mathfrak{R}^2$ and $A \subset \mathfrak{R}^2$ a measurable region. Then $f_{\mathbf{D}}(x)$ will denote the *density function* of \mathbf{D} , and $\mu_{\mathbf{D}}(A) = \int_A f_{\mathbf{D}}(x) dx$ will denote the *measure* of A under distribution \mathbf{D} . If \mathbf{D} is understood, we often simply write $f(x)$ and $\mu(A)$.

▶ **Definition 2.** (See Fig. 3)

Let $D \subseteq \mathfrak{R}^2$, $v \in D$ and $A \subseteq D$.

Define: $P(v) = \{u \in D : u \text{ dominates } v\} \cup \{v\}$, and $P(A) = \bigcup_{v \in A} P(v)$.

Say that A is dominant in D or a dominant region in D , if $P(A) = A$.

Note that, by definition, $\forall v \in D$, $P(v)$ is a dominant region in D . It is straightforward to see that

▶ **Lemma 1.** Let v and S_n be chosen from \mathbf{D} and $A \subseteq D$. Then

- (a) $\Pr(v \in A) = \mu(A)$.
- (b) $\mathbf{E}[|A \cap S_n|] = n\mu(A)$.
- (c) $\Pr(A \cap S_n = \emptyset) = (1 - \mu(A))^n$.

The following observation will be used to prove most of our lower bounds.

▶ **Lemma 2 (Lower Bound).** Let S_n be chosen from \mathbf{D} . Further let A_1, A_2, \dots, A_m be a collection of pairwise disjoint dominant regions in D with $\mu(A_i) = \Omega(1/n)$ for all i . Then

$$\mathbf{E}[M_n] \geq \mathbf{E} \left[\left| \text{MAX} \left(S_n \cap \bigcup_{i=1}^m A_i \right) \right| \right] = \Omega(m).$$

Proof. From Lemma 1, $\Pr(S_n \cap A_i = \emptyset) = (1 - \mu(A_i))^n$. Thus $\mu(A_i) = \Omega(1/n)$ implies

$$\Pr(S_n \cap A_i \neq \emptyset) = 1 - \Pr(S_n \cap A_i = \emptyset) = \Omega(1).$$

If region A is dominant then points in A can only be dominated by other points in A then $A \cap \text{MAX}(S_n) = \text{MAX}(S_n \cap A)$. Since each A_i is dominant, this implies

$$\mathbf{E} [|\text{MAX}(S_n) \cap A_i|] \geq \Pr(S_n \cap A_i \neq \emptyset) = \Omega(1).$$

Since the A_i are pairwise disjoint,

$$\mathbf{E} [|\text{MAX}(S_n)|] \geq \mathbf{E} \left[\left| \text{MAX}(S_n) \cap \left(\bigcup_i A_i \right) \right| \right] \geq \sum_{i=1}^m \Omega(1) = \Omega(m). \quad \blacktriangleleft$$

► **Definition 3.** (See Fig. 3)

Let $D = B_p + \delta B_q$. For $v \in D$ define the preimage of v in B_p as

$$P'(v) = B_q(v, \delta) \cap B_p = (v + \delta B_q) \cap B_p.$$

► **Lemma 3.** Fix $p, q \in [1, \infty]$. Let $\mathbf{D} = \mathbf{B}_p + \delta \mathbf{B}_q$ and let v be a point chosen from \mathbf{D} . Let $A \subseteq \mathfrak{R}^2$. Then

$$f(v) = \frac{1}{a_p a_q} \frac{\text{Area}(\{u \in B_p : v - u \in \delta B_q\})}{\delta^2} = \frac{1}{a_p a_q} \frac{\text{Area}(P'v)}{\delta^2} \quad (1)$$

$$\mu(A) = \frac{1}{a_p a_q} \int_{u \in B_p} \frac{\text{Area}((u + \delta B_q) \cap A)}{\delta^2} du. \quad (2)$$

Proof. Note that for $u \in B_p$, $f_{\mathbf{B}_p}(u) = \frac{1}{a_p}$ and for $u' \in \delta B_q$, $f_{\delta \mathbf{B}_q}(u') = \frac{1}{a_q \delta^2}$. To see Eq. 2,

$$\mu(A) = \int_{u \in B_p} \left(\int_{\substack{w \in \delta B_q \\ u+w \in A}} f_{\delta \mathbf{B}_q}(w) dw \right) f_{\mathbf{B}_p}(u) du = \frac{1}{a_p a_q} \int_{u \in B_p} \frac{\text{Area}((u + \delta B_q) \cap A)}{\delta^2} du.$$

For Eq. 1, use a change of variables $v = u + w$,

$$\begin{aligned} \mu(A) &= \frac{1}{a_p a_q \delta^2} \int_{u \in B_p} \left(\int_{\substack{w \in \delta B_q \\ u+w \in A}} dw \right) du \\ &= \frac{1}{a_p a_q \delta^2} \int_{u \in B_p} \left(\int_{\substack{v \in u + \delta B_q \\ v \in A}} dv \right) du = \frac{1}{a_p a_q} \int_{v \in A} \frac{\text{Area}\{u \in B_p : v - u \in \delta B_q\}}{\delta^2} dv. \end{aligned}$$

Differentiating around v yields Eq. 1. ◀

► **Lemma 4.** Fix $p, q \in [1, \infty]$. Let $\mathbf{D} = \mathbf{B}_p + \delta \mathbf{B}_q$ and $\kappa > 0$ be any constant. Then

- (a) $v \in D \quad \Rightarrow \quad f(v) = O(1).$
- (b) $v \in B_p \text{ and } \delta \leq \kappa \quad \Rightarrow \quad f(v) = \Theta(1).$
- (c) $A \subseteq D \quad \Rightarrow \quad \mu(A) = O(\text{Area}(A)).$
- (d) $A \subseteq B_p \text{ and } \delta \leq \kappa \quad \Rightarrow \quad \mu(A) = \Theta(\text{Area}(A)).$

The constants implicit in the $O()$ in (a) and (c) are only dependent upon p, q , while the constants implicit in the $\Theta()$ in (b) and (d) are only dependent upon p, q, κ .

Proof.

(a) Use the fact that, for $\forall u \in B_p$,

$$\text{Area}(B_p \cap (u + \delta B_q)) \leq \text{Area}(u + \delta B_q) = a_q \delta^2,$$

so from Eq. 1, $f(v) = O(1)$.

Distribution is $\mathbf{D} = \mathbf{B}_\infty + \delta\mathbf{B}_2$.

A is D above the x -axis.

B is D below the x -axis.

$$A(t) = \{u \in A : u.x \geq 1 + \delta - t\}$$

$$B(t) = \{u \in B : u.x \geq 1 + \delta - t\}$$

$\forall t$, $A(t)$ and $B(t)$ have the same measure.

$$S_n \cap B(t') = \{u, w\}.$$

$$X(t') = |S_n \cap B(t')| = 2$$

Any point in $A(t)$ dominates all points in $B \setminus B(t)$.

$$\Rightarrow \text{MAX}(S_n) \cap B \subseteq (S_n \cap B(t'))$$

$$= X(t')$$

$$\Rightarrow |\text{MAX}(S_n) \cap B| \leq 2$$

■ **Figure 4** Illustration of Lemmas 5 and 6. The regions A and B are each swept by parameter t and it is required that $\mu(B(t)) = O(\mu(A(t)))$. In the case above, by the symmetry of distribution \mathbf{D} , $\mu(B(t)) = \mu(A(t))$ trivially. t' is the first time a point in $A(t)$ is found. Since every point in $A(t)$ dominates all points in $B \setminus B(t)$, all maxima in $S_n \cap B$ must be in $B(t')$. The definition of t' intuitively implies that $\mu(A(t')) \sim \frac{1}{n}$ so, also intuitively, the expectation of $|S_n \cap B_n|$ should be $n\mu(B(t')) \sim 1$. This is proven formally in the text.

(b) If $u \in B_p$ then

$$\text{Area}(B_p \cap (u + \delta B_q)) \geq c \text{Area}(u + \delta B_q) = ca_q \delta^2,$$

where c is only dependent upon p, q, κ . Thus, from Eq. 1, $f(v) = \Theta(1)$.

The proofs for (c) and (d) follow from plugging (a) and (b) into Eq. 2. ◀

► **Lemma 5.** (See Fig. 4)

Let \mathbf{D} be any distribution with a continuous density function $f(u)$ and S_n a set of points chosen from \mathbf{D} . Let A, B be two disjoint regions in the support D that are parameterized by $t \in [0, T]$ and satisfy:

- $\mu(A(0)) = \emptyset$.
- $A(T) = A; B(T) = B$.
- (Monotonicity in t) $\forall t_1 < t_2, A(t_1) \subseteq A(t_2)$ and $B(t_1) \subseteq B(t_2)$.
- $\mu(B(t)), \mu(A(t))$ are both continuous in t .
- (Asymptotic dominance in measure) $\forall t, \mu(B(t)) = O(\mu(A(t)))$.

Define the random variables

$$X = |S_n \cap B(t')|, \quad t' = \begin{cases} \min\{t : A(t) \cap S_n \neq \emptyset\} & \text{if } A \cap S_n \neq \emptyset, \\ T & \text{if } A \cap S_n = \emptyset. \end{cases}$$

Then, $\mathbf{E}[X] = O(1)$. (3)

Proof. W.l.o.g. rescale t so that $\mu(A(t)) = t$, and $T = \mu(A)$.

The proof's intuition is that since the "first" point in A appears at t' , then $\mu(A(t')) \sim \frac{1}{n}$. As B is asymptotically dominated by A , $\mu(B(t')) = O(1/n)$ and $\mathbf{E}[X(t')] = n\mu(B(t')) = O(1)$.

Formally, by the continuity of the measure, $\Pr(|S_n \cap A(t')| = 1) = 1$. So we may assume that $|D \setminus A(t')| = n - 1$.

Conditioned on known t' , the remaining $n - 1$ points in S_n are chosen from $D \setminus A(t')$ with the associated conditional distribution. If u is one of those $n - 1$ points,

$$\Pr(u \in B(t') \mid t') = \frac{\mu(B(t'))}{\mu(D \setminus A(t'))} = \frac{\mu(B(t'))}{1 - \mu(A(t'))}.$$

Thus, conditioning on t' , and applying Lemma 1(b)

$$\mathbf{E}[X \mid t'] = (n - 1) \frac{\mu(B(t'))}{1 - \mu(A(t'))},$$

$$\text{therefore } \mathbf{E}[X] = \mathbf{E}[\mathbf{E}[X \mid t']] = \mathbf{E}\left[(n - 1) \frac{\mu(B(t'))}{1 - \mu(A(t'))}\right].$$

From the definition of t' and Lemma 1 (c), $\mu(A(t')) > 1/2$ with exponentially low probability. Therefore, recalling that $\mu(A(t)) = t$,

$$\mathbf{E}[X] = (n - 1)\mathbf{E}[O(\mu(B(t')))] = (n - 1)\mathbf{E}[O(\mu(A(t')))] = (n - 1)O(\mathbf{E}[t']).$$

$$\text{Using Lemma 1 (c) : } \mathbf{E}[t'] = \int_{\alpha=0}^T \Pr(t' \geq \alpha) d\alpha = O\left(\frac{1}{n-1}\right). \quad \blacktriangleleft$$

► **Lemma 6 (Sweep).** (See Fig. 4)

Let \mathbf{D} be any distribution with a continuous density function $f(u)$, and let S_n be a set of points chosen from \mathbf{D} .

Let A, B be two disjoint regions in the support D that are parameterized by $t \in [0, T]$, satisfy conditions 1-3 of Lemma 5 and, in addition satisfy that

$$\forall t \in [0, T], \quad \text{if } u \in A(t) \text{ and } v \in B \setminus B(t) \text{ then } u \text{ dominates } v.$$

In such a case we say that A continuously dominates B . Then

$$\mathbf{E}[|\text{MAX}(S_n) \cap B|] = O(1). \tag{4}$$

Proof. By the definition of t' , $|A(t') \cap S_n| \geq 1$. Since all points in $B \setminus B(t')$ are dominated by all points in $A(t')$, $\text{MAX}(S_n) \cap (B \setminus B(t')) = \emptyset$. Thus from Lemma 5,

$$\mathbf{E}[|\text{MAX}(S_n) \cap B|] = \mathbf{E}[|\text{MAX}(S_n) \cap B(t')|] \leq \mathbf{E}[|S_n \cap B(t')|] = O(1). \quad \blacktriangleleft$$

► **Corollary 7.** Fix $p, q \in [1, \infty]$ and choose S_n from $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$. Let Q_1 be the positive (upper-right) quadrant of the plane and O_1 the first octant, i.e., $Q_1 = \{u \in \mathbb{R}^2 : 0 \leq u.x, 0 \leq u.y\}$ and $O_1 = \{u \in \mathbb{R}^2 : 0 \leq u.y \leq u.x\}$. Then

$$\mathbf{E}[M_n] = \mathbf{E}[|\text{MAX}(S_n)|] = \mathbf{E}[|Q_1 \cap \text{MAX}(S_n)|] + O(1) \tag{5}$$

$$= \Theta\left(\mathbf{E}[|O_1 \cap \text{MAX}(S_n)|]\right). \tag{6}$$

Proof. Restrict $t \in [0, 2 + 2\delta]$ and set

$$\begin{aligned} A &= D \cap \{u \in \mathbb{R}^2 : u.y \geq 0\}, & A(t) &= \{u \in A : u.x \geq 1 + \delta - t\}, \\ B &= D \cap \{u \in \mathbb{R}^2 : u.y < 0\}, & B(t) &= \{u \in B : u.x \geq 1 + \delta - t\}. \end{aligned}$$

Conditions (1) and (2) of Lemma 5 trivially hold. Condition (3) holds because, by x -axis symmetry, $\mu(B(t)) = \mu(A(t))$. The additional condition of Lemma 6 holds because every point in $B \setminus B(t)$ is below and to the left of every point in $A(t)$. Thus the expected number of maximal points in S_n below the x -axis is $O(1)$. Note that this is independent of n .

35:10 Maximal Points of the Convolution of Two 2-D Distributions

Similarly, the expected number of maximal points to the left of the y -axis is $O(1)$. This proves Eq. 5.

To prove Eq. 6 define the second octant to be $O_2 = \{u \in \mathfrak{R}^2 : 0 \leq u.x \leq u.y\}$. By the symmetry between the x and y coordinates in the distribution,

$$\mathbf{E}[|O_1 \cap \text{MAX}(S_n)|] = \mathbf{E}[|O_2 \cap \text{MAX}(S_n)|].$$

Futhermore, since O_1 and O_2 partition Q_1 ,

$$\mathbf{E}[|Q_1 \cap \text{MAX}(S_n)|] = \mathbf{E}[|O_1 \cap \text{MAX}(S_n)|] + \mathbf{E}[|O_2 \cap \text{MAX}(S_n)|] = 2\mathbf{E}[|O_1 \cap \text{MAX}(S_n)|].$$

Thus

$$\mathbf{E}[M_n] = \mathbf{E}[|Q_1 \cap \text{MAX}(S_n)|] + O(1) = \Theta(\mathbf{E}[|O_1 \cap \text{MAX}(S_n)|]). \quad \blacktriangleleft$$

The fact that for $\delta > 0$, u dominates v if and only if δu dominates δv implies the following result which is used very often in this work,

► **Lemma 8 (Scaling).** Fix $p, q \in [1, \infty]$, $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$ and $\mathbf{D}' = \mathbf{B}_q + \frac{1}{\delta}\mathbf{B}_p$.

Let S_n be n points chosen from \mathbf{D} and let S'_n be n points chosen from \mathbf{D}' .

Then $|\text{MAX}(S_n)|$ and $|\text{MAX}(S'_n)|$ have exactly the same distribution.

In particular, $\mathbf{E}[|\text{MAX}(S_n)|] = \mathbf{E}[|\text{MAX}(S'_n)|]$.

Proof. Let $S_n = \{u_1, \dots, u_n\}$ be chosen from \mathbf{D} . Recall that the process of choosing point u from \mathbf{D} is to choose w from \mathbf{B}_p , v from \mathbf{B}_q and return $u = w + \delta v$. Choosing a point u' from \mathbf{D}' is the same except that it returns $u' = v + \frac{1}{\delta}w = \frac{1}{\delta}u$. Thus the distribution of choosing $S_n = \{u_1, \dots, u_n\}$ from \mathbf{D} is exactly the same as choosing $S_n = \{\frac{1}{\delta}u_1, \dots, \frac{1}{\delta}u_n\}$ from \mathbf{D}' .

Finally, note that dominance is invariant under multiplication by a scalar, i.e., p_i dominates p_j if and only if $\frac{1}{\delta}p_i$ dominates $\frac{1}{\delta}p_j$.

Thus $|\text{MAX}(S_n)|$ and $|\text{MAX}(S'_n)|$ have the same distribution, so $\mathbf{E}[|\text{MAX}(S_n)|] = \mathbf{E}[|\text{MAX}(S'_n)|]$. ◀

The next lemma formalizes the intuition that for small values of δ , the value of $\mathbf{E}[M_n]$ for $\mathbf{B}_p + \delta\mathbf{B}_q$ is the same as the value for \mathbf{B}_p .

► **Lemma 9 (Limiting Behavior).** Let $p \in [1, \infty]$, $q \in [1, \infty)$, $\delta = O(1/\sqrt{n})$ and S_n chosen from $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$. Then

$$\mathbf{E}[M_n] = \begin{cases} \Theta(\ln n) & \text{if } p = \infty, \\ \Theta(\sqrt{n}) & \text{if } p \neq \infty. \end{cases}$$

4 General approach to proving Theorem 1

Note that if u is chosen from \mathbf{B}_∞ , then $u.x$ and $u.y$ are independent random variables. Thus, for any $\delta > 0$ if v is chosen from $\mathbf{D} = \mathbf{B}_\infty + \delta\mathbf{B}_\infty$, $v.x$ and $v.y$ are independent random variables. As noted in the introduction, this means that if S_n is chosen from \mathbf{D} , $\mathbf{E}[M_n]$ is exactly the same as if S_n was chosen from \mathbf{B}_∞ , i.e., $\mathbf{E}[M_n] = \Theta(\ln n)$, proving row (i).

Lemma 9 combined with Lemma 8 imply the limiting behavior in columns (b) and (e) of the table in Theorem 1. Note too that for rows (ii) and (iii), column (d) follows directly from applying Lemma 8 to column (c).

Thus, proving Theorem 1 reduces to proving cells (ii) c, (iii) c, (iv) c, d and (v) c, d.

Proving Theorem 1 will require case-by-case analyses of $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$ for the different pairs p, q . The analysis for each pair will all follow the same 4 step pattern:

■ **Figure 5** Illustration of proof $\mathbf{E}[M_n] = \Theta(\sqrt{n})$ when S_n is chosen from \mathbf{B}_1 . All but $O(1)$ maxima will be in quadrant Q_1 ; (b) and (c) illustrate Q_1 . (b) illustrates the lower bound and (c) the upper.

4.1 A Simple Example: $\mathbf{D} = \mathbf{B}_1$

Before sketching our results it is instructive to see how the Lemmas in the previous section can be used to re-derive that fact that, if $\mathbf{D} = \mathbf{B}_1$ then $\mathbf{E}[M_n] = \Theta(\sqrt{n})$. See Fig. 5.

Even though the behavior for $\mathbf{D} = \mathbf{B}_1$ is already well known we provide this to illustrate the generic steps for deriving $\mathbf{E}[M_n]$. These are exactly the same steps that are needed when $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$ and this example permits identifying where the complications can arise in those more general cases. Set $m = \lfloor \sqrt{n} \rfloor$ and let p_i, r_i be the points defined in the figure with $P_i = P(p_i)$ and $B'_i = P(r_i)$. Also set

$$B_i = \left\{ (x, y) : \frac{i-1}{m} \leq x \leq \frac{i}{m}, 0 \leq y \leq 1 - \frac{i+1}{m} \right\}, \quad A_i = \left(\frac{1}{m}, 0 \right) + B_i$$

and $\bar{B}_i = B_i \cup B'_i$. Finally, for $0 \leq t \leq (1+i)/m$ set $B_i(t) = B_i \cap \{(x, y) : y \leq (1+i)/m - t\}$ and $A_i(t) = (\frac{1}{m}, 0) + B_i(t)$. The steps in the derivation are.

Step 1: Restricting to first Quadrant:

Corollary 7 states that $\mathbf{E}[M_n] = \mathbf{E}[|Q_1 \cap \text{MAX}(S_n)|] + O(1)$.

Step 2: Calculating Density and Measure:

Because \mathbf{D} has a uniform density, $\mu(A) = \Theta(\text{Area}(A))$ for all regions $A \subseteq D$.

Step 3: Lower Bound:

The P_i are a collection of m pairwise disjoint dominant regions with

$$\mu(P_i) = \Theta(\text{Area}(P_i)) = \Theta(m^{-2}) = \Theta(1/n).$$

Thus, from Lemma 2, $\mathbf{E}[M_n] = \Omega(m) = \Omega(\sqrt{n})$.

Step 4: Upper bound:

Note that $Q_1 \cap D = \left(\bigcup_{i=1}^{m-1} \bar{B}_i \right) \cup B'_m$ so

$$\begin{aligned} \mathbf{E}[|\text{MAX}(S_n) \cap Q_1|] &= \mathbf{E} \left[\left| \text{MAX}(S_n) \cap \left(\bigcup_{i=1}^m \bar{B}_i \right) \right| \right] + \mathbf{E}[|\text{MAX}(S_n) \cap B'_m|], \\ \mathbf{E} \left[\left| \text{MAX}(S_n) \cap \left(\bigcup_{i=1}^m \bar{B}_i \right) \right| \right] &\leq \sum_{i=1}^m \mathbf{E}[|\text{MAX}(S_n) \cap B_i|] + \sum_{i=1}^m \mathbf{E}[|\text{MAX}(S_n) \cap B'_i|]. \end{aligned}$$

Furthermore, $\forall i, \mu(B'_i) = \Theta(\text{Area}(B'_i)) = \Theta(1/n)$. Thus

$$\forall i, \quad \mathbf{E}[|\text{MAX}(S_n) \cap B'_i|] \leq \mathbf{E}[|S_n \cap B'_i|] = O(n\mu(B'_i)) = O(1).$$

35:12 Maximal Points of the Convolution of Two 2-D Distributions

Since $m = O(\sqrt{n})$ this yields

$$\mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] \leq \sum_{i=1}^m \mathbf{E} [|\text{MAX}(S_n) \cap B_i|] + O(\sqrt{n}).$$

The crucial observation is that, $\forall i$, A_i continuously dominates B_i as defined in Lemmas 5 and 6. Thus, plugging into Lemma 6 yields $\forall i$, $\mathbf{E} [|\text{MAX}(S_n) \cap B_i|] = O(1)$, leading to

$$\mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] = O(m) + O(\sqrt{n}) = O(\sqrt{n}).$$

Combining the $\mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] = O(\sqrt{n})$ from step (3) with the $\mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] = O(\sqrt{n})$ from step (4) with step (1) gives the final result

$$\mathbf{E} [M_n] = \mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] + O(1) = \Theta(\sqrt{n}) + O(1) = \Theta(\sqrt{n}).$$

4.2 The general approach for $\mathbf{D} = \mathbf{B}_p + \delta\mathbf{B}_q$

For each p, q pair the proof of Theorem 1 follows the same four steps as the analysis of $\mathbf{D} = \mathbf{B}_1$ above.

Step 1: *Restricting to first Quadrant:*

Corollary 7 again states that $\mathbf{E} [M_n] = \mathbf{E} [|\text{MAX}(S_n) \cap Q_1|] + O(1)$.

Step 2: *Calculating Density $f(u)$ and Measure $\mu(A)$:*

This step is often quite technical. In the example $\mathbf{D} = \mathbf{B}_1$ case above, the density was constant. For general \mathbf{D} this is no longer true. The density is constant in some region in the center of the support but decreases to zero as the boundary is approached. While Lemma 3 provides an integral formula for general \mathbf{D} this, in many cases, is unusable. A substantial amount of technical work is involved in finding usable functional representations for the densities/measures in different parts of the support.

Step 3: *Lower Bounding $\mathbf{E} [M_n]$:*

For most cases this is a relatively straightforward application of Lemma 2 using the results of Step 2. In the general case, it is still necessary to identify a region that contains an asymptotically dominant number of maxima. It is then necessary to partition this region into pairwise disjoint dominant regions, all of which have measure $\Theta(1/n)$. Note that, unlike in the example $\mathbf{D} = \mathbf{B}_1$ case, these regions might no longer all have the same shape or size.

Step 4: *Upper bounding $\mathbf{E} [M_n]$:*

This is the most delicate part of the proof. It is proven using the Sweep Lemma (Lemma 6) with the major difficulties arising from how to decompose the support into regions that continuously dominate each other. This decomposition strongly depends upon *how* the measure/density is *represented* in Step 2 and can be very differently structured in different parts of the support. In particular, in the case $\mathbf{D} = \mathbf{B}_1 + \delta\mathbf{B}_2$, there are two different parts of the support that require two different decompositions and the decompositions must be designed so that the two upper bounds derived match each other.

More broadly, the density/measure representations developed for $\mathbf{D}_1 = \mathbf{B}_1 + \delta\mathbf{B}_1$ and $\mathbf{D}_2 = \mathbf{B}_2 + \delta\mathbf{B}_2$ are quite different. The analysis of $\mathbf{D}_3 = \mathbf{B}_1 + \delta\mathbf{B}_2$ which is the most delicate, combines the approaches developed for $\mathbf{D}_1, \mathbf{D}_2$. The analysis of $\mathbf{D}_4 = \mathbf{B}_\infty + \delta\mathbf{B}_q$ is different from the first three, but much more straightforward.

5 Conclusion

This paper developed a suite of tools for deriving the expected number of maximal points in a set of n points chosen IID from $\mathbf{B}_p + \delta\mathbf{B}_q$, which is the convolution of two distributions.

The results presented here seem to be the first general analysis of $\mathbf{E}[M_n]$ for non-uniform and non-Gaussian distributions. This paper is only a first step. Obvious next steps are

- The results in the paper were only proven for $p, q \in \{1, 2, \infty\}$ and $p = \infty, q \in [1, \infty]$. The next step would be to attempt to extend the results to *all* pairs $p, q \in [1, \infty]$.
- There is a rich literature stretching back more than fifty years on the average number of points on the *convex hull* of points chosen IID from a uniform distribution in a planar region or a Gaussian distribution, e.g., [14, 19]. It would be interesting to see how the convex hull evolves in the convoluted distributions $\mathbf{B}_p + \delta\mathbf{B}_q$. Such an analysis would require a much tighter understanding of how the distribution behaves “close” to the boundary of its support $B_p + \delta B_q$. One approach might be to introduce some form of measure weighting to the definition of *Macbeath-regions* [3] (which are a known technique for characterizing this boundary region).
- Finally, we note that the results on $\mathbf{E}[M_n]$ for n points chosen IID from a uniform distribution over an L_p ball have analogues in higher dimensions, i.e., $\Theta(\log^{d-1} n)$ if $p = \infty$ and $\Theta(n^{1-\frac{1}{d}})$ if $p \in [1, \infty)$ [4, 14]. The next step would be to attempt to extend the results in this paper to higher dimensions.

Abstract

Let $\Omega_q = \Omega_q(H)$ denote the set of proper $[q]$ -colorings of the hypergraph H . Let Γ_q be the graph with vertex set Ω_q where two vertices are adjacent iff the corresponding colorings differ in exactly one vertex. We show that if $H = H_{n,m;k}$, $k \geq 2$, the random k -uniform hypergraph with $V = [n]$ and $m = dn/k$ hyperedges then w.h.p. Γ_q is connected if d is sufficiently large and $q \gtrsim (d/\log d)^{1/(k-1)}$. This is optimal to the first order in d . Furthermore, with a few more colors, we find that the diameter of Γ_q is $O(n)$ w.h.p, where the hidden constant depends on d . So, with this choice of d, q , the natural Glauber Dynamics Markov Chain on Ω_q is ergodic w.h.p.

1 Introduction

In this paper, we will discuss a structural property of the set Ω_q of proper $[q]$ -colorings of the random hypergraph $H = H_{n,m;k}$, where $m = dn/k$ for some large constant d . Here H has vertex set $V = V(H) = [n]$ and an edge set $E = E(H)$ consisting of m randomly chosen k -sets from $\binom{[n]}{k}$. Note that in the graph case where $k = 2$ we have $H_{n,m;2} = G_{n,m}$. A proper $[q]$ -coloring is a map $\sigma : [n] \rightarrow [q]$ such that $|\sigma(e)| \geq 2$ for all $e \in E$ i.e. no edge is mono-chromatic. Then let us define $\Gamma_q = \Gamma_q(H)$ to be the graph with vertex set Ω_q and an edge $\{\sigma, \tau\}$ iff $h(\sigma, \tau) = 1$ where $h(\sigma, \tau)$ is the Hamming distance $|\{v \in [n] : \sigma(v) \neq \tau(v)\}|$.

Notation. $f(d) \gtrsim g(d)$ if there exists a function $\varepsilon(d) > 0$ such that $\lim_{d \rightarrow \infty} \varepsilon(d) = 0$ and $f(d) \geq (1 + \varepsilon(d))g(d)$ for d large.

Then let

$$\alpha = \left(\frac{(k-1)d}{\log d - 5(k-1)\log \log d} \right)^{\frac{1}{k-1}}, \quad \beta = 3 \log^{3k} d. \quad (1)$$

We prove the following.

► **Theorem 1.** *Suppose that $k \geq 2$ and $p = \frac{d}{\binom{n-1}{k-1}}$ and $m = \binom{n}{k}p$ and that $d = O(1)$ is sufficiently large. Then*

- (i) *If $q \geq \alpha + \beta + 1$ then w.h.p. Γ_q is connected.*
- (ii) *If $q \geq \alpha + 2\beta + 1$ then the diameter of Γ_q is $O(\alpha\beta n)$ w.h.p.*

Note that Γ_q connected implies that the Glauber Dynamics, which in essence is a random walk on Γ_q , is ergodic. At the moment we only know that Glauber Dynamics is rapidly mixing w.h.p. when $q \geq (1.76 \dots)d$, see Efthymiou, Hayes, Štefankovič and Vigoda [6]. So, it would seem that the connectivity of Γ_q is not likely to be a barrier to randomly sampling colorings of sparse random graphs.

In the Statistical Physics literature the definition of Γ_q may be that colorings σ, τ are connected by an edge in Γ_q whenever $h(\sigma, \tau) = o(n)$. Our theorem holds a fortiori if this is the case.

We note that the lower bound for q is close to where the greedy coloring algorithm succeeds w.h.p. For the case $k = 2$ this follows from Shamir and Upfal [15]. For $k \geq 3$, the authors could not find relevant literature. Nevertheless the claim follows (partially) from the current paper. In particular, Lemmas 13 and 14 show that the greedy coloring algorithm uses at most $\alpha + \beta$ colors. Furthermore, a simple argument based on the size of an independent set selected by the greedy algorithm shows that the number of colors required is close to α .

We should note that it has shown, for $k = 2$ by Molloy [14] and for $k \geq 3$ by Ayre and Greenhill [3], that w.h.p. there is no giant component in Γ_q if $q \lesssim \frac{d}{\log d}$. It is somewhat surprising therefore that w.h.p. Γ_q jumps very quickly from having no giant to being connected. One might have expected that $q \gtrsim \frac{d}{\log d}$ would simply imply the existence of a giant component. In Physics terminology, this implies a short *non-reconstruction* phase between *uniqueness* and *reconstruction*.

Prior to this paper, it was shown in [13] that w.h.p. $\Gamma_q, q \geq d + 2$ is connected. The diameter of the *reconfiguration graph* $\Gamma_q(G)$ for graphs G has been studied in the graph theory literature, see Bousquet and Perarnau [5] and Feghali [7]. They show that if the maximum sub-graph density of a graph is at most $d - \varepsilon$ and $q \geq d + 1$ then $\Gamma_q(G)$ has polynomial diameter. Using Theorem 1 of [5] we can show a linear bound on the diameter with a small increase in the number of colors, See (ii) of Theorem 1.

Theorem 1 falls into the area of “Structural Properties of Solutions to Random Constraint Satisfaction Problems”. This is a growing area with connections to Computer Science and Theoretical Physics. In particular, much of the research on the graph Γ_q has been focussed on the structure near the *colorability threshold*, e.g. Bapst, Coja-Oghlan, Hetterich, Rassman and Vilenchik [4], or the *clustering threshold*, e.g. Achlioptas, Coja-Oghlan and Ricci-Tersenghi [1], Molloy [14] or the *condensation threshold*, e.g. Ayre, Coja-Oghlan and Greenhill [2] or the *rigidity threshold*, e.g. Ayre and Greenhill [3]. Other papers heuristically identify a sequence of phase transitions in the structure of Γ_q , e.g., Krz̄akala, Montanari, Ricci-Tersenghi, Semerijan and Zdeborová [11], Zdeborová and Krz̄akala [16] or Gabrié, Dani, Semerjian and Zdeborová [9]. The existence of these transitions has been shown rigorously for some other CSPs. One of the most spectacular examples is due to Ding, Sly and Sun [10] who rigorously showed the existence of a sharp satisfiability threshold for random k -SAT.

Section 3 describes a property (α, β) -greedy-colorability such that if H has this property then $q \geq \alpha + \beta + 1$ implies that Γ_q is connected. Section 4 proves that $H_{n,m;k}, k \geq 2$, is (α, β) -greedy-colorable for α, β defined in (1).

The paper uses some of the ideas from [12] which showed there is a giant component in $\Gamma_q(G_{n,m}), m = dn/2$ w.h.p. when $q \geq cd/\log d$ for $c > 3/2$.

2 Outline argument

We show that with the values $\alpha \approx ((k - 1)d/\log d)^{1/(k-1)} \gg \beta$ given in (1) then w.h.p. $H = H_{n,m;k}$ has the property that **any** greedy coloring of H will need at most α maximal independent sets before being left with a graph without a β -core. (See Lemma 13.) We call the colorings found in this way, *good greedy colorings* and we refer to this property as

(α, β) -greedy-colorability. Any good (α, β) -coloring uses at most $\alpha + \beta$ colors. It follows from this, basically using the argument from [12], that if $\sigma \in \Omega_q$ and $q \geq \alpha + \beta + 1$ then there is a good path in Γ_q to some good greedy coloring σ_1 .

Suppose now that σ_1, τ_1 are good greedy colorings. If $q \geq \alpha + \beta + 1$ then there is a color c that is not used by σ_1 . From σ_1 we move to σ_2 by re-coloring vertices colored 1 in σ_1 by c . Then we move from σ_2 to σ_3 by coloring with color 1, all vertices that have color 1 in τ_1 . At this point, σ_3 and τ_1 agree on color 1. σ_3 may use more than $\alpha + \beta$ colors and so we move by a good path from σ_3 to a coloring σ_4 that uses at most $\alpha + \beta$ colors and does not change the color of any vertex currently with color 1. Here we use the fact that $H_{n,m;k}$ is (α, β) -greedy-colorable. After this, it is induction that completes the proof.

3 (α, β) -Greedy-Colorability

The degree of a vertex $v \in V$ in a hypergraph $H = (V, E)$ is the number of edges $e \in E$ such that $v \in e$. (For completeness, we will state several things in this short paper that one might think can be taken for granted.)

Let $H = (V, E)$. A β -core of H is a maximal subgraph of H in which every vertex has degree at least β . For every $U \subset V$, if the subgraph $H[U]$ of H induced by U does not have a β -core then there is an ordering $\{u_1, u_2, \dots, u_{|U|}\}$ of the vertices in U such that every vertex in $u_\ell \in U$ has degree at most $\beta - 1$ in the sub-hypergraph induced by $\{u_1, u_2, \dots, u_\ell\}$. (Here, we mean by induced that the edges of $H[U]$ are the edges of H contained entirely in U .)

If a hypergraph H does not have a β -core then we can color it with at most β colors. Let v_1, v_2, \dots, v_n be an ordering on V where for every i , there are at most $\beta - 1$ edges that contain v_i and are contained in $\{v_1, v_2, \dots, v_i\}$. Such an ordering must exist when there is no β -core. We can color the vertices in the order v_1, v_2, \dots, v_n and assign to v_i a color that is not *blocked* by the neighbors that precede it. A color c is blocked for vertex v by vertices w_1, w_2, \dots, w_{k-1} if $e = \{v, w_1, \dots, w_{k-1}\} \in E(H)$ and w_1, w_2, \dots, w_{k-1} have already been given color c .

Next let $V_1, V_2, \dots, V_\alpha$ be a sequence of disjoint independent sets of H such that for each $j \geq 1$, V_j is maximal in the sub-hypergraph H_j induced by $V \setminus \bigcup_{1 \leq i < j} V_i$. (A set of vertices is independent if it contains no edges.) We say that such a sequence is a *maximally independent sequence of length α* . Note that we allow $V_j = \emptyset$ here, in order to make our sequences of length exactly α .

► **Definition 2.** We say that a hypergraph H is (α, β) -greedy-colorable if there *does not exist* a maximally independent sequence of length α such that $V \setminus \bigcup_{i \leq \alpha} V_i$ has a β -core.

The main result of this section is the following.

► **Theorem 3.** Let H be (α, β) -greedy-colorable. If $q \geq \alpha + \beta + 1$ then, $\Gamma_q(H)$ is connected. In addition if $q \geq \alpha + 2\beta + 1$ then, the diameter of $\Gamma_q(H)$ is $O(\alpha\beta n)$.

Later, in Section 4 we will show that $H_{n,m;k}, k \geq 2$ is (α, β) -greedy-colorable, for suitable values of m, α, β , viz. the values given in (1).

► **Lemma 4.** Let $H = (V, E)$ be an (α, β) -greedy-colorable hypergraph and $V_1 \subseteq V$ be a maximal independent set of V . Set $V' = V \setminus V_1$ and let H' be the subgraph of H induced by V' . Then H' is $(\alpha - 1, \beta)$ -greedy-colorable.

Proof. Assume that H' is not $(\alpha - 1, \beta)$ -greedy-colorable. Then there exists a partition of V' into $V'_1, \dots, V'_{\alpha-1}$ such that for $j \in [\alpha - 1]$, V'_j is a maximal independent set of $V' \setminus \bigcup_{\ell < j} V'_\ell$ and $W' = V' \setminus \bigcup_{\ell \leq \alpha-1} V'_\ell$ has a β -core. For $j \in [\alpha - 1]$ set $V_{j+1} = V'_j$. Furthermore set $W = V \setminus (\bigcup_{1 \leq \ell \leq \alpha} V_\ell) = V' \setminus (\bigcup_{\ell \leq \alpha-1} V'_\ell) = W'$. Then V_1, \dots, V_α is a maximal independent sequence of length α and W has a β -core which contradicts the fact that H is (α, β) -greedy-colorable. ◀

► **Lemma 5.** *Let H be a hypergraph, $\alpha, \beta \geq 0$ and $q \geq \alpha + \beta + 1$. Let $W \subseteq V$ be such that the subgraph of H induced by W has no β -core. Furthermore let σ and τ be two colorings of H such that*

- (i) *They agree on $V \setminus W$.*
- (ii) *They use only α colors on the vertices in $V \setminus W$.*
- (iii) *τ uses at most β colors on W that are distinct from the ones it uses on $V \setminus W$.*

Then there exists a path from σ to τ in $\Gamma_q(H)$.

Proof. Without loss of generality we may assume that σ and τ use $[\alpha]$ to color $V \setminus W$. The proof that follows is an adaptation to hypergraphs of the proof in [12] that $\Gamma_q(G)$ is connected when a graph G has no q -core. Because W has no β -core there exists an ordering of its vertices, v_1, v_2, \dots, v_r , such that for $i \in [r]$, v_i has at most $\beta - 1$ neighbors in v_1, v_2, \dots, v_{i-1} . For $0 \leq i \leq r$ let τ_i be the coloring that agrees with τ on $\{v_1, \dots, v_i\}$ and with σ on $W \setminus \{v_1, \dots, v_i\}$. On $V \setminus W$ it agrees with both. Thus $\tau_0 = \sigma$ and $\tau_r = \tau$. We note that $\tau_1, \tau_2, \dots, \tau_{r-1}$ may not be proper colorings.

We proceed by induction on i to show that there is a sequence of colorings Σ_i from σ to τ_i such that (i) going from one coloring to the next in Σ_i only re-colors one vertex and (ii) all colorings in the sequence Σ_i are proper for the hypergraph induced by $V \setminus \{v_{i+1}, \dots, v_r\}$. We **do not** claim that the colorings in $\Sigma_i, i < r$ are proper for H . On the other hand, taking $i = r$ we get a sequence of H -proper colorings that starts with σ , ends with τ , such that the consecutive pairs of proper colorings differ on a single vertex. Clearly, such a sequence corresponds to a path from σ to τ in $\Gamma_q(H)$.

The case $i = 1$ is trivial as we have assumed that σ, τ agree on $V \setminus W$ and so we can give v_1 the color $\tau(v_1)$. Assume that the assertion is true for $i = \ell \geq 1$ and let $\sigma = \psi_0, \psi_1, \dots, \psi_s = \tau_\ell$ be a sequence of colorings promised by the inductive assertion. Let (w_j, c_j) denote the *(vertex, color)* change defining the move from ψ_{j-1} to ψ_j . We construct a sequence of colorings of length at most $2s + 1$ that yields the assertion for $i = \ell + 1$. For $j = 1, 2, \dots, s$, we will re-color w_j to color c_j , unless there exists a set X such that $X \cup \{w_j\} \in E$ and $\psi_{j-1}(x) = c_j, x \in X \subseteq \{v_1, v_2, \dots, v_{\ell+1}\}$. The fact that ψ_j is a proper coloring of $V \setminus \{v_{\ell+1}, \dots, v_r\}$ implies that $v_{\ell+1} \in X$. Because $v_{\ell+1}$ has at most $\beta - 1$ neighbors in $\{v_1, \dots, v_\ell\}$ and τ only uses colors in $[\alpha]$ to color $V \setminus W$, there exists a color $c' \neq c_j$ for $v_{\ell+1}$ in $[\alpha + \beta + 1] \setminus [\alpha]$ which is not blocked by a subset of $\{v_1, v_2, \dots, v_\ell\}$ and is different from its current color. We first re-color $v_{\ell+1}$ to c' and then we re-color w_j to c_j , completing the inductive step. At the very end, i.e. after at most $2s + 1$ steps, we give $v_{\ell+1}$ its color in τ . ◀

► **Definition 6.** *A coloring with color sets $V_1, V_2, \dots, V_{\alpha+\beta}$ is said to be a good greedy coloring if (i) $V_1, V_2, \dots, V_\alpha$ is a maximally independent sequence of length α and (ii) $V \setminus \bigcup_{\ell \leq \alpha} V_\ell$ has no β -core.*

We prove Theorem 3 in two steps. In Lemma 7, we show that if $q \geq \alpha + \beta + 1$ and H is (α, β) -greedy-colorable then we can reach a good greedy coloring in $\Gamma_q(H)$ starting from any coloring. Then in Lemma 9, we show that if $q \geq \alpha + \beta + 1$ then any good greedy coloring τ can be reached in $\Gamma_q(H)$ from any other good greedy coloring σ .

► **Lemma 7.** *Let H be an (α, β) -greedy-colorable hypergraph, $q \geq \alpha + \beta + 1$ and σ be a $[q]$ -coloring of H . Then there exists a good greedy coloring τ of H such that there exists a path in $\Gamma_q(H)$ from σ to τ .*

Proof. We generate the coloring τ as follows. Let C_1, C_2, \dots, C_q be the color classes of σ . Then let $V_1 \supseteq C_1$ be a maximal independent set containing C_1 . In general, having defined $V_1, V_2, \dots, V_{\ell-1}$ we let $V_{<\ell} = \bigcup_{1 \leq i < \ell} V_i$ and then we let V_ℓ be a maximal independent set in $V \setminus V_{<\ell}$ that contains $C_\ell \setminus V_{<\ell}$. Thus $V_1, V_2, \dots, V_\alpha$ is a maximal independent sequence of length α . We now describe how we transform the coloring σ vertex by vertex into a coloring σ' in which vertices in V_i get color i for $1 \leq i \leq \alpha$. We first re-color the vertices in $V_1 \setminus C_1$ by giving them color 1, one vertex at a time. The coloring stays proper, as V_1 is an independent set. In general, having re-colored $V_1, V_2, \dots, V_{\ell-1}$ we re-color the vertices in $V_\ell \setminus C_\ell$ with color ℓ . Again, the coloring stays proper, as V_ℓ is an independent set, containing all vertices in C_ℓ that have not been re-colored. We observe that each re-coloring of a vertex v done while turning σ into σ' can be interpreted as moving from a coloring in $\Gamma_q(H)$ to a neighboring coloring.

Let $W = V \setminus \bigcup_{1 \leq i \leq \alpha} V_i$. Because H is (α, β) -greedy-colorable, we find that W has no β -core. Because W has no β -core there exists a proper coloring τ' of the subgraph of H induced by W that uses only colors in $[\alpha + \beta] \setminus [\alpha]$. Set τ to be the coloring that agrees with σ' on $V \setminus W$ and with τ' on W .

Lemma 5 implies that there is a path from σ' to τ . Hence there is a path from σ to τ . ◀

► **Remark 8.** In the proof of Lemma 7 we see that each vertex is re-colored at most twice before we apply Lemma 5. Thus this part of the proof yields at most $O(\alpha n)$ vertex recolorings.

► **Lemma 9.** *Let H be an (α, β) -greedy-colorable hypergraph, $q \geq \alpha + \beta + 1$ and let σ, τ be two good greedy colorings. Then there exists a path from σ to τ in $\Gamma_q(H)$.*

Proof. We proceed by induction on α . For $\alpha = 0$, H is $(0, \beta)$ -greedy-colorable and so it does not have a β -core. Thus the base case follows directly from Lemma 5 by taking $W = V$.

Assume that the statement of the Lemma is true for $\alpha = \ell - 1$ and let $\alpha = \ell$. There exists a maximal independent sequence V_1, V_2, \dots, V_ℓ of length ℓ such that if $V' = V \setminus \bigcup_{1 \leq i \leq \ell} V_i$ then (i) for $i \in [\ell]$, τ assigns the color i to $v \in V_i$ and (ii) τ assigns only colors in $[\ell + \beta] \setminus [\ell]$ to vertices in V' .

Let c be a color not assigned by σ . There is one as $q \geq \ell + \beta + 1$. Starting from σ we recolor all vertices that are colored 1 by color c to create a coloring $\bar{\sigma}$. Then we continue from $\bar{\sigma}$ by recoloring all the vertices in V_1 by color 1 and we let σ' be the resulting coloring. Clearly there is a path P_1 from σ to σ' in $\Gamma_q(H)$.

We now set $H_1 = H \setminus V_1$, and set σ'_1, τ_1 to be the restrictions of σ', τ on H_1 . Observe that since V_1 is a maximal independent set, Lemma 4 implies that H_1 is $(\ell - 1, \beta)$ -greedy-colorable and in addition that τ_1 is a good greedy coloring of H_1 . Lemma 7 implies that in $\Gamma_{q-1}(H_1)$ there is a path P_2 from σ'_1 to some good greedy coloring σ_1 that uses only $\ell - 1 + \beta$ colors from $[q] \setminus \{1\}$. The induction hypothesis implies that in $\Gamma_{q-1}(H_1)$ that there is a path P_3 from σ_1 to τ_1 .

Color 1 is not used in σ'_1, τ_1 or in any of colorings found in the path P_2, P_3 . Thus the path P_2, P_3 corresponds to a path P_4 in $\Gamma_q(H)$ from σ' to τ . Consequently the colorings σ, τ are connected in $\Gamma_q(H)$ by the path $P_1 + P_4$. ◀

Proof of Theorem 3. Let H be (α, β) -greedy-colorable, $q \geq \alpha + \beta + 1$, and let σ_1, σ_2 be two colorings of H . Lemma 7 implies that in $\Gamma_q(H)$, there is path P_i from σ_i to a good greedy coloring τ_i for $i = 1, 2$. Lemma 9 implies that there is a path in $\Gamma_q(H)$ from τ_1 to τ_2 .

When $q \geq \alpha + 2\beta + 1$ Remark 8 shows that while traversing between any pair of proper colorings we perform $O(\alpha n)$ vertex recolorings in the context of Lemma 7. In addition we recolor $\alpha + 2$ times with $2\beta + 1$ colors a hypergraph with no β -core. Theorem 1 of [5] implies that we need $(\alpha + 2) \cdot O(\beta n)$ vertex re-colorings to do this. Thus, there will be $O(\alpha\beta n)$ re-colorings overall and this proves the second part of the theorem. ◀

4 Random Hypergraphs

Theorem 1 follows from

► **Lemma 10.** *Let $k \geq 2$ and suppose that $q \geq \alpha + \beta + 1$ and that d is sufficiently large. If $p = \frac{d}{\binom{n-1}{k-1}}$ and $m = \binom{n}{k}p$ then w.h.p. $\Gamma_q(H_{n,m;k})$ is connected.*

In the following we will assume for simplicity of notation that $d = O(1)$, so that $O(f(d)/n) = O(1/n)$. We do not know if there is an upper bound needed for the growth rate of d , but we doubt it.

To prove Lemma 10 we use Lemmas 11, 13, 14 (below) in order to deduce that w.h.p. $H_{n,m;k}$ is (α, β) -greedy-colorable. Then we apply Theorem 3. (Lemmas 11 and 14 are hardly new or best possible, but we prove them here for completeness.)

We will do our calculations on the random graph $H_{n,p;k}$, $p = d/\binom{n-1}{k-1}$ and use the fact for any hypergraph property \mathcal{P} , we have (see [8])

$$\Pr(H_{n,m;k} \in \mathcal{P}) \leq O(m^{1/2}) \Pr(H_{n,p;k} \in \mathcal{P}). \quad (2)$$

► **Lemma 11.** *Let $p = \frac{d}{\binom{n-1}{k-1}}$ and $k \geq 2$ and d sufficiently large. Then, w.h.p. $H = H_{n,p;k}$ does not contain an independent set of size $\left(\frac{2k \log d}{(k-1)d}\right)^{\frac{1}{k-1}} n$.*

Proof. Let $u = \left(\frac{2k \log d}{(k-1)d}\right)^{\frac{1}{k-1}} n$. The probability that there exists an independent set of size u in H is bounded by

$$\begin{aligned} \binom{n}{u} (1-p)^{\binom{u}{k}} &\leq \left(\frac{en}{u}\right)^u \exp\left\{-\frac{d}{\binom{n-1}{k-1}} \cdot \binom{u}{k}\right\} \\ &\leq \left(\frac{en}{u}\right)^u \exp\left\{-\frac{du}{k} \left(\frac{u}{n}\right)^{k-1} \left(1 + O\left(\frac{1}{n}\right)\right)\right\} \\ &= \left(e^{k-1} \frac{(k-1)d}{2k \log d} \cdot \exp\left\{-2 \log d \left(1 + O\left(\frac{1}{n}\right)\right)\right\}\right)^{u/(k-1)} \\ &= \left(\frac{e^{k-1}(k-1)}{2kd \log d} \left(1 + O\left(\frac{1}{n}\right)\right)\right)^{u/(k-1)} \\ &= o(1). \end{aligned} \quad (3)$$

► **Notation 12.** *We let*

$$m_0 = \frac{n}{\alpha} \text{ and } n_0 = 16m_0 \log^2 d.$$

Furthermore, for $t \leq d$ we let

$$S_t = \left\{ (s_1, s_2, \dots, s_t) \in \left[\left(\frac{2k \log d}{(k-1)d} \right)^{\frac{1}{k-1}} n \right]^t : \sum_{j=1}^t s_j \leq \min \{tm_0, n - n_0\} \right\}.$$

► **Lemma 13.** *If $k \geq 2$ and d is sufficiently large then, w.h.p. there does not exist $1 \leq t \leq d$ and disjoint sets $V_1, \dots, V_t \subset V$ such that:*

- (i) V_1, V_2, \dots, V_t is a maximal independent sequence of length t in $H = H_{n,p;k}$.
- (ii) $(|V_1|, |V_2|, \dots, |V_t|) \in S_t$.

Proof. Fix $t \in [d]$, $(s_1, \dots, s_t) \in S_t$ and let $\bar{s} = \frac{1}{t} \sum_{i \in [t]} s_i$. Since $(s_1, \dots, s_t) \in S_t$ we have that $\bar{s} \leq \frac{1}{t} \cdot tm_0 = m_0$. There are $\binom{n}{s_1, s_2, \dots, s_t, n-t\bar{s}}$ ways to pick disjoint sets $V_1, V_2, \dots, V_t \subseteq V$ of sizes s_1, \dots, s_t respectively. So V_1, \dots, V_t satisfy condition (i) of Lemma 13 only if for every $i \in [t]$ and every $v \in V \setminus \bigcup_{j \in [i]} V_j$, there exist $u_1, \dots, u_{k-1} \in V_i$ such that $\{u_1, \dots, u_{k-1}, v\} \in E(H)$.

So, given V_1, \dots, V_t the probability that we have (i) is at most

$$p_1 = \prod_{i=1}^t (1 - (1-p)^{\binom{s_i}{k-1}})^{n - \sum_{j=1}^i s_j} \leq \exp \left\{ - \sum_{i=1}^t \left((1-p)^{\binom{s_i}{k-1}} \binom{n - \sum_{j=1}^i s_j}{i} \right) \right\}. \quad (4)$$

Now let $t' = \max \left\{ i : \sum_{j \leq i} s_j \leq n - \frac{n}{\log^2 d} \right\}$ and $s' = \sum_{i=1}^{t'} s_i$ and $\bar{s}' = \frac{s'}{t'}$. We consider 2 cases.

Case 1: $t' \geq (1 - \frac{1}{\log d})t$. Now $t\bar{s} \geq t'\bar{s}'$ and so $\bar{s}' - \bar{s} \leq \frac{t-t'}{t}\bar{s}' \leq \frac{\bar{s}'}{\log d}$, which implies that $\bar{s}' \leq \bar{s} \left(1 - \frac{1}{\log d}\right)^{-1} \leq m_0 \left(1 + \frac{2}{\log d}\right)$. Then,

$$\begin{aligned} & \sum_{i=1}^t \left((1-p)^{\binom{s_i}{k-1}} \binom{n - \sum_{j=1}^i s_j}{i} \right) \\ & \geq \sum_{i=1}^{t'} \left((1-p)^{\binom{s_i}{k-1}} \binom{n - \sum_{j=1}^i s_j}{i} \right) \\ & \geq \frac{n}{\log^2 d} \sum_{i=1}^{t'} (1-p)^{\binom{s_i}{k-1}} \geq \frac{nt'}{\log^2 d} (1-p)^{\binom{\bar{s}'}{k-1}} \geq \frac{nt}{2 \log^2 d} (1-p)^{\binom{m_0 \left(1 + \frac{2}{\log d}\right)}{k-1}} \\ & \geq \frac{nt}{2 \log^2 d} \exp \left\{ - (p+p^2) \left(\frac{(\log d - 5(k-1) \log \log d)}{(k-1)d} \right)^{1/(k-1)} \left(1 + \frac{2}{\log d}\right) n \right\} \\ & \geq \frac{nt}{2 \log^2 d} \exp \left\{ - \frac{\log d - 5(k-1) \log \log d}{k-1} \cdot \left(1 + \frac{3(k-1)}{\log d}\right) \right\} \\ & \geq \frac{nt \log^2 d}{d^{1/(k-1)}}. \end{aligned}$$

Now

$$\binom{n}{s_1, \dots, s_t, n - t\bar{s}} \leq \binom{n}{\bar{s}, \dots, \bar{s}, n - t\bar{s}} \leq \prod_{i=1}^t \binom{n}{\bar{s}} \leq \left(\frac{en}{\bar{s}}\right)^{t\bar{s}} \leq \left(\frac{en}{m_0}\right)^{tm_0}.$$

36:8 Connectivity Threshold for Colorings

Thus the probability that for some $t \leq d$ there exist V_1, \dots, V_t satisfying conditions (i), (ii) of Lemma 13 and the condition of Case 1 is bounded by

$$\begin{aligned}
& \sum_{t=1}^d \sum_{(s_1, \dots, s_t) \in S_t} \binom{n}{s_1, s_2, \dots, s_t, n - \sum_{i \in [t]} s_i} p_1 \\
& \leq \sum_{t=1}^d \sum_{(s_1, \dots, s_t) \in S_t} \left(\frac{en}{m_0} \right)^{tm_0} \exp \left\{ -\frac{nt \log^2 d}{d^{1/(k-1)}} \right\} \\
& = \sum_{t=1}^d \sum_{(s_1, \dots, s_t) \in S_t} (ea)^{tm_0} \left(\frac{1}{d^{\log d}} \right)^{nt/d^{1/(k-1)}} \\
& \leq \sum_{t=1}^d n^t \cdot (ea)^{tm_0} \cdot \left(\frac{1}{d^{\log d}} \right)^{nt/d^{1/(k-1)}} \leq \sum_{t=1}^d n^t \left(\frac{(e\alpha)^{(\log d)^{1/(k-1)}}}{d^{\log d}} \right)^{nt/d^{1/(k-1)}} = o(1).
\end{aligned}$$

At the last equality we used that when d is sufficiently large then the term in the parenthesis is smaller than 1.

Case 2: $t' < (1 - \frac{1}{\log d})t$. Thus $t - t' \geq \frac{t}{\log d}$. Observe that from Lemma 11 we can assume that

$$t \geq t' \geq \left(\left(1 - \frac{1}{\log^2 d}\right) / \left(\frac{2k \log d}{(k-1)d}\right)^{\frac{1}{k-1}} \right) - 1 \geq \frac{1}{4} \left(1 - \frac{1}{\log^2 d}\right) \left(\frac{d}{\log d}\right)^{\frac{1}{k-1}}. \quad (5)$$

For (5) we are using Lemma 11 to argue that we need at least this many independent sets to partition a set of size $n \left(1 - \frac{1}{\log^2 d}\right)$. The -1 comes from the fact that the upper bound in the definition of t' may not be tight.

Thus,

$$\begin{aligned}
u & = \frac{1}{t - t'} \sum_{i=t'+1}^t s_i \leq \frac{\log d}{t} \cdot n \left(\frac{1}{\log^2 d} + \left(\frac{2k \log d}{(k-1)d}\right)^{\frac{1}{k-1}} \right) \\
& \leq 4 \left(1 + \frac{2}{\log^2 d}\right) \left(\frac{\log d}{d}\right)^{\frac{1}{k-1}} \cdot \frac{n}{\log d} \quad (6)
\end{aligned}$$

and now with p_1 as defined in (4) we have

$$\begin{aligned}
p_1 & \leq \prod_{i=t'+1}^t (1 - (1-p)^{\binom{s_i}{k-1}})^{n - \sum_{j=1}^i s_j} \leq \prod_{i=t'+1}^t (1 - (1-p)^{\binom{s_i}{k-1}})^{n_0} \\
& \leq \exp \left\{ -n_0 \sum_{i=t'+1}^t (1-p)^{\binom{s_i}{k-1}} \right\} \leq \exp \left\{ -n_0(t-t') \left(\prod_{i=t'+1}^t (1-p)^{\binom{s_i}{k-1}} \right)^{\frac{1}{t-t'}} \right\} \\
& \leq \exp \left\{ -n_0(t-t') \exp \left\{ -(p+p^2) \left[\sum_{i=t'+1}^t \binom{s_i}{k-1} \right] \cdot \frac{1}{t-t'} \right\} \right\}
\end{aligned}$$

$$\begin{aligned}
 \dots &\leq \exp \left\{ -n_0(t-t') \exp \left\{ -(p+p^2) \binom{u}{k-1} \right\} \right\} \\
 &\leq \exp \left\{ -n_0(t-t') \exp \left\{ -d \left(\frac{u}{n} \right)^{k-1} \right\} \left(1 + O \left(\frac{1}{n} \right) \right) \right\} \\
 &\leq \exp \left\{ -n_0(t-t') \exp \left\{ -\frac{4^k \left(1 + \frac{2}{\log^2 d} \right)^k}{\log^{k-2} d} \right\} \right\} \\
 &\leq e^{-(t-t')n_0/2}.
 \end{aligned}$$

Thus the probability that for some $t \leq d$ there exist V_1, \dots, V_t satisfying conditions (i), (ii) of Lemma 13 and the condition of Case 2 is bounded by

$$\begin{aligned}
 P &= \sum_{t=1}^d \sum_{(s_1, \dots, s_t) \in S_t} \left[\prod_{i=1}^{t'} \binom{n - \sum_{j=1}^{i-1} s_j}{s_i} \prod_{i=t'+1}^t \binom{n - \sum_{j=1}^{i-1} s_j}{s_i} \right] p_1 \\
 &\leq \sum_{t=1}^d \sum_{(s_1, \dots, s_t) \in S_t} \left(\frac{en}{\bar{s}'} \right)^{t' \bar{s}'} \left(\frac{en}{u} \right)^{(t-t')u} e^{-(t-t')n_0/2}.
 \end{aligned}$$

For sufficiently large d , (6) implies $u \leq m_0$ and we also have that $n_0 = 16m_0 \log^2 d$. Therefore

$$\left(\frac{en}{u} \right)^{(t-t')u} e^{-(t-t')n_0/4} \leq \left(\frac{en}{m_0} \right)^{(t-t')m_0} e^{-4(t-t')m_0 \log^2 d} \leq e^{-3(t-t')m_0 \log^2 d} \leq e^{-3tm_0 \log d}.$$

Furthermore, Lemma 11 implies that $\bar{s}' \leq \left(\frac{2k \log d}{(k-1)d} \right)^{\frac{1}{k-1}} n \leq 3m_0$. Thus

$$\begin{aligned}
 \left(\frac{en}{\bar{s}'} \right)^{t' \bar{s}'} e^{-(t-t')n_0/4} &\leq \left(\frac{en}{3m_0} \right)^{3tm_0} e^{-4(t-t')m_0 \log^2 d} \leq \\
 &\left(\frac{en}{3m_0} \right)^{3tm_0} e^{-4tm_0 \log d} \leq e^{-tm_0 \log d}.
 \end{aligned}$$

So,

$$P \leq dn^d e^{-4tm_0 \log d} = dn^d e^{-4t\alpha n \log d} = o(1). \quad \blacktriangleleft$$

► **Lemma 14.** *If $k \geq 2$ and d is sufficiently large then w.h.p. every set $S \subset V$ of size at most n_0 spans fewer than $3|S| \log^{3k} d$ edges in H . Hence no subset of size at most n_0 contains a $3 \log^{3k} d$ core.*

Proof. Let $L = 3 \log^{3k} d$. The probability that there exists $S \subset V$ of size at most n_0 that spans at least $t = L|S|$ edges is bounded by

$$\begin{aligned}
 \sum_{s=1}^{n_0} \binom{n}{s} \binom{\binom{s}{k}}{t} p^t &\leq \sum_{s=1}^{n_0} \left(\left(\frac{en}{s} \right)^{s/t} \cdot \frac{e \binom{s}{k}}{t} \cdot \frac{d}{\binom{n-1}{k-1}} \right)^t \leq \sum_{s=1}^{n_0} \left(\left(\frac{en}{s} \right)^{1/L} \frac{eds}{t} \left(\frac{s}{n} \right)^{k-1} \right)^t \\
 &= \sum_{s=1}^{n_0} \left(\left(\frac{s}{n} \right)^{k-1-1/L} \frac{e^{1+1/L} d}{L} \right)^t = o(1). \quad \blacktriangleleft
 \end{aligned}$$

Proof of Theorem 1. Let α, β be as in (1). We argue next that the properties given by Lemmas 11, 13 and 14 imply that $H_{n,p;k}$ is (α, β) -greedy-colorable for d sufficiently large. That is for any sequence of sets $V_1, V_2, \dots, V_\alpha$ such that V_i is maximally independent in $[n] \setminus \bigcup_{j < i} V_j$ for $j \leq \alpha$ we have that $[n] \setminus \bigcup_{i \leq \alpha} V_i$ does not have a β -core. Lemma 10 then follows directly from (2) and Theorem 3.

Consider such a sequence of sets $V_1, V_2, \dots, V_\alpha$. It follows from Lemma 13 that because $\alpha m_0 = n$, we must have $\sum_{i=1}^{\alpha} |V_i| \geq n - n_0$ and then Lemma 14 implies that $[n] \setminus \bigcup_{i \leq \alpha} V_i$ does not have a β -core. ◀

Abstract

The six-vertex model in statistical physics is a weighted generalization of the ice model on \mathbb{Z}^2 (i.e., Eulerian orientations) and the zero-temperature three-state Potts model (i.e., proper three-colorings). The phase diagram of the model represents its physical properties and suggests where local Markov chains will be efficient. In this paper, we analyze the mixing time of Glauber dynamics for the six-vertex model in the ordered phases. Specifically, we show that for all Boltzmann weights in the *ferroelectric phase*, there exist boundary conditions such that local Markov chains require exponential time to converge to equilibrium. This is the first rigorous result bounding the mixing time of Glauber dynamics in the ferroelectric phase. Our analysis demonstrates a fundamental connection between correlated random walks and the dynamics of intersecting lattice path models (or routings). We analyze the Glauber dynamics for the six-vertex model with free boundary conditions in the *antiferroelectric phase* and significantly extend the region for which local Markov chains are known to be slow mixing. This result relies on a Peierls argument and novel properties of weighted non-backtracking walks.

1 Introduction

The *six-vertex model* was first introduced by Pauling in 1935 [33] to study the thermodynamics of crystalline solids with ferroelectric properties, and has since become one of the most compelling models in statistical mechanics. The prototypical instance of the model is the hydrogen-bonding pattern of two-dimensional ice – when water freezes, each oxygen atom must be surrounded by four hydrogen atoms such that two of the hydrogen atoms bond covalently with the oxygen atom and two are farther away. The state space of the six-vertex model consists of orientations of the edges in a finite region of the Cartesian lattice where every internal vertex has two incoming edges and two outgoing edges, also represented as Eulerian orientations of the underlying lattice graph. The model is most often studied on the $n \times n$ square lattice $\Lambda_n \subseteq \mathbb{Z}^2$ with $4n$ additional edges so that each internal vertex has degree 4. There are six possible edge orientations incident to a vertex (see Figure 1).

We assign Boltzmann weights $w_1, w_2, w_3, w_4, w_5, w_6 \in \mathbb{R}_{>0}$ to the six vertex types and define the partition function as $Z = \sum_{x \in \Omega} \prod_{i=1}^6 w_i^{n_i(x)}$, where Ω is the set of Eulerian orientations of Λ_n and $n_i(x)$ is the number of type- i vertices in the configuration x .

■ **Figure 1** The valid edge orientations for internal vertices in the six-vertex model.

In 1967, Lieb discovered exact solutions to the six-vertex model with periodic boundary conditions for three different parameter regimes [25, 26, 27]. In particular, he famously showed that if all six vertex weights are $w_i = 1$, the energy per vertex is $\lim_{n \rightarrow \infty} Z^{1/n^2} = (4/3)^{3/2} = 1.5396007\dots$ (known as Lieb’s square ice constant). His results were immediately generalized to allow for all parameter settings and external electric fields [38, 40]. An equivalence between periodic and free boundary conditions in the limit was established soon after [7], and since then the primary object of study has been the six-vertex model subject to *domain wall boundary conditions*, where the lower and upper boundary edges point into the square and the left and right boundary edges point outwards [20, 22, 6, 3, 4, 5]. There have been several surprisingly profound connections to enumerative combinatorics in this line of work. For instance, Zeilberger gave a sophisticated computer-assisted proof of the *alternating sign matrix conjecture* in 1995 [41]. A year later, Kuperberg [23] produced an elegant and significantly shorter proof using analysis of the partition function of the six-vertex model with domain wall boundary conditions. Other connections of the model to combinatorics and probability include tilings of the Aztec diamond and the arctic circle theorem [11, 14], sampling lozenge tilings [29, 39, 2], and enumerating 3-colorings of lattice graphs [36, 10].

While there has been extraordinary progress in understanding properties of the six-vertex model with periodic or domain wall boundary conditions, remarkably less is known when the model is subject to arbitrary boundary conditions. Sampling configurations using Markov chain Monte Carlo (MCMC) algorithms has been one of the primary means for discovering more general mathematical and physical properties of the six-vertex model [1, 31, 30, 21], and empirically the model is very sensitive to boundary conditions. Numerical studies have often observed slow convergence of local MCMC algorithms under certain parameter settings. For example, according to [30], “it must be stressed that the Metropolis algorithm might be impractical in the antiferromagnetic phase, where the system may be unable to thermalize.” However, there are very few rigorous results for natural Markov chains and the computational complexity of sampling from the Boltzmann distribution for various weights and boundary conditions. This motivates our study of Glauber dynamics, the most widely used MCMC sampling algorithm, for the six-vertex model in the *ferroelectric* and *antiferroelectric* phases.

At first glance, there are six degrees of freedom in the model. However, this conveniently reduces to a two-parameter family due to invariants and standard physical assumptions that relate pairs of vertex types. To see this, it is useful to map configurations of the six-vertex model to sets of intersecting lattice paths by erasing all of the edges that are directed south or west and keeping the others [29]. Using this “routing interpretation,” it is simple to see that the number of type-5 and type-6 vertices must be closely correlated. In addition to revealing invariants, the lattice path representation of configurations turns out to be exceptionally

■ **Figure 2** Phase diagram of the six-vertex model with (a) previously known and (b) our current slowly mixing regions colored in red. Glauber dynamics is conjectured to be rapidly mixing for the entire disordered phase but has only been shown for the uniform distribution indicated by the green point $(1, 1)$ in both figures.

useful for analyzing Glauber dynamics. Moreover, the total weight of a configuration should remain unchanged if all the edge directions are reversed in the absence of an external electric field, so we let $w_1 = w_2 = a$, $w_3 = w_4 = b$, and $w_5 = w_6 = c$. This complementary invariance is known as the *zero field assumption*, and it is often convenient to exploit the conservation laws of the model [4] to reparameterize the system so that $w_1 = a^2$ and $w_2 = 1$. This allows us to ignore empty sites and focus solely on weighted lattice paths. Furthermore, since our goal is to sample configurations from the Boltzmann distribution, we can normalize the partition function by a factor of c^{-n^2} and consider the weights $(a/c, b/c, 1)$ instead of (a, b, c) . We collectively refer to these properties as the invariance of the Gibbs measure for the six-vertex model.

The phase diagram of the six-vertex model represents physical properties of the system and is partitioned into three regions: the *disordered* (DO) phase, the *ferroelectric* (FE) phase, and the *antiferroelectric* (AFE) phase. To establish these regions, we consider the parameter

$$\Delta = \frac{a^2 + b^2 - c^2}{2ab}.$$

The disordered phase is the set of parameters $(a, b, c) \in \mathbb{R}_{>0}^3$ that satisfy $|\Delta| < 1$, and Glauber dynamics is expected to be rapidly mixing in this region because there are no long-range correlations in the system. The ferroelectric phase is defined by $\Delta > 1$, or equivalently when $a > b + c$ or $b > a + c$. We show in this paper that Glauber dynamics can be slow mixing at any point in this region (Figure 2b). The antiferroelectric phase is defined by $\Delta < -1$, or equivalently when $a + b < c$, and our second result significantly extends the antiferroelectric subregion for which Glauber dynamics is known to be slow mixing. The phase diagram is symmetric over the main positive diagonal, which follows from the fact that a and b are interchangeable under the automorphism that rotates each of the six vertex types by ninety degrees clockwise. Under the zero field assumption, this is equivalent to rotating the entire model, so we can assume without loss of generality that if a mixing result holds for one point in the phase diagram, it also holds at the point reflected over the main diagonal.

Cai, Liu, and Lu [9] recently provided strong evidence supporting conjectures about the approximability of the six-vertex model. In particular, they designed a *fully randomized approximation scheme* (FPRAS) for a subregion of the disordered phase that works for all 4-regular graphs via the winding framework for Holant problems [32, 19]. They also showed

that there cannot exist an FPRAS for 4-regular graphs in the ferroelectric or antiferroelectric phases unless $\mathbf{RP} = \mathbf{NP}$. We note that their hardness result uses nonplanar gadgets and the larger class of 4-regular graphs, so it does not reveal anything about the complexity of Glauber dynamics for the six-vertex model on regions of \mathbb{Z}^2 . A dichotomy theorem for the (exact) computability of the partition function of the six-vertex model on 4-regular graphs was also recently proven in [8]. As for the positive results, Luby, Randall, and Sinclair [29] proved rapid mixing of a Markov chain that leads to a fully polynomial almost uniform sampler for Eulerian orientations on any region of the Cartesian lattice with fixed boundaries (i.e., the unweighted case when $a/c = b/c = 1$). Randall and Tetali [36] then used a comparison technique to argue that Glauber dynamics for Eulerian orientations on lattice graphs is rapidly mixing by relating this Markov chain to the Luby-Randall-Sinclair chain. Goldberg, Martin, and Paterson [16] extended their approach to show that Glauber dynamics is rapidly mixing on rectangular lattice regions with free boundary conditions.

Liu [28] recently gave the first rigorous result that Glauber dynamics is slowly mixing in a subregion of an ordered phase by showing that local Markov chains require exponential time to converge in the antiferroelectric subregion defined by $\max(a, b) < c/\mu$, where $\mu = 2.6381585\dots$ is the connective constant for self-avoiding walks on the square lattice (Figure 2a). He also showed that the directed loop algorithm mixes slowly in the same antiferroelectric subregion and for all of the ferroelectric region, but this has no bearing on the efficiency of Glauber dynamics in the ferroelectric region. We note that the partition function is exactly computable for all boundary conditions at the free-fermion point when $\Delta = 0$, or equivalently $a^2 + b^2 = c^2$, via a reduction to domino tilings and a Pfaffian computation [14]. There is strong evidence that exact counting is unlikely anywhere else for arbitrary boundary conditions [8].

1.1 Main Results

In this paper we show that there exist boundary conditions for which Glauber dynamics mixes slowly for the six-vertex model in the ferroelectric and antiferroelectric phases. We start by proving that there are boundary conditions that cause Glauber dynamics to be slow for all Boltzmann weights that lie in the ferroelectric region of the phase diagram, where the mixing time is exponential in the number of vertices in the lattice. This is the first rigorous result for the mixing time of Glauber dynamics in the ferroelectric phase and it gives a complete characterization.

► **Theorem 1 (Ferroelectric phase).** *For any $(a, b, c) \in \mathbb{R}_{>0}^3$ such that $a > b + c$ or $b > a + c$, there exist boundary conditions for which Glauber dynamics mixes exponentially slowly on Λ_n .*

We note that our approach naturally breaks down at the critical line in a way that reveals a trade-off between the energy and entropy of the system. Additionally, our analysis suggests an underlying combinatorial interpretation for the phase transition between the ferroelectric and disordered phases in terms of the adherence strength of intersecting lattice paths and the momentum parameter of correlated random walks.

Our second mixing result builds on the topological obstruction framework developed in [35] to show that Glauber dynamics with free boundary conditions mixes slowly in most of the antiferroelectric region. Specifically, we generalize the recent antiferroelectric mixing result in [28] with a Peierls argument that uses multivariate generating functions for weighted non-backtracking walks instead of the connectivity constant for (unweighted) self-avoiding walks to better account for the discrepancies in Boltzmann weights.

► **Theorem 2 (Antiferroelectric phase).** *For any $(a, b, c) \in \mathbb{R}_{>0}^3$ such that $ac + bc + 3ab < c^2$, Glauber dynamics mixes exponentially slowly on Λ_n with free boundary conditions.*

We illustrate the new regions for which Glauber dynamics can be slowly mixing in Figure 2. Observe that our antiferroelectric subregion significantly extends Liu's and pushes towards the conjectured threshold.

1.2 Techniques

We take significantly different approaches for our analysis of the ferroelectric and antiferroelectric phases. In the ferroelectric phase, where $a > b + c$ and type- a vertices are preferred to type- b and type- c vertices, we construct boundary conditions that induce polynomially-many paths separated by a critical distance that allows all of the paths to (1) behave independently and (2) simultaneously intersect with their neighbors maximally. (This analysis also covers the case $b > a + c$ by a standard invariant that shows symmetry in the phase diagram over the line $y = x$.) From here, we analyze the dynamics of a single path in isolation as an escape probability, which eventually allows us to bound the conductance of the Markov chain. The dynamics of a single lattice path are equivalent to those of a *correlated random walk*. In Appendix A we present a new tail inequality for correlated random walks that accurately bounds the probability of large deviations from the starting position. We note that decomposing the dynamics of lattice models into one-dimensional random walks has recently been shown to achieve nearly tight bounds for escape probabilities in a different setting [12].

One of the key technical contributions in this paper is our analysis of the tail behavior of correlated random walks in Appendix A. While there is a simple combinatorial expression for the position of a correlated random walk written as a sum of marginals, it is not immediately useful for bounding the displacement from the origin. To achieve an exponentially small tail bound for these walks, we first construct a smooth function that tightly upper bounds the marginals and then optimize this function to analyze the asymptotics of the log of the maximum marginal. Once we obtain an asymptotic equality for the maximum marginal, we can upper bound the deviation of a correlated random walk, and hence the deviation of a lattice path in a configuration. Ultimately, this allows us to show that there exists a balanced cut in the state space that has an exponentially small escape probability, which implies that the Glauber dynamics are slowly mixing.

In the antiferroelectric phase, on the other hand, the Boltzmann weights satisfy $a + b < c$ so type- c vertices are preferred. It follows that there are two (arrow-reversal) symmetric ground states of maximum probability containing only type- c vertices. To move between configurations that agree predominantly with different ground states, the Markov chain must pass through configurations with a large number of type- a or type- b vertices. Using the idea of *fault lines* introduced in [35], we use self-avoiding walks to characterize such configurations and construct a cut set with exponentially small probability mass that separates the ground states. Liu [28] follows this Peierls argument approach and bounds the weight of the cut by separately considering the minimum energy gain of the corresponding inverse map and the number of preimages (i.e., the entropy). Instead, we directly bound the free energy (rather than as a product of the upper bounds for the energy and entropy terms) and are able to show slow mixing for a much larger region of the phase diagram. Our key observation for accurately bounding the free energy is that when a fault line changes direction, the vertices along it switch from type- a to type- b or vice versa. Therefore, we introduce the notion of *weighted non-backtracking walks* and solve their multivariate generating function by diagonalizing a system of linear recurrences to exactly account for disparities between the weights of a and b along fault lines.

2 Preliminaries

We start by reviewing some necessary background on Markov chains, Glauber dynamics, and correlated random walks.

2.1 Markov Chains and Mixing Times

Let \mathcal{M} be an ergodic, reversible Markov chain with finite state space Ω , transition probability matrix P , and stationary distribution π . The t -step transition probability from states x to y is denoted as $P^t(x, y)$. The total variation distance between the probability distributions μ and ν on Ω is

$$\|\mu - \nu\|_{\text{TV}} = \frac{1}{2} \sum_{x \in \Omega} |\mu(x) - \nu(x)|.$$

The *mixing time* of \mathcal{M} is $\tau(1/4) = \min\{t \in \mathbb{Z}_{\geq 0} : \max_{x \in \Omega} \|P^t(x, \cdot) - \pi\|_{\text{TV}} \leq 1/4\}$. We say that \mathcal{M} is rapidly mixing if its mixing time is $O(\text{poly}(n))$, where n is the size of each configuration in the state space. Similarly, we say that \mathcal{M} is slow mixing if its mixing time is $\Omega(\exp(n^c))$ for some constant $c > 0$.

The mixing time of a Markov chain is characterized by its *conductance* (up to polynomial factors). The conductance of a nonempty set $S \subseteq \Omega$ is

$$\Phi(S) = \frac{\sum_{x \in S, y \notin S} \pi(x)P(x, y)}{\pi(S)},$$

and the conductance of the Markov chain is $\Phi^* = \min_{S \subseteq \Omega: 0 < \pi(S) \leq 1/2} \Phi(S)$. It is often useful to view the conductance of a set as an escape probability – starting from stationarity and conditioned on being in S , the conductance $\Phi(S)$ is the probability that \mathcal{M} leaves S in one step.

► **Theorem 3** ([24]). *For an ergodic, reversible Markov chain with conductance Φ^* , we have $\tau(1/4) \geq 1/(4\Phi^*)$.*

To show that a Markov chain is slow mixing, it suffices to show that the conductance is exponentially small.

In this paper we study single-site *Glauber dynamics* for the six-vertex model. This Markov chain makes local moves by (1) choosing an internal cell of the lattice uniformly at random and (2) reversing the orientations of the edges that bound the chosen cell if they form a cycle. In the lattice path interpretation of the model, these dynamics correspond to the mountain-valley Markov chain that flips corners. Transitions between states are made according to the Metropolis-Hastings acceptance probability so that the Markov chain converges to the desired stationary distribution.

2.2 Correlated Random Walks

A key tool in our analysis for the ferroelectric phase are correlated random walks, which generalize simple symmetric random walks by accounting for momentum. A *one-dimensional correlated random walk* with momentum parameter $p \in [0, 1]$ starts at the origin and is defined as follows. Let X_1 be a uniform random variable with support $\{-1, 1\}$. For all subsequent steps $i \geq 2$, the direction of the process is correlated with the direction of the previous step and satisfies

$$X_{i+1} = \begin{cases} X_i & \text{with probability } p, \\ -X_i & \text{with probability } 1 - p. \end{cases}$$

We denote the position of the walk at time t by $S_t = \sum_{i=1}^t X_i$. It will often be useful to make the change of variables $p = \mu/(1 + \mu)$ when analyzing the six-vertex model. In many cases this also leads to cleaner expressions. We use the following probability density function (PDF) for the position of a correlated random walk to develop a new tail inequality (Lemma 8) that holds for all values of p .

► **Lemma 4** ([18]). *For any $n \geq 1$ and $m \geq 0$, the PDF of a correlated random walk is*

$$\Pr(S_{2n} = 2m) = \begin{cases} \frac{1}{2} p^{2n-1} & \text{if } 2m = 2n, \\ \sum_{k=1}^{n-m} \binom{n+m-1}{k-1} \binom{n-m-1}{k-1} (1-p)^{2k-1} p^{2n-1-2k} \binom{n(1-p)+k(2p-1)}{k} & \text{if } 2m < 2n. \end{cases}$$

3 Slow Mixing in the Ferroelectric Phase

We start with the ferroelectric phase where $a > b + c$ or $b > a + c$, and we give a conductance-based argument to show that Glauber dynamics can be slowly mixing in the entire ferroelectric region. Specifically, we show that there exist boundary conditions that induce an exponentially small, asymmetric bottleneck in the state space, revealing a natural trade-off between the energy and entropy in the system. Viewing the six-vertex model in the intersecting lattice interpretation suggests how to plant polynomially-many paths in the grid that can (1) be analyzed independently, while (2) being capable of intersecting maximally. This path independence makes our analysis tractable and allows us to interpret the dynamics of a path as a correlated random walk, for which we develop an exponentially small tail bound in Appendix A. Since escape probabilities govern mixing times [34], we show how to relate the expected maximum deviation of a correlated walk to the conductance of the Markov chain to prove slow mixing. In addition to showing slow mixing up to the conjectured threshold, a surprising feature of our argument is that it potentially gives a combinatorial explanation for the phase transition from the ferroelectric to disordered phase. In particular, Lemma 9 demonstrates how the parameters of the model delicately balance the probability mass of the Markov chain.

Next, we exploit the invariance of the Gibbs measure and the lattice path interpretation of the six-vertex model to conveniently reparameterize the Boltzmann weights. Specifically, we let $w_1 = \lambda^2$ and $w_2 = 1$ so that we can ignore empty sites. Note that $a = \sqrt{w_1 w_2} = \lambda$. We also let $b = w_2 = w_3 = \mu$ and $c = w_5 = w_6 = 1$ so that the weight of a configuration only comes from straight segments and intersections of neighboring lattice paths.

3.1 Constructing the Boundary Conditions and Cut

We begin with a few colloquial definitions for lattice paths that allow us to easily construct the boundary conditions and make arguments about the conductance of the Markov chain. We call a $2n$ -step, north-east lattice path γ starting from $(0, 0)$ a *path of length $2n$* , and if the path ends at (n, n) we describe it as *tethered*. If $\gamma = ((0, 0), (x_1, y_1), (x_2, y_2), \dots, (x_{2n}, y_{2n}))$, we define the *deviation* of γ to be $\max_{i=0..2n} \|(x_i, y_i) - (i/2, i/2)\|_1$. Geometrically, path deviation captures the (normalized) maximum perpendicular distance of the path to the line $y = x$. We refer to vertices (x_i, y_i) along the path as *corners* or *straights* depending on whether or not the path turned. If two paths intersect at a vertex we call this site a *cross*. Note that this classifies all vertex types in the six-vertex model.

We consider the following *independent paths boundary condition* for an $n \times n$ six-vertex model for the rest of the section. To construct this boundary condition, we consider its lattice path interpretation. First, place a tethered path γ_0 that enters $(0, 0)$ horizontally and exits (n, n) horizontally. Next, place $2\ell = \lfloor n^{1/8} \rfloor$ translated tethered paths of varying

■ **Figure 3** Examples of states with the independent paths boundary condition: (a) is a state in S with the deviation bounds highlighted and (b) is the ground state in the ferroelectric phase.

length above and below the main diagonal, each separated from its neighbors by distance $d = \lfloor 32n^{3/4} \rfloor$. Specifically, the paths $\gamma_1, \gamma_2, \dots, \gamma_\ell$ below the main diagonal begin at the vertices $(d, 0), (2d, 0), \dots, (\ell d, 0)$ and end at the vertices $(n, n-d), (n, n-2d), \dots, (n, n-\ell d)$, respectively. The paths $\gamma_{-1}, \gamma_{-2}, \dots, \gamma_{-\ell}$ above the main diagonal begin at $(0, d), (0, 2d), \dots, (0, \ell d)$ and end at $(n-d, n), (n-2d, n), \dots, (n-\ell d, n)$. The deviation of a translated tethered path is the deviation of the same path starting at $(0, 0)$. To complete the boundary condition, we force the paths below the main diagonal to enter vertically and exit horizontally. Symmetrically, we force the paths above the main diagonal to enter horizontally and exit vertically. See Figure 3a for an illustration of the construction when all paths have small deviation.

Next, we construct an asymmetric cut in the state space induced by this boundary condition in terms of its internal lattice paths. In particular, we analyze a set S of configurations such that every path in a configuration has small deviation. Formally, we let

$$S \stackrel{\text{def}}{=} \left\{ x \in \Omega : \text{the deviation of each path in } x \text{ is less than } 8n^{3/4} \right\}.$$

Observe that by our choice of separation distance $d = \lfloor 32n^{3/4} \rfloor$ and the deviation limit for S , no paths in any configuration of S intersect. It follows that the partition function for S factors into a product of $2\ell + 1$ partition functions, one for each path with bounded deviation. This intuition is useful when analyzing the conductance $\Phi(S)$ as an escape probability from stationarity.

3.2 Lattice Paths as Correlated Random Walks

Now we consider weighting the internal paths according to the six-vortex model. The main result in this subsection is that random tethered paths are exponentially unlikely to deviate past $\omega(n^{1/2})$, even if drawn from a Boltzmann distribution that favors straights (Lemma 5). Let $\Gamma(\mu, n)$ denote the distribution over tethered paths of length $2n$ such that

$$\Pr(\gamma) \propto \mu^{(\# \text{ of straights in } \gamma)}.$$

► **Lemma 5.** *Let $\mu, \varepsilon > 0$ and $m = o(n)$. For n sufficiently large and $\gamma \sim \Gamma(\mu, n)$, we have $\Pr(\gamma \text{ deviates by at least } 2m) \leq e^{-(1-\varepsilon)\frac{m^2}{\mu n}}$.*

We defer the proof of Lemma 5 to the full version of the paper [13]. Instead, we sketch its key ideas to demonstrate the connection between biased tethered paths and correlated random walks, and to show how the supporting lemmas interact.

First, observe that there is a natural measure-preserving bijection between biased tethered paths of length $2n$ and correlated random walks of length $2n$ that return to the origin. Concretely, for a correlated random walk $(S_0, S_1, \dots, S_{2n})$ parameterized by $p = \mu/(1 + \mu)$,

$$\Pr(\gamma \text{ deviates by at least } 2m) = \Pr\left(\max_{i=0..2n} |S_i| \geq 2m \mid S_{2n} = 0\right). \quad (1)$$

Now we present an asymptotic equality that generalizes the return probability of simple symmetric random walks. This allows us to relax the condition in (1) that a correlated random walk returns to the origin, and instead we bound $\Pr(\max_{i=0..2n} |S_i| \geq 2m)$ at the expense of an additional polynomial factor.

► **Lemma 6** ([15]). *For any constant $\mu > 0$, the return probability of a correlated random walk is $\Pr(S_{2n} = 0) \sim 1/\sqrt{\mu\pi n}$.*

Another result needed to prove Lemma 5 is that the PDF for correlated random walks is unimodal.

► **Lemma 7.** *For any momentum parameter $p \in (0, 1)$ and n sufficiently large, the probability of the position of a correlated random walk is unimodal. Concretely, for $m \in \{0, 1, \dots, n-1\}$, we have $\Pr(S_{2n} = 2m) \geq \Pr(S_{2n} = 2(m+1))$.*

Last, we give an upper bound for the position of a correlated random walk. We fully develop this inequality in Appendix A by analyzing the asymptotic behavior of the PDF in Lemma 4. Observe that Lemma 8 demonstrates exactly how the tail behavior of simple symmetric random walks generalizes to correlated random walks as a function of μ .

► **Lemma 8.** *Let $\mu, \varepsilon > 0$ and $m = o(n)$. For n sufficiently large, a correlated random walk satisfies $\Pr(S_{2n} = 2m) \leq e^{-(1-\varepsilon)\frac{m^2}{\mu n}}$.*

To complete the proof sketch of Lemma 5, we start by using Lemma 6 to relax the conditional probability. It follows from Lemma 7 and union bounds that

$$\Pr\left(\max_{i=0..2n} |S_i| \geq 2m \mid S_{2n} = 0\right) \leq 2\sqrt{\mu\pi n} \cdot 2n^2 \cdot \Pr(S_{2n} = 2m). \quad (2)$$

Applying Lemma 8 to (2) with a smaller error completes the proof. See [13] for more details.

3.3 Bounding the Conductance and Mixing Time

Next, we bound the conductance of the Markov chain by viewing $\Phi(S)$ as an escape probability. We start by claiming that $\pi(S) \leq 1/2$ (as required by the definition of conductance) if and only if the parameters are in the ferroelectric phase. Due to space constraints, we also defer the proof of Lemma 9 to [13]. Then we use the correspondence between tethered paths and correlated random walks (Section 3.2) to prove that $\Phi(S)$ is exponentially small.

► **Lemma 9.** *Let $\mu > 0$ and $\lambda > 1 + \mu$ be constants. For n sufficiently large, $\pi(S) \leq 1/2$.*

Our analysis of the escape probability from S critically relies on the fact that paths in any state $x \in S$ are non-intersecting. Combinatorially, we exploit the factorization of the generating function for states in S as a product of $2\ell+1$ independent path generating functions.

37:10 Slow Mixing of Glauber Dynamics for the Six-Vortex Model in the Ordered Phases

► **Lemma 10.** *Let $\mu, \varepsilon > 0$ be constants. For n sufficiently large, $\Phi(S) \leq e^{-(1-\varepsilon)\mu^{-1}n^{1/2}}$.*

Proof. The conductance $\Phi(S)$ can be understood as the following escape probability. Sample a state $x \in S$ from the stationary distribution π conditioned on $x \in S$, and run the Markov chain from x for one step to get a neighboring state y . The definition of conductance implies that $\Phi(S)$ is the probability that $y \notin S$. Using this interpretation, we can upper bound $\Phi(S)$ by the probability mass of states that are near the boundary of S in the state space, since the process must escape in one step. Therefore, it follows from the independent paths boundary condition and the definition of S that

$$\Phi(S) \leq \Pr\left(\text{there exists a path in } x \text{ deviating by at least } 4n^{3/4} \mid x \in S\right).$$

Next, we use a union bound over the $2\ell + 1$ different paths in a configuration and consider the event that a particular path γ_k deviates by at least $4n^{3/4}$. Because all of the paths in S are independent, we only need to consider the behavior of γ_k in isolation. This allows us to rephrase the conditional event. Relaxing the conditional probability of each term in the sum gives

$$\begin{aligned} \Phi(S) &\leq \sum_{k=-\ell}^{\ell} \Pr\left(\gamma_k \text{ deviates by at least } 4n^{3/4} \mid x \in S\right) \\ &= \sum_{k=-\ell}^{\ell} \Pr\left(\gamma_k \text{ deviates by at least } 4n^{3/4} \mid \gamma_k \text{ deviates by less than } 8n^{3/4}\right) \\ &\leq \sum_{k=-\ell}^{\ell} \frac{\Pr(\gamma_k \text{ deviates by at least } 4n^{3/4})}{1 - \Pr(\gamma_k \text{ deviates by at least } 8n^{3/4})}. \end{aligned}$$

For large enough n , the length of every path γ_k is in the range $[n, 2n]$ since we eventually have $n - \ell d \geq n/2$. Therefore, we can apply Lemma 5 with the error $\varepsilon/2$ to each term and use the universal upper bound

$$\frac{\Pr(\gamma_k \text{ deviates by at least } 4n^{3/4})}{1 - \Pr(\gamma_k \text{ deviates by at least } 8n^{3/4})} \leq \frac{e^{-(1-\frac{\varepsilon}{2})\frac{16n^{3/2}}{\mu n}}}{1 - e^{-(1-\frac{\varepsilon}{2})\frac{64n^{3/2}}{\mu n}}} \leq 2e^{-(1-\frac{\varepsilon}{2})\frac{16n^{3/2}}{\mu n}}.$$

It follows from the union bound and previous inequality that the conductance $\Phi(S)$ is bounded by

$$\Phi(S) \leq (2\ell + 1) \cdot 2e^{-(1-\frac{\varepsilon}{2})\frac{16n^{3/2}}{\mu n}} \leq e^{-(1-\varepsilon)\mu^{-1}n^{1/2}},$$

which completes the proof. ◀

► **Theorem 11.** *Let $\mu, \varepsilon > 0$ and $\lambda > 1 + \mu$. For n sufficiently large, $\tau(1/4) \geq e^{(1-\varepsilon)\mu^{-1}n^{1/2}}$.*

Proof. Since $\pi(S) \leq 1/2$ by Lemma 9, we have $\Phi^* \leq \Phi(S)$. The proof follows from Theorem 3 and the conductance bound in Lemma 10 with a smaller error $\varepsilon/2$. ◀

Last, we restate our main theorem and use Theorem 11 to show that Glauber dynamics for the six-vortex model can be slow mixing for all parameters in the ferroelectric phase.

► **Theorem 1 (Ferroelectric phase).** *For any $(a, b, c) \in \mathbb{R}_{>0}^3$ such that $a > b + c$ or $b > a + c$, there exist boundary conditions for which Glauber dynamics mixes exponentially slowly on Λ_n .*

Proof. Without loss of generality, we reparameterized the model so that $a = \lambda$, $b = \mu$, and $c = 1$. Therefore, Glauber dynamics with the independent paths boundary condition is slow mixing if $a > b + c$ by Theorem 11. Since the rotational invariance of the six-vertex model implies that a and b are interchangeable parameters, this mixing time result also holds in the case $b > a + c$. ◀

4 Slow Mixing in the Antiferroelectric Phase

Now we consider the mixing time of Glauber dynamics in the antiferroelectric phase, where $c > a + b$ and corners (type- c vertices) are preferred. The main insight behind our slow mixing proof is that when c is sufficiently large, the six-vertex model can behave like the low-temperature hardcore model on \mathbb{Z}^2 where configurations predominantly agree with one of two ground states. Liu recently formalized this argument in [28] and showed that Glauber dynamics for the six-vertex model with free boundary conditions requires exponential time when $\max(a, b) < \mu c$, where $\mu \leq 2.639$ is the connective constant of self-avoiding walks on the square lattice [17]. His proof uses a Peierls argument based on topological obstructions introduced by Randall [35] in the context of independent sets. We extend Liu's result to the region depicted in Figure 2b by computing a closed-form multivariate generating function that upper bounds the number of self-avoiding walks and accounts for disparities in their Boltzmann weights induced by the parameters of the six-vertex model.

4.1 Topological Obstruction Framework

We start with a recap of the definitions and framework laid out in [28]. There are two ground states in the antiferroelectric phase such that every interior vertex is a corner: x_R (Figure 4a) and x_G (Figure 4b). These configurations are edge reversals of each other, so for any $x \in \Omega$ we can color its edges *red* if they are oriented as in x_R or *green* if they are oriented as in x_G . See Figure 4c for an example. It follows from case analysis of the six vertex types (Figure 1) that the number of red edges incident to any internal vertex is even, and if there are only two red edges then they must be rotationally adjacent to each other. The same property holds for green edges by symmetry. Note that the four edges bounding a cell of the lattice are monochromatic if and only if they are oriented cyclically, and thus reversible by Glauber dynamics. We say that a simple path from a horizontal edge on the left boundary of Λ_n to a horizontal edge on the right boundary is a *red horizontal bridge* if it contains only red edges. We define green horizontal bridges and monochromatic vertical bridges similarly. A configuration has a *red cross* if it contains both a red horizontal bridge and a red vertical bridge, and we define a *green cross* likewise. Let $C_R \subseteq \Omega$ be the set of all states with a red cross, and let $C_G \subseteq \Omega$ be the set of all states with a green cross. We have $C_R \cap C_G = \emptyset$ by Lemma 12.

■ **Figure 4** Edge colorings of (a) the red ground state x_R , (b) the green ground state x_G , and (c) an example configuration with free boundary conditions that does not have a monochromatic cross.

Next, we define the dual lattice L_n to describe configurations in $\Omega \setminus (C_R \cup C_G)$. The vertices of L_n are the centers of the cells in Λ_n , including the cells on the boundary that are partially enclosed, and we connect dual vertices by an edge if their corresponding cells are diagonally adjacent. Note that L_n is a union of two disjoint graphs (Figure 5a). For any state $x \in \Omega$ there is a corresponding dual subgraph L_x defined as follows: for each interior vertex v in Λ_n , if v is incident to two red edges and two green edges, then L_x contains the dual edge passing through v that separates the two red edges from the two green edges. This construction is well-defined because the red edges are rotationally adjacent. See Figure 5b for an example. For any $x \in \Omega$, we say that x has a *horizontal fault line* if L_x contains a simple path from a left dual boundary vertex to a right dual boundary vertex. We define horizontal fault lines similarly and let $C_{FL} \subseteq \Omega$ be the set of all states containing a horizontal or vertical fault line. Observe that fault lines completely separate red and green edges, and hence are topological obstructions that prohibit monochromatic bridges.

■ **Figure 5** Illustrations of (a) the dual lattice L_n as a union of disjoint cyan and purple subgraphs, (b) an example configuration overlaid with its dual graph, and (c) the example under the injective fault line map.

Last, we extend the notion of fault lines to *almost fault lines*. We say that $x \in \Omega$ has a horizontal almost fault line if there is a simple path in L_n connecting a left dual boundary vertex to a right dual boundary vertex such that all edges except for one are in L_x . We define vertical almost fault lines similarly and let the set $C_{AFL} \subseteq \Omega$ denote all states containing an almost fault line. Finally, let $\partial C_R \subseteq \Omega$ denote the set of states not in C_R that one move away from C_R in the state space according to the Glauber dynamics.

► **Lemma 12** ([28]). *We can partition the state space into $\Omega = C_R \cup C_{FL} \cup C_G$. Furthermore, we have $\partial C_R \subseteq C_{FL} \cup C_{AFL}$.*

4.2 Weighted Non-Backtracking Walks and a Peierls Argument

In this subsection we show that $\pi(C_{FL} \cup C_{AFL})$ is an exponentially small bottleneck in the state space Ω . The analysis relies on Lemma 12 and a new multivariate upper bound for weighted self-avoiding walks (Lemma 13). Our key observation is that when a fault line changes direction, the vertices in its path change from type- a to type- b or vice versa. Therefore, our goal in this subsection is to generalize the trivial 3^{n-1} upper bound for the number of self-avoiding walks by accounting for their changes in direction in aggregate. We achieve this by using generating functions to solve a system of linear recurrence relations.

We start by encoding *non-backtracking walks* that start from the origin and take their first step northward using the characters in $\{S, L, R\}$, representing straight, left, and right steps. For example, the walk SLRSSL corresponds uniquely to the sequence

$((0, 0), (0, 1), (-1, 1), (-1, 2), (-1, 3), (-1, 4), (-2, 4))$. If a fault line is the same shape as SLRSSL up to a rotation about the origin, then there are only two possible sequences of vertex types through which it can pass: $abaaab$ and $babbba$. This follows from the fact that once the first vertex type is determined, only turns in the self-avoiding walk (i.e., the L and R characters) cause the vertex type to switch. We define the weight of a fault line to be the product of the vertex types through which it passes. More generally, we define the weight of a non-backtracking walk that initially passes through a fixed vertex type to be the product of the induced vertex types according to the rule that turns toggle the current type. Formally, we let $g_a(\gamma) : \{S\} \times \{S, L, R\}^{n-1} \rightarrow \mathbb{R}$ denote the weight of a non-backtracking walk γ that starts by crossing a type- a vertex. We define the function $g_b(\gamma)$ similarly and note that $g_a(\text{SLRSSL}) = a^4b^2$ and $g_b(\text{SLRSSL}) = a^2b^4$. Last, observe that a sequence of vertex types can have many different walks in its preimage. The non-backtracking walk SRRSSR also maps to $abaaab$ and $babbba$ – in fact, there are $2^3 = 8$ such walks in this example since we can interchange L and R characters.

The idea of enumerating the preimages of a binary string corresponding to sequence of vertex types suggests a recursive approach for computing the sum of weighted non-backtracking walks. This naturally leads to the use of generating functions, so overload the variables x and y to also denote function arguments. For nonempty binary string $s \in \{0, 1\}^n$, let $h(s)$ count the number of pairs of adjacent characters that are not equal and let $|s|$ denote the number of ones in s (e.g., if $s = 010001$ then $h(s) = 3$ and $|s| = 2$). The sum of weighted self-avoiding walks is upper bounded by the sum of weighted non-backtracking walks, so we proceed by analyzing the following function:

$$F_n(x, y) \stackrel{\text{def}}{=} \sum_{\gamma \in \{S\} \times \{S, L, R\}^{n-1}} g_x(\gamma) + g_y(\gamma) = \sum_{s \in \{0, 1\}^n} 2^{h(s)} x^{|s|} y^{n-|s|}. \tag{3}$$

Note that $F_n(1, 1) = 2 \cdot 3^{n-1}$ recovers the number of non-backtracking walks that initially cross type- a or type- b vertices. We compute a closed-form solution for $F_n(x, y)$ in the full version [13] by diagonalizing a matrix corresponding to the system of recurrence relations, which allows us to accurately capture the discrepancy between fault lines when the Boltzmann weights a and b differ.

► **Lemma 13.** *Let $F_n(x, y)$ be the generating function for weighted non-backtracking walks defined in (3). For any integer $n \geq 1$ and $x, y \in \mathbb{R}_{>0}$, we have*

$$F_n(x, y) \leq 3(x + y) \left(\frac{x + y + \sqrt{x^2 + 14xy + y^2}}{2} \right)^{n-1}.$$

We are now ready to present our Peierls argument to bound $\pi(C_{\text{FL}} \cup C_{\text{AFL}})$, which gives us a bound on the conductance and allows us to prove Theorem 2. First, we describe which antiferroelectric parameters cause $F_n(a/c, b/c)$ to decrease exponentially fast.

► **Lemma 14.** *If $(a, b, c) \in \mathbb{R}_{>0}^3$ is antiferroelectric and $3ab + ac + bc < c^2$, then we have $a + b + \sqrt{a^2 + 14ab + b^2} < 2c$.*

► **Lemma 15.** *If $(a, b, c) \in \mathbb{R}_{>0}^3$ is antiferroelectric and $3ab + ac + bc < c^2$, for free boundary conditions we have*

$$\pi(C_{\text{FL}} \cup C_{\text{AFL}}) \leq \text{poly}(n) \left(\frac{a + b + \sqrt{a^2 + 14ab + b^2}}{2c} \right)^n.$$

Proof. For any self-avoiding walk γ and dual vertices $s, t \in L_n$ on the boundary, let $\Omega_{\gamma, s, t} \subseteq \Omega$ be the set of states containing γ as a fault line or an almost fault line such that γ starts at s and ends at t . Without loss of generality, assume that the (almost) fault line is vertical. Reversing the direction of all edges on the left side of γ defines the injective map $f_{\gamma, s, t} : \Omega_{\gamma, s, t} \rightarrow \Omega \setminus \Omega_{\gamma, s, t}$ such that if γ is a fault line of $x \in \Omega_{\gamma, s, t}$, then the weight of its image $f_{\gamma, s, t}(x)$ is amplified by $c^{|\gamma|}/g_a(\gamma)$ or $c^{|\gamma|}/g_b(\gamma)$. See Figure 5c for an example. Similarly, if γ is an almost fault line, decompose γ into subpaths γ_1 and γ_2 separated by a type- c vertex such that γ_1 starts at s and γ_2 ends at t . In this case, the weight of the images of almost fault lines is amplified by a factor of $\min(a, b)/c \cdot c^{|\gamma_1|+|\gamma_2|}/(g_\alpha(\gamma_1)g_\beta(\gamma_2))$ for some $(\alpha, \beta) \in \{a, b\}^2$. Using the fact that $f_{\gamma, s, t}$ is injective and summing over the states containing γ as a fault line and an almost fault line separately gives us

$$\pi(\Omega_{\gamma, s, t}) \leq \frac{g_a(\gamma) + g_b(\gamma)}{c^{|\gamma|}} + \frac{c}{\min(a, b)} \sum_{\gamma_1 + \gamma_2 = \gamma} \frac{g_a(\gamma_1) + g_b(\gamma_1)}{c^{|\gamma_1|}} \cdot \frac{g_a(\gamma_2) + g_b(\gamma_2)}{c^{|\gamma_2|}}, \quad (4)$$

where the sum is over all $\Theta(|\gamma|)$ decompositions of γ into γ_1 and γ_2 .

Equipped with (4) and Lemma 13, we use a union bound over all pairs of terminals (s, t) and fault line lengths ℓ to upper bound $\pi(C_{\text{FL}} \cup C_{\text{AFL}})$ in terms of our generating function for weighted non-backtracking walks $F_\ell(x, y)$. Since the antiferroelectric weights satisfy $3ab + ac + bc < c^2$, it follows from Lemma 14 that

$$\begin{aligned} \pi(C_{\text{FL}} \cup C_{\text{AFL}}) &\leq \sum_{(s, t)} \sum_{\ell=n}^{n^2} \left(F_\ell(a/c, b/c) + \frac{c}{\min(a, b)} \sum_{k=0}^{\ell} F_k(a/c, b/c) F_{\ell-k}(a/c, b/c) \right) \\ &\leq \sum_{(s, t)} \sum_{\ell=n}^{n^2} \text{poly}(\ell) \left(\frac{a + b + \sqrt{a^2 + 14ab + b^2}}{2c} \right)^\ell \\ &\leq \text{poly}(n) \left(\frac{a + b + \sqrt{a^2 + 14ab + b^2}}{2c} \right)^n. \end{aligned}$$

Note that the convolutions in the first inequality generate all *almost* weighted non-backtracking walks. \blacktriangleleft

► **Theorem 2 (Antiferroelectric phase).** *For any $(a, b, c) \in \mathbb{R}_{>0}^3$ such that $ac + bc + 3ab < c^2$, Glauber dynamics mixes exponentially slowly on Λ_n with free boundary conditions.*

Proof of Theorem 2. Let $\Omega_{\text{MIDDLE}} = C_{\text{FL}} \cup C_{\text{AFL}}$, $\Omega_{\text{LEFT}} = C_{\text{R}} \setminus \Omega_{\text{MIDDLE}}$, and $\Omega_{\text{RIGHT}} = C_{\text{G}} \setminus \Omega_{\text{MIDDLE}}$. It follows from Lemma 12 that $\Omega = \Omega_{\text{LEFT}} \cup \Omega_{\text{MIDDLE}} \cup \Omega_{\text{RIGHT}}$ is a partition with the properties that $\partial\Omega_{\text{LEFT}} \subseteq \Omega_{\text{MIDDLE}}$ and $\pi(\Omega_{\text{LEFT}}) = \pi(\Omega_{\text{RIGHT}})$. Since the partition is symmetric, Lemma 15 implies that $1/4 \leq \pi(\Omega_{\text{LEFT}}) \leq 1/2$, for n sufficiently large. Therefore, we can upper bound the conductance by $\Phi^* \leq \Phi(\Omega_{\text{LEFT}}) \leq 4\pi(\Omega_{\text{MIDDLE}})$. Using Theorem 3 with Lemma 15 and Lemma 14 gives the desired mixing time bound. \blacktriangleleft

A Tail Behavior of Correlated Random Walks

In this section we prove Lemma 8, which gives an exponentially small upper bound for the tail of a correlated random walk as a function of its momentum parameter μ . Our proof builds off of the PDF for the position of a correlated random walk given as Lemma 4, which is combinatorial in nature and not readily amenable for tail inequalities. Specifically, the probability $\Pr(S_{2n} = 2m)$ is a sum of marginals conditioned on the number of turns that the walk makes [37].

There are two main ideas in our approach to develop a more useful bound for the position of a correlated random walk $\Pr(S_{2n} = 2m)$. First, we construct a smooth function that upper bounds the marginals as a function of x (a continuation of the number of turns in the walk k), and then we determine its maximum value. Next we show that the log of the maximum value is asymptotically equivalent to $m^2/(\mu n)$ for $m = o(n)$, which gives us desirable bounds

for sufficiently large values of n . We point out that this analysis illustrates precisely how correlated random walks generalize simple symmetric random walks and how the momentum parameter μ controls the exponential decay.

A.1 Upper Bounding the Marginal Probabilities

We start by using Stirling's approximation to construct a smooth function that upper bounds the marginal terms in the sum of the PDF for correlated random walks. For $x \in (0, n - m)$, let

$$f(x) \stackrel{\text{def}}{=} \begin{cases} 1 & \text{if } x = 0, \\ \frac{(n+m)^{n+m}}{x^x (n+m-x)^{n+m-x}} \cdot \frac{(n-m)^{n-m}}{x^x (n-m-x)^{n-m-x}} \cdot \mu^{-2x} & \text{if } x \in (0, n - m), \\ \mu^{-2(n-m)} & \text{if } x = n - m. \end{cases} \quad (5)$$

It can easily be checked that $f(x)$ is continuous on all of $[0, n - m]$ since $\lim_{x \rightarrow 0} x^x = 1$.

► **Lemma 16.** *For any integer $m \geq 0$, a correlated random walk satisfies*

$$\Pr(S_{2n} = 2m) \leq \text{poly}(n) \sum_{k=0}^{n-m} \left(\frac{\mu}{1+\mu} \right)^{2n} f(k).$$

Proof. Consider the probability density function for $\Pr(S_{2n} = 2m)$ in Lemma 4. If $2m = 2n$ the claim is clearly true, so we focus on the other case. We start by bounding the rightmost polynomial term in the sum. For all $n \geq 1$, we have $n(1-p) + k(2p-1) \leq 2nk$. Next, we reparameterize the marginals in terms of μ , where $p = \mu/(1+\mu)$, and use a more convenient upper bound for the binomial coefficients. Observe that

$$\begin{aligned} \Pr(S_{2n} = 2m) &\leq 2n \sum_{k=1}^{n-m} \binom{n+m-1}{k-1} \binom{n-m-1}{k-1} \left(\frac{1}{1+\mu} \right)^{2k-1} \left(\frac{\mu}{1+\mu} \right)^{2n-1-2k} \\ &\leq \text{poly}(n) \sum_{k=0}^{n-m} \binom{n+m}{k} \binom{n-m}{k} \left(\frac{\mu}{1+\mu} \right)^{2n} \mu^{-2k}. \end{aligned}$$

Stirling's approximation states that for all $n \geq 1$ we have $e(n/e)^n \leq n! \leq en(n/e)^n$, so we can bound the products of binomial coefficients up to a polynomial factor by

$$\begin{aligned} \binom{n+m}{k} \binom{n-m}{k} &\leq \text{poly}(n) \cdot \frac{\left(\frac{n+m}{e} \right)^{n+m}}{\left(\frac{k}{e} \right)^k \left(\frac{n+m-k}{e} \right)^{n+m-k}} \cdot \frac{\left(\frac{n-m}{e} \right)^{n-m}}{\left(\frac{k}{e} \right)^k \left(\frac{n-m-k}{e} \right)^{n-m-k}} \\ &= \text{poly}(n) \cdot \frac{(n+m)^{n+m}}{k^k (n+m-k)^{n+m-k}} \cdot \frac{(n-m)^{n-m}}{k^k (n-m-k)^{n-m-k}}. \end{aligned}$$

The proof follows the definition of $f(x)$ given in (5). ◀

There are polynomially-many marginal terms in the sum of the PDF, so if the maximum term is exponentially small, then the total probability is exponentially small. Since the marginal terms are bounded above by an expression involving $f(x)$, we can proceed by maximizing $f(x)$ on its support.

► **Lemma 17.** *The function $f(x)$ is maximized at the critical point*

$$x^* = \begin{cases} \frac{n^2 - m^2}{2n} & \text{if } \mu = 1, \\ \frac{n}{1-\mu^2} \left(1 - \sqrt{\mu^2 + (1-\mu^2) \frac{m^2}{n^2}} \right) & \text{otherwise.} \end{cases}$$

37:18 Slow Mixing of Glauber Dynamics for the Six-Vortex Model in the Ordered Phases

Proof. We start by showing that $f(x)$ is log-concave on $(0, n - m)$, which implies that it is unimodal. It follows that a local maximum of $f(x)$ is a global maximum. Since n and k are fixed as constants and because the numerator is positive, it is sufficient to show that

$$\begin{aligned} g(x) &= -\log(x^x(n+m-x)^{n+m-x} \cdot x^x(n-m-x)^{n-m-x} \cdot \mu^{2x}) \\ &= -(2x \log(\mu x) + (n+m-x) \log(n+m-x) + (n-m-x) \log(n-m-x)) \end{aligned}$$

is concave. Observe that the first derivative of $g(x)$ is

$$\begin{aligned} g'(x) &= -2(1 + \log(\mu x)) + (1 + \log(n+m-x)) + (1 + \log(n-m-x)) \\ &= -2 \log(\mu x) + \log(n+m-x) + \log(n-m-x), \end{aligned}$$

and the second derivative is

$$g''(x) = -\frac{2}{x} - \frac{1}{n+m-x} - \frac{1}{n-m-x}.$$

Because $g''(x) < 0$ on $(0, n - m)$, the function $f(x)$ is log-concave and hence unimodal.

To identify the critical points of $f(x)$, it suffices to determine where $g'(x) = 0$ since $\log x$ is increasing. Using the previous expression for $g'(x)$, it follows that

$$g'(x) = \log \left[\frac{(n-x)^2 - m^2}{\mu^2 x^2} \right]. \quad (6)$$

Therefore, the critical points are the solutions of $(n-x)^2 - m^2 = \mu^2 x^2$, so we have

$$x^* = \begin{cases} \frac{n^2 - m^2}{2n} & \text{if } \mu = 1, \\ \frac{n - \sqrt{n^2 - (1 - \mu^2)(n^2 - m^2)}}{1 - \mu^2} & \text{otherwise.} \end{cases}$$

It remains and suffices to show that x^* is a local maximum since $f(x)$ is unimodal. Observing that $\frac{\partial}{\partial x} \log f(x) = g'(x)$ and differentiating $f(x) = \exp(\log f(x))$ using the chain rule, the definition of x^* gives

$$f''(x^*) = e^{\log f(x^*)} \left[g''(x^*) + g'(x^*)^2 \right] = f(x^*) g''(x^*).$$

We know $f(x^*) > 0$, so $f''(x^*)$ has the same sign as $g''(x^*) < 0$. Therefore, x^* is a local maximum of $f(x)$. Using the continuity of $f(x)$ on $[0, n - m]$ and log-concavity, $f(x^*)$ is a global maximum. ◀

A.2 Asymptotic Behavior of the Maximum Log Marginal

Now that we have a formula for x^* , and hence an expression for $f(x^*)$, we want to show that

$$\left(\frac{\mu}{1 + \mu} \right)^{2n} f(x^*) \leq e^{-n^c},$$

for some constant $c > 0$. Because there are polynomially-many marginals in the sum, this leads to an exponentially small upper bound for $\Pr(S_{2n} = 2m)$. Define the *maximum log marginal* to be

$$h(n) \stackrel{\text{def}}{=} -\log \left[\left(\frac{\mu}{1 + \mu} \right)^{2n} f(x^*) \right]. \quad (7)$$

Equivalently, we show that $h(n) \geq n^c$ for sufficiently large n using asymptotic equivalences.

► **Lemma 18.** *The maximum log marginal $h(n)$ can be symmetrically expressed as*

$$h(n) = (n + m) \log \left[\left(\frac{1 + \mu}{\mu} \right) \left(1 - \frac{x^*}{n + m} \right) \right] + (n - m) \log \left[\left(\frac{1 + \mu}{\mu} \right) \left(1 - \frac{x^*}{n - m} \right) \right].$$

Proof. Grouping the terms of $h(n)$ by factors of n , m and x^* gives

$$n \log \left[\left(\frac{1 + \mu}{\mu} \right)^2 \frac{(n - x^*)^2 - m^2}{(n + m)(n - m)} \right] + m \log \left[\frac{(n - m)(n + m - x^*)}{(n + m)(n - m - x^*)} \right] + x^* \log \left[\frac{(\mu x^*)^2}{(n - x^*)^2 - m^2} \right].$$

Using (6), observe that the last term is

$$x^* \log \left[\frac{(\mu x^*)^2}{(n - x^*)^2 - m^2} \right] = -x^* g'(x^*) = 0.$$

The proof follows by grouping the terms of the desired expression by factors of n and m . ◀

The following lemma is the crux of our argument, as it presents an asymptotic equality for the maximum log marginal in the PDF for correlated random walks. We remark that we attempted to bound this quantity directly using Taylor expansions instead of an asymptotic equivalence, and while this seems possible, the expressions are unruly. Our asymptotic equivalence demonstrates that second derivative information is needed, which makes the earlier approach even more unmanageable.

► **Lemma 19.** *For $\mu > 0$ and $m = o(n)$, the maximum log marginal satisfies $h(n) \sim m^2/(\mu n)$.*

Proof. The proof is by case analysis for μ . In both cases we analyze $h(n)$ as expressed in Lemma 18, consider a change of variables, and use L'Hospital's rule twice. In the first case, we assume $\mu = 1$. The value of x^* in Lemma 17 gives us

$$1 - \frac{x^*}{n + m} = \frac{2n(n + m) - (n^2 - m^2)}{2n(n + m)} = \frac{n + m}{2n}$$

$$1 - \frac{x^*}{n - m} = \frac{2n(n - m) - (n^2 - m^2)}{2n(n - m)} = \frac{n - m}{2n}.$$

It follows that $h(n)$ can be simplified as

$$h(n) = n \log \left[\left(\frac{1 + \mu}{\mu} \right)^2 \left(\frac{n^2 - m^2}{4n^2} \right) \right] + m \log \left(\frac{n + m}{n - m} \right) = n \log \left(1 - \frac{m^2}{n^2} \right) + m \log \left(1 + \frac{2m}{n - m} \right).$$

To show $h(n) \sim m^2/n$, by the definition of asymptotic equivalence we need to prove that

$$\lim_{n \rightarrow \infty} \frac{n \log \left(1 - \frac{m^2}{n^2} \right) + m \log \left(1 + \frac{2m}{n - m} \right)}{\frac{m^2}{n}} = 1.$$

Make the change of variables $y = m/n$. Since $m = o(n)$, this is equivalent to showing

$$\lim_{y \rightarrow 0} \frac{\log(1 - y^2) + y \log \left(1 + \frac{2y}{1 - y} \right)}{y^2} = 1.$$

Using L'Hospital's rule twice with the derivatives

$$\frac{\partial}{\partial y} \left[\log(1 - y^2) + y \log \left(1 + \frac{2y}{1 - y} \right) \right] = \log \left(-\frac{y + 1}{y - 1} \right)$$

$$\frac{\partial^2}{\partial y^2} \left[\log(1 - y^2) + y \log \left(1 + \frac{2y}{1 - y} \right) \right] = \frac{2}{1 - y^2},$$

it follows that

$$\lim_{y \rightarrow 0} \frac{\log(1-y^2) + y \log\left(1 + \frac{2y}{1-y}\right)}{y^2} = \lim_{y \rightarrow 0} \frac{\log\left(\frac{-y+1}{y-1}\right)}{2y} = \lim_{y \rightarrow 0} \frac{\frac{2}{1-y^2}}{2} = 1.$$

This completes the proof for $\mu = 1$.

The case when $\mu \neq 1$ is analogous but messier. Making the same change of variables $y = m/n$, it is equivalent to show that

$$(1+y) \log \left[\left(\frac{1+\mu}{\mu} \right) \left(1 - \frac{1}{1-\mu^2} \cdot \frac{1}{1+y} \cdot \left(1 - \sqrt{\mu^2 + (1-\mu^2)y^2} \right) \right) \right] \\ + (1-y) \log \left[\left(\frac{1+\mu}{\mu} \right) \left(1 - \frac{1}{1-\mu^2} \cdot \frac{1}{1-y} \cdot \left(1 - \sqrt{\mu^2 + (1-\mu^2)y^2} \right) \right) \right] \sim \mu^{-1}y^2, \quad (8)$$

because the value of x^* for $\mu \neq 1$ in Lemma 17 gives us

$$1 - \frac{x^*}{n+m} = 1 - \frac{1}{n+m} \cdot \frac{n}{1-\mu^2} \cdot \left(1 - \sqrt{\mu^2 + (1-\mu^2)\frac{m^2}{n^2}} \right).$$

Denoting the left-hand side of (8) by $g(y)$, one can verify the first two derivatives of $g(y)$ are

$$g'(y) = \log \left(\frac{\mu^2 - \sqrt{\mu^2 - \mu^2 y^2 + y^2} + (\mu^2 - 1)y}{(\mu - 1)\mu(y + 1)} \right) - \log \left(\frac{-\mu^2 + \sqrt{\mu^2 - \mu^2 y^2 + y^2} + (\mu^2 - 1)y}{(\mu - 1)\mu(y - 1)} \right) \\ g''(y) = \frac{2}{(1+y)(1-y)\sqrt{y^2 - \mu^2(y^2 - 1)}}.$$

Observing that $g(0) = g'(0) = 0$ due to cancellations and using L'Hospital's rule twice,

$$\lim_{y \rightarrow 0} \frac{g(y)}{\mu^{-1}y^2} = \lim_{y \rightarrow 0} \frac{g'(y)}{2\mu^{-1}y} = \lim_{y \rightarrow 0} \frac{2}{(1+y)(1-y)\sqrt{y^2 - \mu^2(y^2 - 1)}} \cdot \frac{\mu}{2} = 1.$$

This completes the proof for all cases of μ . ◀

► **Lemma 8.** *Let $\mu, \varepsilon > 0$ and $m = o(n)$. For n sufficiently large, a correlated random walk satisfies $\Pr(S_{2n} = 2m) \leq e^{-(1-\varepsilon)\frac{m^2}{\mu n}}$.*

Proof. For n sufficiently large, the asymptotic equality for $h(n)$ in Lemma 19 gives us

$$h(n) \geq \left(1 - \frac{\varepsilon}{2}\right) \frac{m^2}{\mu n}.$$

It follows from our construction of $f(x)$ and the definition of the maximum log marginal that

$$\Pr(S_{2n} = 2m) \leq \text{poly}(n) \cdot \left(\frac{\mu}{1+\mu}\right)^{2n} f(x^*) \\ = \text{poly}(n) \cdot e^{-h(n)} \\ \leq \text{poly}(n) \cdot e^{-(1-\frac{\varepsilon}{2})\frac{m^2}{\mu n}} \\ \leq e^{-(1-\varepsilon)\frac{m^2}{\mu n}},$$

as desired. ◀

Lifted Multiplicity Codes and the Disjoint Repair Group Property

Abstract

Lifted Reed Solomon Codes (Guo, Kopparty, Sudan 2013) were introduced in the context of locally correctable and testable codes. They are multivariate polynomials whose restriction to any line is a codeword of a Reed-Solomon code. We consider a generalization of their construction, which we call *lifted multiplicity codes*. These are multivariate polynomial codes whose restriction to any line is a codeword of a multiplicity code (Kopparty, Saraf, Yekhanin 2014). We show that lifted multiplicity codes have a better trade-off between redundancy and a notion of locality called the t -disjoint-repair-group property than previously known constructions. More precisely, we show that, for $t \leq \sqrt{N}$, lifted multiplicity codes with length N and redundancy $O(t^{0.585}\sqrt{N})$ have the property that any symbol of a codeword can be reconstructed in t different ways, each using a disjoint subset of the other coordinates. This gives the best known trade-off for this problem for any super-constant $t < \sqrt{N}$. We also give an alternative analysis of lifted Reed Solomon codes using dual codes, which may be of independent interest.

Acknowledgements We thank Eitan Yaakobi for helpful conversations. We thank Julien Lavauzelle for pointing out the reference [26] and also for pointing out an error in an earlier version of this paper. We thank Nikita Polianskii for pointing out an error in an earlier version of this paper. A previous version claimed that a lifted code is exactly the span of all good monomials, but in fact the span of all good monomials only forms a subset of the lifted code (see Remark 18). This does not change our main result, as our lower bound on the number of good monomials still gives the same lower bound on the rate of the lifted code. We thank anonymous reviewers for helpful comments on an earlier draft of this paper.

1 Introduction

In this work we study *lifted multiplicity codes*, and show how they provide improved constructions of codes with the t -disjoint repair group property (t -DRGP), a notion of locality in error correcting codes.

An *error correcting code* of length N over an alphabet Σ is a set $\mathcal{C} \subseteq \Sigma^N$. There are several desirable properties in error correcting codes, and in this paper we study the trade-off between two of them. The first is the size of \mathcal{C} , which we would like to be as big as possible given N . The second desirable property is *locality*. Informally, a code \mathcal{C} exhibits locality if, given (noisy) access to $c \in \mathcal{C}$, one can learn the i 'th symbol c_i of c in sublinear time. As we discuss more below, locality arises in a number of areas, from distributed storage to complexity theory.

Two constructions of codes with locality are *lifted codes* [6] and *multiplicity codes* [15]; in fact, both of these constructions were among the first known high-rate Locally Correctable Codes. In this work, consider a combination of the two ideas in *lifted multiplicity codes*, and we show that these codes exhibit locality beyond what's known for either lifted codes or for multiplicity codes.

More precisely, we study a particular notion of locality called the *t-disjoint-repair-group property* (*t-DRGP*). Informally, we say that \mathcal{C} has the *t-DRGP* if any symbol c_i of $c \in \mathcal{C}$ can be obtained in t different ways, each of which involves a disjoint set of coordinates of c . Formally, we have the following definition.

► **Definition 1.** *A code $\mathcal{C} \subseteq \Sigma^N$ has the t -disjoint repair property if for every $i \in [N]$, there is a collection of t disjoint subsets $S_1, \dots, S_t \subseteq [N] \setminus \{i\}$, and functions f_1, \dots, f_t so that for all $c \in \mathcal{C}$ and for all $j \in [t]$, $f_j(c|_{S_j}) = c_i$. The sets S_1, \dots, S_t are called repair groups.*

As discussed more in Section 1.1 below, the *t-DRGP* naturally interpolates between many different notions of locality. The *t-DRGP* is well-studied both when $t = O(1)$ is small (where it is related to Locally Repairable Codes and nearly equivalently to Private Information Retrieval Codes) and $t = \Omega(N)$ is large (where it is equivalent to Locally Correctable Codes). For this reason, it is natural to study the *t-DRGP* when t is intermediate; for example, when $t = N^a$ for $a \in (0, 1)$. In this case, it is possible for the size of the code $|\mathcal{C}|$ to be quite large: more precisely, it is possible for the *rate* $R = \frac{\log_{|\Sigma|} |\mathcal{C}|}{N}$ to approach 1 (notice that we always have $|\mathcal{C}| \leq |\Sigma|^N$, hence we always have $R \leq 1$). Thus, the goal is to understand exactly how quickly the rate can approach 1. That is, given t , how small can the *redundancy* $N - RN$ be?

Several works have tackled this question, and we illustrate previous results in Figure 1. Our main result is that lifted multiplicity codes improve on the best-known trade-offs for all super-constant $t \leq \sqrt{N}$.

Contributions

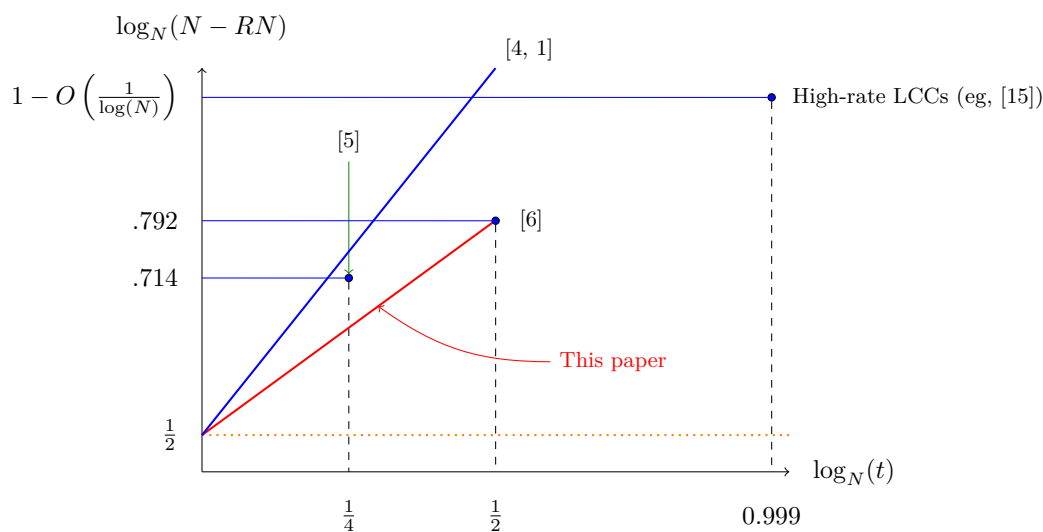

We summarize the main contributions of this work below.

1. For $t \leq \sqrt{N}$, we construct codes with the *t-DRGP* and redundancy at most

$$O\left(t^{\log_2(3)-1} \sqrt{N}\right) \approx O\left(t^{0.585} \sqrt{N}\right).$$

This gives the best known construction for all t so that $t = \omega(1)$ and $t \leq \sqrt{N}$; the only previous result that held non-trivially for a range of t was redundancy $O(t\sqrt{N})$ [4, 2, 1] and our result also surpasses the specialized bound for $t = N^{1/4}$ of [5]. Moreover, both our argument and our construction are quite clean.

2. We give a new analysis of bivariate lifts of multiplicity codes. Both multiplicity codes and lifted codes have been studied before (even in the context of the *t-DRGP*), but to the best of our knowledge the only work to consider lifted multiplicity codes is [26]. That work studies m -variate lifts of multiplicity codes, where m is large; its goal is to obtain new constructions of high-rate locally correctable codes. In the context of our discussion, this corresponds to the *t-DRGP* when $t = N^{0.99}$. In contrast, for bivariate lifts, we are able to obtain more refined bounds which lead to improved results for the *t-DRGP* when $t \leq \sqrt{N}$.

■ **Figure 1** The best trade-offs known between the number t of disjoint repair groups and the redundancy $N - RN$. Blue points and lines indicate upper bounds (possibility results), and the red line indicates our upper bound. The best lower bound (impossibility result) available is that we must have $\log_N((1 - R)N) \geq 1/2$ for any $t \geq 2$, and this is shown as the dotted orange line.

Organization

In the remainder of the introduction, we survey related work and give an overview of our approach. In Section 2, we give the formal definitions about polynomials and derivatives that we need. In Section 3, we formally define lifted multiplicity codes. In Section 4, we prove that lifted multiplicity codes have high rate, and in Section 5, we prove that they have the t -DRGP, which gives rise to our main theorem, Theorem 2.

1.1 Background and Related Work

1.1.1 Disjoint Repair Groups

The t -DRGP and related notions have been studied both implicitly and explicitly across several communities. When $t = O(1)$ is small, several notions related to the t -DRGP have been studied, motivated primarily by distributed storage. These include codes for Private Information Retrieval (PIR) [4, 2, 1], Locally Repairable Codes (LRCs) with availability [23, 18, 21, 22], and batch codes [10, 19, 1]. In more detail, PIR codes are basically equivalent to codes with the DRGP, with the slight difference that PIR codes generally require that every message symbol should be recoverable by many disjoint repair groups, rather than every codeword symbol. LRCs with availability are a slightly stronger notion where the disjoint repair groups should additionally be small. Batch codes are also a slightly stronger notion, where one should be able to access any t -tuple of symbols (possibly with repetition) in t disjoint ways. We refer the reader to [20] for a survey of these notions.

To see why the t -DRGP might be relevant for distributed storage, consider a setting where some data is encoded as $c \in \mathcal{C}$, and then each c_i is sent to a separate server. If server i is later unavailable, we might want to reconstruct c_i without contacting too many other servers. This can be done if each symbol has one small repair group; this is the defining

property of LRCs. Now suppose that several (say, $t - 1$) servers are unavailable. If \mathcal{C} has the t -DRGP then all $t - 1$ unavailable symbols can be locally reconstructed: each node has at least t disjoint repair groups and at most $t - 1$ of them have been compromised.

On the other hand, when $t = \Omega(N)$ is large, the t -DRGP has been studied in the context of Locally Decodable Codes and Locally Correctable Codes (LDCs/LCCs). In fact, the $\Omega(N)$ -DRGP is equivalent to a constant-query LCC, and the notion has been used to prove impossibility results for such codes [11, 24].

Because of these motivations, there are several constructions of t -DRGP codes for a wide range of t ; we illustrate the relevant ones in Figure 1. In the context of coded PIR, [4, 2, 1] give constructions of t -DRGP codes with redundancy $O(t\sqrt{N})$. This is known to be tight for $t = 2$ [17, 25], but no better lower bound is known.¹ When $t = \Omega(N)$ is very large, constructing codes with the t -DRGP is equivalent to constructing constant-query LCCs, and it is known that the rate of the code must tend to zero [24]. On the other hand, for any $\epsilon > 0$, when $t = O(N^{1-\epsilon})$ is just slightly smaller, then work on high-rate LCCs [15, 6, 8, 14] (see also [1]) imply that there are codes with rate 0.99 (or any constant less than 1) with the t -DRGP.²

When $t = \sqrt{N}$, there are a few constructions known that beat the $O(t\sqrt{N})$ bound mentioned above, including difference-set codes (see, e.g., [16]) and, relevant for us, lifted parity-check codes [6]. These constructions achieve redundancy $N^{\log_4(3)} \approx N^{0.79}$ when $t = \sqrt{N}$. In Appendix B, we include a new proof of the fact that the lifted codes of [6] have this redundancy using a dual view of lifted codes.

When $t < \sqrt{N}$, there is only one construction known which beats the $O(t\sqrt{N})$ bound, due to [5]. For the special case of $t = N^{1/4}$, they give a construction based on “partially lifted codes” which has redundancy $O(N^{0.72}) = O(t^{0.88}\sqrt{N})$.

1.1.2 Lifting and multiplicity codes

Lifted multiplicity codes are based on lifted codes and multiplicity codes, both of which have a long history in the study of locality in error correcting codes.

1.1.2.1 Lifted Codes

Lifting was introduced by Guo, Kopparty and Sudan in [6]. The basic idea can be illustrated by Reed-Solomon (RS) codes. An RS code of degree d over \mathbb{F}_q is the code

$$\text{RS}_{d,q} = \{(f(x_1), \dots, f(x_q)) : f \in \mathbb{F}_q[X], \deg(f) < d\},$$

where x_1, \dots, x_q are the elements of \mathbb{F}_q . There is a natural multi-variate version of RS codes, known as Reed-Muller codes:

$$\text{RM}_{d,q,m} = \{(f(\mathbf{x}_1), \dots, f(\mathbf{x}_q^m)) : f \in \mathbb{F}_q[X_1, \dots, X_m], \deg(f) < d\},$$

where $\mathbf{x}_1, \dots, \mathbf{x}_q^m$ are the elements of \mathbb{F}_q^m . Reed-Muller codes have a very nice locality property, which is that the restriction of a RM codeword to a line in \mathbb{F}_q^m yields an RS codeword. This fact has been taken advantage of extensively in applications like local decoding, local list-decoding and property testing. However, RM codes have a downside,

¹ When the size s of the repair groups is bounded, it is known that the redundancy must be at least $\Omega(N \ln(t)/s)$ [22].

² In fact we may even take ϵ slightly sub-constant using the construction of [14].

which is that if $d < q$ (required for the above property to kick in), they have very low rate. With this inspiration, we could ask for the set \mathcal{C} which contains evaluations of *all* m -variate polynomials which restrict to low-degree univariate polynomials on every line. Surprisingly, [6] showed that this set \mathcal{C} can be much larger than the corresponding RM code! This code \mathcal{C} is called a *lifted* Reed-Solomon code, and the main structural result of [6] is that \mathcal{C} is the span of the monomials whose restrictions to lines are low-degree. This property is key when analyzing the rate of these codes. Moreover [6] showed that this is the case when we begin with *any* affine-invariant code, not just RS codes.

The original motivation for lifted codes was to construct LCCs, but [6] actually also give a code with the \sqrt{N} -DRGP, mentioned above; we give an alternate proof that this construction has the \sqrt{N} -DRGP in Appendix B. A variant of lifting was also used in [5] to construct $N^{1/4}$ -DRGP codes; however, the analysis of this construction is quite brittle and seems difficult to extend to non-trivial constructions for $t \neq N^{1/4}$.

1.1.2.2 Multiplicity Codes

Multiplicity codes were introduced by Kopparty, Saraf and Yekhanin [15] with the goal of constructing high-rate LCCs. The basic idea of multiplicity codes is to get around the low rate of RM codes discussed above in a different way, by appending derivative information to allow for higher-degree polynomials. That is, it is not useful to have an RS code with degree $d > q$, since $x^q = x$ for any $x \in \mathbb{F}_q$. However, if we replace the single evaluation $f(x)$ with a vector of evaluations $(f(x), f^{(1)}(x), \dots, f^{(r-1)}(x))$, where $f^{(i)}$ denotes the i 'th derivative, then it does make sense to take $d > q$. The m -variate multiplicity code $\text{Mult}_{d,q,m,r}$ of degree d and order r over \mathbb{F}_q is then defined similarly to $\text{RM}_{d,q,m}$:

$$\text{Mult}_{d,q,m,r} = \left\{ (f^{(<r)}(\mathbf{x}_1), \dots, f^{(<r)}(\mathbf{x}_{q^m})) : f \in \mathbb{F}_q[X_1, \dots, X_m], \deg(f) < d \right\},$$

where $f^{(<r)}(\mathbf{x}) \in \mathbb{F}_q^{\binom{m+r-1}{m}}$ is a vector containing all of the partial derivatives of f of order less than r , evaluated at \mathbf{x} . Since their introduction, multiplicity codes have found several uses beyond LCCs, including list-decoding [12, 7], and have even been used to explicitly construct codes with the t -DRGP [1].

1.1.2.3 Lifted Multiplicity Codes

To the best of our knowledge, the only work to study lifted multiplicity codes is the work of Wu [26]. The goal of that work is to obtain versions of multiplicity codes which are still high-rate LCCs but which require lower-order derivatives than the construction of [15]. The main result is that lifted multiplicity codes of rate $1 - \alpha$ are LCCs with locality N^ϵ (this corresponds roughly to having the t -DRGP with $t = O(N^{1-\epsilon})$). However, since the number of variables in the lift is large, it is hard to get a very precise handle on the codimension, and in particular the codimension of the code in that work is not shown to be $o(N)$.

In contrast, we study bivariate lifts of multiplicity codes. By focusing only on bivariate lifts, we are able to get a more precise handle on the codimension of lifted multiplicity codes, which gives results for the t -DRGP for $t \leq \sqrt{N}$.

We note that the construction in [26] is similar to the construction presented here. Since this construction is somewhat non-trivial (for reasons discussed below), we include the details.

1.2 Our approach

We study lifted multiplicity codes to obtain improved constructions of codes with the t -DRGP. We focus on bivariate lifts in this paper in order to obtain codes with t -DRGP for $t \leq \sqrt{N}$. We expect that lifted multiplicity codes in more than two variables also give better codes for the t -DRGP when $t > \sqrt{N}$.

1.2.1 Definition of lifted multiplicity codes

It is not immediately obvious how to apply lifting (and in particular, the nice characterization of it developed in [6] as the span of “good” monomials) to univariate multiplicity codes. We first note that the univariate multiplicity code $\text{Mult}_{d,q,1,r} \subseteq (\mathbb{F}_q^r)^q$ does not fit the affine-invariant framework of [6], so their results do not immediately apply. Instead, we might try to define the bivariate lift of $\text{Mult}_{d,q,1,r}$ as the set of vectors $(f^{(<r)}(\mathbf{x}_1), \dots, f^{(<r)}(\mathbf{x}_{q^2}))$ for all polynomials f so that every restriction of f to a line agrees with some polynomial of degree less than d on its first $r - 1$ derivatives; that is, the restriction of f is *equivalent up to order r* to a polynomial of degree less than d . This works, but there are two non-trivial things to deal with.

1. First, in order to get a handle on the rate of the code, as in [6] we show that the set of valid polynomials f includes the span of a large set of “good” monomials. In contrast to [6], the good monomials in this work do not span the entire code. However, lower bounding the number of good monomials, which in turns gives a lower bound on the rate of the code, turns out to be enough for our results.
2. Second, we need to take some care about what monomials we allow. With lifted RS codes, one only allows monomials $X^a Y^b$ with individual degrees $a, b < q$; otherwise, we could have multiple monomials which correspond to the same codeword which leads to problems if we are counting monomials in order to understand the dimension of the code. As we show in Lemma 14, it turns out that with multiplicity codes, we should only allow monomials $X^a Y^b$ with $\lfloor a/q \rfloor + \lfloor b/q \rfloor < r$; otherwise, we would have multiple monomials the correspond to the same codeword and this would create similar problems.

Dealing with these issues leads us to the final code and rate analysis, where we define the lifted multiplicity code to be all polynomials spanned by monomials $X^a Y^b$ with $\lfloor a/q \rfloor + \lfloor b/q \rfloor < r$, such that the restriction of the polynomial to a line is equivalent up to order r to some univariate polynomial of degree less than d . We then lower bound the number of evaluations of monomials in this code, giving a lower bound on the rate. We note that the work [26] considers a similar construction.

1.2.2 Lifted multiplicity codes have the t -DRGP

In Corollary 21 we give a lower bound on the number of (q, r, d) -good monomials, and this leads to a lower bound on the dimension of the lifted multiplicity code; crucially, this can be quite a bit bigger than the dimension of the corresponding multivariate multiplicity code.

Finally, we observe that lifted multiplicity codes have the t -DRGP for a range of values of t . Similarly to previous constructions based on multivariate polynomial codes, the disjoint repair groups to recover the symbol $f^{(<r)}(\mathbf{x})$ are given by disjoint collections of lines through \mathbf{x} . More precisely, the values $f^{(<r)}(\mathbf{y})$ for the set of \mathbf{y} that lie on r distinct lines through \mathbf{x} can be used to recover $f^{(<r)}(\mathbf{x})$. Thus, the number of disjoint repair groups is $q/r = \sqrt{N}/r$. By adjusting r , we obtain the trade-off shown in Figure 1. Our main theorem is as follows.

► **Theorem 2.** For $q = 2^\ell$ and $r = 2^{\ell'}$ with $1 \leq \ell' \leq \ell$, there exists a code \mathcal{C} over $\mathbb{F}_q^{\binom{r+1}{2}}$ with the following properties.

- The length of the code is q^2 .
- The rate of the code is at least

$$1 - \frac{3r^{\log_2(8/3)} q^{\log_2(3)}}{\binom{r+1}{2} q^2},$$

so that the redundancy is at most

$$\frac{3r^{\log_2(8/3)} q^{\log_2(3)}}{\binom{r+1}{2}}.$$

- The code has the q/r -disjoint repair group property.

As a remark, our techniques can also recover any symbol from any one of its repair groups in polynomial time. For any $\gamma \in [0, 1]$, choosing $q = 2^\ell$ and $r = 2^{\ell'}$ with $\gamma \approx \ell'/\ell$ gives a code with length $N = q^2$ and redundancy at most

$$6N^{\log_4(3) - \gamma(1 - \log_4(8/3))}$$

with the $N^{(1-\gamma)/2}$ -DRGP. This is made formal in the following corollary.

► **Corollary 3.** For any $\epsilon > 0$, there are infinitely many N so that, for $t = \lfloor N^\epsilon \rfloor$, there exists a code of length N which has the t -DRGP and redundancy at most $6t^{\log_2(3)-1} \sqrt{N}$.

We note that Theorem 2 also yields results for constant t , not just for $t = N^\epsilon$ as presented in Corollary 3. For example, by setting $r = q/2$ we obtain a code with the 2-DRGP and redundancy at most $9\sqrt{N}$. The constant 9 is not optimal here (the optimal constant for $t = 2$ is known to be $\sqrt{2}$ [17]), but to the best of our knowledge, Theorem 2 does yield the best known bounds for any super-constant t .

2 Preliminaries

In this section, we introduce the background we need on polynomials and derivatives over finite fields. Throughout this paper, we assume that q is a power of 2. Let \mathbb{F}_q denote the finite field of order q , and let \mathbb{F}_q^* denote its multiplicative subgroup.

If a and b are nonnegative integers with binary representations $a = \overline{a_{\ell-1} \cdots a_0}$ and $b = \overline{b_{\ell-1} \cdots b_0}$, then we write $a \leq_2 b$ if $a_i \leq b_i$ for $i = 0, \dots, \ell - 1$. If a is an integer, let $(a \bmod c)$ denote the element of $\{0, \dots, c - 1\}$ congruent to $a \bmod c$. We write $a \leq_2^\ell b$ if $(a \bmod 2^\ell) \leq_2 (b \bmod 2^\ell)$.

As in [6], we use Lucas's theorem.

► **Proposition 4** (Lucas's theorem). Let p be a prime and $a = \overline{a_{\ell-1} \cdots a_0}, b = \overline{b_{\ell-1} \cdots b_0}$ be written in base p . Then

$$\binom{a}{b} \equiv \prod_{i=0}^{\ell-1} \binom{a_i}{b_i} \pmod{p} \tag{1}$$

In particular, if $p = 2$, then $\binom{a}{b} \equiv 1 \pmod{p}$ if and only if $a \leq_2 b$.

2.1 Polynomials and derivatives

For a vector $\mathbf{i} = (i_1, \dots, i_m)$ of nonnegative integers, its *weight*, denoted $\text{wt}(\mathbf{i})$, equals $\sum_{k=1}^m i_k$. For a field \mathbb{F} , let $\mathbb{F}[X_1, \dots, X_m] = \mathbb{F}[\mathbf{X}]$ be the ring of polynomials in the variables X_1, \dots, X_m with coefficients in \mathbb{F} . For a vector of nonnegative integers $\mathbf{i} = (i_1, \dots, i_m)$ and a vector $\mathbf{X} = (X_1, \dots, X_m)$ of variables, let $\mathbf{X}^{\mathbf{i}}$ denote the monomial $\prod_{j=1}^m X_j^{i_j} \in \mathbb{F}[\mathbf{X}]$, and for a vector $\mathbf{a} = (\alpha_1, \dots, \alpha_m) \in \mathbb{F}^m$, let $\mathbf{a}^{\mathbf{i}}$ denote the value $\prod_{j=1}^m \alpha_j^{i_j}$, where $0^0 \stackrel{\text{def}}{=} 1$. For nonnegative vectors $\mathbf{i} = (i_1, \dots, i_m)$ and $\mathbf{j} = (j_1, \dots, j_m)$, we write $\mathbf{i} \leq \mathbf{j}$ if $i_k \leq j_k$ for all k . We also write $\binom{\mathbf{i}+\mathbf{j}}{\mathbf{i}}$ to denote $\prod_{k=1}^m \binom{i_k+j_k}{i_k}$. For nonnegative vector \mathbf{i} , we let $[\mathbf{X}^{\mathbf{i}}]P(\mathbf{X})$ denote the coefficient of $\mathbf{X}^{\mathbf{i}}$ in the polynomial $P(\mathbf{X})$.

We will use Hasse derivatives, a notion of derivatives over finite fields:

► **Definition 5** (Hasse derivatives). *For $P(\mathbf{X}) \in \mathbb{F}[\mathbf{X}]$ and a nonnegative vector \mathbf{i} , the i -th (Hasse) derivative of P , denoted $P^{(\mathbf{i})}(\mathbf{X})$ or $D^{(\mathbf{i})}P(\mathbf{X})$, is the coefficient of $\mathbf{Z}^{\mathbf{i}}$ in the polynomial $\tilde{P}(\mathbf{X}, \mathbf{Z}) \stackrel{\text{def}}{=} P(\mathbf{X} + \mathbf{Z}) \in \mathbb{F}[\mathbf{X}, \mathbf{Z}]$. Thus,*

$$P(\mathbf{X} + \mathbf{Z}) = \sum_{\mathbf{i}} P^{(\mathbf{i})}(\mathbf{X}) \mathbf{Z}^{\mathbf{i}}. \quad (2)$$

For $\mathbf{x} \in \mathbb{F}_q^m$ and $P(\mathbf{X}) \in \mathbb{F}_q[\mathbf{X}]$, we use the notation $P^{(<r)}(\mathbf{x}) \in \mathbb{F}_q^{\binom{m+r-1}{m}}$ to denote the vector containing $P^{(\mathbf{i})}(\mathbf{x})$ for all \mathbf{i} so that $\text{wt}(\mathbf{i}) < r$. We record a few useful (well-known) properties of Hasse derivatives below (see [9]).

► **Proposition 6** (Properties of Hasse derivatives). *Let $P(\mathbf{X}), Q(\mathbf{X}) \in \mathbb{F}[\mathbf{X}]^m$ and let \mathbf{i}, \mathbf{j} be vectors of nonnegative integers. Then*

1. $P^{(\mathbf{i})}(\mathbf{X}) + Q^{(\mathbf{i})}(\mathbf{X}) = (P + Q)^{(\mathbf{i})}(\mathbf{X})$.
2. $(P \cdot Q)^{(\mathbf{i})}(\mathbf{X}) = \sum_{\mathbf{0} \leq \mathbf{e} \leq \mathbf{i}} P^{(\mathbf{e})}(\mathbf{X}) \cdot Q^{(\mathbf{i}-\mathbf{e})}(\mathbf{X})$.
3. $(P^{(\mathbf{i})})^{(\mathbf{j})}(\mathbf{X}) = \binom{\mathbf{i}+\mathbf{j}}{\mathbf{i}} P^{(\mathbf{i}+\mathbf{j})}$.

Using the above, we obtain the following useful derivative computation, and we provide a proof in Appendix A for completeness.

► **Proposition 7.** *Let $1 \leq r < q$ with q a power of 2, and let $P(X) = (X^q - X)^r$. Then,*

$$P^{(i)}(X) = \begin{cases} \binom{r}{i} (X^q - X)^{r-i} & 0 \leq i \leq r \\ 0 & i > r \end{cases} \quad (3)$$

2.2 Polynomial local recovery

A key property exploited by earlier work on multiplicity codes [15, 13] is that $f^{(<r)}(\mathbf{x})$ can be recovered from $f^{(<q)}(\mathbf{y})$ for \mathbf{y} that lie on a collection of lines through \mathbf{x} . More precisely, let \mathcal{L}_m be the set of lines $L(T)$ of the form $\mathbf{a}T + \mathbf{b}$ with $\mathbf{a}, \mathbf{b} \in \mathbb{F}_q^m$. Given a multivariate polynomial $P(\mathbf{X}) \in \mathbb{F}_q[X_1, \dots, X_m]$, if L is the line $\mathbf{a}T + \mathbf{b}$, let $P_L(T) \in \mathbb{F}_q[T]$ denote the univariate polynomial $P(\mathbf{a}T + \mathbf{b})$. Let \mathcal{L} be the set of lines in \mathbb{F}_q^2 of the form $L(T) = (T, \alpha T + \beta)$ for $\alpha, \beta \in \mathbb{F}_q$.

For simplicity – and because it is enough for our application to the t -DRGP – we will consider only bivariate polynomials in this paper, although (see for example [13]) the same basic idea works for any m . We will further specialize to lines in \mathcal{L} – that is, lines of the form $L(T) = (T, \alpha T + \beta)$ – because it will simplify some computations later in the paper. With these restrictions, we can specialize Equation (4) of [13] to obtain the following relationship between the derivatives of $P_L(T)$ and the derivatives of $P(X, Y)$.

► **Lemma 8** (Follows from, e.g., [15, 13]). *Suppose that L_1, \dots, L_r are r lines in \mathcal{L} all passing through a point (γ, δ) , with L_k being the line $(T, \alpha_k T + \beta_k)$. Then, for all polynomials $P(X, Y) \in \mathbb{F}_q[X, Y]$, the following matrix equality holds for all $i = 0, \dots, r - 1$.*

$$\begin{bmatrix} P_{L_1}^{(i)}(\gamma) \\ P_{L_2}^{(i)}(\gamma) \\ \vdots \\ P_{L_{i+1}}^{(i)}(\gamma) \end{bmatrix} = \begin{bmatrix} \alpha_1^0 & \alpha_1^1 & \cdots & \alpha_1^i \\ \alpha_2^0 & \alpha_2^1 & \cdots & \alpha_2^i \\ \vdots & \vdots & \ddots & \vdots \\ \alpha_{i+1}^0 & \alpha_{i+1}^1 & \cdots & \alpha_{i+1}^i \end{bmatrix} \begin{bmatrix} P^{(i,0)}(\gamma, \delta) \\ P^{(i-1,1)}(\gamma, \delta) \\ \vdots \\ P^{(0,i)}(\gamma, \delta) \end{bmatrix}. \tag{4}$$

When lines L_1, \dots, L_k are distinct, the middle matrix in (4) is a Vandermonde matrix, and Vandermonde matrices are invertible in polynomial time. Hence, we immediately have the following corollary.

► **Corollary 9.** *Suppose that L_1, \dots, L_r are r distinct lines of the form $L_k(T) = (T, \alpha_k T + \beta_k)$ all passing through a point $(\gamma, \delta) \in \mathbb{F}_q^2$. For a polynomial $P(X, Y) \in \mathbb{F}_q[X, Y]$, given the polynomials $P_{L_1}(T), \dots, P_{L_r}(T)$, the derivatives $P^{(i)}(\gamma, \delta)$ are uniquely determined and computable efficiently for all \mathbf{i} such that $\text{wt}(\mathbf{i}) < r$.*

3 Lifted multiplicity codes

In this section, we define lifted multiplicity codes. As noted in the introduction, we restrict our attention to bivariate codes because this is enough for our application to the t -DRGP. However, everything in this section extends to general m -variate codes. We define bivariate lifted multiplicity codes as the vectors $(f^{(<r)}(\mathbf{x}))_{\mathbf{x} \in \mathbb{F}_q^2}$ for polynomials $f(X)$ that live in the span of “good” monomials. In order to define these “good” monomials, we need a few more definitions.

3.1 Polynomial equivalence

We first define a notion of polynomial equivalence.

► **Definition 10.** *We say that two univariate polynomials $A(X), B(X) \in \mathbb{F}_q[X]$ are equivalent up to order r , written $A \equiv_r B$, if $A^{(i)}(\gamma) = B^{(i)}(\gamma)$ for all $i = 0, \dots, r - 1$ and $\gamma \in \mathbb{F}_q$.*

It is easy to see that the above definition does in fact give an equivalence relation. There is a simple way to characterize this equivalence.

► **Lemma 11.** *For $A(X), B(X) \in \mathbb{F}_q[X]$ we have $A(X) \equiv_r B(X)$ if and only if $(X^q - X)^r | A(X) - B(X)$.*

Proof. By considering the polynomial $A(X) - B(X)$, it suffices to prove $A(X)$ is equivalent to the zero polynomial up to order r if and only if $(X^q - X)^r | A(X)$. If $A(X) = (X^q - X)^r C(X)$ for some polynomial $C(X) \in \mathbb{F}_q[X]$, then, by part 2 of Proposition 6 and Proposition 7, for $0 \leq i < r$, we have $X^q - X | A^{(i)}(X)$, so $A^{(i)}(\gamma) = 0$ for all $0 \leq i < r$ and all $\gamma \in \mathbb{F}_q$, so $A(X) \equiv_r 0$.

Conversely, suppose that $A(X) \equiv_r 0$. By the definition of Hasse derivatives, we have $A(X) = A(\gamma + (X - \gamma)) = \sum_i A^{(i)}(\gamma)(X - \gamma)^i$. Since $A^{(i)}(\gamma) = 0$ for $i = 0, \dots, r - 1$, we have $(X - \gamma)^r | A(X)$. Thus is true for all γ , so $\prod_{\gamma} (X - \gamma)^r | A(X)$, so $(X^q - X)^r | A(X)$. ◀

Lemma 11 gives the following corollary.

► **Lemma 12.** *Let q be a power of 2 and $r \geq 1$. For every univariate polynomial $A(X)$, there exists a unique degree-at-most $rq - 1$ polynomial $B(X)$ such that $A(X) \equiv_r B(X)$. Furthermore, if r is a power of 2, then for all a such that $\deg A - (qr - r) < a < qr$, we have $[X^a]A(X) = [X^a]B(X)$.*

Proof. For existence of $B(X)$, note that, by Lemma 11, we can subtract an appropriate multiple of $(X^q - X)^r$ from $A(X)$ to obtain the desired $B(X)$. For uniqueness of $B(X)$, suppose that $B_1(X)$ and $B_2(X)$ are equivalent to $A(X)$ up to order r and are of degree at most $rq - 1$. By Lemma 11, we have $(X^q - X)^r | B_1(X) - B_2(X)$. Additionally, $B_1(X) - B_2(X)$ has degree at most $rq - 1$, so $B_1(X) - B_2(X) = 0$.

Now suppose r is a power of 2. Then $(X^q - X)^r = X^{rq} + X^r$. Above, to obtain $B(X)$ from $A(X)$, we need only to subtract terms of the form $X^{qr} + X^r, X^{qr+1} + X^{r+1}, \dots, X^{\deg A} + X^{\deg A - qr + r}$. Thus, for a such that $\deg A - qr + r < a < qr$, the coefficients of X^a in $A(X)$ and $B(X)$ are equal. ◀

3.2 Type- r polynomials

Define the order- r evaluation map $\text{eval}_{q,r} : \mathbb{F}_q[X, Y] \rightarrow \left(\mathbb{F}_q^{\binom{r+1}{2}} \right)^{q^2}$ by

$$\text{eval}_{q,r}(P) := (P^{(<r)}(\mathbf{x}))_{\mathbf{x} \in \mathbb{F}_q^2}, \quad (5)$$

We will want to restrict our attention to a subset of monomials $M(X, Y) = X^a Y^b$ whose order- r evaluations $\text{eval}_{q,r}(M)$ form a basis for the space $\{\text{eval}_{q,r}(P) : P \in \mathbb{F}_q[X, Y]\}$. To that end, we introduce the following definition.

► **Definition 13** (Type- r monomials). *Call a monomial $X^a Y^b$ type- r if $\lfloor a/q \rfloor + \lfloor b/q \rfloor \leq r - 1$. Let $\mathcal{F}_{q,r}$ be the family of polynomials $P \in \mathbb{F}_q[X, Y]$ that are spanned by type- r monomials.*

It is easy to see that $\mathcal{F}_{q,r}$ is a dimension $\binom{r+1}{2} q^2$ vector space over \mathbb{F}_q . We now show that the type- r polynomials form a basis for bivariate polynomials, up to order r equivalence.

► **Lemma 14.** *The evaluation map $\text{eval}_{q,r} : \mathcal{F}_{q,r} \rightarrow \left(\mathbb{F}_q^{\binom{r+1}{2}} \right)^{q^2}$ is a bijection.*

Proof of Lemma 14. Since $\text{eval}_{q,r}$ is a linear map and $\mathcal{F}_{q,r}$ and $\mathbb{F}_q^{\binom{r+1}{2} q^2}$ have the same \mathbb{F}_q dimension, it suffices to prove the map has trivial kernel. We prove by induction.

Base Case: $r = 1$. Suppose $P \in \mathcal{F}_{q,1}$ and $\text{eval}_1(P)$ is the 0-vector. Then $P(X, Y) = 0$ for all X, Y . For any $\delta \in \mathbb{F}_q$, the polynomial $P(X, \delta) \in \mathbb{F}_q[X]$ has degree at most $q - 1$ but has q roots, so the polynomial must be 0. Hence, $(Y - \delta) | P(X, Y)$ for all δ , so $Y^q - Y | P(X, Y)$, which implies $P = 0$. This proves that eval_1 has trivial kernel.

Inductive step. Assume $r \geq 1$ and $\text{eval}_{q,r}$ has trivial kernel. We prove that $\text{eval}_{q,r+1}$ has trivial kernel.

Assume $P(X, Y)$ is a polynomial spanned by type- $(r+1)$ monomials with all i th derivatives equal to 0 for $\text{wt}(\mathbf{i}) < r + 1$. Let $\delta \in \mathbb{F}_q$ and $B_\delta(X) \stackrel{\text{def}}{=} P(X, \delta)$. Then, for $0 \leq i < r$, we have $B_\delta^{(i)}(\gamma) = B^{(i,0)}(\gamma, \delta) = 0$ for all $\gamma \in \mathbb{F}_q$. Hence, for all $\gamma \in \mathbb{F}_q$, we have $(X - \gamma)^r | B_\delta(X)$. Hence, $(X^q - X)^r | B_\delta(X)$. Since $\deg B_\delta(X) \leq \deg_X P(X, Y) < qr$ for all δ , we have $B_\delta(X) = 0$. Thus, $P(X, \delta)$ is the 0 polynomial for all δ , so $Y - \delta | P(X, Y)$ for all δ , so $Y^q - Y | P(X, Y)$. Hence, we may write $P(X, Y) = (Y^q - Y)Q(X, Y)$ for some polynomial $Q(X, Y) \in \mathbb{F}_q[X, Y]$.

As polynomial P is type- $(r + 1)$, polynomial Q is type- r : if Q had a nonzero coefficient for $X^a Y^b$ with $\lfloor a/q \rfloor + \lfloor b/q \rfloor > r - 1$, then the coefficient $X^a Y^{b+a}$ is nonzero in P , which is a contradiction. For all i, j with $i \geq 0, j \geq 1$ and $i + j \leq r$, we have

$$P^{(i,j)}(X, Y) = (Y^q - Y)Q^{(i,j)}(X, Y) - Q^{(i,j-1)}(X, Y). \tag{6}$$

Here we applied part 2 of Proposition 6 and the $r = 1$ case of Proposition 7. At every X and Y , the left side is 0 by assumption on P and the right side $Q^{(i,j-1)}(X, Y)$. We conclude that $Q^{(i',j')}$ evaluates to 0 everywhere for every nonnegative i' and j' satisfying $i' + j' \leq r - 1$. Since Q is type- r , we have $Q = 0$ by the induction hypothesis, so $P = 0$. This completes the induction, completing the proof. ◀

3.3 Definition of lifted multiplicity codes

Finally we are ready to define lifted multiplicity codes, which we define as the set of evaluations $\text{eval}_{q,r}(P)$ of polynomials whose restrictions to lines³ are equivalent, up to order r , to a low degree polynomial:

► **Definition 15** (Lifted multiplicity codes, first definition). *The (q, r, d) (bivariate) lifted multiplicity code is a code \mathcal{C} over alphabet $\Sigma = \mathbb{F}_q^{\binom{r+1}{2}}$ of length q^2 given by*

$$\mathcal{C} = \left\{ \text{eval}_{q,r}(P) : \begin{array}{l} P \in \mathbb{F}_q[X, Y] \text{ and, for any } L(T) \in \mathcal{L}, \\ P(L(T)) \equiv_r Q(T) \text{ for some } Q \in \mathbb{F}_q[T] \text{ of degree at} \\ \text{most } d. \end{array} \right\}$$

Definition 15 is natural but difficult to get a handle on directly. Following the approach of previous work [6, 5], we observe that lifted multiplicity code contains the set of vectors $\text{eval}_{q,r}(P)$ for P that lie in the span of a set of “good” monomials, which makes it easier to bound the rate. Informally, a monomial is (q, r, d) -good if its restriction along every line is equivalent, up to order r , to a polynomial of degree at most d .

► **Definition 16** ((q, r, d) -good monomials). *Call a monomial $M_{a,b}(X, Y) = X^a Y^b \in \mathbb{F}_q[X, Y]$ (q, r, d) -good (or simply good, when r and d are understood) if it is type- r and for every line $(T, \alpha T + \beta) \in \mathcal{L}$, the univariate polynomial $M_{a,b}(T, \alpha T + \beta)$ is equivalent, up to order r , to polynomial of degree less than d , and call it (q, r, d) -bad otherwise.*

By definition all good monomials lie in our lifted multiplicity code, so to lower bound the rate of the code it suffices to lower bound the number of good monomials.

► **Lemma 17.** *Let \mathcal{C} be the bivariate (q, r, d) lifted multiplicity code. Then, for every (q, r, d) -good monomial $M(X, Y)$, $\text{eval}_{q,r}(M) \in \mathcal{C}$, and the rate of \mathcal{C} is at least $\frac{\#(q, r, d)\text{-good monomials}}{\binom{r+1}{2}q^2}$.*

Proof. The first part follows from the definition of good monomial. For the second part, \mathcal{C} is linear and the \mathbb{F}_q -span of all good monomials have pairwise distinct evaluations by Lemma 14, so $|\mathcal{C}| \geq q^{\#(q, r, d)\text{-good monomials}}$. As \mathcal{C} is a length q^2 code over an alphabet of size $|\Sigma| = q^{\binom{r+1}{2}}$, the rate is at least $\frac{\log |\mathcal{C}|}{q^2 \log |\Sigma|} = \frac{\#(q, r, d)\text{-good monomials}}{\binom{r+1}{2}q^2}$. ◀

³ To simplify calculations, we consider restrictions to lines of the form $L(T) = (T, \alpha T + \beta)$. That is, we do not include lines of the form $L(T) = (\alpha, T)$.

► **Remark 18.** A previous version of this paper incorrectly asserted that every codeword of the lifted multiplicity code is spanned by good monomials. As observed by Nikita Polianskii, this is in fact not true. For example, when $r = 2$ and $d = 2q - 1$, the monomials $X^{2q-2}Y$ and $X^{q-1}Y^q$ are not (q, r, d) -good as verified by the line (T, T) , but their sum $X^{2q-2}Y + X^{q-1}Y^q$ is in the (q, r, d) -lifted multiplicity code: the restriction of the sum to a line $(T, \alpha T + \beta) \in \mathcal{L}$ has a T^{2q-1} coefficient of $\alpha + \alpha^q = 0$ and hence has degree strictly less than $d = 2q - 1$.

4 The rate of lifted multiplicity codes

In this section, we bound the rate (and hence, the redundancy) of lifted multiplicity codes. Our final result on the rate is Corollary 21 below, which implies that for r, q and d of an appropriate form, the lifted multiplicity code over order r and degree d over \mathbb{F}_q has rate at least

$$1 - \frac{6}{r} \left(r - \frac{d}{q} \right)^{\log_2(4/3)}.$$

In the next section, we will choose $d = qr - r$, which will yield a code of rate $1 - \frac{6}{r} \left(\frac{r}{q} \right)^{\log_2(4/3)}$ and will give us Theorem 2. We begin with a lemma that will be useful.

► **Lemma 19.** *Let $s = 2^{\ell_s}$ and $q = 2^\ell$ with $\ell_s \leq \ell$. The number of $a_1, b_1 \in \{0, 1, \dots, q - 1\}$ such that at least one of the following is true*

$$\begin{aligned} q - 1 - a_1 &\leq_2^\ell b_1 \\ q - 2 - a_1 &\leq_2^\ell b_1 \\ &\vdots \\ q - s - a_1 &\leq_2^\ell b_1 \end{aligned} \tag{7}$$

is at most $2 \cdot 3^\ell \cdot (4/3)^{\ell_s} = 2 \cdot 3^\ell \cdot s^{\log_2(4/3)}$.

Proof. Suppose we write the numbers $(q - 1 - a_1 \bmod q), (q - 2 - a_1 \bmod q), \dots, (q - s - a_1 \bmod q)$ in binary with ℓ digits (possibly with leading zeros). As these numbers span 2^{ℓ_s} consecutive integers mod q , when written in this binary form, their most significant $\ell - \ell_s$ coordinates take on at most 2 values. Let $a_2 = \lfloor \frac{(q-1-a_1 \bmod q)}{2^{\ell_s}} \rfloor$ and $b_2 = \lfloor \frac{b_1}{2^{\ell_s}} \rfloor$ so that $a_2, b_2 \in \{0, \dots, 2^{\ell-\ell_s} - 1\}$, and a_2 and b_2 are the most significant $\ell - \ell_s$ coordinates of $(q - 1 - a_1 \bmod q)$ and b_1 , respectively, when written in ℓ -digit binary. Then if one of the equations of (7) is true, then we must have either $a_2 \leq_2 b_2$ or $a_2 - 1 \leq_2 b_2$. This gives at most $2 \cdot 3^{\ell-\ell_s}$ choices for the pair (a_2, b_2) . Given a_2 and b_2 , there are 2^{ℓ_s} choices for each of a_1 and b_1 , for a total of at most $2 \cdot 3^{\ell-\ell_s} \cdot 4^{\ell_s}$ solutions to (7). ◀

► **Lemma 20.** *Let $r = 2^{\ell_r}$, $s = 2^{\ell_s}$ and $q = 2^\ell$ with $\ell_r, \ell_s \in \{1, \dots, \ell - 1\}$. The number of $(q, r, rq - s)$ -good monomials is at least $\binom{r+1}{2} 4^\ell - 3rs^{\log_2(4/3)} \cdot 3^\ell$.*

Proof. The number of type- r monomials is $\binom{r+1}{2} q^2 = \binom{r+1}{2} 4^\ell$. A monomial $M_{a,b}$ is $(q, r, rq - s)$ -good if, for every $\alpha, \beta \in \mathbb{F}_q$, we have

$$M_{a,b,\alpha,\beta}(T) \stackrel{\text{def}}{=} T^a(\alpha T + \beta)^b = \sum_{i=0}^b \alpha^i \beta^{b-i} T^{a+i} \binom{b}{i}. \tag{8}$$

can be represented as a polynomial of degree less than $rq - s$. Next, we apply Lemma 12, which says that there is a unique polynomial $B(T)$ so that $\deg(B) \leq rq - 1$ so that $B(T) \equiv_r$

$M_{a,b,\alpha,\beta}(T)$, and further that all of the coefficients $[T^c]B(T)$ for $\deg(M_{a,b,\alpha,\beta}) - (qr - r) < c < qr$ are equal to the corresponding coefficient of $B(T)$. The degree of the polynomial $M_{a,b,\alpha,\beta}$ is at most $(r + 1)q - 2$, and

$$((r + 1)q - 2) - (qr - r) = r + q - 2 < qr - s$$

for any allowed choice of q, r, s , so $[T^c]B(T) = [T^c]M_{a,b,\alpha,\beta}(T)$ for all c so that

$$qr - s \leq c \leq qr.$$

Thus, to show that $B(T)$ has degree less than $qr - s$, it suffices to show that the coefficients of $T^{qr-s}, T^{qr-s+1}, \dots, T^{qr-1}$ in $M_{a,b,\alpha,\beta}$ are all zero.

Write $a = a_0q + a_1$ and $b = b_0q + b_1$ where $a_0 + b_0 \leq r - 1$ and $0 \leq a_1, b_1 \leq q - 1$. Note that if $a_0 + b_0 < r - 1$, then for $s' = 1, \dots, s$ coefficient $[T^{rq-s'}]M_{a,b,\alpha,\beta}$ is always zero except possibly when $a_0 + b_0 = r - 2$ and $a_1 + b_1 \geq 2q - s$. This can happen for at most $\frac{rs^2}{2}$ pairs (a, b) . Hence, for $a_0 + b_0 < r - 1$, there are $\leq \frac{rs^2}{2}$ bad monomials (a, b) .

Now assume $a_0 + b_0 = r - 1$. For $s' = 1, \dots, s$, the coefficient of $T^{rq-s'}$ in $T^a(\alpha T + \beta)^b$ is 0 if $rq - s' < a$ or $a + b < rq - s'$. Otherwise, the coefficient is

$$\alpha^{rq-s'-a} \beta^{b-rq+s'+a} \binom{b}{rq-s'-a} = \alpha^{rq-s'-a} \beta^{b-rq+s'+a} \binom{b_0q + b_1}{b_0q + q - s' - a_1}. \quad (9)$$

By Proposition 4, the binomial coefficient is nonzero (mod 2) if and only if $b_0q + q - s' - a_1 \leq_2 b_0q + b_1$, which, as q is a power of 2, happens only if $q - s' - a_1 \leq_2 b_1$. Hence, if $a_0 + b_0 = r - 1$, the monomial $M_{a,b}$ is $(r, rq - s)$ -bad only if some $s' = 1, \dots, s$ satisfies $q - s' - a_1 \leq_2 b_1$. Hence, by Lemma 19, for a fixed a_0, b_0 with $a_0 + b_0 = r - 1$, there are at most $2s^{\log_2(4/3)}3^\ell$ bad monomials $M_{a,b}$, so there are at most $r \cdot s^{\log_2(4/3)}3^\ell$ bad monomials $M_{a,b}$ over all a_0, b_0 with $a_0 + b_0 = r - 1$. As we showed, there are at most $\frac{rs^2}{2}$ bad monomials when $a_0 + b_0 < r - 1$. Hence, there are at least $\binom{r+1}{2}4^\ell - 2rs^{\log_2(4/3)}3^\ell - \frac{rs^2}{2} \geq \binom{r+1}{2}q^2 - 3rs^{\log_2(4/3)}q^{\log_2(3)}$ good monomials, as desired. \blacktriangleleft

Lemma 20 and Lemma 17 together imply Corollary 21, which in turn implies the informal result stated at the beginning of the section.

► **Corollary 21.** *Let $r = 2^{\ell_r}$, $s = 2^{\ell_s}$ and $q = 2^\ell$ with $\ell_r, \ell_s \in \{1, \dots, \ell - 1\}$. A $(q, r, rq - s)$ lifted multiplicity code has rate at least $1 - 6r^{-1}s^{\log_2(4/3)}q^{\log_2(3/4)}$.*

► **Remark 22.** We apply Corollary 21 for $r = s \leq q$, giving that a lifted multiplicity code of rate at least $1 - 6r^{\log_2(2/3)}q^{\log_2(3/4)}$. By comparison [15], a 2-variate multiplicity code of order r evaluations of degree at most $rq - r$ polynomials over \mathbb{F}_q has rate $\frac{\binom{rq-r+2}{2}}{\binom{r+1}{2}q^2} \leq 1 - \Omega(\frac{1}{r})$, which is smaller than the rate of lifted multiplicity codes for $r \ll q$.

5 Disjoint repair groups of lifted multiplicity codes

Finally, we prove Theorem 2, which we repeat below.

► **Theorem (Theorem 2, restated).** *Let $r = 2^{\ell_r}$ and $q = 2^\ell$ with $\ell_r < \ell$ and \mathcal{C} be the $(q, r, rq - r)$ lifted multiplicity code.*

- *The length of the code is q^2 .*
- *The rate of the code is at least $1 - 6r^{\log_2(2/3)}q^{\log_2(3/4)}$.*
- *The code has the q/r -disjoint repair group property.*

Proof. The first item follows from the definition of \mathcal{C} , and the second item is by Corollary 21. To see the third item, we show that, given a point $(\gamma, \delta) \in \mathbb{F}_q^2$, lines L_1, \dots, L_r passing through (γ, δ) , and $P^{(<r)}(\mathbf{y})$ at all points \mathbf{y} on the lines L_1, \dots, L_r except (γ, δ) itself, we can (efficiently) recover $P^{(<r)}(\gamma, \delta)$. This guarantees the q/r -disjoint repair group property, because we can group the q lines of \mathcal{L} of the form $L(T) = (T, \alpha T + \beta)$ passing through (γ, δ) arbitrarily into groups of r , giving q/r disjoint repair groups. For any line L_k , the polynomial $P_{L_k}(T)$ has degree at most $rq - r - 1$, as P is $(q, r, qr - r)$ -good. By taking linear combinations of directional derivatives (Lemma 8), we can efficiently compute $P_{L_k}^{(i)}(\gamma')$ for every $i = 0, \dots, r - 1$, every $k = 1, \dots, r$, and every $\gamma' \neq \gamma$. We can compute $P_{L_k}(T)$ using a generalization of polynomial interpolation. This can be done in $O(D \log D)$ time, where $D < rq$ is the degree of the polynomial (see e.g. [3]). Hence, by Corollary 9, from $P_{L_1}(T), \dots, P_{L_r}(T)$, we can efficiently compute $P^{(i,j)}(\gamma, \delta)$ for all i, j with $0 \leq i + j \leq r - 1$. ◀

6 Conclusion

We conclude with some open questions.

1. We have shown that lifted multiplicity codes with redundancy $O(t^{0.585} \sqrt{N})$ have the t -DRGP for a range of $t \leq \sqrt{N}$. However, we do not know of any general lower bounds beyond the lower bound for $t = 2$ which implies that the redundancy must be at least $\Omega(\sqrt{N})$ for any t . Thus, it is an open question whether or not our bound is tight or whether one can do better.
2. Lifted multiplicity codes display better locality for the t -DRGP problem for $t \leq \sqrt{N}$; it is a natural question to ask whether they can be used for larger t , and in particular whether they could lead to improved constructions of locally correctable codes.

A Proofs of polynomial facts

Proof of Proposition 7. By part 2 of Proposition 6,

$$P^{(i)}(X) = \sum_{j_1 + \dots + j_r = i} \prod_{k=1}^r D^{(j_k)}(X^q - X). \quad (10)$$

We have $D^{(1)}(X^q - X) = 1$ (the field has characteristic 2). For $2 \leq i < q$, the i th derivative of $X^q - X$ is $\binom{q}{i} X^{q-i}$, which is 0, as $\binom{q}{i}$ is even by Proposition 4. The summand above is nonzero if and only if $j_1, j_2, \dots, j_r \leq 1$. When $i \leq r$, this happens when i of the j_k 's are 1 and $r-i$ are 0, which happens for $\binom{r}{i}$ choices of (j_1, \dots, j_r) . This gives $P^{(i)}(X) = \binom{r}{i} (X^q - X)^{r-i}$ for $0 \leq i \leq r$. When $i > r$, some j_k is at least 2, in which case $P^{(r)}(X) = 0$ for $r < i < q$. ◀

38:16 Lifted Multiplicity Codes and the Disjoint Repair Group Property

Proof of Lemma 8. Let \mathbf{a}_k denote the vector $(1, \alpha_k)$, and let \mathbf{b}_k denote the vector $(0, \beta_k)$. By assumption, we have that $\mathbf{a}_k\gamma + \mathbf{b}_k = (\gamma, \delta)$. By the definition of Hasse derivatives, we have, for all $k = 1, \dots, r$

$$\begin{aligned} P_{L_k}(T + Z) &= P(\mathbf{a}_k T + \mathbf{b}_k + \mathbf{a}_k Z) \\ &= \sum_{\mathbf{i} \in \mathbb{N}^2} P^{(\mathbf{i})}(\mathbf{a}_k T + \mathbf{b}_k) \cdot (\mathbf{a}_k Z)^{\mathbf{i}} \\ &= \sum_{\mathbf{i} \in \mathbb{N}^2} P^{(\mathbf{i})}(\mathbf{a}_k T + \mathbf{b}_k) \cdot \mathbf{a}_k^{\mathbf{i}} Z^{\text{wt}(\mathbf{i})} \\ P_{L_k}(T + Z) &= \sum_{i \geq 0} P_{L_k}^{(i)}(T) Z^i \end{aligned} \tag{11}$$

Hence, for all $i \geq 0$ and $k = 1, \dots, r$, we have

$$P_{L_k}^{(i)}(T) = \sum_{\mathbf{i}: \text{wt}(\mathbf{i})=i} P^{(\mathbf{i})}(\mathbf{a}_k T + \mathbf{b}_k) \mathbf{a}_k^{\mathbf{i}} \tag{12}$$

By plugging in $T = \gamma$, we have for all $i \geq 0$ and $k = 1, \dots, r$,

$$P_{L_k}^{(i)}(\gamma) = \sum_{\mathbf{i}: \text{wt}(\mathbf{i})=i} P^{(\mathbf{i})}(\gamma, \delta) \mathbf{a}_k^{\mathbf{i}}. \tag{13}$$

Rewriting this in matrix form gives the desired result. \blacktriangleleft

B Lifted codes via dual codes

It was shown in [6] that bivariate lifted parity-check codes over \mathbb{F}_q , where $q = 2^\ell$, have co-dimension 3^ℓ . Here, we give an alternative proof using dual codes. The techniques in this proof are not directly related to the techniques that we used in the main body of the paper, but we found this alternative proof illuminating so we include it.

Let $q = 2^\ell$. Recall \mathcal{L} is the set of lines expressible as $L(T) = (T, \alpha T + \beta)$ where $\alpha, \beta \in \mathbb{F}_q$. One way to think about codes with locality is by considering their dual code. If the code is a subset of $\mathbb{F}_q^{q \times q}$, then the dual code corresponds to lines of repair groups. Given a line $L(T)$ in \mathcal{L} , define the corresponding dual codeword:

$$(c_L^\perp)_{ij} \stackrel{\text{def}}{=} \begin{cases} 1 & (i, j) = L(t) \text{ for some } t \in \mathbb{F}_q \\ 0 & \text{o/w} \end{cases} \tag{14}$$

Let

$$V_{\mathcal{L}} \stackrel{\text{def}}{=} \text{span} \{c_L^\perp : L \in \mathcal{L}\}. \tag{15}$$

Note that $V_{\mathcal{L}}$ is spanned by 4^ℓ elements, so the trivial bound on the dimension is 4^ℓ . We give the following improved bound, matching the analysis of [6].

► Lemma 23. *The subspace $V_{\mathcal{L}}$ has dimension at most 3^ℓ .*

Proof. A codeword c_L^\perp is the evaluation of the following polynomial on $\mathbb{F}_q^{q \times q}$:

$$P_L(X, Y) \stackrel{\text{def}}{=} \prod_{\beta \neq \beta_L} (\alpha_L X + \beta - Y). \tag{16}$$

If $(X, Y) \notin L$, then the polynomial evaluates to 0 as $Y - \alpha_L X \neq \beta_L$, and otherwise it evaluates to

$$\prod_{\beta \neq \beta_L} (\beta - \beta_L) = \prod_{\beta \in \mathbb{F}_q^*} \beta = 1. \tag{17}$$

For $a + b \geq q$, the coefficient of $X^a Y^b$ in $P_L(X, Y)$ is 0. For $a + b \leq q$, the coefficient of $X^a Y^b$ in $P_L(X, Y)$ is

$$\binom{a+b}{a} \alpha_L^a (-1)^b \sum_{\substack{\beta_1, \dots, \beta_{q-1-a-b} \in \mathbb{F}_q \\ \text{distinct, } \neq \beta_L}} \prod_{j=1}^{q-1-a-b} \beta_j. \tag{18}$$

This is because we first chose $a + b$ terms that contain X or Y , then choose which terms are X and which terms are Y , and this gives us a many α_L 's and b many -1 's, and we sum over the choices of the β terms that we choose. Hence, the only a, b such that $[X^a Y^b]P_L(X, Y) \neq 0$ for any L are the pairs (a, b) such that $a + b \leq q - 1$ and $\binom{a+b}{a} \equiv 1 \pmod{2}$. There are at most 3^ℓ pairs by Proposition 4. It follows that the polynomials $P_L(X, Y)$ are spanned by 3^ℓ monomials $X^a Y^b$ with $\binom{a+b}{a} \equiv 1 \pmod{2}$. Hence, the vector space $V_{\mathcal{L}}$ is spanned by 3^ℓ dual codewords in $\mathbb{F}_q^{q \times q}$ and thus has dimension at most 3^ℓ . ◀

Revision Notice

This is a revised version of the eponymous paper that appeared in the proceedings of AP-PROX/RANDOM 2019 (LIPIcs, volume 145, <http://www.dagstuhl.de/dagpub/978-3-95977-125-2>, published in September, 2019), in which an incorrect proposition (formerly Proposition 18) and the corresponding proof (formerly Appendix B) was deleted and in which the exposition was adjusted accordingly. Previously it was claimed that the lifted code is exactly the span of all good monomials. In fact the span of good monomial forms only a subset of the lifted code.

Abstract

We study the r -complex contagion influence maximization problem. In the influence maximization problem, one chooses a fixed number of initial seeds in a social network to maximize the spread of their influence. In the r -complex contagion model, each uninfected vertex in the network becomes infected if it has at least r infected neighbors.

In this paper, we focus on a random graph model named the *stochastic hierarchical blockmodel*, which is a special case of the well-studied *stochastic blockmodel*. When the graph is not exceptionally sparse, in particular, when each edge appears with probability $\omega(n^{-(1+1/r)})$, under certain mild assumptions, we prove that the optimal seeding strategy is to put all the seeds in a single community. This matches the intuition that in a nonsubmodular cascade model placing seeds near each other creates synergy. However, it sharply contrasts with the intuition for submodular cascade models (e.g., the independent cascade model and the linear threshold model) in which nearby seeds tend to erode each others' effects.

Finally, we show that this observation yields a polynomial time dynamic programming algorithm which outputs optimal seeds if each edge appears with a probability either in $\omega(n^{-(1+1/r)})$ or in $o(n^{-2})$.

1 Introduction

A *cascade*, or a *contagion*¹, is a fundamental process on social networks: starting with some seed agents, the infection then spreads to their neighbors. A natural question known as influence maximization [4, 6, 18, 28] asks how to place a fixed number of initial seeds to maximize the spread of the resulting cascade. For example, which students can most effectively be enrolled in an intervention to decrease student conflict at a school [30]?

Influence maximization is extensively studied when the contagion process is submodular (a node’s marginal probability of becoming infected after a new neighbor is infected decreases when the number of previously infected neighbors increases [22]). However, many examples of nonsubmodular contagions have been reported, including pricey technology innovations, the change of social behaviors, the decision to participate in a migration, etc [14, 27, 31, 2, 24]. In this case, a node’s marginal influence may increase in the presence of other nodes – creating a kind of synergy.

Network structure and seed placement

We address this lack of understanding for nonsubmodular influence maximization by characterizing the optimal seed placement for certain settings which we will remark on shortly. In these settings, the optimal seeding strategy is to put all the seeds near each other. This is significantly different than in the submodular setting, where the optimal solutions tend to spread out the seeds, lest they erode each others’ influence. We demonstrate this in the appendix (Sect. A) by presenting an example of submodular influence maximization where the optimal seeding strategy is to spread out the seeds.

This formally captures the intuition, as presented by Angell and Schoenebeck [1], that it is better to target one market to saturation first (act locally) and then to allow the success in this initial market to drive broader success (think globally) rather than to initially attempt a scattershot approach (act globally). It also underscores the need to understand the particular nature of a contagion before blindly applying influence maximization tools.

We consider a well-known nonsubmodular cascade model which is also the most extreme one (in terms of nonsubmodularity), the r -complex contagion [19, 7, 8, 16] (a node is infected if and only if at least r of its neighbors are infected, also known as *bootstrap percolation*) when $r \geq 2$.

We consider networks formed by the *stochastic hierarchical blockmodel* [32, 33] which is a special case of the stochastic blockmodel [15, 20, 36] equipped with a hierarchical structure. Vertices are partitioned into m blocks. The blocks are arranged in a hierarchical structure which represents blocks merging to form larger and larger blocks (communities). The probability of an edge’s presence between two vertices is based solely on smallest block to which both the vertices belong. This model captures the intuitive hierarchical structure which is also observed in many real-world networks [17, 12]. The stochastic hierarchical blockmodel is rather general and captures other well-studied models (e.g. Erdős-Rényi random graphs, and the planted community model) as special cases.

Result 1. We first prove that, for the influence maximization problem on the stochastic hierarchical blockmodel with r -complex contagion, under certain mild technical assumptions, the optimal seeding strategy is to put all the seeds in a single community, if, for each

¹ As is common in the literature, we use these terms interchangeably.

vertex-pair (u, v) , the probability that the edge (u, v) is included satisfies $p_{uv} = \omega(n^{-(1+1/r)})$. Notice that the assumption $p_{uv} = \omega(n^{-(1+1/r)})$ captures many real life social networks. In fact, it is well-known that an Erdős-Rényi graph $\mathcal{G}(n, p)$ with $p = o(1/n)$ is globally disconnected: with probability $1 - o(1)$, the graph consists of a union of tiny connected components, each of which has size $O(\log n)$.

The technical heart of this result is a novel coupling argument in Proposition 16. We simultaneously couple four cascade processes to compare two probabilities: 1) the probability of infection spreading throughout an Erdős-Rényi graph after the $(k + 1)$ -st seed, conditioned on not already being entirely infected after k seeds; 2) the probability of infection spreading throughout the same graph after the $(k + 2)$ -nd seed, conditioned on not already being entirely infected after $k + 1$ seeds. This shows that the marginal rate of infection always goes up, revealing the “supermodular” nature of the r -complex contagion. The supermodular property revealed by Proposition 16 is a property for cascade behavior on Erdős-Rényi random graphs in general, so it is also interesting on its own.

Our result is in sharp contrast to Balkanski et al.’s observation. Balkanski et al. [3] studies the stochastic blockmodel with a well-studied submodular cascade model, *the independent cascade model*, and remarks that “when an influential node from a certain community is selected to initiate a cascade, the marginal contribution of adding another node from that same community is small, since the nodes in that community were likely already influenced.”

Algorithmic aspects

For influence maximization in submodular cascades, a greedy algorithm efficiently finds a seeding set with influence at least a $(1 - 1/e)$ fraction of the optimal [22], and much of the work following Kempe et al. [22], which proposed the greedy algorithm, has attempted to make greedy approaches efficient and scalable [10, 11, 26, 13, 35, 34].

Greedy approaches, unfortunately, can perform poorly in the nonsubmodular setting [1]. Moreover, in contrast to the submodular case which has efficient constant approximation algorithms, for general nonsubmodular cascades, it is NP-hard even to approximate influence maximization to within an $\Omega(n^{1-\epsilon})$ factor of the optimal [23]. This inapproximability result has been extended to several much more restrictive nonsubmodular models [9, 25, 32, 33]. Intuitively, nonsubmodular influence maximization is hard because the potential synergy of multiple seeds makes it necessary to consider groups of seeds rather than just individual seeds. In contrast, with submodular influence maximization, not much is lost by considering seeds one at a time in a myopic way.

Can the $\Omega(n^{1-\epsilon})$ inapproximability results of Kempe et al. [23] be circumvented if we further assume the stochastic hierarchical blockmodel? On the one hand, the stochastic hierarchical structure seems optimized for a dynamic programming approach: perform dynamic programming from the bottom to the root in the tree-like community structure. On the other hand, Schoenebeck and Tao [32, 33] show that the $\Omega(n^{1-\epsilon})$ inapproximability results extend to the setting where the networks are stochastic hierarchical blockmodels.

Result 2. However, Result 1 (when the network is reasonably dense, putting all the seeds in a single community is optimal) can naturally be extended to a dynamic programming algorithm. We show that this algorithm is optimal if the probability p_{uv} that each edge appears does not fall into a narrow regime. Interestingly, a heuristic based on dynamic programming works fairly well in practice [1]. Our second result theoretically justifies the success of this approach, at least in the setting of r -complex contagions.

2 Preliminaries

We study complex contagions on social networks with community structure. This section defines the complex contagion and our model for social networks with community structure.

2.1 r -Complex Contagion

Given a social network modeled as an undirected graph $G = (V, E)$, in a cascade, a subset of nodes $S \subseteq V$ is chosen as the seed set; these seeds, being infected, then spread their influence across the graph according to some specified model.

In this paper, we consider a well-known cascade model named *r -complex contagion*, also known as *bootstrap percolation* and the *fixed threshold model*: a node is infected if and only if at least r of its neighbors are infected. We use $\sigma_{r,G}(S)$ to denote the total number of infected vertices at the end of the cascade, and $\sigma_{r,G}(S) = \mathbb{E}_{G \sim \mathcal{G}} [\sigma_{r,G}(S)]$ if the graph G is sampled from some distribution \mathcal{G} . Notice that the function $\sigma_{r,G}(\cdot)$ is deterministic once the graph G and r are fixed.

Submodularity of a cascade model

Other than the r -complex contagion, most cascade models are stochastic: the total number of infected vertices is not deterministic but rather a *random variable*. $\sigma_G(S)$ usually refers to the *expected* number of infected vertices given the seed set S . A cascade model is *submodular* if, given any graph, subsets of vertices $S \subseteq T \subseteq V$, and any additional vertex $v \in V \setminus T$, we have

$$\sigma_G(S \cup \{v\}) - \sigma_G(S) \geq \sigma_G(T \cup \{v\}) - \sigma_G(T),$$

and it is *nonsubmodular* otherwise. Typical submodular cascade models include *the linear threshold model* and *the independent cascade model* [22], which are studied in an enormous past literature. The r -complex contagion, on the other hand, is a paradigmatic nonsubmodular model.

2.2 Stochastic hierarchical blockmodels

We study the *stochastic hierarchical blockmodel* first introduced in [33]. The stochastic hierarchical blockmodel is a special case of the *stochastic blockmodel* [20]. Intuitively, the stochastic blockmodel is a stochastic graph model generating networks with community structure, and the stochastic hierarchical blockmodel further assumes that the communities form a hierarchical structure. Our definition in this section follows closely to [33].

► **Definition 1.** A stochastic hierarchical blockmodel is a distribution $\mathcal{G} = (V, T)$ of unweighted undirected graphs sharing the same vertex set V , where $T = (V_T, E_T, w)$ is a weighted tree called a hierarchy tree. The third parameter is the weight function $w : V_T \rightarrow [0, 1]$ satisfying $w(t_1) < w(t_2)$ for any $t_1, t_2 \in V_T$ such that t_1 is an ancestor of t_2 . Let $L_T \subseteq V_T$ be the set of leaves in T . Each leaf node $t \in L_T$ corresponds to a subset of vertices $V(t) \subseteq V$, where the $V(t)$ sets partition the vertices in V . In general, if $t \notin L_T$, we define $V(t) = \bigcup_{t' \in L_T: t' \text{ is an offspring of } t} V(t')$.

The graph $G = (V, E)$ is sampled from \mathcal{G} in the following way. The vertex set V is deterministic. For $u, v \in V$, the edge (u, v) appears in G with probability equal to the weight of the least common ancestor of u and v in T . That is $\Pr((u, v) \in E) = \max_{t: u, v \in V(t)} w(t)$.

In the rest of this paper, we use the words *tree node* and *vertex* to refer to the vertices in V_T and V respectively. In Definition 1, the tree node $t \in V_T$ corresponds to community $V(t) \subseteq V$ in the social network. Moreover, if t is not a leaf and t_1, t_2, \dots are the children of t in V_T , then $V(t_1), V(t_2), \dots$ partition $V(t)$ into sub-communities. Thus, our assumption that for any $t_1, t_2 \in V_T$ where t_1 is an ancestor of t_2 we have $w(t_1) < w(t_2)$ implies that the relation between two vertices is stronger if they are in a same sub-community in a lower level, which is natural.

To capture the scenario where the advertiser has the information on the high-level community structure but lacks the knowledge of the detailed connections inside the communities, when defining the influence maximization problem as an optimization problem, we would like to include T as a part of input, but not G . Rather than choosing which specific vertices are seeds, the seed-picker decides the number of seeds on each leaf and the graph $G \sim \mathcal{G}(n, T)$ is realized after seeds are chosen. Moreover, we are interested in large social networks with $n \rightarrow \infty$, so we would like that a single encoding of T is compatible with varying n . To enable this feature, we consider the following variant of the stochastic hierarchical block model.

► **Definition 2.** A succinct stochastic hierarchical blockmodel is a distribution $\mathcal{G}(n, T)$ of unweighted undirected graphs sharing the same vertex set V with $|V| = n$, where n is an integer which is assumed to be extremely large. The hierarchy tree $T = (V_T, E_T, w, v)$ is the same as it is in Definition 1, except for the followings.

1. Instead of mapping a tree node t to a weight in $[0, 1]$, the weight function $w : V_T \rightarrow \mathcal{F}$ maps each tree node to a function $f \in \mathcal{F} = \{f \mid f : \mathbb{Z}^+ \rightarrow [0, 1]\}$ which maps an integer (denoting the number of vertices in the network) to a weight in $[0, 1]$. The weight of t is then defined by $(w(t))(n)$. We assume \mathcal{F} is the space of all functions that can be succinctly encoded.
2. The fourth parameter $v : V_T \rightarrow (0, 1]$ maps each tree node $t \in V_T$ to a fraction of vertices in $V(t)$. That is: $v(t) = |V(t)|/n$. Naturally, we have $\sum_{t \in L_T} v(t) = 1$ and $\sum_{t': t' \text{ is a child of } t} v(t') = v(t)$.

We assume throughout that $\mathcal{G}(n, T)$ has the following properties.

Large communities. For tree node $t \in V_T$, because $v(t)$ does not depend on n , $|V(t)| = v(t)n = \Theta(n)$. In particular, $|V(t)|$ goes to infinity as n does.

Proper separation. $w(t_1) = o(w(t_2))$ for any $t_1, t_2 \in V_T$ such that t_1 is an ancestor of t_2 . That is, the connection between sub-community t_2 is asymptotically (with respect to n) denser than its super-community t_1 .

Our definitions of w and v are designed so that we can fix a hierarchy tree $T = (V_T, E_T, w, v)$ and naturally define $\mathcal{G}(n, T)$ for any n . As we will see in the next subsection, this allows us to take T as input and then allow $n \rightarrow \infty$ when considering INFMAX (to be defined soon). This enables us to consider graphs having arbitrarily many vertices.

Finally, we define the *density* of a tree node.

► **Definition 3.** Given a hierarchy tree $T = (V_T, E_T, w, v)$ and a tree node $t \in V_T$, the density of the tree node is $\rho(t) = w(t) \cdot (v(t)n)^{1/r}$.

2.3 The InfMax problem

We study the r -complex contagion on the succinct stochastic hierarchical blockmodel. Roughly speaking, given hierarchy tree T and an integer K , we want to choose K seeds which maximize the expected total number of infected vertices, where the expectation is taken over the graph sampling $G \sim \mathcal{G}(n, T)$ as $n \rightarrow \infty$.

► **Definition 4.** The influence maximization problem INFMAX is an optimization problem which takes as input an integer r , a hierarchy tree $T = (V_T, E_T, w, v)$ as in Definition 2, and an integer K , and outputs $\mathbf{k} \in \mathbb{N}_{\geq 0}^{|L_T|}$ – an allocation of K seeds into the leaves L_T with $\sum_{t \in L_T} k_t = K$ that maximizes

$$\Sigma_{r,T}(\mathbf{k}) := \lim_{n \rightarrow \infty} \frac{\mathbb{E}_{G \sim \mathcal{G}(n,T)} [\sigma_{r,G}(S_{\mathbf{k}})]}{n},$$

the expected fraction of infected vertices in $\mathcal{G}(n,T)$ with the seeding strategy defined by \mathbf{k} , where $S_{\mathbf{k}}$ denotes the seed set in G generated according to \mathbf{k} .

Before we move on, the following remark is very important throughout the paper.

► **Remark 5.** In Definition 4, n is not part of the inputs to the INFMAX instance. Instead, the tree T is given as an input to the instance, and we take $n \rightarrow \infty$ to compute $\Sigma_{r,T}(\mathbf{k})$ after the seed allocation is determined. Therefore, asymptotically, all the input parameters to the instance, including K, r and the encoding size of T , are *constants* with respect to n . Thus, there are two different asymptotic scopes in this paper: *the asymptotic scope with respect to the input size* and *the asymptotic scope with respect to n* . Naturally, when we are analyzing the running time of an INFMAX algorithm, we should use the asymptotic scope with respect to the input size, not of n . On the other hand, when we are analyzing the number of infected vertices after the cascade, we should use the asymptotic scope with respect to n .

In this paper, we use $O_I(\cdot), \Omega_I(\cdot), \Theta_I(\cdot), o_I(\cdot), \omega_I(\cdot)$ to refer to the asymptotic scope with respect to the input size, and we use $O(\cdot), \Omega(\cdot), \Theta(\cdot), o(\cdot), \omega(\cdot)$ to refer to the asymptotic scope with respect to n . For example, with respect to n we always have $r = \Theta(1)$, $K = \Theta(1)$ and $|V_T| = \Theta(1)$.

Lastly, we have assumed that $r \geq 2$, so that the contagion is nonsubmodular. When $r = 1$, the cascade model becomes a special case of the *independent cascade model* [22], which is a submodular cascade model. As mentioned, for submodular INFMAX, a simple greedy algorithm is known to achieve a $(1 - 1/e)$ -approximation to the optimal influence [22, 23, 29].

2.4 r -Complex Contagion on Erdős-Rényi graphs

In this section, we consider the r -complex contagion on the Erdős-Rényi random graph $\mathcal{G}(n, p)$. We review some results from [21] which are used in our paper.

► **Definition 6.** The Erdős-Rényi random graph $\mathcal{G}(n, p)$ is a distribution of graphs with the same vertex set V with $|V| = n$. For each pair of vertices u, v , the edge (u, v) is included in E independently with probability p .

The INFMAX problem in Definition 4 on $\mathcal{G}(n, p)$ is trivial, as there is only one possible allocation of the K seeds: allocate all the seeds to the single leaf node of T , which is the root. Therefore, $\sigma_{r,T}(\cdot)$ in Definition 4 depends only on the *number* of seeds $K = |\mathbf{k}|$, not on the seed allocation \mathbf{k} itself. In this section, we slightly abuse the notation σ such that it is a function mapping an *integer* to $\mathbb{R}_{\geq 0}$ (rather than mapping *an allocation of K seeds* to $\mathbb{R}_{\geq 0}$ as it is in Definition 4). Let $\sigma_{r,\mathcal{G}(n,p)}(k)$ denote the expected number of infected vertices after the cascade given k seeds. Correspondingly, let $\sigma_{r,G}(k)$ denote the actual number of infected vertices after the graph G is sampled from $\mathcal{G}(n, p)$.

► **Theorem 7** (A special case of Theorem 3.1 in [21]). *Suppose $r \geq 2$, $p = o(n^{-1/r})$ and $p = \omega(n^{-1})$. We have*

1. *if k is a constant, then $\sigma_{r,\mathcal{G}(n,p)}(k) \leq 2k$ with probability $1 - o(1)$;*
2. *if $k = \omega((1/np^r)^{1/(r-1)})$, then $\sigma_{r,\mathcal{G}(n,p)}(k) = n - o(n)$ with probability $1 - o(1)$.*

► **Theorem 8** (Theorem 5.8 in [21]). *If $r \geq 2$, $p = \omega(n^{-1/r})$ and $k \geq r$, then we have $\Pr_{G \sim \mathcal{G}(n,p)}[\sigma_{r,G}(k) = n] = 1 - o(1)$.*

When $p = \Theta(n^{-1/r})$, the probability that k seeds infect all the n vertices is positive, but bounded away from 1. We use $\text{Po}(\lambda)$ to denote the Poisson distribution with mean λ .

► **Theorem 9** (Theorem 5.6 and Remark 5.7 in [21]). *If $r \geq 2$, $p = cn^{-1/r} + o(n^{-1/r})$ for some constant $c > 0$, and $k \geq r$ is a constant, then*

$$\lim_{n \rightarrow \infty} \Pr(\sigma_{r,\mathcal{G}(n,p)}(k) = n) = \zeta(k, c),$$

for some $\zeta(k, c) \in (0, 1)$. Furthermore, there exist numbers $\zeta(k, c, \ell) > 0$ for $\ell \geq k$ such that

$$\lim_{n \rightarrow \infty} \Pr(\sigma_{r,\mathcal{G}(n,p)}(k) = \ell) = \zeta(k, c, \ell)$$

for each $\ell \geq k$, and $\zeta(k, c) + \sum_{\ell=k}^{\infty} \zeta(k, c, \ell) = 1$.

Moreover, the numbers $\zeta(k, c, \ell)$'s and $\zeta(k, c)$ can be expressed as the hitting probabilities of the following inhomogeneous random walk. Let $\xi_\ell \sim \text{Po}\left(\binom{\ell-1}{r-1}c^r\right)$, $\ell \geq 1$ be independent, and let $\tilde{S}_\ell := \sum_{j=1}^{\ell} (\xi_j - 1)$ and $\tilde{T} := \min\{\ell : k + \tilde{S}_\ell = 0\} \in \mathbb{N} \cup \{\infty\}$. Then

$$\zeta(k, c) = \Pr(\tilde{T} = \infty) = \Pr(k + \tilde{S}_\ell \geq 1 \text{ for all } \ell \geq 1) \tag{1}$$

and $\zeta(k, c, \ell) = \Pr(\tilde{T} = \ell)$.

We have the following corollary for Theorem 9, saying that when $p = \Theta(n^{-1/r})$, if not all vertices are infected, then the number of infected vertices is constant. As a consequence, if the cascade spreads to more than constantly many vertices, then all vertices will be infected.

► **Corollary 10** (Lemma 11.4 in [21]). *If $r \geq 2$, $p = cn^{-1/r} + o(n^{-1/r})$ for some constant $c > 0$, and $k \geq r$, then*

$$\lim_{n \rightarrow \infty} \Pr(\phi(n) \leq \sigma_{r,\mathcal{G}(n,p)}(k) < n) = 0$$

for any function $\phi : \mathbb{Z}^+ \rightarrow \mathbb{R}^+$ such that $\lim_{n \rightarrow \infty} \phi(n) = \infty$.

3 Our main result

Our main result is the following theorem, which states that the optimal seeding strategy is to put all the seeds in a community with the highest density, when the root has a weight in $\omega(1/n^{1+1/r})$.

► **Theorem 11.** *Consider the INFMAX problem with $r \geq 2$, $T = (V_T, E_T, w, v)$, $K > 0$ and the weight of the root node satisfying $w(\text{root}) = \omega(1/n^{1+1/r})$. Let $t^* \in \operatorname{argmax}_{t \in L_T} \rho(t)$ and \mathbf{k}^* be the seeding strategy that puts all the K seeds on t^* . Then $\mathbf{k}^* \in \operatorname{argmax}_{\mathbf{k}} \Sigma_{r,T}(\mathbf{k})$.*

Notice that the assumption $w(\text{root}) = \omega(1/n^{1+1/r})$ captures many real life social networks. In fact, it is well-known that an Erdős-Rényi graph $\mathcal{G}(n, p)$ with $p = o(1/n)$ is globally disconnected: with probability $1 - o(1)$, the graph consists of a union of tiny connected components, each of which has size $O(\log n)$.

The remaining part of this section is dedicated to proving Theorem 11. We assume $w(\text{root}) = \omega(1/n^{1+1/r})$ in this section from now on. It is worth noting that, in many parts of this proof, and also in the proof of Theorem 23, we have used the fact that an infection of $o(n)$ vertices contributes 0 to the objective $\Sigma_{r,T}(\mathbf{k})$, as we have taken the limit $n \rightarrow \infty$ and divided the expected number of infections by n in Definition 4.

► **Definition 12.** Given $T = (V_T, E_T, w, v)$, a tree node $t \in V_T$ is supercritical if $w(t) = \omega(1/n^{1/r})$, is critical if $w(t) = \Theta(1/n^{1/r})$, and is subcritical if $w(t) = o(1/n^{1/r})$.

From the results in Sect. 2.4, if we allocate $k \geq r$ seeds on a supercritical leaf $t \in L_T$, then with probability $1 - o(1)$ all vertices in $V(t)$ will be infected; if we allocate k seeds on a subcritical leaf $t \in L_T$, at most a negligible number of vertices, $2k = \Theta(1)$, will be infected; if we allocate $k \geq r$ seeds on a critical leaf $t \in L_T$, the number of infected vertices in $V(t)$ follows Theorem 9.

We say a tree node $t \in V_T$ is *activated* in a cascade process if the number of infected vertices in $V(t)$ is $v(t)n - o(n)$, i.e., almost all vertices in $V(t)$ are infected. Given a seeding strategy \mathbf{k} , let $P_{\mathbf{k}}$ be the probability that at least one tree node is activated when $n \rightarrow \infty$. Notice that this is equivalent to at least one leaf being activated. The proof of Theorem 11 consists of two parts. We will first show that, $P_{\mathbf{k}}$ completely determines $\Sigma_{r,T}(\mathbf{k})$ (Lemma 13). Secondly, we show that placing all the seeds on a single leaf with the maximum density will maximize $P_{\mathbf{k}}$ (Lemma 14).

► **Lemma 13.** Given any two seeding strategies $\mathbf{k}_1, \mathbf{k}_2$, if $P_{\mathbf{k}_1} \leq P_{\mathbf{k}_2}$, then $\Sigma_{r,T}(\mathbf{k}_1) \leq \Sigma_{r,T}(\mathbf{k}_2)$.

► **Lemma 14.** Let \mathbf{k} be the seeding strategy that allocates all the K seeds on a leaf $t^* \in \operatorname{argmax}_{t \in L_T}(\rho(t))$. Then \mathbf{k} maximizes $P_{\mathbf{k}}$.

Lemma 13 and Lemma 14 imply Theorem 11. The proof of Lemma 13 is available in the full version. We prove Lemma 14 in the next section.

3.1 Proof of Lemma 14

We first handle some corner cases. If $K < r$, then the cascade will not even start, and any seeding strategy is considered optimal. If T contains a supercritical leaf, the leaf with the highest density is also supercritical. Putting all the $K \geq r$ seeds in this leaf, by Theorem 8, will activate the leaf with probability $1 - o(1)$. Therefore, this strategy makes $P_{\mathbf{k}} = 1$, which is clearly optimal. In the remaining part of this subsection, we shall only consider the case $K \geq r$ and all the leaves are either critical or subcritical. Notice that, by the proper separation assumption, all internal tree nodes of T are subcritical.

We split the cascade process into two stages. In **Stage I**, we restrict the cascade within the leaf blocks $(V(t) \text{ where } t \in L_T)$, and temporarily assume there are no edges between two different leaf blocks (similar to if $w(t) = 0$ for all $t \notin L_T$). After **Stage I**, **Stage II** consists of the remaining cascade process.

Proposition 15 shows that maximizing $P_{\mathbf{k}}$ is equivalent to maximizing the probability that a leaf is activated in **Stage I**. Therefore, we can treat T such that all the leaves, each of which corresponds to a $\mathcal{G}(n, p)$ random graph, are isolated.

► **Proposition 15.** If no leaf is activated after **Stage I**, then with probability $1 - o(1)$ no vertex will be infected in **Stage II**, i.e., the cascade will end after **Stage I**.

We defer the proof of Proposition 15 to Appendix C. Notice that Proposition 15 is the only part where we have used the proper separation assumption.

Since Theorem 7 suggests that any constant number of seeds will not activate a subcritical leaf, we should only consider putting seeds in critical leaves. In Proposition 16, we show that in a critical leaf t , the probability that the $(i + 1)$ -th seed will activate t conditioning on the first i seeds failing to do so is increasing as i increases. Intuitively, Proposition 16 reveals a

super-modular nature of the r -complex contagion on a critical leaf, making it beneficial to put all seeds together so that the synergy is maximized, which intuitively implies Lemma 14. The proof of Proposition 16 is the most technical result of this paper, we will present it in Sect. 4.

► **Proposition 16** (log-concavity of $\lim_{n \rightarrow \infty} \Pr(E_k^n)$). *Consider an Erdős-Rényi random graph $\mathcal{G}(n, p)$ with $p = cn^{-1/r} + o(n^{-1/r})$, and assume an arbitrary order on the n vertices. Let E_k^n be the event that seeding the first k vertices does not make all the n vertices infected. We have $\lim_{n \rightarrow \infty} \Pr(E_{k+2}^n | E_{k+1}^n) < \lim_{n \rightarrow \infty} \Pr(E_{k+1}^n | E_k^n)$ for any $k \geq r - 1$.*

Equipped with Proposition 16, to show Lemma 14, we show that the seeding strategy that allocates $K_1 > 0$ seeds on a critical leaf t_1 and $K_2 > 0$ seeds on a critical leaf t_2 cannot be optimal. Firstly, it is obvious that both K_1 and K_2 should be at least r , for otherwise those K_1 (K_2) seeds on t_1 (t_2) are simply wasted.

Let E_k^n be the event that the first k seeds on t_1 fail to activate t_1 and F_k^n be the event that the first k seeds on t_2 fail to activate t_2 . By Proposition 16, we have $\lim_{n \rightarrow \infty} \Pr(E_{K_1+1}^n | E_{K_1}^n) < \lim_{n \rightarrow \infty} \Pr(E_{K_1}^n | E_{K_1-1}^n)$ and $\lim_{n \rightarrow \infty} \Pr(F_{K_2+1}^n | F_{K_2}^n) < \lim_{n \rightarrow \infty} \Pr(F_{K_2}^n | F_{K_2-1}^n)$, which implies

$$\begin{aligned} & \lim_{n \rightarrow \infty} \frac{\Pr(E_{K_1+1}^n) \Pr(F_{K_2-1}^n)}{\Pr(E_{K_1}^n) \Pr(F_{K_2}^n)} \cdot \frac{\Pr(E_{K_1-1}^n) \Pr(F_{K_2+1}^n)}{\Pr(E_{K_1}^n) \Pr(F_{K_2}^n)} \\ &= \lim_{n \rightarrow \infty} \frac{\Pr(E_{K_1+1}^n | E_{K_1}^n) \Pr(F_{K_2+1}^n | F_{K_2}^n)}{\Pr(E_{K_1}^n | E_{K_1-1}^n) \Pr(F_{K_2}^n | F_{K_2-1}^n)} < 1. \end{aligned}$$

Therefore, we have either $\lim_{n \rightarrow \infty} \frac{\Pr(E_{K_1+1}^n) \Pr(F_{K_2-1}^n)}{\Pr(E_{K_1}^n) \Pr(F_{K_2}^n)}$ or $\lim_{n \rightarrow \infty} \frac{\Pr(E_{K_1-1}^n) \Pr(F_{K_2+1}^n)}{\Pr(E_{K_1}^n) \Pr(F_{K_2}^n)}$ is less than 1. This means either the strategy putting $K_1 + 1$ seeds on t_1 and $K_2 - 1$ seeds on t_2 , or the strategy putting $K_1 - 1$ seeds on t_1 and $K_2 + 1$ seeds on t_2 makes it more likely that at least one of t_1 and t_2 is activated. Therefore, the strategy putting K_1 and K_2 seeds on t_1 and t_2 respectively cannot be optimal. This implies an optimal strategy should not allocate seeds on more than one leaf.

Finally, a critical leaf t with $v(t)n$ vertices and weight $w(t)$ can be viewed as an Erdős-Rényi random graph $\mathcal{G}(m, p)$ with $m = v(t)n$ and $p = w(t) = \rho(t) \cdot (v(t)n)^{-1/r} = \rho(t)m^{-1/r}$, where $\rho(t) = \Theta(1)$ when t is critical. Taking $c = \rho(t)$ in Theorem 9, we can see that ξ_ℓ has a larger Poisson mean if c is larger, making it more likely that the $\mathcal{G}(m, p)$ is fully infected (to see this more naturally, larger c means larger p if we fix m). Thus, given that we should put all the K seeds in a single leaf, we should put them on a leaf with the highest density. This concludes Lemma 14.

4 Proof for Proposition 16

Since the event E_{k+1}^n implies E_k^n , we have $\Pr(E_{k+1}^n | E_k^n) = \Pr(E_{k+1}^n) / \Pr(E_k^n)$. Therefore, the inequality we are proving is equivalent to $\lim_{n \rightarrow \infty} \Pr(E_{k+2}^n) / \Pr(E_{k+1}^n) < \lim_{n \rightarrow \infty} \Pr(E_{k+1}^n) / \Pr(E_k^n)$, and it suffices to show that

$$\lim_{n \rightarrow \infty} \Pr(E_{k+2}^n) \lim_{n \rightarrow \infty} \Pr(E_k^n) < \lim_{n \rightarrow \infty} \Pr(E_{k+1}^n) \lim_{n \rightarrow \infty} \Pr(E_{k+1}^n). \quad (2)$$

Proposition 16 shows that the failure probability, $\lim_{n \rightarrow \infty} \Pr(E_k^n)$, is logarithmically concave.

The remaining part of the proof is split into four parts: In Sect. 4.1, we begin by translating Eqn (2) in the language of inhomogeneous random walks. In Sect. 4.2, we present a coupling of two inhomogeneous random walks to prove Eqn. (2). In Sect. 4.3, we prove the validity of the coupling. In Sect. 4.4, we finally show the coupling implies Eqn. (2).

4.1 Inhomogeneous random walk interpretation

We adopt the inhomogeneous random walk interpretation from Theorem 9, and view the event E_k^n as the following: the random walk starts at $x = k$; in the i -th iteration, x moves to the left by 1 unit, and moves to the right by $\alpha(i) \sim \text{Po}\left(\binom{i-1}{r-1}c^r\right)$ units; Let \mathcal{E}_k be the event that the random walk reaches $x = 0$. By Theorem 9, $\Pr(\mathcal{E}_k) = \lim_{n \rightarrow \infty} \Pr(E_k^n)$. Thus, $\lim_{n \rightarrow \infty} \Pr(E_{k+2}^n) \lim_{n \rightarrow \infty} \Pr(E_k^n) = \Pr(\mathcal{E}_{k+2}) \Pr(\mathcal{E}_k)$. In this proof, we let $\lambda(i) = \binom{i-1}{r-1}c^r$, and in particular, $\lambda(0) = \lambda(1) = \dots = \lambda(r-1) = 0$. Note that as i increases, the expected movement of the walk increases, and make it harder to reach 0. This observation is important for our proof.

To compute $\Pr(\mathcal{E}_{k+2}) \Pr(\mathcal{E}_k)$, we consider the following process. A random walk in \mathbb{Z}^2 starts at $(k+2, k)$. In each iteration i , the random walk moves from (x, y) to $(x-1 + \alpha(i), y-1 + \beta(i))$ where $\alpha(i)$ and $\beta(i)$ are sampled from $\text{Po}(\lambda(i))$ independently. If the random walk hits the axis $y = 0$ after a certain iteration \mathcal{T} , then it is stuck to the axis, i.e., for any $i > \mathcal{T}$, the update in the i -th iteration is from $(x, 0)$ to $(x-1 + \alpha(i), 0)$; similarly, after reaching the axis $x = 0$, the random walk is stuck to the axis $x = 0$ and updates to $(0, y-1 + \beta(i))$. Then, $\Pr(\mathcal{E}_{k+2}) \Pr(\mathcal{E}_k)$ is the probability that the random walk starting from $(k+2, k)$ reaches $(0, 0)$.

To prove (2), we consider two random walks in \mathbb{Z}^2 defined above. Let A be the random walk starting from $(k+2, k)$, and let B be the random walk starting from $(k+1, k+1)$. Let H_A and H_B be the event that A and B reaches $(0, 0)$ respectively. To prove (2), it is sufficient to show:

$$\Pr(H_A) < \Pr(H_B).$$

To formalize this idea, we define a coupling between A and B such that: 1) whenever A reaches $(0, 0)$, B also reaches $(0, 0)$, and 2) with a positive probability, B reaches $(0, 0)$ but A never does.

In defining the coupling, we use the idea of splitting and merging of Poisson processes [5]. We reinterpret the random walk by breaking down each *iteration* i into $J(i)$ *steps* such that it is symmetric in the x - and y -directions (with respect to the line $y = x$) and the movement in each step is “small”.

If at the beginning of iteration i the process is at (x, y) with $x > 0$ and $y > 0$:

- At step 0 of iteration i , we sample $J(i) \sim \text{Po}(2\lambda(i))$, set $(\alpha(i, 0), \beta(i, 0)) = (-1, -1)$, and update $(x, y) \mapsto (x + \alpha(i, 0), y + \beta(i, 0))$;
- At each step j for $j = 1, \dots, J(i)$, $(\alpha(i, j), \beta(i, j)) = (1, 0)$ with probability 0.5, and $(\alpha(i, j), \beta(i, j)) = (0, 1)$ otherwise. Update $(x, y) \mapsto (x + \alpha(i, j), y + \beta(i, j))$;³

On the other hand, if $x = 0$ (or $y = 0$) at the beginning of iteration:

- At step 0 of iteration i , we sample $J(i) \sim \text{Po}(2\lambda(i))$, set $(\alpha(i, 0), \beta(i, 0)) = (0, -1)$ (or $(-1, 0)$ if $y = 0$), and update $(x, y) \mapsto (x + \alpha(i, 0), y + \beta(i, 0))$;
- At each step j for $j = 1, \dots, J(i)$, with probability 0.5 $(\alpha(i, j), \beta(i, j)) = (1, 0)$, (or $(\alpha(i, j), \beta(i, j)) = (0, 1)$) and $(\alpha(i, j), \beta(i, j)) = (0, 0)$, otherwise. Update $(x, y) \mapsto (x + \alpha(i, j), y + \beta(i, j))$;

If at the end of iteration i , $(x, y) = (0, 0)$ we stop the process.

³ Standard results from Poisson process indicate that, $\sum_{j=1}^{J(i)} \alpha(i, j) \sim \text{Po}(\lambda(i))$, and $\sum_{j=1}^{J(i)} \beta(i, j) \sim \text{Po}(\lambda(i))$ which are two independent Poisson random variables.

Notice that we only switch from one type of iteration to the other if $x = 0$ (or $y = 0$) at the *end* of an iteration i . Here we say the random walk is stuck to the axis $x = 0$ (or the axis $y = 0$). If this happens, it will be stuck to this axis forever. Also, notice that in each step we have at most 1 unit movement. Also, in steps $j = 1, \dots, J(i)$ the walk can only move further away from both axes $y = 0$ and $x = 0$.

Let $(x(i, j), y(i, j))$ be the position of the random walk after iteration i step j , and $(x(i), y(i))$ be its position at the end of iteration i . Moreover, let $\alpha(i) = \sum_{j=1}^{J(i)} \alpha(i, j)$ be the net movement in x direction during iteration i excluding the movement in Step 0, and let $\bar{\alpha}(i) = \alpha(i) + \alpha(i, 0)$ be the net movement including movement at step 0. Similarly define y -directional movements $\beta(i) = \sum_{j=1}^{J(i)} \beta(i, j)$ and $\bar{\beta}(i)$.

4.2 The coupling

We want to show that the probability of A reaching the origin is less than that of B . To this end, we create a coupling between the two walks, which we outline here. Fig. 1 and Fig. 2 illustrate most aspects of this coupling. In the description of the coupling, we will let B move “freely”, and define how A is “coupled with” B .

Recall that A starts at $(k + 2, k)$ and B starts at $(k + 1, k + 1)$. At the beginning, we set A 's movement to be identical to B 's. Before one of them hits the origin, either of the following two events must happen: A and B become symmetric to the line $x = y$ at some step, $\mathcal{E}_{\text{symm}}$, or A reaches the axis $y = 0$ at the end of some iteration, $\mathcal{E}_{\text{skew}}$. This is called Phase I and is further discussed in Sect. 4.2.1.

In the first case $\mathcal{E}_{\text{symm}}$, the positions of A and B are symmetric. We set A 's movement to mirror B 's movement. Therefore, in this case, A and B will both hit the origin, or neither of them will. This is called Phase II Symm and is further discussed in Sect. 4.2.2.

For the latter case $\mathcal{E}_{\text{skew}}$, A reaches the axis $y = 0$ at iteration $\mathcal{T}_{\text{skew}}$. We call the process in Phase II Skew and further discussed in Sect. 4.2.3. Because B starts one unit above A and one unit to the left of A , at iteration $\mathcal{T}_{\text{skew}}$, B is at the axis $y = 1$ and one unit to the left of A . Next we couple A 's movement in the x -direction to be identical to B 's, so that B is always one unit to the left of A . This coupling continues unless B hits the axis $x = 0$. Denote this iteration \mathcal{T}^* . At time \mathcal{T}^* , A is one unit to the right of the axis $x = 0$. Recall that at iteration $\mathcal{T}_{\text{skew}}$ when $\mathcal{E}_{\text{skew}}$ happens, B is one unit above the axis so that $y = 1$. Therefore, we can couple the movement of A in the x -direction after iteration \mathcal{T}^* with B 's movement in the y -direction after iteration $\mathcal{T}_{\text{skew}}$. Because $\lambda(i)$ increases with i , we can couple the walks in such a way as to ensure that A moves toward the origin at a strictly slower rate than B does. Therefore, A only reaches the y -axis $x = 0$ if B reaches the x -axis $y = 0$, and we have shown that A is less likely to reach the origin than B does.

Let $(x^A(i, j), y^A(i, j))$, and $(x^B(i, j), y^B(i, j))$ be the coordinates for A and B respectively after iteration i step j . Similarly, let $J^A(i)$ and $J^B(i)$ be the number of steps for A and B in iteration i . Let $\alpha^A(i, j)$ and $\alpha^B(i, j)$ be the x -direction movements of both walks in iteration i step j , and $\beta^A(i, j)$ and $\beta^B(i, j)$ be the corresponding y -direction movements.

4.2.1 Phase I

Starting with $(x^A(0), y^A(0)) = (k + 2, k)$ and $(x^B(0), y^B(0)) = (k + 1, k + 1)$, A moves in exactly the same way as B , i.e., $J^A(i) = J^B(i)$, $\alpha^A(i, j) = \alpha^B(i, j)$ and $\beta^A(i, j) = \beta^B(i, j)$, until one of the following two events happens.

39:12 Optimal Seeding for Nonsubmodular Influence Maximization

Event $\mathcal{E}_{\text{symm}}$. The current position of A and B are symmetric with respect to the line $y = x$, i.e., $x^A(i, j) - x^B(i, j) = y^B(i, j) - y^A(i, j)$ and $x^A(i, j) + x^B(i, j) = y^A(i, j) + y^B(i, j)$. Notice that $\mathcal{E}_{\text{symm}}$ may happen in some middle step j of an iteration i . When $\mathcal{E}_{\text{symm}}$ happens, we move on to Phase II Symm.

Event $\mathcal{E}_{\text{skew}}$. A hits the axis $y = 0$ at the end of an iteration. Notice that this means A is then stuck to the axis $y = 0$ forever. When $\mathcal{E}_{\text{skew}}$ happens, we move on to Phase II Skew. Note that B is one unit away from the axis $y = 0$, $y^B = 1$. We remark that in the third part we show, if event $\mathcal{E}_{\text{skew}}$ happens, B has a higher chance to reach $(0, 0)$ than A .

The following three claims will be useful.

▷ **Claim 17.** A is always below the line $y = x$ before $\mathcal{E}_{\text{symm}}$ happens, so A will never hit the axis $x = 0$ in Phase I.

Proof. To see this, A can only have four types of movements in each step: lower-left $(x, y) \mapsto (x - 1, y - 1)$, up $(x, y) \mapsto (x, y + 1)$, and right $(x, y) \mapsto (x + 1, y)$. It is easy to see that, 1) A will never step across the line $y = x$ in one step, and 2) if A ever reaches the line $y = x$ at (w, w) for some w , then A must be at $(w, w - 1)$ in the previous step. However, when A is at $(w, w - 1)$, B should be at $(w - 1, w)$ according to the relative position of A, B . In this case event $\mathcal{E}_{\text{symm}}$ already happens. ◁

▷ **Claim 18.** $\mathcal{E}_{\text{symm}}$ and $\mathcal{E}_{\text{skew}}$ cannot happen simultaneously.

Proof. Suppose $\mathcal{E}_{\text{symm}}$ and $\mathcal{E}_{\text{skew}}$ happen at the same time, then it must be that A is at $(1, 0)$ and B is at $(0, 1)$, as the relative position of A and B is unchanged in Phase I, and this must be at the end of a certain iteration. In the previous iteration, A must be at $(2, 1)$, since $\mathcal{E}_{\text{skew}}$ did not happen yet and A is below the line $y = x$. However, B is at $(1, 2)$ when A is at $(2, 1)$, implying that case $\mathcal{E}_{\text{symm}}$ has already happened in the previous iteration, which is a contradiction. ◁

▷ **Claim 19.** B cannot reach the axis $x = 0$ before either $\mathcal{E}_{\text{symm}}$ or $\mathcal{E}_{\text{skew}}$ happen.

Proof. If $\mathcal{E}_{\text{symm}}$ happens before $\mathcal{E}_{\text{skew}}$, B cannot reach the axis $x = 0$ before $\mathcal{E}_{\text{symm}}$ as A is always below the line $y = x$ and B is always on the upper-left diagonal of A . If $\mathcal{E}_{\text{skew}}$ happens before $\mathcal{E}_{\text{symm}}$, B cannot reach the axis $x = 0$ before $\mathcal{E}_{\text{skew}}$, or even by the time $\mathcal{E}_{\text{skew}}$ happens: by the time $\mathcal{E}_{\text{skew}}$ happens, A can only be at one of $(2, 0), (3, 0), (4, 0), \dots$ (A cannot be at $(1, 0)$, for otherwise $\mathcal{E}_{\text{symm}}$ and $\mathcal{E}_{\text{skew}}$ happen simultaneously, which is impossible as shown just now), in which case B will not be at the axis $x = 0$. ◁

4.2.2 Phase II Symm

Let A move in a way that is symmetric to B with respect to the line $y = x$: $J^A(i) = J^B(j)$, $\alpha^A(i, j) = \beta^B(i, j)$ and $\beta^A(i, j) = \alpha^B(i, j)$. Notice that, in Phase II Symm, A may cross the line $y = x$, after which A is above the line $y = x$ while B is below.

4.2.3 Phase II Skew

If event $\mathcal{E}_{\text{skew}}$ happens, we need a more complicated coupling. Suppose Phase II Skew starts after iteration $\mathcal{T}_{\text{skew}}$. Here we use \mathcal{T}_S^A (and \mathcal{T}_S^B) to denote the hitting time of A (and B) to a set of states S which is the first iteration of the process into the set S . For example $i = \mathcal{T}_{y=1}^B$ is the hitting time of B such that $y^B(i) = 1$. Here we list six relevant hitting times and their relationship.

$$\mathcal{T}_{\text{skew}} = \mathcal{T}_{y=1}^B = \mathcal{T}_{y=0}^A < \mathcal{T}_{y=0}^B, \text{ and } \mathcal{T}_{\text{skew}} < \mathcal{T}_{x=0}^B = \mathcal{T}_{x=1}^A < \mathcal{T}_{x=0}^A.$$

■ **Figure 1** The coupling with Phase I ended at Event $\mathcal{E}_{\text{symm}}$.

Back to the coupling, we first let the x -direction movement of A be the same with that of B . To be specific, in each iteration $\mathcal{T}_{\text{skew}} < i \leq \mathcal{T}_{x=0}^B$, set $J^A(i) = J^B(i)$. At step j , we set $\alpha^A(i, j) = \alpha^B(i, j)$ and $\beta^A(i, j) = 0$ ($\beta^A(i, j)$ is always 0 now, as A is stuck to the axis $y = 0$). Till now, the relative position of A and B in x -coordinate is preserved $x^A(i, j) = x^B(i, j) + 1$. Let \mathcal{E}^* be the event that B reaches the axis $x = 0$, and let \mathcal{E}^* happens at the end of iteration $\mathcal{T}^* = \mathcal{T}_{x=0}^B$. We further define $\Delta = \mathcal{T}^* - \mathcal{T}_{\text{skew}}$ to be the additional time before $x^B = 0$ (if both stopping times exist), and $L = \mathcal{T}_{y=0}^B - \mathcal{T}_{\text{skew}}$ to be the additional time before $y^B = 0$ (if both stopping times exist).

At the end of iteration \mathcal{T}^* , the positions for A is one unit to the right of the origin. That is $x^A(\mathcal{T}^*) = 1$ while $y^A(\mathcal{T}^*) = 0$. Informally, we want to couple the movement of A from $(1, 0)$ at \mathcal{T}^* to the movement of B in the y -direction at $\mathcal{T}_{\text{skew}}$ which is one unit above the axis at $y = 1$. Formally, starting at $(1, 0)$, A is a 1-dimensional random walk on the axis $y = 0$, and we couple it to B in the following way.

- For each $t = 1, \dots, L$, we couple A 's movement in the x direction at iteration $\mathcal{T}^* + t$ with B 's movement Δ steps earlier in the y direction at iteration $\mathcal{T}^* + t - \Delta = \mathcal{T}_{\text{skew}} + t$ such that $\alpha^A(\mathcal{T}^* + t) \sim \text{Po}(\lambda(\mathcal{T}^* + t))$ and $\alpha^A(\mathcal{T}^* + t) \geq \beta^B(\mathcal{T}_{\text{skew}} + t)$.⁴
- We do not couple A to B for future iterations after $\mathcal{T}^* + L$.

A key property of this coupling is that the x -coordinate of A at $\mathcal{T}^* + t$ is always greater or equal to the y -coordinate of B at iteration $\mathcal{T}_{\text{skew}} + t$.

▷ **Claim 20.** For all $t = 1, \dots, L$, $x^A(\mathcal{T}^* + t) \geq y^B(\mathcal{T}_{\text{skew}} + t)$.

Proof. We use induction. For the base case, we have $1 = x^A(\mathcal{T}^*) = y^B(\mathcal{T}_{\text{skew}})$ from the definitions of $\mathcal{T}_{\text{skew}}$ and \mathcal{T}^* . For the inductive case, $\alpha^A(\mathcal{T}^* + t) \geq \beta^B(\mathcal{T}_{\text{skew}} + t)$ due to our coupling. ◁

⁴ Here is an example of such a coupling. Consider iteration $i = \mathcal{T}^* + t$ for A , and we want to couple it with B 's movement at iteration $\iota = \mathcal{T}_{\text{skew}} + t$. Let $J^B(\iota)$ be the number of steps of B in the iteration ι which is not necessary equal to the number of steps of A after iteration \mathcal{T}^* . At step 0, we sample a non-negative integer $d(i) \sim \text{Po}(2(\lambda(i) - \lambda_\iota))$ independent to $J^B(\iota)$, and set the number of steps of A to be $J^A(i) = J^B(\iota) + d(i)$. Then set $\alpha^A(i, 0) = -1$ and $\beta(i, 0)^A = 0$. At each step $j = 1, \dots, J^B(\iota)$, we set $(\alpha^A(i, j), \beta^A(i, j)) = (\beta_{\iota, j}^B, 0)$. At the later steps $j = J^B(\iota) + 1, \dots, J^A(i)$, we set $(\alpha^A(i, j), \beta^A(i, j)) = (1, 0)$ with probability 0.5, or $(0, 0)$ otherwise.

■ **Figure 2** The coupling with Phase I ended at Event $\mathcal{E}_{\text{skew}}$, if \mathcal{E}^* happens.

4.3 Validity of the coupling

The coupling induces the correct marginal random walk process for B , as we have defined the coupling in a way that B is moving “freely” and A is being “coupled” with B . The only non-trivial part is to show that the coupling induces the correct marginal random walk process for A . It is straightforward to check that the marginal probabilities are correct during Phase I, before the event \mathcal{E}^* occurs, or if the event \mathcal{E}^* does not occur. If the process enters Phase II Skew and B reaches the axis $x = 0$, the movement of A in the x direction is coupled with B ’s movement in y direction $\Delta = \mathcal{T}^* - \mathcal{T}_{\text{skew}}$ iterations ago. We note that B ’s movements in the x direction and the y direction are independent and A does not contain two iterations that are coupled to a same iteration of B . Therefore, the movements of A in x direction after \mathcal{T}^* are independent to its previous movement, so the marginal distribution is correct. Fig. 3 illustrates the coupling time line.

■ **Figure 3** The time line for the coupling after event $\mathcal{E}_{\text{skew}}$ happens.

► **Remark 21.** The coupling of the two random walks A and B in \mathbb{Z}^2 in the proof above can be alternatively viewed as a coupling of four independent random walks in \mathbb{Z} (this is why we have said that “we simultaneously couple four cascade processes” in the introduction), as the x -directional and y -directional movements for both A and B correspond to the four terms in inequality (2), which are intrinsically independent.

4.4 Proof of Inequality (2)

It suffices to show that in our coupling $H_A \subseteq H_B$ and $H_B \setminus H_A$ is not empty, because this implies inequality (2): $\Pr(H_A) = \Pr(H_B \cap H_A) < \Pr(H_B \cap H_A) + \Pr(H_B \setminus H_A) = \Pr(H_B)$. We aim to show that:

1. if the coupling never moves to Phase II, neither A nor B reaches $(0, 0)$;
2. if the coupling moves to Phase II Symm, A reaches $(0, 0)$ if and only if B reaches $(0, 0)$;
3. if the coupling moves to Phase II Skew, A reaches $(0, 0)$ implies that B also reaches $(0, 0)$;
4. with a positive probability, there is an event such that B reaches $(0, 0)$ but A does not.

The first, second, and third show $H_A \subseteq H_B$. The last one shows $H_B \setminus H_A$ has a positive probability.

1 is trivial. 2 follows from symmetry.

To see 3, first notice that in Phase II Skew, \mathcal{E}^* must happen if A ever reaches $(0, 0)$: because A can move to the left by at most 1 unit in each iteration, A must first reach $(1, 0)$, but at this point $x^B = 0$ and event \mathcal{E}^* happens. Now consider the case that B never reaches the origin after event \mathcal{E}^* . Then the x movement of A remains coupled to the y -movement of B in such a way that $\bar{\alpha}^A(\mathcal{T}^* + t) \geq \bar{\beta}^B(\mathcal{T}_{\text{skew}} + t)$. Walk A starts at $x^A = 1$, and walk B starts at $y^B = 1$. Therefore, A cannot reach the origin if B does not. In the case walk B meets the origin, the statement is vacuously true.

For 4, to show $\Pr(H_B \setminus H_A) > 0$, we define the following event which consists of four parts. i) For all $i = 1, \dots, k$, it happens that $\alpha^A(i) = \beta^A(i) = 0$, in which case the event $\mathcal{E}_{\text{skew}}$ happens at $\mathcal{T}_{\text{skew}} = k$ and A reaches $(2, 0)$. ii) For $i = k + 1$, it happens that $\alpha^A(i) = 0$ and $\beta^B(i) = 1$, in which case A reaches $(1, 0)$ and B reaches $(0, 1)$, and the process B reaches the axis $x = 0$ at iteration $\mathcal{T}^* = k + 1$. iii) In iteration $i = \mathcal{T}^* + 1$, it happens that $\beta^B(i) = 0$, so B reaches $(0, 0)$. On the other hand, by the coupling $\alpha^A(\mathcal{T}^* + 1) \geq \beta^B(\mathcal{T}_{\text{skew}} + 1) = 1$, so A does not reach $(0, 0)$ at iteration $\mathcal{T}^* + 1 = k + 2$. iv) Finally, it happens that $\alpha^A(i) \geq 1$ for all $i > k + 2$. It is straightforward the i), ii), and iii) happen with positive probabilities. By direct computations, iv) happens with a positive probability as well.⁵ Since the above event consisted of i), ii), iii) and iv) belongs to $H_B \setminus H_A$ and each of the four sub-events happens with a positive probability, 4 is implied.

From 2, 3, and 4, we learn that the probability that B reaches $(0, 0)$ is strictly larger than that of A , which implies inequality (2) and concludes the proof.

A Optimal seeds in submodular InfMax

We have seen that putting all the K seeds in a single leaf is optimal for r -complex contagion, when the root node has weight $\omega(1/n^{1+1/r})$. To demonstrate the sharp difference between r -complex contagion and a submodular cascade model, we present a submodular INFMAX example where the optimal seeding strategy is to put no more than one seed in each leaf. The hierarchy tree T in our example meets all the assumptions we have made in the previous sections, including large communities, proper separation, and $w(\text{root}) = \omega(1/n^{1+1/r})$, where r is now an arbitrarily fixed integer with $r \geq 2$.

We consider a well-known submodular cascade model, *the independent cascade model* [22], where, after seeds are placed, each edge (u, v) in the graph appears with probability p_{uv} and vertices in all the connected components of the resultant graph that contain seeds are infected. In our example, the probability p_{uv} is the same for all edges, and it is $p = 1/n^{1-\frac{1}{4r}}$. The hierarchy tree T contains only two levels: a root and K leaves. The root has weight $1/n^{1+\frac{1}{2r}}$, and each leaf has weight 1. After $G \sim \mathcal{G}(n, T)$ is sampled and each edge in G is sampled with probability p , the probability that an edge appears between two vertices from different leaves is $(1/n^{1-\frac{1}{4r}}) \cdot (1/n^{1+\frac{1}{2r}}) = o(1/n^2)$, and the probability that an edge appears between two vertices from a same leaf is $1 \cdot (1/n^{1-\frac{1}{4r}}) = \omega(\log n/n)$. Therefore, with probability $1 - o(1)$, the resultant graph is a union of K connected components, each of which corresponds to a leaf of T . It is then straightforward to see that the optimal seeding strategy is to put a single seed in each leaf.

B A dynamic programming algorithm

In this section, we present an algorithm which finds an optimal seeding strategy when all $w(t)$'s fall into two regimes: $w(t) = \omega(1/n^{1+1/r})$ and $w(t) = o(1/n^2)$. We will assume this for $w(t)$'s throughout this section. Since a parent tree node always has less weight than its children (see Definition 1), we can decompose T into *the upper part* and *the lower part*, where the lower part consists of many subtrees whose roots have weights in $\omega(1/n^{1+1/r})$, and the upper part is a single tree containing only tree nodes with weights in $o(1/n^2)$ and whose leaves are the parents of those roots of the subtrees in the lower part. We call each subtree in the lower part a *maximal dense subtree* defined formally below.

► **Definition 22.** *Given a hierarchy tree $T = (V_T, E_T, w, v)$, a subtree rooted at $t \in V_T$ is a maximal dense subtree if $w(t) = \omega(1/n^{1+1/r})$, and either t is the root, or $w(t') = O(1/n^{1+1/r})$ where t' is the parent of t .*

Since we have assumed either $w(t) = \omega(1/n^{1+1/r})$ or $w(t) = o(1/n^2)$, $w(t') = O(1/n^{1+1/r})$ in the definition above implies $w(t') = o(1/n^2)$.

The idea of our algorithm is the following: firstly, after the decomposition of T into the upper and lower parts, we will show that the weights of the tree nodes in the upper part, falling into $w(t) = o(1/n^2)$, are negligible so that we can treat the whole tree T as a forest with only those maximal dense subtrees in the lower part (that is, we can remove the entire upper part from T); secondly, Theorem 11 shows that when we have decided the number of seeds to be allocated for each maximal dense subtree, the optimal seeding strategy is to put all the seeds together in a single leaf that has the highest density, where the density of a leaf $t \in L_T$ is defined in Definition 3; finally, the only problem remaining is how to allocate the K seeds among those maximal dense subtrees, and we decide this allocation by a dynamic programming approach.

Now, we are ready to describe our algorithm, presented in Algorithm 1.

The correctness of Algorithm 1 follows immediately from Theorem 23 (below) and Theorem 11. Recall Theorem 23 shows that we can ignore the upper part of T and treat T as the forest consisting of all the maximal dense subtrees of T when considering the INFMAX problem. Theorem 11 shows that for each subtree T_i and given the number of seeds, the optimal seeding strategy is to put all the seeds on the leaf with the highest density.

► **Theorem 23.** *Given $T = (V_T, E_T, w, v)$, let $\{T_1, \dots, T_m\}$ be the set of all T 's maximal dense subtrees and let T^- be the forest consisting of T_1, \dots, T_m . For any seeding strategy \mathbf{k} and any $r \geq 2$, we have $\Sigma_{r,T}(\mathbf{k}) = \Sigma_{r,T^-}(\mathbf{k})$.*

Proof. Let $V(T_i)$ be the set of vertices corresponding to the subtree T_i . Since the total number of possible edges between those $V(T_i)$'s is upper bounded by n^2 and each edge appears with probability $o(1/n^2)$, the expected number of edges is $o(1)$. By Markov's inequality the probability there exists edges between those $V(T_i)$'s is $o(1)$. Therefore, we have

$$\frac{\mathbb{E}_{G \sim \mathcal{G}(n,T)} [\sigma_{r,G}(\mathbf{k})]}{n} = \frac{o(1)O(n) + (1 - o(1)) \mathbb{E}_{G \sim \mathcal{G}(n,T')} [\sigma_{r,G}(\mathbf{k})]}{n}.$$

Taking $n \rightarrow \infty$ concludes the proof. ◀

Finally, it is straightforward to see the time complexity of Algorithm 1, in terms of the number of evaluations of $\Sigma_{r,\mathcal{G}(n,T)}(\cdot)$.

► **Theorem 24.** *Algorithm 1 requires $O_I(|V_T|K^2)$ computations of $\Sigma_{r,\mathcal{G}(n,T)}(\cdot)$.*

■ **Algorithm 1** The INFMAX algorithm.

-
- 1: **Input:** $r \in \mathbb{Z}$ with $r \geq 2$, $T = (V_T, E_T, w, v)$, and $K \in \mathbb{Z}^+$
 - 2: Find all maximal dense subtrees T_1, \dots, T_m , and let r_1, \dots, r_m be their roots (Definition 22).
 - 3: For each T_i and each $k = 0, 1, \dots, K$, let $\mathbf{s}_i^*(k)$ be the seeding strategy that puts k seeds in the leaf $t \in L_{T_i}$ with the highest density, and let

$$h(T_i, k) = \lim_{n \rightarrow \infty} \frac{\mathbb{E}_{G \sim \mathcal{G}(v(r_i) \cdot n, T_i)}[\sigma_{r, G}(\mathbf{s}_i^*(k))]}{n}$$

be the expected number of infected vertices in the subgraph defined by T_i , normalized by the total number of vertices in the whole graph.

- 4: Let $S[i, k]$ store a seeding strategy that allocates k seeds in the first i subtrees T_1, \dots, T_i , and let $H[i, k]$ be the expected total number of infected vertices corresponding to $S[i, k]$, divided by n .
 - 5: **for** $k = 0, 1, \dots, K$ **do**
 - 6: set $S[1, k] = \mathbf{s}_1^*(k)$ and $H[1, k] = h(T_1, k)$.
 - 7: **end for**
 - 8: **for** each $i = 2, \dots, m$ **do**
 - 9: **for** $k = 0, 1, \dots, K$ **do**
 - 10: $k_i = \operatorname{argmax}_{k_i \in \{0, 1, \dots, k\}} H[i-1, k - k_i] + h(T_i, k_i)$;
 - 11: set $S[i, k]$ be the strategy that allocates $k - k_i$ seeds among T_1, \dots, T_{i-1} according to $S[i-1, k - k_i]$ and puts the remaining k_i seeds in the leaf of T_i with the highest density;
 - 12: set $H[i, k] = H[i-1, k - k_i] + h(T_i, k_i)$;
 - 13: **end for**
 - 14: **end for**
 - 15: **Output:** the seeding strategy $S[m, K]$.
-

C Proof of Proposition 15

By Theorem 7 and Corollary 10, if no leaf is activated by the local seeds, then there can be at most constantly many infected vertices. Consider an arbitrary vertex v that is not infected, and let t be the leaf such that $v \in V(t)$. Let K_{in} be the number of infected vertices in $V(t)$ after Stage I and K_{out} be the number of infected vertices outside $V(t)$. By our assumption, $K_{in} = O(1)$ and $K_{out} = O(1)$. We compute an upper bound on the probability that v is infected in the next cascade iteration. Let X_v be the number of v 's infected neighbors in $V(t)$ and Y_v be the number of v 's infected neighbors outside $V(t)$.

Since the probability that v is connected to each of those K_{out} vertices is $o(n^{-1/r})$, we have

$$\Pr(Y_v \geq r - a) \leq \binom{K_{out}}{r - a} \left(o(n^{-1/r})\right)^{r-a} = o\left(n^{-(r-a)/r}\right)$$

for each $a \in \{0, 1, \dots, r - 1\}$.

Ideally, we would also like to claim that

$$\Pr(X_v \geq a) \leq \binom{K_{in}}{a} w(t)^a = O\left(n^{-a/r}\right), \quad (3)$$

39:20 Optimal Seeding for Nonsubmodular Influence Maximization

so that putting together we have,

$$\Pr(v \text{ is infected}) \leq \sum_{a=0}^{r-1} \Pr(X_v \geq a) \Pr(Y_v \geq r-a) = r \cdot O\left(n^{-a/r}\right) \cdot o\left(n^{-(r-a)/r}\right) = o\left(\frac{1}{n}\right).$$

and conclude that the expected number of infected vertices in the next iteration is $o(1)$, which implies the proposition by the Markov's inequality.

However, conditioning on the cascade in $V(t)$ stopping after K_{in} infections, there is no guarantee that the probability an edge between v and one of the K_{in} infected vertices is still $w(t)$. Moreover, for any two vertices u_1, u_2 that belong to those K_{in} infected vertices, we do not even know if the probability that v connects to u_1 is still independent of the probability that v connects to u_2 . Therefore, (3) does not hold in a straightforward way. The remaining part of this proof is dedicated to proving (3).

Consider a different scenario where we have put K_{in} seeds in $V(t)$ (instead of that the cascade in $V(t)$ ends at K_{in} infections), and let \bar{X}_v be the number of edges between v and those K_{in} seeds (where v is not one of those seeds). Then we know each edge appears with probability $w(t)$ independently, and (3) holds for \bar{X}_v :

$$\Pr(\bar{X}_v \geq a) \leq \binom{K_{in}}{a} w(t)^a = O\left(n^{-a/r}\right).$$

Finally, (3) follows because \bar{X}_v stochastically dominates X_v (i.e., $\Pr(\bar{X}_v \geq a) \geq \Pr(X_v \geq a)$ for each $a \in \{0, 1, \dots, r-1\}$), which is easy to see:

$$\begin{aligned} \Pr(X_v \geq a) &= \Pr(\bar{X}_v \geq a \mid \bar{X}_v \leq r-1) = \frac{\Pr(a \leq \bar{X}_v \leq r-1)}{\Pr(\bar{X}_v \leq r-1)} \\ &= \frac{\Pr(\bar{X}_v \geq a) - \Pr(\bar{X}_v \geq r)}{1 - \Pr(\bar{X}_v \geq r)} \leq \Pr(\bar{X}_v \geq a), \end{aligned}$$

where the first equality holds as $\Pr(\bar{X}_v \geq a \mid \bar{X}_v \leq r-1)$ exactly describes the probability that v has at least a infected neighbors among K_{in} conditioning on v not yet being infected.

Direct Sum Testing: The General Case

Abstract

A function $f : [n_1] \times \dots \times [n_d] \rightarrow \mathbb{F}_2$ is a direct sum if it is of the form $f(a_1, \dots, a_d) = f_1(a_1) \oplus \dots \oplus f_d(a_d)$, for some d functions $f_i : [n_i] \rightarrow \mathbb{F}_2$ for all $i = 1, \dots, d$, and where $n_1, \dots, n_d \in \mathbb{N}$. We present a 4-query test which distinguishes between direct sums and functions that are far from them. The test relies on the BLR linearity test (Blum, Luby, Rubinfeld, 1993) and on the direct product test constructed by Dinur & Steurer (2014).

We also present a different test, which queries the function $(d + 1)$ times, but is easier to analyze.

In multiplicative ± 1 notation, this reads as follows. A d -dimensional tensor with ± 1 entries is called a tensor product if it is a tensor product of d vectors with ± 1 entries, or equivalently, if it is of rank 1. The presented tests can be read as tests for distinguishing between tensor products and tensors that are far from being tensor products.

1 Introduction

Let us first fix some notations and definitions. By $[n]$ we mean the set $\{0, 1, 2, \dots, n\}$. For d positive integers n_1, \dots, n_d , we denote $[\bar{n}; d] = [n_1] \times \dots \times [n_d]$. For two functions $F, G : X \rightarrow Y$, we denote by $\text{dist}(F, G)$ the relative Hamming distance between them, namely $\text{dist}(F, G) = \Pr_{x \in X}[F(x) \neq G(x)]$. We say that $F : X \rightarrow Y$ is ε -close to have some Property, if there exists a function $G : X \rightarrow Y$ such that G has the Property and $\text{dist}(F, G) \leq \varepsilon$.

Given d functions $f_i : [n_i] \rightarrow \mathbb{F}_2$, $i = 1, \dots, d$, where $n_1, \dots, n_d \in \mathbb{N}$, their direct sum is the function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$ given by $f(a_1, \dots, a_d) = f_1(a_1) \oplus f_2(a_2) \oplus \dots \oplus f_d(a_d)$, where \oplus stands for addition in the field \mathbb{F}_2 . We denote $f = f_1 \oplus \dots \oplus f_d$. We study the testability question: given a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$ test if it is a direct sum, namely if it belongs to the set

$$\text{DirectSum}_{[\bar{n}; d]} = \{f_1 \oplus \dots \oplus f_d \mid f_i : [n_i] \rightarrow \mathbb{F}_2, i = 1, \dots, d\}.$$

Direct sum is a natural construction that is often used in complexity for hardness amplification [15, 8, 9, 13, 14]. It is related to the direct product construction: a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2^d$ is the direct product of f_1, \dots, f_d as above if $f(a_1, \dots, a_d) = (f_1(a_1), \dots, f_d(a_d))$ for all $(a_1, \dots, a_d) \in [\bar{n}; d]$. The testability of direct products has received attention

40:2 Direct Sum Testing: The General Case

[7, 5, 4, 10, 6] as abstraction of certain PCP tests. It was not surprising to find [3] that there is a connection between testing direct products to testing direct sum. However, somewhat unsatisfyingly this connection was confined to testing a certain type of *symmetric* direct sum. A symmetric direct sum is a function $f : [n]^d \rightarrow \mathbb{F}_2$ that is a direct product with all components equal; namely such that there is a single $g : [n] \rightarrow \mathbb{F}_2$ such that

$$f(a_1, \dots, a_d) = g(a_1) \oplus g(a_2) \oplus \dots \oplus g(a_d).$$

In [3], a 3-query test was presented for testing if a given f is a symmetric direct sum, and the analysis carried out relying on the direct product test. It was left as an open question to devise and analyze a test for the property of being a (not necessarily symmetric) direct sum.

We design and analyze a four-query test which we call the “square in a cube” test, and show that it is a strong absolute local test for being a direct sum. That is, the number of queries is an absolute constant (namely, 4), and the distance from a function to the subspace of direct sums is bounded by some absolute constant (independent of n and d) times the probability of the failure of the test on this function. We also describe a simpler $(d+1)$ -query test, whose easy analysis we defer to Section 3.

In order to define the test, we need to introduce the following notation. Given two strings $a, b \in [\bar{n}; d]$ and a set $S \subseteq [d]$, denote by $a_S b$ the string in $[\bar{n}; d]$ whose i -th coordinate equals a_i if $i \in S$ and b_i otherwise.

■ Test 1 Square in a Cube test.

Given a query access to a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$:

1. Choose $a, b \in [\bar{n}; d]$ uniformly at random.
2. Choose two subsets $S, T \subseteq [d]$ uniformly at random, and let $U = S \Delta T$ be their symmetric difference.
3. Accept iff

$$f(a) \oplus f(a_S b) \oplus f(a_T b) \oplus f(a_U b) = 0.$$

We prove the following theorem for Test 1.

► **Theorem 1.1 (Main).** *There exists an absolute constant $c > 0$ s.t. for all $d \in \mathbb{N}$ and $n_1, \dots, n_d \in \mathbb{N}$, given $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$,*

$$\text{dist}(f, \text{DirectSum}_{[\bar{n}; d]}) \leq c \cdot \Pr_{a, b, S, T} [f(a) \oplus f(a_S b) \oplus f(a_T b) \oplus f(a_{S \Delta T} b) \neq 0]$$

where a, b are chosen independently and uniformly from the domain of f , and S, T are random subsets of $[d]$.

Our proof, similarly to [3], relies on a combination of the BLR linearity testing theorem [2] and the direct product test of [6]. The trick is to find the right combination. We first observe that once we fix a, b , the test is confined to a set of at most 2^d points in the domain, and can be viewed as performing a BLR (affinity rather than linearity) test on this piece of the domain. From the BLR theorem, we deduce an affine linear function on this piece. The next step is to combine the different affine linear functions, one from each piece, into one global direct sum, and this is done by reducing to direct product.

Testing if a tensor has rank 1

An equivalent way to formulate our question is as a test for whether a d -dimensional tensor with ± 1 entries has rank 1. Indeed moving to multiplicative notation and writing $h_i = (-1)^{f_i}$ and $h = (-1)^f$, we are asking whether there are h_1, \dots, h_d such that

$$h = h_1 \otimes \dots \otimes h_d.$$

Denoting

$$\text{TensorProduct}_{[\bar{n};d]} = \{h_1 \otimes \dots \otimes h_d \mid h_i : [n_i] \rightarrow \{-1, 1\}, i = 1, \dots, d\}$$

we have

► **Corollary 1.2.** *There exists an absolute constant $c > 0$ s.t. for all $d \in \mathbb{N}$ and $n_1, \dots, n_d \in \mathbb{N}$, for every $h : [\bar{n}; d] \rightarrow \{-1, 1\}$,*

$$\text{dist}(h, \text{TensorProduct}_{[\bar{n};d]}) \leq c \cdot \Pr_{a,b,S,T} [h(a) \cdot h(a_S b) \cdot h(a_T b) \cdot h(a_{S \Delta T} b) \neq 1].$$

Structure of the Paper

In Sections 2 and 3 we present two different approaches for testing whether a d -dimensional binary tensor is a tensor product. In Section 4 we discuss possible directions for future research. In Appendix A, we give a proof of the proposition which expands the range of parameters in the direct product test of [6]. This is used in the course of the proof in Section 2.

2 Square in a Cube Test

In this section we present the Square in a Cube Test. Then we introduce the required background: the BLR test for a function being Affine in Subsection 2.1, the direct product test of Dinur & Steurer in Subsection 2.2. Finally, in Subsection 2.3 we prove the main result on the test.

We start by introducing some notation.

Given two vectors $a = (a_1, \dots, a_d), b = (b_1, \dots, b_d) \in [\bar{n}; d]$, define

- $\Delta(a, b) = \{i : a_i \neq b_i\} \subseteq [d]$;
- the induced subcube $C_{a,b}$ is the binary cube $\mathbb{F}_2^{\Delta(a,b)}$;
- the projection map $\rho_{a,b} : C_{a,b} \rightarrow [\bar{n}; d]$ defined for $x \in C_{a,b}$ as

$$\rho_{a,b}(x)_i = \begin{cases} a_i = b_i, & i \notin \Delta(a, b); \\ b_i, & i \in \Delta(a, b) \text{ and } x_i = 1; \\ a_i, & i \in \Delta(a, b) \text{ and } x_i = 0; \end{cases}$$

The following test is the same as Test 1 in Introduction.

■ Test 2 Square in a Cube test.

Given a query access to a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$:

1. Choose $a, b \in [\bar{n}; d]$ uniformly at random.
 2. Choose $x, y \in C_{a,b}$ uniformly at random.
 3. Query f at $\rho_{a,b}(0), \rho_{a,b}(x), \rho_{a,b}(y)$ and $\rho_{a,b}(x \oplus y)$.
 4. Accept iff $f(\rho_{a,b}(0)) \oplus f(\rho_{a,b}(x)) \oplus f(\rho_{a,b}(y)) \oplus f(\rho_{a,b}(x \oplus y)) = 0$.
-

► **Theorem 2.1.** *Suppose a function $f : [\bar{n}; d]^d \rightarrow \mathbb{F}_2$ passes Test 2 with probability $1 - \varepsilon$ for some $\varepsilon > 0$, then f is $O(\varepsilon)$ -close to a tensor product.*

2.1 The BLR affinity test

The Blum-Luby-Rubinfeld linearity test was introduced in [2], where its remarkable properties were proven. Later a simpler proof via Fourier analysis was presented, e.g. see [1]. Below we give a variation of this test for affine functions, see [12, Chapter 1].

► **Definition 2.2.** A function $g : \mathbb{F}_2^d \rightarrow \mathbb{F}_2$ is called *affine*, if there exists a set $S \subseteq [d]$ and a constant $c \in \mathbb{F}_2$ such that for every vector $x \in \mathbb{F}_2^d$

$$g(x) = c \oplus \bigoplus_{i \in S} x_i.$$

Note that (see [12, Exercise 1.26]) a function g is affine iff for any two vectors $x, y \in \mathbb{F}_2^d$ it satisfies

$$g(0) \oplus g(x) \oplus g(y) \oplus g(x \oplus y) = 0. \quad (1)$$

The BLR test implies that if a function $g : \mathbb{F}_2^d \rightarrow \mathbb{F}_2$ satisfies (1) with high probability, then it is close to an affine function.

■ **Test 3** The BLR affinity test.

Given a query access to a function $f : \mathbb{F}_2^d \rightarrow \mathbb{F}_2$:

1. Choose $x \sim \mathbb{F}_2^d$ and $y \sim \mathbb{F}_2^d$ independently and uniformly at random.
 2. Query g at $0, x, y$ and $x \oplus y$.
 3. Accept if $g(0) \oplus g(x) \oplus g(y) \oplus g(x \oplus y) = 0$.
-

► **Theorem 2.3** ([2]). Suppose $g : \mathbb{F}_2^d \rightarrow \mathbb{F}_2$ passes the affinity test with probability $1 - \varepsilon$ for some $\varepsilon > 0$. Then g is ε -close to being affine.

2.2 Direct Product Test

► **Definition 2.4.** For $k, M, N \in \mathbb{N}$, and k functions $g_1, \dots, g_k : [N] \rightarrow [M]$, their *direct product* is the function $g : [N]^k \rightarrow [M]^k$ denoted $g = g_1 \times \dots \times g_k$ and defined as $g((x_1, \dots, x_k)) = (g_1(x_1), \dots, g_k(x_k))$. A function $g : [N]^k \rightarrow [M]^k$, is called a *direct product* if there exist k functions $g_1, \dots, g_k : [N] \rightarrow [M]$ such that $g = g_1 \times \dots \times g_k$ for all $(x_1, \dots, x_k) \in [N]^k$.

Dinur & Steurer [6] presented a 2-query test, Test 4, that, with constant probability, distinguishes between direct products and functions that are far from direct product.

■ **Test 4** Two-query test $\mathcal{T}(t)$.

Given a query access to a function $g : [N]^k \rightarrow [M]^k$:

1. Choose $x \sim \mathbb{F}_2^d$ and $y \sim \mathbb{F}_2^d$ independently and uniformly at random.
 2. Query g at $0, x, y$ and $x \oplus y$.
 3. Accept if $g(0) \oplus g(x) \oplus g(y) \oplus g(x \oplus y) = 0$.
-

► **Theorem 2.5** ([6, Theorem 1.1]). Let k, M, N be positive integers, let $t \leq \alpha k$, where $0 < \alpha < 1$, and let $\varepsilon > 0$. Let $g : [N]^k \rightarrow [M]^k$ be given such that

$$\Pr_{A, x, y} (g(x)_A = g(y)_A) \geq 1 - \varepsilon,$$

where A, x, y are chosen w.r.t. the test distribution $\mathcal{T}(t)$. Then there exists a direct product function g' such that $\mathbb{E}_x [\text{dist}(g(x), g'(x))] = O(\varepsilon k/t)$.

► **Remark 2.6.** The above formulation of Theorem 2.5 is slightly more general than the original statement in [6], as there it is proved for $0 < \alpha < 1/2$. In order to show that the Theorem holds for $0 < \alpha < 1$, we prove the following reduction statement:

If a function g passes Test $\mathcal{T}(t)$ with probability at least $1 - \varepsilon$ for $t = \alpha k$ with $1/2 \leq \alpha < 1$, then g passes Test $\mathcal{T}(t')$ with probability at least $1 - \varepsilon'$ for $t' = \alpha' k$, where $0 < \alpha' < 1/2$, $\varepsilon' = r\varepsilon/\alpha$ and r is a positive integer.

This reduction shows that Theorem 2.5 is true as it is stated for $t = \alpha k$ for all $0 < \alpha < 1$, as the reduction affects only the constant in the $O(\cdot)$ notation.

For a more detailed explanation, see Appendix A.

2.3 Proof of Theorem 2.1

For a positive integer D , we denote by $\mu_{2/3}(\mathbb{F}_2^D)$ the distribution on \mathbb{F}_2^D , where each coordinate, independently, is equal to 0 with probability $1/3$ and to 1 with probability $2/3$.

We use the following proposition in the course of the proof.

► **Proposition 2.7.** *Let $S \subseteq [D]$ be a set and $\chi_S : \mathbb{F}_2^D \rightarrow \mathbb{F}_2$ be the corresponding linear function, i.e., $\chi_S(x) = \bigoplus_{i \in S} x_i$. Suppose*

$$\Pr_{x \sim \mu_{2/3}(\mathbb{F}_2^D)} (\chi_S(x) = 0) > \frac{2}{3},$$

then $S = \emptyset$.

Proof. Consider $(-1)^{\chi_S}$. Then

$$\Pr_{x \sim \mu_{2/3}(\mathbb{F}_2^D)} (\chi_S(x) = 0) = \Pr_{x \sim \mu_{2/3}(\mathbb{F}_2^D)} \left((-1)^{\chi_S(x)} = 1 \right).$$

Also the following holds

$$\begin{aligned} \frac{1}{3} &< \left| 2 \Pr_{x \sim \mu_{2/3}(\mathbb{F}_2^D)} \left((-1)^{\chi_S(x)} = 1 \right) - 1 \right| = \left| \mathbb{E}_{x \sim \mu_{2/3}(\mathbb{F}_2^D)} (-1)^{\chi_S(x)} \right| = \\ & \left| \prod_{i \in [D]} \mathbb{E}_{x_i \sim \mu_{2/3}(\mathbb{F}_2)} (-1)^{x_i} \right| = \left| \left(-\frac{1}{3} \right)^{|S|} \right| = \left(\frac{1}{3} \right)^{|S|}, \end{aligned}$$

and the statement follows. ◀

Proof of Theorem 2.1. Assume Test 2 rejects a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$ with probability less than ε , i.e.,

$$\Pr_{\substack{a, b \sim [\bar{n}; d] \\ x, y \sim C_{a, b}}} (f_{a, b}(0) \oplus f_{a, b}(x) \oplus f_{a, b}(y) \oplus f_{a, b}(x \oplus y) = 0) > 1 - \varepsilon,$$

where all distributions are uniform, and $f_{a, b}$ is a shorthand for $f \circ \rho_{a, b}$. Then there exists $a \in [\bar{n}; d]$ such that

$$\Pr_{\substack{b \sim [\bar{n}; d] \\ x, y \sim C_{a, b}}} (f_{a, b}(0) \oplus f_{a, b}(x) \oplus f_{a, b}(y) \oplus f_{a, b}(x \oplus y) = 0) > 1 - \varepsilon.$$

40:6 Direct Sum Testing: The General Case

Note that the operations re-indexing the domain $[\bar{n}; d]^1$, as well as *flipping* a function, i.e., adding the constant one function to it element-wise, preserve the distance between functions. Hence, w.l.o.g. we can assume for convenience that $a = (0, \dots, 0)$ and that $f(a) = 0$.

We write C_b for $C_{a,b}$ and f_b for $f_{a,b}$. Then for every $b \in [\bar{n}; d]$,

$$\Pr_{x,y \sim C_b} (f_b(0) \oplus f_b(x) \oplus f_b(y) \oplus f_b(x \oplus y) = 0) = 1 - \varepsilon_b.$$

The BLR theorem (Theorem 2.3) implies that for each $b \in [\bar{n}; d]$ there exists a subset $S(b) \subseteq \Delta(a, b)$, such that

$$\Pr_{x \sim C_b} (f_b(x) = \chi_{S(b)}(x)) = 1 - \varepsilon_b.$$

► **Remark 2.8.** By the BLR theorem, there should be the ‘greater or equal to’ sign instead of the equality. We assume equality for convenience.

Let $F : [\bar{n}; d] \rightarrow \mathbb{F}_2^d$ be a function defined as follows. For each $b \in [\bar{n}; d]$, the set $S(b) \subseteq \Delta(a, b)$ can be viewed as a subset of $[d]$, since $\Delta(a, b) \subseteq [d]$. Then $F(b)$ is defined as the element of \mathbb{F}_2^d corresponding to the set $S(b)$.

We now show that F passes Test 4 with high probability and hence is close to a direct product.

Let $b \in [\bar{n}; d]$ be chosen uniformly at random, and let $b' \in [\bar{n}; d]$ be chosen with respect to the following distribution $D(b)$. For each $i \in [d]$,

$$b'_i = \begin{cases} b_i, & \text{w.p. } 3/4; \\ \text{chosen uniformly at random from } [n] \setminus \{b_i\}, & \text{w.p. } 1/4. \end{cases}$$

Note that the distribution on pairs (b, b') , where b is chosen uniformly from $[\bar{n}; d]$ and b' w.r.t. $D(b)$, is equivalent to the following: for each $i \in [d]$,

$$\begin{cases} b_i = b'_i \text{ chosen uniformly from } [n], & \text{w.p. } 3/4; \\ b_i \neq b'_i \text{ both chosen uniformly from } [n] & \text{w.p. } 1/4. \end{cases} \quad (2)$$

In particular, it is symmetric in the sense that choosing $b' \sim [\bar{n}; d]$ uniformly at random first, and then $b \sim D(b')$, leads to the same distribution on pairs (b, b') as the one described above.

For such a pair (b, b') define distribution $\mathcal{D}_{b,b'}$ on $[\bar{n}; d]$ as follows. For a vector $x \sim \mathcal{D}_{b,b'}$,

$$x_i = \begin{cases} 0, & \text{if } i \in \Delta(b, b'); \\ 0, & \text{w.p. } 1/3; \\ b_i = b'_i & \text{w.p. } 2/3. \end{cases} \quad \text{if } i \notin \Delta(b, b').$$

Note that the distribution $\mathcal{D}_{b,b'}$ is supported on a binary cube of dimension $d - |\Delta(b, b')|$ inside $[\bar{n}; d]$. Denote

$$\varepsilon_{b,b'} = \Pr_{x \sim \mathcal{D}_{b,b'}} (f(x) \neq \chi_{F(b)}(x)).$$

We claim that the following holds

$$\varepsilon_b = \Pr_{x \sim C_b} (f(x) \neq \chi_{F(b)}(x)) = \mathbb{E}_{b' \sim D(b)} \varepsilon_{b,b'}. \quad (3)$$

¹ By this we mean selecting permutations π_i on $[n_i]$ for $i = 1, \dots, d$, and setting $f^{\pi_1, \dots, \pi_d}(x_1, \dots, x_d) = f(\pi_1(x_1), \dots, \pi_d(x_d))$

To see (3) note that since b is chosen uniformly, b' is chosen w.r.t. $D(b)$, and $x \sim \mathcal{D}_{b,b'}$, the resulting distribution for x is

$$x_i = \begin{cases} 0, & \text{w.p. } 1/2; \\ b_i & \text{w.p. } 1/2, \end{cases}$$

which is exactly the uniform distribution on C_b .

We now show that

$$\Pr_{\substack{b \sim [\bar{n}; d] \\ b' \sim D(b)}} \left(\varepsilon_{b,b'} + \varepsilon_{b',b} > \frac{1}{3} \right) < 6\varepsilon \tag{4}$$

First note that it follows from the definitions that

$$\mathbb{E}_{b \sim [\bar{n}; d]} \mathbb{E}_{b' \sim D(b)} \varepsilon_{b,b'} = \mathbb{E}_{b \sim [\bar{n}; d]} \varepsilon_b = \varepsilon.$$

And by the symmetry of the distribution on pairs (b, b') ,

$$\mathbb{E}_{b \sim [\bar{n}; d]} \mathbb{E}_{b' \sim D(b)} \varepsilon_{b',b} = \mathbb{E}_{b' \sim D(b)} \mathbb{E}_{b \sim [\bar{n}; d]} \varepsilon_{b',b} = \varepsilon.$$

Combined together, the previous two equations imply that

$$\mathbb{E}_{b \sim [\bar{n}; d]} \mathbb{E}_{b' \sim D(b)} (\varepsilon_{b,b'} + \varepsilon_{b',b}) = 2\varepsilon,$$

and by the Markov inequality, Inequality 4 follows. By the definition of $\varepsilon_{b,b'}$,

$$\Pr_{x \sim \mathcal{D}_{b,b'}} \left(\chi_{F(b)}(x) = \chi_{F(b')}(x) \right) > 1 - (\varepsilon_{b,b'} + \varepsilon_{b',b}).$$

which is equivalent to

$$\Pr_{x \sim \mathcal{D}_{b,b'}} \left(\chi_{F(b) \Delta F(b')}(x) = 1 \right) > 1 - (\varepsilon_{b,b'} + \varepsilon_{b',b}).$$

Proposition 2.7 implies that if $1 - (\varepsilon_{b,b'} + \varepsilon_{b',b}) > \frac{2}{3}$, then

$$F(b)_{C_b \cap C_{b'}} = F(b')_{C_b \cap C_{b'}}.$$

By Theorem 2.5, the function $F : [\bar{n}; d] \rightarrow \mathbb{F}_2^d$ is close to a direct product, i.e., there exist d functions $F_1, \dots, F_d : [n] \rightarrow \mathbb{F}_2$ such that

$$\Pr_{b \sim [\bar{n}; d]} (F(b) = (F_1(b_1), \dots, F_d(b_d))) \geq 1 - O(\varepsilon).$$

Therefore,

$$\Pr_{b \sim [\bar{n}; d]} \left(f(b) = \bigoplus_{i=1}^d F_i(b_i) \right) \geq 1 - O(\varepsilon). \quad \blacktriangleleft$$

3 The Shapka Test

In this section we present a different test for whether a tensor is a tensor product. It queries the tensor at $(d + 2)$ places at most, but the proof is simpler than for the previous test.

In [11], Kaufman and Lubotzky showed an interesting connection between the theory of high-dimensional expanders and property testing. Namely, they showed that \mathbb{F}_2 -coboundary expansion of a 2-dimensional complete simplicial complex implies testability of whether a symmetric \mathbb{F}_2 -matrix is a tensor square of a vector. The following test is inspired by their work and in a way generalizes it. However, since the description below does not employ neither terminology nor machinery of high-dimensional expanders, we refer to [11] for the connection between this theory and property testing.

Given two strings $a, b \in [\bar{n}; d]$, for $i \in [d]$ denote by $a_b^i \in [\bar{n}; d]$ the vector which coincides with a in every coordinate except for the i -th one, where it coincides with b , i.e.,

$$(a_b^i)_j = \begin{cases} a_j, & \text{if } j \neq i; \\ b_i, & \text{if } j = i. \end{cases}$$

For a string $a \in [\bar{n}; d]$, and a number $x \in [n_i]$, we write a_x^i for the string which is equal to a in every coordinate except for the i -th one, where it is equal to x , i.e.,

$$a_x^i = (a_1, \dots, a_{i-1}, x, a_{i+1}, \dots, a_d).$$

Test 5 The Shapka Test.

Given a query access to a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$:

1. Choose $a, b \in [\bar{n}; d]$ uniformly at random.
 2. Define the query set $Q_{a,b} \subseteq [\bar{n}; d]$ to consist of a, a_b^j for all $j \in [d]$, and also b if d is even.
 3. Query f at the elements of $Q_{a,b}$.
 4. Accept iff $\bigoplus_{q \in Q_{a,b}} f(q) = 0$.
-

► **Remark 3.1.** Shapka is the Russian word for a winter hat (derived from Old French *chape* for a *cap*). The name *the Shapka test* comes from the fact that the set $Q_{a,b}$ consists of the two top layers of the induced binary cube $C_{a,b}$ (and also the bottom layer if d is even).

► **Theorem 3.2.** *Suppose a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$ passes Test 5 with probability $1 - \varepsilon$ for some $\varepsilon > 0$, then f is ε -close to a tensor product.*

Proof. Let δ be the relative Hamming distance from f to the subspace of direct sums, i.e., for every direct sum $g : [\bar{n}; d] \rightarrow \mathbb{F}_2$ it holds that

$$\Pr_{x \sim [\bar{n}; d]} (f(x) \neq g(x)) \geq \delta.$$

For a vector $a \in [\bar{n}; d]$, let us define the local view of f from a , that is d functions f_1^a, \dots, f_d^a , where $f_i^a : [n_i] \rightarrow \mathbb{F}_2$, $i = 1, \dots, d$, that are defined as follows. For $1 \leq i \leq d - 1$, and $x \in [n_i]$,

$$f_i^a(x) = f(a_x^i).$$

For $i = d$, the definition of $f_d^a : [n_d] \rightarrow \mathbb{F}_2$ depends on the parity of d and goes as follows

$$\begin{cases} f_d^a(x) = f(a_x^d), & \text{if } d \text{ is odd,} \\ f_d^a(x) = f(a_x^d) \oplus f(a), & \text{if } d \text{ is even.} \end{cases}$$

Given a collection of d functions, $g_i : [n_i] \rightarrow \mathbb{F}_2$, $i = 1, \dots, d$, recall that their direct sum is the function $g_1 \oplus \dots \oplus g_d$ such that for a vector $x \in [\bar{n}; d]$ the following holds

$$g_1 \oplus \dots \oplus g_d = \bigoplus_{i \in [d]} g_i(x_i).$$

The following holds for any $[\bar{n}; d]$,

$$(f - f_1^a \oplus \dots \oplus f_d^a)(b_1, \dots, b_d) = \bigoplus_{q \in Q_{a,b}} f(q). \quad (5)$$

As $f_1^a \oplus \dots \oplus f_d^a$ is a direct sum, it is at least δ -far from f , and hence for any $a \in [\bar{n}; d]$,

$$\Pr_{b \sim [\bar{n}; d]} ((f - f_1^a \oplus \dots \oplus f_d^a)(b) = 1) \geq \delta. \quad (6)$$

Assume now that f fails Test 5 with probability ε , i.e.,

$$\varepsilon = \Pr_{a, b \sim [\bar{n}; d]} \left(\bigoplus_{q \in Q_{a,b}} f(q) = 1 \right).$$

Combining this equality with (5) and (6), we get the following

$$\varepsilon = \mathbb{E}_{a \sim [\bar{n}; d]} \Pr_{b \sim [\bar{n}; d]} ((f - f_1^a \oplus \dots \oplus f_d^a)(b_1, \dots, b_d) = 1) \geq \left(\mathbb{E}_{a \sim [\bar{n}; d]} \delta \right) = \delta,$$

which completes the proof. ◀

4 Further Directions

Below we present possible directions for future research.

1. Can the original function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$ be reconstructed by a voting scheme using the Shapka Test 5?
2. It is plausible that the Square in the Cube test 2 can be analyzed by the Fourier transform approach similarly to the analysis of the BLR test.
3. Another test in the spirit of the Shapka Test is the following.

Test 6 The Shapka Test.

Given a query access to a function $f : [\bar{n}; d] \rightarrow \mathbb{F}_2$:

- a. Choose $a, b \in [\bar{n}; d]$ uniformly at random.
 - b. Choose $x \in C_{a,b}$ uniformly at random.
 - c. Query f at $\rho_{a,b}(0), \rho_{a,b}(x), \rho_{a,b}(1)$ and $\rho_{a,b}(x \oplus 1)$.
 - d. Accept iff $f(\rho_{a,b}(0)) \oplus f(\rho_{a,b}(x)) \oplus f(\rho_{a,b}(1)) \oplus f(\rho_{a,b}(x \oplus 1)) = 0$.
-

We conjecture that this test is also good, i.e., if a function passes the test with high probability then it is close to a tensor product.

A Appendix: Proof of Remark 2.6

In this section we show that Theorem 2.5 holds for a wider range of parameters than in its original formulation in [6]. This was used in the course of the proof of 2.1.

In [6], Dinur and Steurer proved Theorem 2.5 for $0 < \alpha < 1/2$. The following reduction shows that the theorem is true for all $0 < \alpha < 1$ by a reduction from $1/2 \leq \alpha < 1$ to some $0 < \alpha' < 1/2$. Recall that Test 4 makes two queries according to the distribution $\mathcal{T}(t)$, which is the following distribution: (1) Choose a set $A \subset [k]$ of size t uniformly at random. (2) Choose $x, y \in [N]^k$ uniformly at random, conditioned $x_A = y_A$.

► **Proposition A.1.** *Let $\text{agr}(g, \alpha)$ denote the probability that a function g passes Test 4 with respect to distribution $\mathcal{T}(\alpha k)$. If $\text{agr}(g, \alpha) \geq 1 - \varepsilon$ for some $1/2 \leq \alpha \leq 1$, then $\text{agr}(g, \alpha') \geq 1 - r\varepsilon$ for $0 < \alpha' \leq 1/2$, where $r = \left\lceil \frac{1}{2(1-\alpha)} \right\rceil$ and $\alpha' = 1 - (1 - \alpha)r$.*

In addition, if $\text{agr}(g, 1/2) \geq 1 - \varepsilon$, then also $\text{agr}(g, \alpha - 1/k) \geq 1 - 2\varepsilon$.

Proof. Fix a function $g : [N]^k \rightarrow [M]^k$, and suppose $\text{agr}(g, \alpha) \geq 1 - \varepsilon$ for some $1/2 \leq \alpha < 1$, i.e.,

$$\Pr_{A, x, y \sim \mathcal{T}(\alpha k)} (g(x)_A = g(y)_A) \geq 1 - \varepsilon.$$

We will show that $\text{agr}(g, \alpha') > 1 - r\varepsilon$ where $r = \left\lceil \frac{1}{2(1-\alpha)} \right\rceil$ and $\alpha' = 1 - (1 - \alpha)r$. Note that α' satisfies $0 < \alpha' \leq 1/2$.

Given a pair of random vectors x_0, x_r and a set A distributed according to $\mathcal{T}(\alpha'k)$, we construct a sequence of vectors x_1, \dots, x_{r-1} such that for all $1 \leq i \leq r$, the pair x_{i-1}, x_i is distributed according to $\mathcal{T}(\alpha k)$.

The complement of A has size $(1 - \alpha)rk$. Partition it randomly into r parts of equal size $(1 - \alpha)k$, $[k] \setminus A = B_1 \cup \dots \cup B_r$. Denote $C_i = [k] \setminus B_i$ for all $1 \leq i \leq r$.

For each $1 \leq i \leq r - 1$, construct x_i such that it agrees with x_0 on the coordinates in $[k] \setminus \bigcup_{j=1}^i B_j$ and with x_r on the rest of the coordinates $\bigcup_{j=i}^r B_j$. Then for each $1 \leq i \leq r$, x_i agrees with x_{i-1} on the set C_i of the size αk . Therefore,

$$\Pr (g(x_{i-1})_{A_i} = g(x_i)_{A_i}) \geq 1 - \varepsilon.$$

Hence,

$$1 - r \cdot \varepsilon \leq \Pr (\forall 1 \leq i \leq r : g(x_{i-1})_{A_i} = g(x_i)_{A_i}) \leq \Pr_{A_r, x, y \sim \mathcal{T}(\alpha'k)} (g(x_0)_{A_r} = g(x_r)_{A_r}).$$

The case of $\alpha' = 1/2$ has to be treated separately. In this case there is a reduction to $\alpha'' = 1/2 - 1/k$ as follows. Given two vectors x_0, x_2 distributed w.r.t. $\mathcal{T}(k/2 - 1)$ construct an intermediate random vector x_1 which agrees on exactly half of the coordinates with both x_0 and x_2 . ◀

Abstract

For spin systems, such as the hard-core model on independent sets weighted by fugacity $\lambda > 0$, efficient algorithms for the associated approximate counting/sampling problems typically apply in the high-temperature region, corresponding to low fugacity. Recent work of Jenssen, Keevash and Perkins (2019) yields an FPTAS for approximating the partition function (and an efficient sampling algorithm) on bounded-degree (bipartite) expander graphs for the hard-core model at sufficiently high fugacity, and also the ferromagnetic Potts model at sufficiently low temperatures. Their method is based on using the cluster expansion to obtain a complex zero-free region for the partition function of a polymer model, and then approximating this partition function using the polynomial interpolation method of Barvinok. We present a simple discrete-time Markov chain for abstract polymer models, and present an elementary proof of rapid mixing of this new chain under sufficient decay of the polymer weights. Applying these general polymer results to the hard-core and ferromagnetic Potts models on bounded-degree (bipartite) expander graphs yields fast algorithms with running time $O(n \log n)$ for the Potts model and $O(n^2 \log n)$ for the hard-core model, in contrast to typical running times of $n^{O(\log \Delta)}$ for algorithms based on Barvinok’s polynomial interpolation method on graphs of maximum degree Δ . In addition, our approach via our polymer model Markov chain is conceptually simpler as it circumvents the zero-free analysis and the generalization to complex parameters. Finally, we combine our results for the hard-core and ferromagnetic Potts models with standard Markov chain comparison tools to obtain polynomial mixing time for the usual spin system Glauber dynamics restricted to even and odd or “red” dominant portions of the respective state spaces.

1 Introduction

The hard-core model from statistical physics is defined on the set of independent sets of a graph G , where the independent sets are weighted by a fugacity $\lambda > 0$. The associated Gibbs distribution $\mu_{G,\lambda}$ is defined as follows, for an independent set I :

$$\mu_{G,\lambda}(I) = \frac{\lambda^{|I|}}{Z_{G,\lambda}} \quad (1)$$

where $Z_{G,\lambda} = \sum_{I \in \mathcal{I}(G)} \lambda^{|I|}$ is the hard-core partition function (also called the independence polynomial), $\mathcal{I}(G)$ is the set of independent sets of G , and $\lambda > 0$ is the *fugacity*.

In applications, there are two important computational tasks associated to a spin system such as the hard-core model. Given an error parameter $\varepsilon \in (0, 1)$, an ε -approximate counting algorithm outputs a number \hat{Z} so that $e^{-\varepsilon} Z_{G,\lambda} \leq \hat{Z} \leq e^{\varepsilon} Z_{G,\lambda}$, and an ε -approximate sampling algorithm outputs a random sample I with distribution $\hat{\mu}$ so that the total variation distance satisfies $\|\mu_\lambda - \hat{\mu}\|_{TV} < \varepsilon$.

While classical statistical physics is most interested in studying the hard-core model on the integer lattice \mathbb{Z}^d , the perspective of computer science is to consider wider families of graphs, such as the set of all graphs, all graphs of maximum degree Δ , or all bipartite graphs of maximum degree Δ .

Almost all proven efficient algorithms for approximate counting and sampling from the hard-core model work for low fugacities (*high temperatures* in the language of statistical physics). In the high temperature regime there are at least three distinct algorithmic approaches to approximate counting and sampling: Markov chains, correlation decay, and polynomial interpolation. One striking advantage of the Markov chain approach is that the algorithms are much faster and simpler than the algorithms from the other approaches. In

particular, it is common for a Markov chain sampling algorithm to run in time $O(n \log n)$, e.g., see [8, 10], while typical running times for algorithms based on correlation decay [26, 21] and polynomial interpolation [1] are $n^{O(\log \Delta)}$ where Δ is the maximum degree of the graph.

In general there are no known efficient algorithms at low temperatures (high fugacities), but recently efficient algorithms have been developed for some special classes of graphs including subsets of \mathbb{Z}^d [14], random regular bipartite graphs, and bipartite expander graphs in general [16, 20]. What these bipartite graphs have in common is that for large enough λ , typical independent sets drawn from $\mu_{G,\lambda}$ align closely with one side or the other of the bipartition (the two ground states). This phenomenon is related to the phase transition phenomenon in infinite graphs, and implies the exponentially slow mixing time of local Markov chains [4, 12, 22]. The algorithms introduced in [14] exploit this phenomenon by expressing the partition function $Z_{G,\lambda}$ in terms of deviations from the two ground states, and then using a truncation of a convergent series expansion (the Taylor series or the cluster expansion) to approximate the log partition function. In statistical physics this is called a *perturbative* approach, and while in general it does not work in the largest possible range of parameter space, when it does work it gives a very detailed probabilistic understanding of the model [24, 6, 7].

To apply the perturbative approach at low temperatures, one rewrites the original spin model as a new model in which single spin interactions are replaced by the interaction of connected components representing deviations from a chosen ground state. Such models are called *abstract polymer models*, as detailed below, and have long been used in statistical physics to understand phase transitions. In this paper, we show that once a low temperature spin model has been transformed into an abstract polymer model, Markov chains once again become an effective algorithmic tool. Using this approach we obtain nearly linear and quadratic time sampling algorithms for low temperature models on expander graphs in cases where only $n^{O(\log \Delta)}$ -time algorithms were previously known.

1.1 Abstract polymer models

Abstract polymer models, as defined by Gruber and Kunz in 1971 [13], (or “animal models” in Dobruishin’s terminology [7]) are an important tool in studying the equilibrium phases of statistical physics models on lattices (e.g. [19, 6] among many others; see [3] for a brief history of their use in statistical physics and combinatorics). Recently they have been used to develop efficient algorithms for sampling and approximating the partition functions of statistical physics models on lattices [14] and expander graphs [16, 20] at low temperatures, the regime in which Markov chains like the Glauber dynamics are known to mix slowly.

We will study the following polymer models. We start with a host graph G and a set $[q] = \{0, \dots, q-1\}$ of spins. For each vertex v , there is a ground-state spin g_v . A polymer γ consists of a connected set of vertices together with an assignment σ_γ of spins from $\{0, \dots, q-1\} \setminus g_v$ to each vertex $v \in \gamma$ (we abuse notation and use γ to denote both the polymer and the associated set of vertices). The size of a polymer, $|\gamma|$, is the number of vertices in γ . The set of all polymers is $\mathcal{P}(G)$.

A polymer model on G consists of a set $\mathcal{C}(G) \subseteq \mathcal{P}(G)$ of “allowed” polymers, and a non-negative weight w_γ for each polymer $\gamma \in \mathcal{C}(G)$. We denote this model by $(\mathcal{C}(G), w)$. Two polymers γ and γ' are “compatible” (written $\gamma \sim \gamma'$) if their distance in the host graph is at least 2; otherwise they are incompatible (written $\gamma \approx \gamma'$). The state space of allowable configurations is $\Omega = \{\Gamma \subseteq \mathcal{C}(G) \mid \forall \gamma, \gamma' \in \Gamma, \gamma \sim \gamma'\}$.

The partition function of the polymer model is $Z(G) = \sum_{\Gamma \in \Omega} \prod_{\gamma \in \Gamma} w_\gamma$, where the empty set of polymers contributes 1 to the partition function. The Gibbs measure μ_G is the probability distribution on Ω given by $\mu_G(\Gamma) = \frac{\prod_{\gamma \in \Gamma} w_\gamma}{Z(G)}$.

The polymer model is in fact a hard-core model on the “incompatibility graph” of $\mathcal{C}(G)$ (two polymers joined by an edge if they are incompatible), with non-uniform fugacities given by the weights w_γ . However, the geometry inherited from the host graph G and the sizes of the polymers adds additional structure to the model.

► **Example 1.** One instance of a polymer model is the hard-core model itself: polymers are single vertices of the graph G , labeled with “1” (for occupied) against a ground state “0” (for unoccupied). Each polymer (vertex) v comes with the weight function $w_v = \lambda$. Then the set of allowable polymer configurations is exactly the set of independent sets of G , and so the polymer model partition function is exactly the partition function of the hard-core model on G .

► **Example 2.** A second instance of a polymer model is related to the ferromagnetic q -color Potts model on a graph G (see Definition 8 below). Fix a color $g \in [q]$ to be the ground state color, and define polymers to be connected subgraphs of G of size at most M , with vertices labeled by the remaining colors $[q] \setminus \{g\}$. A polymer γ has weight function $w_\gamma = e^{-\beta B(\gamma)}$ where $B(\gamma)$ is the number of bichromatic edges in γ plus the size of the edge boundary of γ in G . A configuration of compatible polymers maps to a Potts configuration σ in which all connected components of non- g -colored vertices have size at most M , and the weight of σ in the Potts model is exactly the product of the weight functions of the polymers. The polymer model partition function $Z(G)$, with an appropriate choice of M , represents the contribution to the Potts model partition function of colorings with dominant color g .

As with the hard-core model, there are two main computational problems associated to a polymer model: approximate sampling from μ_G and approximate counting of $Z(G)$. We will approach them both via Markov chain algorithms. In general we will be interested in families of polymer models defined on classes of graphs. We denote such a family $(\mathcal{C}(\cdot), w, \mathcal{G})$, where for each graph $G \in \mathcal{G}$, $(\mathcal{C}(G), w)$ is a polymer model. We will always use n to denote the number of vertices of a graph G .

We consider two conditions on the weight functions w_γ and give their algorithmic consequences.

► **Definition 1.** A polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ satisfies the polymer mixing condition if there exists $\theta \in (0, 1)$ such that

$$\sum_{\gamma' \sim \gamma} |\gamma'| w_{\gamma'} \leq \theta |\gamma| \tag{2}$$

for all $G \in \mathcal{G}$ and all $\gamma \in \mathcal{C}(G)$.

We postpone the formal definition of mixing time to Section 2 and state our first main result here.

► **Theorem 2.** Suppose that a polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ satisfies the polymer mixing condition (2). Then for each $G \in \mathcal{G}$ there is a Markov chain making single polymer updates with stationary distribution μ_G and mixing time $T_{\text{mix}}(\varepsilon) = O(n \log(n/\varepsilon))$.

Theorem 2 on its own does not guarantee an efficient algorithm for sampling from μ_G because the Markov chain only yields an efficient sampling algorithm if we can implement each step efficiently. We will show that under a stronger condition we can do this.

► **Definition 3.** A polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ is said to be computationally feasible if, for each $G \in \mathcal{G}$ and each $\gamma \in \mathcal{P}(G)$, we can determine, in time polynomial in $|\gamma|$, whether $\gamma \in \mathcal{C}(G)$, and compute w_γ if it is.

► **Definition 4.** A computationally feasible polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ with q spins on a class \mathcal{G} of graphs of maximum degree Δ satisfies the polymer sampling condition with constant $\tau \geq 5 + 3 \log((q-1)\Delta)$ if

$$w_\gamma \leq e^{-\tau|\gamma|} \tag{3}$$

for all $G \in \mathcal{G}$ and all $\gamma \in \mathcal{C}(G)$.

We have the following theorem.

► **Theorem 5.** If a computationally feasible polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ satisfies the polymer sampling condition (3) then for all $G \in \mathcal{G}$ there is an ε -approximate sampling algorithm for μ_G with running time $O(n \log(n/\varepsilon))$.

Finally, we can use the sampling algorithm and simulated annealing to give a fast approximate counting algorithm.

► **Theorem 6.** If a computationally feasible polymer model $(\mathcal{C}(\cdot), w, \mathcal{G})$ satisfies the polymer sampling condition (3) then for all $G \in \mathcal{G}$ there is a randomized ε -approximate counting algorithm for $Z(G)$ with running time $O((n/\varepsilon)^2 \log^2(n/\varepsilon))$ and success probability at least $3/4$.

Fernández, Ferrari, and Garcia [11] introduced a condition very similar to the polymer mixing condition in the setting of polymer models on \mathbb{Z}^d . Their objective was to derive probabilistic properties of polymer models directly, without going through the combinatorics and complex analysis inherent in the cluster expansion for the log partition function. They introduced a continuous time stochastic process whose stationary distribution was the infinite volume Gibbs measure of their polymer model and their version of condition (2) implied an exponentially fast rate of convergence of this process. They remarked that such an approach had the potential to be an efficient computational tool.

Here we take an algorithmic point of view, and use the polymer mixing and sampling conditions to show that a simple discrete time Markov chain mixes rapidly and can be used to design efficient sampling and approximation algorithms. Our approach differs from that of [11] in that while they are interested primarily in the probabilistic properties of spin models on \mathbb{Z}^d , we are interested in algorithmic problems involving spin models on general families of graphs. Our setting of discrete time processes on finite graphs is also more suitable to studying algorithmic questions. Our work confirms the central point of [11]: that complex analysis and absolute convergence of the cluster expansion is not necessary to derive many important properties of a polymer model.

1.2 Applications

We apply our results for abstract polymer models to two specific examples: the ferromagnetic Potts model and the hard-core model on expander graphs. To state these results we need some definitions.

► **Definition 7.** Let $\alpha > 0$. A graph G is an α -expander graph if for all $S \subset V(G)$ with $|S| \leq |V(G)|/2$, we have $e(S, S^c) \geq \alpha|S|$, where $S^c = V(G) \setminus S$ and $e(S, S^c)$ is the number of edges exiting the set S .

► **Definition 8.** The q -color ferromagnetic Potts model with parameter $\beta > 0$ is a random assignment of q colors to the vertices of a graph defined by

$$\mu_{G,\beta}(\sigma) = \frac{e^{-\beta m(G,\sigma)}}{Z_{G,\beta}}$$

where $m(G,\sigma)$ is the number of bichromatic edges of G under the coloring σ and $Z_{G,\beta} = \sum_{\sigma} e^{-\beta m(G,\sigma)}$ is the Potts model partition function. The parameter β is known as the inverse temperature.

Jenssen, Keevash, and Perkins [16] gave an FPTAS and polynomial-time sampling algorithm for the Potts model on expander graphs, with an algorithm based on the cluster expansion and Barvinok's method of polynomial interpolation. Under essentially the same conditions on the parameters we give a Markov chain based sampling algorithm with near linear running time.

► **Theorem 9.** Suppose $q \geq 2$, $\Delta \geq 3$ are integers and $\alpha > 0$ is a real. Then for $\beta \geq \frac{5+3 \log((q-1)\Delta)}{\alpha}$ and any $qe^{-n} \leq \varepsilon < 1$, there is an ε -approximate sampling algorithm for the q -state ferromagnetic Potts model with parameter β on all n -vertex α -expander graphs of maximum degree Δ with running time $O(n \log(n/\varepsilon))$. There is also an ε -approximate counting algorithm with running time $O((n/\varepsilon)^2 \log^2(n/\varepsilon))$ and success probability at least $3/4$.

► **Definition 10.** Let $\alpha \in (0, 1)$. A bipartite graph $G = (V, E)$ with bipartition $V = V^0 \cup V^1$ is a bipartite α -expander if, for $i \in \{0, 1\}$ and all $S \subseteq V^i$ where $|S| \leq |V^i|/2$, we have $N_G(S) \geq (1 + \alpha)|S|$ where $N_G(S)$ denotes the set of vertices that are adjacent to some vertex in S .

Again we give a fast Markov chain based algorithm for sampling from the hard-core model for essentially the same range of parameters for which an FPTAS is given in [16].

► **Theorem 11.** Suppose $\Delta \geq 3$ is an integer and $\alpha \in (0, 1)$ is a real. Then for any $\lambda \geq (3\Delta)^{6/\alpha}$ and $4e^{-n} \leq \varepsilon < 1$, there is an ε -approximate sampling algorithm for the hard-core model with parameter λ on all n -vertex bipartite α -expander graphs of maximum degree Δ . There is also an ε -approximate counting algorithm for the hard-core model with success probability at least $1 - \varepsilon$. Both algorithms run in time $O((n/\varepsilon)^2 \log^3(n/\varepsilon))$.

The extra factor of n in the running time of the sampling algorithm for the hard-core model as compared to the Potts model is due to the fact that the hard-core model on a bipartite graph does not in general exhibit exact symmetry between the ground states, and so we must approximate the partition functions of the even and odd dominant independent sets to sample.

We can extend these algorithms to obtain fast sampling algorithms in most situations in which a counting problem can be put in the framework of abstract polymer models. For instance, we can use Theorems 5 and 6 to improve the running times of the algorithms given by [17, 20] for sampling and counting proper q -colorings in Δ -regular bipartite graphs (for large Δ). Section 5 of [17] gives a polymer model for proper q -colorings on Δ -regular bipartite graphs. The polymer model is computationally feasible. They prove in Section 5.1 that it satisfies the Kotecký-Preiss condition – in fact, their proof establishes the polymer sampling condition (3). Thus, we get the following corollary of Theorem 5 and 6.

► **Corollary 12.** *There is an absolute constant $C > 0$ so that for all even $q \geq 3$, all $\Delta \geq Cq^2 \log^2 q$ and all $\varepsilon > e^{-n/(8q)}$, there is an ε -approximate sampling algorithm to sample a uniformly random proper q -coloring from a random Δ -regular bipartite graph running in time $O(n \log(n/\varepsilon))$. Furthermore, there is a randomized ε -approximation algorithm for the number of proper q -colorings with running time $O((n/\varepsilon)^2 \log^2(n/\varepsilon))$ and success probability at least $3/4$. For odd q , there are ε -approximate counting and sampling algorithms that both run in time $O((n/\varepsilon)^2 \log^3(n/\varepsilon))$.*

As with independent sets, the extra factor of n in the running time for odd q comes from the fact that the ground states (colorings in which one side of the bipartition is assigned $\lfloor q/2 \rfloor$ colors and the other side $\lfloor q/2 \rfloor$ colors) are exactly symmetric only if q is even.

Finally, we remark that the approximate counting algorithms for these applications based on truncating the cluster expansion can run faster than $n^{O(\log \Delta)}$ if the parameters (expansion, fugacity, inverse temperature) are high enough (see [17, Theorem 8]), but the sampling algorithms derived from this approach will not match the $\tilde{O}(n)$ or $\tilde{O}(n^2)$ sampling algorithms we obtain here.

1.3 Comparison to spin Glauber dynamics

A very natural idea to sample at low temperatures (large β for the Potts model, large λ for the hard-core model) is to use a single-spin update Markov chain like the Glauber dynamics, but to start in one of the ground states of the model chosen at random. For example, pick one of the q -colors with equal probability then start the Potts model Glauber dynamics in the monochromatic configuration with that color. The intuition is that the Glauber dynamics will mix well within the portion of the state space close to the chosen ground state, and the randomness in the choice of ground state will ensure that an accurate sample from the full measure is obtained. Analyzing this algorithm was suggested in [14] and [16].

While we are not yet able to show that this algorithm succeeds, we make partial progress. We show that Glauber dynamics, restricted to remain in a portion of the state space, mixes rapidly (in polynomial time). It is easiest to state our result for the ferromagnetic Potts model.

For a ground state color $g \in [q]$ and an integer M , let $\Omega_M^g(G)$ be the set of q -colorings of the vertices of G so that every connected component of G colored with the palette of colors $[q] \setminus g$ is of size at most M . The set $\Omega_M^g(G)$ consists of colorings that come from the valid polymer configurations from Example 2 above. In [16] it is shown that for an appropriate choice of M , the set $\{\Omega_M^g(G)\}_{g \in [q]}$ forms an “almost partition” of the set of all colorings, in that the weight of both the overlap of the almost partition and the set of colorings uncovered by the almost partition is at most ε under the conditions of Theorem 9. In particular, an ε -approximate sample from the Potts model restricted to $\Omega_M^g(G)$ for $M = O(\log(n/\varepsilon))$ is enough (by symmetry) to obtain a $(q\varepsilon)$ -approximate sample from the Potts distribution $\mu_{G,\beta}$ (cf. Lemma 28 of the full version). Using Markov chain comparison, we show in Section 5.3.1 of the full version that an efficient sampler can be obtained using the usual spin Glauber dynamics restricted to remain in $\Omega_M^g(G)$.

► **Theorem 13.** *Under the conditions of Theorem 9, and with $M = O(\log(n/\varepsilon))$, the Glauber dynamics restricted to $\Omega_M^g(G)$ has mixing time $T_{\text{mix}}(\varepsilon)$ polynomial in n and $1/\varepsilon$.*

Theorem 13 shows that, despite the exponentially slow mixing of the Glauber dynamics on the full state space, it can still be used by restricting the state space to obtain a polynomial-time approximate sampling algorithm.

In Section 5 of the full version, we give a result (Theorem 23) which is similar to Theorem 13 but applies much more generally – to polymer models which satisfy the polymer mixing condition and other mild conditions. We also obtain a similar theorem (Theorem 29) specifically for the hard-core model.

We leave for future work two important extensions that would complete the picture: 1) showing that *unrestricted* Glauber dynamics starting from a well chosen configuration works, and 2) reducing the running time to $O(n \log n)$ from the large polynomial that we obtain in the theorem.

2 Polymer models and Markov chains

In the full version, we show that the polymer sampling condition (3) implies the well-known Kotecký–Preiss [18] condition $\sum_{\gamma' \approx \gamma} e^{|\gamma'|} w_{\gamma'} \leq |\gamma|$. The Kotecký–Preiss condition, in turn, implies the polymer mixing condition (2), which is weaker than the Kotecký–Preiss [18] condition.

We next introduce the polymer Markov chain. For each $v \in V(G)$, let $\mathcal{A}(v) = \{\gamma \in \mathcal{C}(G) : v \in \gamma\}$ denote the collection of all polymers containing v and let $a(v) = \sum_{\gamma \in \mathcal{A}(v)} w_{\gamma}$. By applying (2) to the smallest γ' containing v we have $a(v) \leq \theta < 1$ for all $v \in V(G)$. Define the probability distribution ν_v on $\mathcal{A}(v) \cup \{\emptyset\}$ by $\nu_v(\gamma) = w_{\gamma}$ for $\gamma \in \mathcal{A}(v)$ and $\nu_v(\emptyset) = 1 - a(v)$.

The polymer dynamics on Ω are defined by the following transition rule from a configuration Γ_t to a configuration Γ_{t+1} :

Polymer Dynamics

1. Choose $v \in V(G)$ uniformly at random. Let $\gamma_v \in \Gamma_t \cap \mathcal{A}(v)$ if $\Gamma_t \cap \mathcal{A}(v) \neq \emptyset$ and let $\gamma_v = \emptyset$ otherwise. Note that γ_v is well defined since Γ_t can have at most one polymer containing v .
2. Mutually exclusively do the following:
 - With probability $\frac{1}{2}$, let $\Gamma_{t+1} = \Gamma_t \setminus \gamma_v$.
 - With probability $\frac{1}{2}$, sample γ from ν_v , set $\Gamma_{t+1} = \Gamma_t \cup \gamma$ if this is in Ω and set $\Gamma_{t+1} = \Gamma_t$ otherwise.

In the full version, we verify that the stationary distribution of the polymer dynamics is μ_G by checking detailed balance. Recall that if \mathcal{M} is an ergodic Markov chain with transition matrix P and stationary distribution ν then the mixing time of \mathcal{M} from a state x is given by

$$T_x(\varepsilon) = \min\{t > 0 \mid \text{for all } t' \geq t, \|P^{t'}(x, \cdot) - \nu(\cdot)\|_{TV} \leq \varepsilon\},$$

where $\|\nu' - \nu\|_{TV}$ denotes the total variation distance between distributions ν and ν' . The mixing time of \mathcal{M} is given by $T_{\text{mix}}(\varepsilon) = \max_x T_x(\varepsilon)$.

Proof of Theorem 2. We will show that under condition 2 the mixing time of the polymer dynamics is $O(n \log(n/\varepsilon))$ by applying the path coupling technique. We define a metric $D(\cdot, \cdot)$ on Ω by setting $D(\Gamma, \Gamma') = 1$ if $\Gamma' = \Gamma \cup \{\gamma\}$ or $\Gamma = \Gamma' \cup \{\gamma\}$ for a polymer γ and extending this as a shortest path metric; i.e., $D(\Gamma, \Gamma') = |\Gamma \Delta \Gamma'|$ for any $\Gamma, \Gamma' \in \Omega$ where Δ denotes the symmetric difference of two sets. The diameter W of Ω under $D(\cdot, \cdot)$ is no more than $2n$.

Now suppose we couple two chains X_t and Y_t by attempting the same updates in both chains at each step. Suppose that $X_t = Y_t \cup \{\gamma\}$ for some polymer γ . With probability $\frac{|\gamma|}{n} \cdot \frac{1}{2}$ we pick $v \in \gamma$ and remove γ_v which yields $X_{t+1} = Y_{t+1} = X_t$. On the other hand, we may

attempt to add a polymer $\gamma' \approx \gamma$ so that $Y_t \cup \{\gamma'\} \in \Omega$. That is, $X_{t+1} = X_t = Y_t \cup \{\gamma\}$ and $Y_{t+1} = Y_t \cup \{\gamma'\}$. This occurs with probability $\frac{|\gamma'|}{n} \cdot \frac{1}{2} \cdot w_{\gamma'}$ and in this case $D(X_{t+1}, Y_{t+1}) \leq 2$. Putting these together we can bound

$$\mathbb{E}[D(X_{t+1}, Y_{t+1})] \leq 1 + \frac{1}{2n} \left[-|\gamma| + \sum_{\gamma' \approx \gamma} |\gamma'| w_{\gamma'} \right].$$

Using (2) we have $\sum_{\gamma' \approx \gamma} |\gamma'| w_{\gamma'} \leq \theta |\gamma|$, and so $\mathbb{E}[D(X_{t+1}, Y_{t+1})] \leq 1 - |\gamma| \frac{1-\theta}{2n} \leq 1 - \frac{1-\theta}{2n}$. By the path coupling lemma (see [9, Section 6]), the mixing time is at most $\log(W/\varepsilon) 2n / (1-\theta) = O(n \log(n/\varepsilon))$. \blacktriangleleft

To prove Theorem 5 we will show that a single update of the polymer dynamics can be computed in constant expected time.

Assume the polymer sampling condition (3) holds with constant $\tau \geq 5 + 3 \log((q-1)\Delta)$. We will use the following algorithm. Let $r = \tau - 2 - \log((q-1)\Delta) \geq 3 + 2 \log((q-1)\Delta)$ and let $\mathcal{A}_k(v) = \{\gamma \in \mathcal{A}(v) : |\gamma| \leq k\}$.

Single polymer sampler

1. Choose \mathbf{k} according to the following geometric distribution: for k a non-negative integer, $\Pr[\mathbf{k} = k] = (1 - e^{-r})e^{-rk}$. This gives $\Pr[\mathbf{k} \geq k] = e^{-rk}$.
2. Enumerate all polymers in $\mathcal{A}_{\mathbf{k}}(v)$ and compute their weight functions.
3. Mutually exclusively output $\gamma \in \mathcal{A}_{\mathbf{k}}(v)$ with probability $w_{\gamma} e^{r|\gamma|}$, and with all remaining probability output \emptyset . In particular if $\mathbf{k} = 0$, then output \emptyset with probability 1.

We now proceed to prove the following lemma.

► Lemma 16. *Under the polymer sampling condition (3) the output distribution of the single polymer sampler is ν_v and its expected running time is constant.*

Proof. We first show that the probabilities $w_{\gamma} e^{r|\gamma|}$ sum to less than 1, which shows the last step of the sampling algorithm is well defined. Since $\tau - r = 2 + \log((q-1)\Delta)$,

$$\sum_{\gamma \in \mathcal{A}(v)} w_{\gamma} e^{r|\gamma|} \leq \frac{1}{2} \sum_{k \geq 1} (e\Delta)^{k-1} (q-1)^k e^{-\tau k + rk} = \frac{1}{2e\Delta} \sum_{k \geq 1} e^{-k} < 1,$$

where the first inequality uses the fact that, given a degree Δ graph and a vertex v , there are at most $(e\Delta)^{k-1}/2$ connected size- k subgraphs containing v – a fact proved by Borgs, Chayes, Kahn, and Lovász [5, Lemma 2.1].

We next show that the output of the algorithm has distribution ν_v . Given $\gamma \in \mathcal{A}(v)$, to output γ we must choose $\mathbf{k} \geq |\gamma|$. This happens with probability $e^{-r|\gamma|}$ by the distribution of \mathbf{k} . Conditioned on choosing such a \mathbf{k} , the probability we output γ is $w_{\gamma} e^{r|\gamma|}$, and multiplying these probabilities together gives w_{γ} as desired. Since this is true for all $\gamma \in \mathcal{A}(v)$, the output distribution is exactly ν_v .

Finally we analyze the expected running time. To do this, we appeal to Lemma 3.7 of [23] which gives an algorithm with running time $O(k^5 (e\Delta)^{2k})$ for listing all connected subgraphs containing a given vertex v of size at most k (given a graph of degree at most Δ). Consequently, conditioned on the event that $\mathbf{k} = k$, the enumeration step of our algorithm takes time $O(k^5 (e\Delta)^{2k})$, and the time taken to determine which polymers are allowed and to compute their weights is $O(k^c (q-1)^k (e\Delta)^{k-1}/2)$ for some $c > 0$, since the polymer model is computationally feasible. In expectation therefore, the running time is

$$\begin{aligned}
& O \left(1 + \sum_{k \geq 1} \Pr[\mathbf{k} = k] (k^5 (e\Delta)^{2k} + k^c (e(q-1)\Delta)^k) \right) \\
& = O \left(1 + \sum_{k \geq 1} e^{-rk} k^c (e(q-1)\Delta)^{2k} \right) = O \left(1 + \sum_{k \geq 1} k^c e^{-(\tau'+1)k} \right) = O(1),
\end{aligned}$$

where $\tau' = \tau - 5 - 3 \log((q-1)\Delta) \geq 0$. \blacktriangleleft

Proof of Theorem 5. By Theorem 2, there is $T_\varepsilon = O(n \log(n/\varepsilon))$ so that if we start with the empty configuration $\Gamma_0 = \emptyset$ and run the polymer dynamics, then Γ_{T_ε} has distribution within $\varepsilon/2$ total variation distance of μ_G . By Lemma 16, in expectation the running time will be $O(n \log(n/\varepsilon))$, but we want an upper bound on the worst case running time as well. To do this, we will simply stop the algorithm and output the empty configuration if the total running time exceeds L for some $L = O(n \log(n/\varepsilon))$ with a sufficiently large leading constant. We next show that the probability that the algorithm terminates in L steps is at most $\varepsilon/2$, which therefore yields that the output distribution has total variation distance at most ε from μ_G .

The randomness in the running time comes from the choice of the geometric random variable \mathbf{k} at each step and the time taken to enumerate polymers in $\mathcal{A}_{\mathbf{k}}(v)$. By the choice of r , the random variable that takes the value $k^5 (e\Delta)^{2k} + k^c (e(q-1)\Delta)^k$ with probability $(1 - e^{-r})e^{-rk}$ has exponential tails, and so a Chernoff bound shows that the probability that the sum of $\Theta(n \log(n/\varepsilon))$ independent copies of such a random variable is at least twice its expectation is bounded by $e^{-\Theta(n \log(n/\varepsilon))}$ which is at most $\varepsilon/2$ (for large enough choice of constants), finishing the proof. \blacktriangleleft

3 Approximate counting algorithm

In this section we show how to use a sampling oracle to approximately compute the partition function of the polymer model. One standard way is by self-reducibility. In [14] an efficient sampling algorithm for polymer models is derived from an efficient approximate counting algorithm by applying self-reducibility on the level of polymers. While we could apply polymer self-reducibility in the other direction to obtain counting algorithms from our sampling algorithm, here we use the simulated annealing method instead (see [2, 15, 25]) to obtain a faster implementation of counting from sampling.

Suppose that $(\mathcal{C}(G), w)$ is a computationally feasible polymer model. Let ρ be a parameter and define a weight function $w_\gamma(\rho) = w_\gamma e^{-\rho|\gamma|}$ for all $\gamma \in \mathcal{C}(G)$. Then for each $\rho \geq 0$ this defines a computationally feasible polymer model $(\mathcal{C}(G), w(\rho))$ on G , where setting $\rho = 0$ recovers the original model $(\mathcal{C}(G), w)$. If the original model $(\mathcal{C}(G), w)$ satisfies the polymer sampling condition (3), then so does $(\mathcal{C}(G), w(\rho))$ for every $\rho \geq 0$ as the weight function $w_\gamma(\rho)$ is monotone decreasing in ρ . Given the graph G , we write the partition function of the polymer model $(\mathcal{C}(G), w(\rho))$ as a function of ρ :

$$Z(\rho) = Z(G; \rho) = \sum_{\Gamma \in \Omega} \prod_{\gamma \in \Gamma} w_\gamma(\rho) = \sum_{\Gamma \in \Omega} \prod_{\gamma \in \Gamma} w_\gamma e^{-\rho|\gamma|}.$$

The associated Gibbs distribution is denoted by $\mu_\rho = \mu_{G; \rho}$. Since $\lim_{\rho \rightarrow \infty} w_\gamma(\rho) = 0$, we have $\lim_{\rho \rightarrow \infty} Z(\rho) = 1$ (only the empty configuration Γ contributes to this limit), and so we will use simulated annealing to interpolate between $Z(\infty) = 1$ and our goal $Z(0)$, assuming

access to a sampling oracle for $(\mathcal{C}(G), w(\rho))$ for all $\rho \geq 0$. To apply the simulated annealing method, roughly speaking, we find a sequence of parameters $0 = \rho_0 < \rho_1 < \dots < \rho_\ell < \infty$ called a *cooling schedule* where $\ell \in \mathbb{N}^+$, and then estimate $Z(0)$ using the telescoping product

$$\frac{1}{Z(0)} = \frac{1}{Z(\rho_0)} = \frac{Z(\rho_1)}{Z(\rho_0)} \frac{Z(\rho_2)}{Z(\rho_1)} \dots \frac{Z(\rho_\ell)}{Z(\rho_{\ell-1})} \frac{1}{Z(\rho_\ell)}.$$

To estimate each term $Z(\rho_{i+1})/Z(\rho_i)$, we define independent random variables $W_i = \prod_{\gamma \in \Gamma_i} \frac{w_\gamma(\rho_{i+1})}{w_\gamma(\rho_i)}$, where $\Gamma_i \sim \mu_{\rho_i}$. It is straightforward to see that $\mathbb{E}[W_i] = Z(\rho_{i+1})/Z(\rho_i)$ (see Lemma 17 of the full version, where we also require the variance). Using the sampling oracle for μ_{ρ_i} , we can sample W_i for all i , and by taking the product we get an estimate for $1/Z(0)$.

The key ingredient of simulated annealing is finding a good cooling schedule. There are nonadaptive schedules [2] that depend only on n , and adaptive schedules [15, 25] that also depend on the structure of $Z(\cdot)$. Usually the latter leads to faster algorithms than the former. In this paper we use a simple nonadaptive schedule: $\rho_i = i/n$ for $i = 1, \dots, \ell$ where $\ell = O(n \log(n/\varepsilon))$. We show that this cooling schedule already gives us a fast algorithm for the polymer model. The reason behind it is that the weight function $w_\gamma(\rho)$ decays exponentially fast, and so (see Lemma 18 of the full version) the partition function $Z(\rho_\ell)$ is bounded by a constant when $\rho_\ell = O(\log n)$, leading to a short cooling schedule. Our algorithm is as follows.

Polymer approximate counting algorithm

1. Let $\rho_i = i/n$ for $i = 0, 1, \dots, \ell$ where $\ell = \lceil n \log(4e(q-1)\Delta n/\varepsilon) \rceil$;
2. For $j = 1, \dots, m$ where $m = \lceil 64\varepsilon^{-2} \rceil$:
 - a. For $0 \leq i \leq \ell - 1$:
 - (i) Sample $\Gamma_i^{(j)}$ from μ_{ρ_i} ;
 - (ii) Let $W_i^{(j)} = \prod_{\gamma \in \Gamma_i^{(j)}} e^{-|\gamma|/n}$;
 - b. Let $W^{(j)} = \prod_{i=0}^{\ell-1} W_i^{(j)}$;
3. Let $\widehat{W} = \frac{1}{m} \sum_{j=1}^m W^{(j)}$ and output $\widehat{Z} = 1/\widehat{W}$.

For $0 \leq i \leq \ell - 1$ we define Γ_i to be an independent random sample from μ_{ρ_i} and $W_i = \prod_{\gamma \in \Gamma_i} e^{-|\gamma|/n}$. Finally, we let $W = \prod_{i=0}^{\ell-1} W_i$.

Proof of Theorem 6. In this version, we assume that we have access to an exact sampler $\mathcal{S}_{\text{exact}}$ that samples from μ_ρ for all $\rho \geq 0$ (in the full version we show how to adapt the argument to the situation where we only have an approximate sampler). Using this sampler in the Polymer approximate counting algorithm, we find that, for each j and each i , $\Gamma_i^{(j)}$ is an exact sample from the distribution μ_{ρ_i} and hence $W_i^{(j)}$ is an exact sample of W_i , independently for every j and i . Thus, $W^{(j)}$ is a sample of W independently for every j , and \widehat{W} is the sample mean of $W^{(j)}$'s. We deduce from Lemmas 17 and 18 of the full version that

$$(1 + \varepsilon/2)\mathbb{E}[W] \leq \frac{e^{\varepsilon/2}Z(\rho_\ell)}{Z(0)} \leq \frac{e^\varepsilon}{Z(0)} \text{ and } (1 - \varepsilon/2)\mathbb{E}[W] \geq \frac{e^{-\varepsilon}Z(\rho_\ell)}{Z(0)} \geq \frac{e^{-\varepsilon}}{Z(0)}$$

where we use $1 + \varepsilon/2 \leq e^{\varepsilon/2}$ and $e^{-\varepsilon} \leq 1 - \varepsilon/2$ for all $0 < \varepsilon < 1$. Then

$$\Pr\left(\frac{e^{-\varepsilon}}{Z(0)} \leq \widehat{W} \leq \frac{e^\varepsilon}{Z(0)}\right) \geq \Pr\left(\left|\widehat{W} - \mathbb{E}[W]\right| \leq (\varepsilon/2)\mathbb{E}[W]\right).$$

41:12 Fast Algorithms at Low Temperatures via Markov Chains

By Chebyshev's inequality we have

$$\Pr\left(\left|\widehat{W} - \mathbb{E}[W]\right| \geq (\varepsilon/2)\mathbb{E}[W]\right) \leq \frac{4 \operatorname{Var}(W)}{\varepsilon^2 m (\mathbb{E}[W])^2} \leq \frac{4(e-1)}{\varepsilon^2 m} \leq \frac{1}{8}$$

where the second to last inequality follows from Lemmas 17 and 19 of the full version which enable us to show that

$$\frac{\operatorname{Var}(W)}{(\mathbb{E}[W])^2} = \frac{\mathbb{E}[W^2]}{(\mathbb{E}[W])^2} - 1 = \frac{Z(0)}{Z(\rho_1)} \frac{Z(\rho_{\ell+1})}{Z(\rho_\ell)} - 1 \leq e - 1.$$

Thus, we deduce that

$$\Pr\left(e^{-\varepsilon} Z(0) \leq \widehat{Z} \leq e^\varepsilon Z(0)\right) = \Pr\left(\frac{e^{-\varepsilon}}{Z(0)} \leq \widehat{W} \leq \frac{e^\varepsilon}{Z(0)}\right) \geq \frac{7}{8}$$

(so the error probability is at most $1/8$). Note that the number of samples that we used is ℓm . Finally, we consider the running time of our algorithm. By Theorem 5, the running time of step 2(a)(i) is $O(n \log(8\ell mn)) = O(n \log(n/\varepsilon))$, and for step 2(a)(ii) the running time is $O(n)$. Thus, the running time of the algorithm is upper bounded by $\ell m \cdot O(n \log(n/\varepsilon)) = O((n/\varepsilon)^2 \log^2(n/\varepsilon))$. ◀

4 Applications

In this section, we prove Theorem 9 for the Potts model. The proof of Theorem 11 (for the hard-core model) can be found in Section 4.2 of the full version. Throughout this section, we will work under the assumptions/conditions of Theorem 9. That is, we fix a real number $\alpha > 0$, integers $q \geq 3$ and $\Delta \geq 3$ and a real number $\beta \geq \frac{5+3 \log((q-1)\Delta)}{\alpha}$. We let \mathcal{G} be the class of α -expander graphs G with maximum degree at most Δ .

Consider the polymer model defined in Example 2 on an n -vertex graph $G \in \mathcal{G}$ with $M = n/2$ and ground state color $g \in [q]$. We will use $\mathcal{C}^g = \mathcal{C}^g(G)$ to denote the polymers and w_γ^g to denote the weight of a polymer $\gamma \in \mathcal{C}^g$; recall that $w_\gamma^g = e^{-\beta B(\gamma)}$, where $B(\gamma)$ counts the number of external edges of γ plus the number of bichromatic internal edges. Let $Z^g(G)$ be the partition function of the polymer model $(\mathcal{C}^g(G), w^g)$.

► **Lemma 20.** *Under the conditions of Theorem 9, the polymer model $(\mathcal{C}^g(\cdot), w^g, \mathcal{G})$ satisfies the polymer sampling condition (3) with $\tau = \alpha\beta$.*

Proof. Since every $G \in \mathcal{G}$ is an α -expander, for $\gamma \in \mathcal{C}^g$ we have $B(\gamma) \geq \alpha|\gamma|$ and hence $w_\gamma^g \leq e^{-\tau|\gamma|}$. ◀

► **Lemma 21** ([17, Lemma 12]). *For any n -vertex α -expander graph G and $\beta \geq 2 \log(eq)/\alpha$, $qZ^g(G)$ is an e^{-n} -approximation of the Potts partition function $Z_{G,\beta}$.*

Proof of Theorem 9. Let \mathcal{G} be the class of α -expander graphs of maximum degree at most Δ . Clearly, the polymer models $(\mathcal{C}^g(\cdot), w^g, \mathcal{G})$ are computationally feasible. By Lemma 20, the models also satisfy the polymer sampling condition and therefore Theorems 5 and 6 apply. Consider any n -vertex graph $G \in \mathcal{G}$. Since $\beta \geq \frac{5+3 \log((q-1)\Delta)}{\alpha} > \frac{2 \log(eq)}{\alpha}$, Lemma 21 applies to G .

For the sampling algorithm, we pick a color $g \in [q]$ uniformly at random and generate an (ε/q) -approximate sample from the Gibbs measure associated to $Z^g(G)$ using the algorithm of Theorem 5, in time $O(n \log(n/\varepsilon))$. By Lemma 21, we conclude that the resulting output is an ε -approximate sample for the Potts model.

For the counting algorithm, we pick an arbitrary $g \in [q]$ and produce using the algorithm of Theorem 6 a number \hat{Z} in time $O((n/\varepsilon)^2 \log^2(n/\varepsilon))$, which is an $\varepsilon/(2q)$ -approximation to $Z^g(G)$ with probability $\geq 3/4$. By Lemma 21, we conclude that $q\hat{Z}$ is an ε -approximation for the partition function of the Potts model (with the same probability). ◀

Abstract

We give a deterministic, nearly logarithmic-space algorithm that given an undirected graph G , a positive integer r , and a set S of vertices, approximates the conductance of S in the r -step random walk on G to within a factor of $1 + \epsilon$, where $\epsilon > 0$ is an arbitrarily small constant. More generally, our algorithm computes an ϵ -spectral approximation to the normalized Laplacian of the r -step walk.

Our algorithm combines the derandomized square graph operation [21], which we recently used for solving Laplacian systems in nearly logarithmic space [16], with ideas from [5], which gave an algorithm that is time-efficient (while ours is space-efficient) and randomized (while ours is deterministic) for the case of even r (while ours works for all r). Along the way, we provide some new results that generalize technical machinery and yield improvements over previous work. First, we obtain a nearly linear-time randomized algorithm for computing a spectral approximation to the normalized Laplacian for odd r . Second, we define and analyze a generalization of the derandomized square for irregular graphs and for sparsifying the product of two distinct graphs. As part of this generalization, we also give a strongly explicit construction of expander graphs of every size.

1 Introduction

Random walks provide the most dramatic example of the power of randomized algorithms for solving computational problems in the space-bounded setting, as they only require logarithmic space (to store the current state or vertex). In particular, since undirected graphs have polynomial cover time, random walks give a randomized logspace (**RL**) algorithm for UNDIRECTED S-T CONNECTIVITY [1]. Reingold [19] showed that this algorithm can be derandomized, and hence that UNDIRECTED S-T CONNECTIVITY is in deterministic logspace (**L**). However, Reingold's algorithm does not match the full power of random walks on undirected graphs; in particular it does not allow us to approximate properties of the random walk at lengths below the mixing time.

In this work, we provide a nearly logarithmic-space algorithm for approximating properties of arbitrary-length random walks on an undirected graph, in particular the *conductance* of any set of vertices:

► **Definition 1.** Let $G = (V, E)$ be an undirected graph, r a positive integer, and $S \subseteq V$ a set of vertices. The *conductance* of S under the r -step random walk on G is defined as

$$\Phi_r(S) = \Pr[V_r \notin S | V_0 \in S],$$

where V_0, V_1, \dots, V_r is a random walk on G started at the stationary distribution $\Pr[V_0 = v] = \deg(v)/2|E|$.

► **Theorem 2.** There is a deterministic algorithm that given an undirected multigraph G on n vertices, a positive integer r , a set of vertices S , and $\epsilon > 0$, computes a number $\tilde{\Phi}$ such that

$$(1 - \epsilon) \cdot \Phi_r(S) \leq \tilde{\Phi} \leq (1 + \epsilon) \cdot \Phi_r(S)$$

and runs in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$, where N is the bit length of the input graph G .

Previously, approximating conductance could be done in $O(\log^{3/2}(N/\epsilon) + \log \log r)$ space, which follows from Saks' and Zhou's proof that **RL** is in **L**^{3/2} [22].

Two interesting parameter regimes where we improve the Saks-Zhou bound are when $r = 1/\epsilon = 2^{O(\sqrt{\log N})}$, in which case our algorithm runs in space $O(\log N)$, or when $\epsilon = 1/\text{polylog}(N)$ and $r \leq \text{poly}(N)$, in which case our algorithm runs in space $\tilde{O}(\log N)$. When r exceeds the $\text{poly}(N) \cdot \log(1/\epsilon)$ time for random walks on undirected graphs to mix to within distance ϵ of the stationary distribution, the conductance can be approximated in space $O(\log(N/\epsilon) + \log \log r)$ by using Reingold's algorithm to find the connected components of G , and the bipartitions of the components that are bipartite and calculating the stationary probability of S restricted to each of these pieces, which is proportional to the sum of degrees of vertices in S .

We prove Theorem 2 by providing a stronger result that with the same amount of space it is possible to compute an ϵ -spectral approximation to the *normalized Laplacian* of the r -step random walk on G .

► **Definition 3.** Let G be an undirected graph with adjacency matrix A , diagonal degree matrix D , and transition matrix $T = AD^{-1}$. The transition matrix for the r -step random walk on G is T^r . The *normalized Laplacian* of the r -step random walk is the symmetric matrix $I - M^r$ for $M = D^{-1/2}AD^{-1/2}$.

Note that the normalized Laplacian can also be expressed as $I - M^r = D^{-1/2}(I - T^r)D^{1/2}$, so it does indeed capture the behavior of r -step random walks on G .¹

► **Theorem 4 (Main result).** *There is a deterministic algorithm that given an undirected multigraph G on n vertices with normalized Laplacian $I - M$, a nonnegative integer r , and $\epsilon > 0$, constructs an undirected multigraph \tilde{G} whose normalized Laplacian \tilde{L} is an ϵ -spectral approximation of $L = I - M^r$. That is, for all vectors $v \in \mathbb{R}^n$*

$$(1 - \epsilon) \cdot v^T L v \leq v^T \tilde{L} v \leq (1 + \epsilon) \cdot v^T L v.$$

The algorithm runs in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$, where N is the bit length of the input graph G .

Theorem 2 follows from Theorem 4 by taking v to be $D^{1/2}e_S$ where e_S is the characteristic vector of the set S and normalizing appropriately (See Section 5).

Our main technique for proving Theorem 4 is the *derandomized product*, a new generalization of the *derandomized square*, which was introduced by Rozenman and Vadhan [21] to give an alternative proof that

UNDIRECTED S-T CONNECTIVITY is in **L**. Our main result follows from carefully applying the derandomized product and analyzing its properties with inequalities from the theory of spectral approximation. Specifically, our analysis is inspired by the work of Cheng, Cheng, Liu, Peng, and Teng [5], who studied the approximation of random walks by randomized algorithms running in nearly linear time. We emphasize that the work of [5] gives a randomized algorithm with high space complexity (but low time complexity) for approximating properties of even length walks while we give a deterministic, space-efficient algorithm for approximating properties of walks of every length. Interestingly, while the graphs in our results are all undirected, some of our analyses use techniques for spectral approximation of *directed* graphs introduced by Cohen, Kelner, Peebles, Peng, Rao, Sidford, and Vladu [7, 6].

The derandomized square can be viewed as applying the pseudorandom generator of Impagliazzo, Nisan, and Wigderson [10] to random walks on labelled graphs. It is somewhat surprising that repeated derandomized squaring does not blow up the error by a factor proportional to the length of the walk being derandomized. For arbitrary branching programs, the INW generator does incur error that is linear in the length of the program. Some special cases such as regular [3, 4, 8] and permutation [8, 24] branching programs of constant width have been shown to have a milder error growth as a function of the walk length. Our work adds to this list by showing that properties of random walks of length k on undirected graphs can be estimated in terms of spectral approximation without error accumulating linearly in k .

In our previous work [16], we showed that the Laplacian of the derandomized square of a *regular* graph spectrally approximates the Laplacian of the true square, $I - M^2$, and this was used in a recursion from [18] to give a nearly logarithmic-space algorithm for approximately solving Laplacian systems $Lx = b$. A natural idea to approximate the Laplacian of higher powers, $I - M^r$, is to repeatedly derandomized square. This raises three challenges, and we achieve our result by showing how to overcome each:

1. It is not guaranteed from [16] that repeated derandomized squaring preserves spectral approximation. For this, we use ideas from [5] to argue that it does.
2. When r is not a power of 2, the standard approach would be to write $r = b_0 + 2 \cdot b_1 + \dots + 2^z \cdot b_z$ where b_i is the i th bit of r and multiply approximations to M^{2^i} for all i such that $b_i \neq 0$. The problem is that multiplying spectral approximations of matrices

¹ When G is irregular, the matrix $I - T^r$ is not necessarily symmetric. It is a *directed Laplacian* as defined in [7, 6]. See Definition 9.

does not necessarily yield a spectral approximation of their product. Our solution is to generalize the derandomized square to produce sparse approximations to the product of *distinct* graphs. In particular, given $I - M$ and an approximation $I - \tilde{M}$ to $I - M^k$, our derandomized product allows us to combine M and \tilde{M} to approximate $I - M^{k+1}$. Although our generalized graph product is defined for undirected graphs, its analysis uses machinery for spectral approximation of directed graphs, introduced in [6].

3. We cannot assume that our graph is regular without loss of generality. In contrast, [19, 21, 16] could do so, since adding self-loops does not affect connectivity or solutions to Laplacian systems of G , however, it does affect random walks. Our solution is to define and analyze the derandomized product for irregular graphs.

A key element in the derandomized product is a strongly explicit (i.e. neighbor relations can be computed in space $O(\log N)$) construction of expander graphs whose sizes equal the degrees of the vertices in the graphs being multiplied. This is problematic when we are not free to add self loops to the graphs because strongly explicit constructions of expander graphs only exist for graph sizes that are certain subsets of \mathbb{N} such as powers of 2 (Cayley graphs based on [17] and [2]), perfect squares [14, 9], and other size distributions [20] or are only explicit in the sense of running time or parallel work [13]. To address this issue, we give a strongly explicit construction of expander graphs of all sizes by giving a reduction from existing strongly explicit constructions in Section 3.

Many of our techniques are inspired by Cheng, Cheng, Liu, Peng, and Teng [5], who gave two algorithms for approximating random walks. One is a nearly linear time randomized algorithm for approximating random walks of *even* length and another works for all walk lengths r but has a running time that is quadratic in r , and so only yields a nearly linear time algorithm for r that is polylogarithmic in the size of the graph. In addition, [11] studied the problem of computing sparse spectral approximations of random walks but the running time in their work also has a quadratic dependence on r . We extend these results by giving a nearly linear time randomized algorithm for computing a spectral approximation to $I - M^r$ for *all* r . This is discussed in Section 5.

2 Preliminaries

2.1 Spectral Graph Theory

Given an undirected multigraph G the *Laplacian* of G is the symmetric matrix $D - A$, where D is the diagonal matrix of vertex degrees and A is the adjacency matrix of G . The *transition matrix* of the random walk on G is $T = AD^{-1}$. T_{ij} is the probability that a uniformly random edge from vertex j leads to vertex i (i.e. the number of edges between j and i divided by the degree of j). The *normalized Laplacian* of G is the symmetric matrix $I - M = D^{-1/2}(D - A)D^{-1/2}$. Note that when G is regular, the matrix $M = D^{-1/2}AD^{-1/2} = AD^{-1} = T$. The *transition matrix of the r -step random walk* on G is T^r . For all probability distributions π , $T^r\pi$ is the distribution over vertices that results from picking a random vertex according to π and then running a random walk on G for r steps. The transition matrix of the r -step random walk on G is related to the normalized Laplacian in the following way:

$$I - M^r = D^{-1/2}(I - T^r)D^{1/2}.$$

For undirected multigraphs, the matrix $M = D^{-1/2}AD^{-1/2}$ has real eigenvalues between -1 and 1 and so $I - M^r$ has eigenvalues in $[0, 2]$ and thus is positive semidefinite (PSD). The *spectral norm* of a real matrix M , denoted $\|M\|$, is the largest singular value of M . That is,

the square root of the largest eigenvalue of $M^T M$. When M is symmetric, $\|M\|$ equals the largest eigenvalue of M in absolute value. For an undirected graph G with adjacency matrix A , we write $k \cdot G$ to denote the graph with adjacency matrix $k \cdot A$, i.e. the multigraph G with all edges duplicated to have multiplicity k .

Given a symmetric matrix L , its *Moore-Penrose Pseudoinverse*, denoted L^\dagger , is the unique matrix with the same eigenvectors as L such that for each eigenvalue λ of L , the corresponding eigenvalue of L^\dagger is $1/\lambda$ if $\lambda \neq 0$ and 0 otherwise. When L is a Laplacian, we write $L^{\dagger/2}$ to denote the unique symmetric PSD matrix square root of the pseudoinverse of L .

To measure the approximation between graphs we use spectral approximation²[23]:

► **Definition 5.** Let $L, \tilde{L} \in \mathbb{R}^{n \times n}$ be symmetric PSD matrices. We say that \tilde{L} is an ϵ -approximation of L (written $\tilde{L} \approx_\epsilon L$) if for all vectors $v \in \mathbb{R}^n$

$$(1 - \epsilon) \cdot v^T L v \leq v^T \tilde{L} v \leq (1 + \epsilon) \cdot v^T L v.$$

Note that Definition 5 is not symmetric in L and \tilde{L} . Spectral approximation can also be written in terms of the Loewner partial ordering of PSD matrices:

$$(1 - \epsilon) \cdot L \preceq \tilde{L} \preceq (1 + \epsilon) \cdot L$$

where for two matrices A, B , we write $A \preceq B$ if $B - A$ is PSD. Spectral approximation has a number of useful properties listed in the following proposition.

► **Proposition 6.** If $W, X, Y, Z \in \mathbb{R}^{n \times n}$ are PSD symmetric matrices then:

1. If $X \approx_\epsilon Y$ for $\epsilon < 1$ then $Y \approx_{\epsilon/(1-\epsilon)} X$
2. If $X \approx_{\epsilon_1} Y$ and $Y \approx_{\epsilon_2} Z$ then $X \approx_{\epsilon_1 + \epsilon_2 + \epsilon_1 \cdot \epsilon_2} Z$,
3. If $X \approx_\epsilon Y$ and V is any $n \times n$ matrix then $V^T X V \approx_\epsilon V^T Y V$,
4. If $X \approx_\epsilon Y$ then $X + Z \approx_\epsilon Y + Z$,
5. If $W \approx_{\epsilon_1} X$ and $Y \approx_{\epsilon_2} Z$ then $W + Y \approx_{\max\{\epsilon_1, \epsilon_2\}} X + Z$, and
6. If $X \approx_\epsilon Y$ then $c \cdot X \approx_\epsilon c \cdot Y$ for all nonnegative scalars c

For regular undirected graphs, we use the measure introduced by [15] for the rate at which a random walk converges to the uniform distribution.

► **Definition 7** ([15]). Let G be a regular undirected graph with transition matrix T . Define

$$\lambda(G) = \max_{\substack{v \perp \mathbf{1} \\ v \neq 0}} \frac{\|Tv\|}{\|v\|} = \text{2nd largest absolute value of the eigenvalues of } T \in [0, 1].$$

$1 - \lambda(G)$ is called the spectral gap of G .

$\lambda(G)$ is known to be a measure of how well-connected a graph is. The smaller $\lambda(G)$, the faster a random walk on G converges to the uniform distribution. Graphs G with $\lambda(G)$ bounded away from 1 are called *expanders*. Expanders can equivalently be characterized as graphs that spectrally approximate the complete graph. This is formalized in the next lemma.

► **Lemma 8.** Let H be a c -regular undirected multigraph on n vertices with transition matrix T and let $J \in \mathbb{R}^{n \times n}$ be a matrix with $1/n$ in every entry (i.e. J is the transition matrix of the complete graph with a self loop on every vertex). Then $\lambda(H) \leq \lambda$ if and only if $I - T \approx_\lambda I - J$.

² In [16], we use an alternative definition of spectral approximation where $\tilde{L} \approx_\epsilon L$ if for all $v \in \mathbb{R}^n$, $e^{-\epsilon} \cdot v^T L v \leq v^T \tilde{L} v \leq e^\epsilon \cdot v^T L v$. We find Definition 5 more convenient for this paper.

A proof of Lemma 8 can be found in the full version of the paper. In [6] Cohen, Kelner, Peebles, Peng, Rao, Sidford, and Vladu introduced a definition of spectral approximation for *asymmetric matrices*. Although the results in our paper only concern undirected graphs, some of our proofs use machinery from the theory of directed spectral approximation.

► **Definition 9** (Directed Laplacian [7, 6]). *A matrix $L \in \mathbb{R}^{n \times n}$ is called a directed Laplacian if $L_{ij} \leq 0$ for all $i \neq j$ and $L_{ii} = -\sum_{j \neq i} L_{ji}$ for all $i \in [n]$. The associated directed graph has n vertices and an edge (i, j) of weight $-L_{ji}$ for all $i \neq j \in [n]$ with $L_{ji} \neq 0$.*

► **Definition 10** (Asymmetric Matrix Approximation [6]). *Let \tilde{L} and L be (possibly asymmetric) matrices such that $U = (L + L^T)/2$ is PSD. We say that \tilde{L} is a directed ϵ -approximation of L if:*

1. $\ker(U) \subseteq \ker(\tilde{L} - L) \cap \ker((\tilde{L} - L)^T)$, and
2. $\|U^{\dagger/2}(\tilde{L} - L)U^{\dagger/2}\|_2 \leq \epsilon$

Below we state some useful lemmas about directed spectral approximation. The first gives an equivalent formulation of Definition 10.

► **Lemma 11** ([6] Lemma 3.5). *Let $L \in \mathbb{R}^{n \times n}$ be a (possibly asymmetric) matrix and let $U = (L + L^T)/2$. A matrix \tilde{L} is a directed ϵ -approximation of L if and only if for all vectors $x, y \in \mathbb{R}^n$*

$$x^T(\tilde{L} - L)y \leq \frac{\epsilon}{2} \cdot (x^T U x + y^T U y).$$

► **Lemma 12** ([6] Lemma 3.6). *Suppose \tilde{L} is a directed ϵ -approximation of L and let $U = (L + L^T)/2$ and $\tilde{U} = (\tilde{L} + \tilde{L}^T)/2$. Then $\tilde{U} \approx_\epsilon U$.*

Lemma 12 says that directed spectral approximation implies the usual notion from Definition 5 for “symmetrized” versions of the matrices L and \tilde{L} . In fact, when the matrices L and \tilde{L} are both symmetric, the two definitions are equivalent:

► **Lemma 13**. *Let \tilde{L} and L be symmetric PSD matrices. Then \tilde{L} is a directed ϵ -approximation of L if and only if $\tilde{L} \approx_\epsilon L$.*

A proof of Lemma 13 can be found in the full version of the paper.

2.2 Space Bounded Computation

We use a standard model of space-bounded computation where the machine \mathcal{M} has a read-only input tape, a constant number of read/write work tapes, and a write-only output tape. If throughout every computation on inputs of length at most n , \mathcal{M} uses at most $s(n)$ total tape cells on all the work tapes, we say \mathcal{M} runs in space $s = s(n)$. Note that \mathcal{M} may write more than s cells (in fact as many as $2^{O(s)}$) but the output tape is write-only. The following proposition describes the behavior of space complexity when space bounded algorithms are composed.

► **Proposition 14**. *Let f_1, f_2 be functions that can be computed in space $s_1(n), s_2(n) \geq \log n$, respectively, and f_1 has output of length at most $\ell_1(n)$ on inputs of length n . Then $f_2 \circ f_1$ can be computed in space*

$$O(s_2(\ell_1(n)) + s_1(n)).$$

2.3 Rotation Maps

In the space-bounded setting, it is convenient to use local descriptions of graphs. Such descriptions allow us to navigate large graphs without loading them entirely into memory. For this we use *rotation maps*, functions that describe graphs through their neighbor relations. Rotation maps are defined for graphs with labeled edges as described in the following definition.

► **Definition 15** ([20]). *A two-way labeling of an undirected multigraph $G = (V, E)$ with vertex degrees $(d_v)_{v \in V}$, is a labeling of the edges in G such that*

1. *Every edge $(u, v) \in E$ has two labels: one in $[d_u]$ as an edge incident to u and one in $[d_v]$ as an edge incident to v ,*
2. *For every vertex $v \in V$, the labels of the d_v edges incident to v are distinct.*

In [21], two-way labelings are referred to as *undirected* two-way labelings. Note that every graph has a two-way labeling where each vertex “names” its neighbors uniquely in some canonical way based on the order they’re represented in the input. We will describe multigraphs with two-way labelings using rotation maps:

► **Definition 16** ([20]). *Let G be an undirected multigraph on n vertices with a two-way labeling. The rotation map Rot_G is defined as follows: $Rot_G(v, i) = (w, j)$ if the i th edge to vertex v leads to vertex w and this edge is the j th edge incident to w .*

We will use expanders that have efficiently computable rotation maps. We call such graphs *strongly explicit*. The usual definition of strong explicitness only refers to time complexity, but we will use it for both time and space.

► **Definition 17.** *A family of two-way labeled graphs $\mathcal{G} = \{G_{n,c}\}_{(n,c)}$, where $G_{n,c}$ is a c -regular graph on n vertices, is called strongly explicit if given n, c , a vertex $v \in [n]$ and an edge label $a \in [c]$, $Rot_{G_{n,c}}(v, a)$ can be computed in time $\text{poly}(\log(nc))$ and space $O(\log nc)$.*

3 The Derandomized Product and Expanders of All Sizes

In this section we introduce our derandomized graph product. The derandomized product generalizes the *derandomized square* graph operation that was introduced by Rozenman and Vadhan [21] to give an alternative proof that UNDIRECTED S-T CONNECTIVITY is in **L**. Unlike the derandomized square, the derandomized product is defined for *irregular* graphs and produces a sparse approximation to the product of any two (potentially different) graphs with the same vertex degrees.

Here, by the “product” of two graphs G_0, G_1 , we mean the reversible Markov chain with transitions defined as follows: from a vertex v , with probability $1/2$ take a random step on G_0 followed by a random step on G_1 and with probability $1/2$ take a random step on G_1 followed by a random step on G_0 .

When $G_0 = G_1 = G$, this is the same as taking a 2-step random walk on G . Note, however, that when G is irregular, a 2-step random walk is *not* equivalent to doing a 1-step random walk on the graph G^2 , whose edges correspond to paths of length 2 in G . Indeed, even the stationary distribution of the random walk on G^2 may be different than on G .³ Nevertheless, our goal in the derandomized product is to produce a relatively sparse graph whose 1-step random walk approximates the 2-step random walk on G .

³ For example, let G be the graph on two vertices with one edge (u, v) connecting them and a single self loop on u . Then $[2/3, 1/3]$ is the stationary distribution of G and $[3/5, 2/5]$ is the stationary distribution of G^2 .

The intuition behind the derandomized product is as follows: rather than build a graph with every such two-step walk, we use expander graphs to pick a pseudorandom subset of the walks. Specifically, we first pick $b \in \{0, 1\}$ at random. Then, as before we take a truly random step from v to u in G_b . But for the second step, we don't use an arbitrary edge leaving u in $G_{\bar{b}}$, but rather correlate it to the edge on which we arrived at u using a c -regular expander on $\deg(u)$ vertices, where we assume that the vertex degrees in G_0 and G_1 are the same. When $c < \deg(u)$, the vertex degrees of the resulting two-step graph will be sparser than without derandomization. However using the pseudorandom properties of expander graphs, we can argue that the derandomized product is a good approximation of the true product.

► **Definition 18** (Derandomized Product). *Let G_0, G_1 be undirected multigraphs on n vertices with two-way labelings and identical vertex degrees d_1, d_2, \dots, d_n . Let $\mathcal{H} = \{H_i\}$ be a family of two-way labeled, c -regular expanders of sizes including d_1, \dots, d_n . The derandomized product with respect to \mathcal{H} , denoted $G_0 \mathfrak{P}_{\mathcal{H}} G_1$, is an undirected multigraph on n vertices with vertex degrees $2 \cdot c \cdot d_1, \dots, 2 \cdot c \cdot d_n$ and rotation map $\text{Rot}_{G_0 \mathfrak{P}_{\mathcal{H}} G_1}$ defined as follows: For $v_0 \in [n], j_0 \in [d_{v_0}], a_0 \in [c]$, and $b \in \{0, 1\}$ we compute $\text{Rot}_{G_0 \mathfrak{P}_{\mathcal{H}} G_1}(v_0, (j_0, a_0, b))$ as*

1. Let $(v_1, j_1) = \text{Rot}_{G_b}(v_0, j_0)$
2. Let $(j_2, a_1) = \text{Rot}_{H_{d_{v_1}}}(j_1, a_0)$
3. Let $(v_2, j_3) = \text{Rot}_{G_{\bar{b}}}(v_1, j_2)$
4. Output $(v_2, (j_3, a_1, \bar{b}))$

where \bar{b} denotes the bit-negation of b .

Note that when $G_0 = G_1$ the derandomized product generalizes the derandomized square [21] to irregular graphs, albeit with each edge duplicated twice. To see that $G_0 \mathfrak{P}_{\mathcal{H}} G_1$ is undirected, one can check that $\text{Rot}_{G_0 \mathfrak{P}_{\mathcal{H}} G_1}(\text{Rot}_{G_0 \mathfrak{P}_{\mathcal{H}} G_1}(v_0, (j_0, a_0, b))) = (v_0, (j_0, a_0, b))$.

Note that Definition 18 requires that each vertex i has the same degree d_i in G_0 and G_1 , ensuring that the random walks on G_0, G_1 , and $G_0 \mathfrak{P}_{\mathcal{H}} G_1$ all have the same stationary distribution. This can be generalized to the case that there is an integer k such that for each vertex v with degree d_v in G_1 , v has degree $k \cdot d_v$ in G_0 . For this, we can duplicate each edge in G_1 k times to match the degrees of G_0 and then apply the derandomized product to the result. In such cases we abuse notation and write $G_0 \mathfrak{P}_{\mathcal{H}} G_1$ to mean $G_0 \mathfrak{P}_{\mathcal{H}} k \cdot G_1$.

In [16] we showed that the derandomized square produces a spectral approximation to the true square. We now show that the derandomized product also spectrally approximates a natural graph product.

► **Theorem 19.** *Let G_0, G_1 be undirected multigraphs on n vertices with two-way labelings, and normalized Laplacians $I - M_0$ and $I - M_1$. Let G_0 have vertex degrees d_1, \dots, d_n and G_1 have vertex degrees d'_1, \dots, d'_n where for all $i \in [n]$, $d_i = k \cdot d'_i$ for a positive integer k . Let $\mathcal{H} = \{H_i\}$ be a family of two-way labeled, c -regular expanders with $\lambda(H_i) \leq \lambda$ for all $H_i \in \mathcal{H}$, of sizes including d_1, \dots, d_n . Let $I - \tilde{M}$ be the normalized Laplacian of $\tilde{G} = G_0 \mathfrak{P}_{\mathcal{H}} G_1$. Then*

$$I - \tilde{M} \approx_{\lambda} I - \frac{1}{2} \cdot (M_0 M_1 + M_1 M_0).$$

A proof of Theorem 19 can be found in Appendix A.

Note that for a graph G with normalized Laplacian $I - M$ and transition matrix T , approximating $I - \frac{1}{2} \cdot (M_0 M_1 + M_1 M_0)$ as in Theorem 19 for $M_0 = M^{k_0}$ and $M_1 = M^{k_1}$ gives a form of approximation to random walks of length $k_1 + k_2$ on G , as

$$\begin{aligned} I - T^{k_1+k_2} &= D^{1/2}(I - M^{k_1+k_2})D^{-1/2} \\ &= I - \frac{1}{2} \cdot D^{1/2}(M_0 M_1 + M_1 M_0)D^{-1/2}. \end{aligned}$$

To apply the derandomized product, we need an expander family \mathcal{H} with sizes equal to all of the vertex degrees. However, existing constructions of strongly explicit expander families only give graphs of sizes that are subsets of \mathbb{N} such as all powers of 2 or all perfect squares. In [21, 16] this was handled by adding self loops to make the vertex degrees all equal and matching the sizes of expanders in explicit families. Adding self loops was acceptable in those works because it does not affect connectivity (the focus of [21]) or the Laplacian (the focus of [16]). However it does affect long random walks (our focus), so we cannot add self loops. Instead, we show how to obtain strongly explicit expanders of all sizes. Our construction works by starting with a strongly explicit expander from one of the existing constructions and merging vertices to achieve any desired size:

► **Theorem 20.** *There exists a family of strongly explicit expanders \mathcal{H} such that for all $n > 1$ and $\lambda \in (0, 1)$ there is a $c = \text{poly}(1/\lambda)$ and a c -regular graph $H_{n,c} \in \mathcal{H}$ on n vertices with $\lambda(H_{n,c}) \leq \lambda$.*

A proof of Theorem 20 can be found in Appendix B.

4 Main Result

In this section we prove Theorem 4, our main result regarding space bounded computation of the normalized Laplacian of the r -step random walk on G .

The algorithm described below is inspired by techniques used in [5] to approximate random walks with a randomized algorithm in nearly linear time. Our analyses use ideas from the work of Cohen, Kelner, Peebles, Peng, Rao, Sidford, and Vladu on *directed* Laplacian system solvers even though all of the graphs we work with are undirected.

4.1 Algorithm Description and Proof Overview

Let $I - M$ be the normalized Laplacian of our input and r be the target power. We will first describe an algorithm for computing $I - M^r$ without regard for space complexity and then convert it into a space-efficient approximation algorithm. The algorithm iteratively approximates larger and larger powers of M . On a given iteration, we will have computed $I - M^k$ for some $k < r$ and we use the following operations to increase k :

- Square: $I - M^k \rightarrow I - M^{2k}$,
- Plus one: $I - M^k \rightarrow I - \frac{1}{2} \cdot (M \cdot M^k + M^k \cdot M) = I - M^{k+1}$.

Interleaving these two operations appropriately can produce any power r of M , invoking each operation at most $\log_2 r$ times. To see this, let $b_z b_{z-1} \dots b_0$ be the bits of r in its binary representation where b_0 is the least significant bit and $b_z = 1$ is the most significant. We are given $I - M = I - M^{b_z}$. The algorithm will have z iterations and each one will add one more bit from most significant to least significant to the binary representation of the exponent. So after iteration i we will have $I - M^{b_z b_{z-1} \dots b_{z-i}}$.

For iterations $1, \dots, z$, we read the bits of r from b_{z-1} to b_0 one at a time. On each iteration we start with some power $I - M^k$. If the corresponding bit is a 0, we square to create $I - M^{2k}$ (which adds a 0 to the binary representation of the current exponent) and proceed to the next iteration. If the corresponding bit is a 1, we square and then invoke a plus one operation to produce $I - M^{2k+1}$ (which adds a 1 to the binary representation of the current exponent). After iteration z we will have $I - M^r$.

42:10 Deterministic Approximation of Random Walks in Small Space

Implemented recursively, this algorithm has $\log_2 r$ levels of recursion and uses $O(\log N)$ space at each level for the matrix multiplications, where N is the bit length of the input graph. This results in total space $O(\log r \cdot \log N)$, which is more than we want to use (cf. Theorem 4). We reduce the space complexity by replacing each square and plus one operation with the corresponding derandomized product, discussed in Section 3.

Theorem 19 says that the derandomized product produces spectral approximations to the square and the plus one operation. Since we apply these operations repeatedly on successive approximations, we need to maintain our ultimate approximation to a power of $I - M$. In other words, we need to show that given \tilde{G} such that $I - \tilde{M} \approx_\epsilon I - M^k$ we have:

1. $I - \tilde{M}^2 \approx_\epsilon I - M^{2k}$
2. $I - \frac{1}{2} \cdot (M\tilde{M} + \tilde{M}M) \approx_\epsilon I - M^{k+1}$.

We prove these in Lemmas 21 and 22. The transitive property of spectral approximation (Proposition 6 Part 2) will then complete the proof of spectral approximation.

We only know how to prove items 1 and 2 when M^k is PSD. This is problematic because M is not guaranteed to be PSD for arbitrary graphs and so M^k may only be PSD when k is even. Simple solutions like adding self loops (to make the random walk lazy) are not available to us because loops may affect the random walk behavior in unpredictable ways. Another attempt would be to replace the plus one operation in the algorithm with a “plus two” operation

■ Plus two: $I - M^k \rightarrow I - \frac{1}{2} \cdot (M^2 \cdot M^k + M^k \cdot M^2) = I - M^{k+2}$.

Interleaving the square and plus two would preserve the positive semidefiniteness of the matrix we’re approximating and can produce any even power of M . If r is odd, we could finish with one plus one operation, which will produce a spectral approximation because $I - M^{r-1}$ is PSD. A problem with this approach is that the derandomized product is defined only for unweighted multigraphs and M^2 may not correspond to an unweighted multigraph when G is irregular. (When G is regular, the graph G^2 consisting of paths of length 2 in G does have normalized Laplacian $I - M^2$.)

For this reason we begin the algorithm by constructing an unweighted multigraph G_0 whose normalized Laplacian $I - M_0$ approximates $I - M^2$ and where M_0 is PSD. We can then approximate any power $I - M_0^r$ using the square and plus one operation and hence can approximate $I - M^r$ for any even r (see Lemma 23). For odd powers, we again can finish with a single plus one operation.

Our main algorithm is presented below. Our input is an undirected two-way labeled multigraph G with normalized Laplacian $I - M$, $\epsilon \in (0, 1)$, and $r = b_z b_{z-1} \dots b_1 b_0$.

■ **Algorithm 1** Computing a spectral approximation to the r -step random walk.

Input: G with normalized Laplacian $I - M$, $\epsilon \in (0, 1)$, $r = b_z b_{z-1} \dots b_1 b_0$

Output: G_z with normalized Laplacian $I - M_z$ such that $I - M_z \approx_\epsilon I - M^r$

1. Set $\mu = \epsilon / (32 \cdot z)$
 2. Let \mathcal{H} be family of expanders of every size such that $\lambda(H) \leq \mu$ for all $H \in \mathcal{H}$.
 3. Construct G_0 such that $I - M_0 \approx_{\epsilon/(16 \cdot z)} I - M^2$ and M_0 is PSD.
 4. For i in $\{1, \dots, z-1\}$
 - a. If $b_{z-i} = 0$, $G_i = G_{i-1} \mathbb{P}_{\mathcal{H}} G_{i-1}$
 - b. Else $G_i = (G_{i-1} \mathbb{P}_{\mathcal{H}} G_{i-1}) \mathbb{P}_{\mathcal{H}} G_0$
 5. If $b_0 = 0$ (r even), $G_z = G_{z-1}$
 6. Else (r is odd), $G_z = G_{z-1} \mathbb{P}_{\mathcal{H}} G$
 7. Output G_z
-

Note that each derandomized product multiplies every vertex degree by a factor of $2 \cdot c$. So the degrees of G, G_0, \dots, G_z are all proportional to one another and the derandomized products in Algorithm 1 are well-defined.

4.2 Proof of Main Result

In this section we prove Theorem 4 by showing that Algorithm 1 yields a spectral approximation of our target power $I - M^r$ and can be implemented space-efficiently. First we show that our two operations, square and plus one, preserve spectral approximation.

► **Lemma 21** (Adapted from [5]). *Let N and \tilde{N} be symmetric matrices such that $I - \tilde{N} \approx_\epsilon I - N$ and N is PSD, then $I - \tilde{N}^2 \approx_\epsilon I - N^2$.*

The proof of Lemma 21 can be found in [5] as well as the full version of this paper. Next we show that the plus one operation in our algorithm also preserves spectral approximation.

► **Lemma 22.** *Let \tilde{N} , N_1 , and N_2 be symmetric matrices with spectral norm at most 1 and suppose that N_1 is PSD and commutes with N_2 . If $I - \tilde{N} \approx_\epsilon I - N_1$ then*

$$I - \frac{1}{2} \cdot (\tilde{N}N_2 + N_2\tilde{N}) \approx_\epsilon I - N_2N_1.$$

A proof of Lemma 22 can be found in the full version of the paper.

Setting $N_1 = M^k$ and $N_2 = M$ in Lemma 22 shows that the plus one operation preserves spectral approximation whenever M^k is PSD. Recall that the first step in Algorithm 1 is to construct a graph G_0 with normalized Laplacian $I - M_0$ such that M_0 is PSD and $I - M_0$ approximates $I - M^2$. We can then approximate $I - M_0^k$ for any k using squaring and plus one because M_0^k will always be PSD. The following Lemma says that $I - M_0^k$ spectrally approximates $I - M^{2k}$.

► **Lemma 23.** *Let r be a positive integer with bit length $\ell(r)$ and A and B be symmetric PSD matrices with $\|A\|, \|B\| \leq 1$ such that $I - A \approx_\epsilon I - B$ and $I - B \approx_\epsilon I - A$ for $\epsilon \leq 1/(2 \cdot \ell(r))$. Then $I - A^r \approx_{2 \cdot \epsilon \cdot \ell(r)} I - B^r$.*

A proof of Lemma 23 can be found in the full version of the paper.

Now we can prove Theorem 4. We prove the theorem with three lemmas: Lemma 24 shows how to construct the graph G_0 needed in Algorithm 1, Lemma 25 argues that the algorithm produces a spectral approximation to $I - M^r$, and Lemma 26 shows that the algorithm can be implemented in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$.

4.2.1 Building G_0

► **Lemma 24.** *There is an algorithm that takes an undirected, unweighted multigraph G with normalized Laplacian $I - M$ and a parameter $\epsilon > 0$, and outputs a rotation map Rot_{G_0} for an undirected, unweighted multigraph G_0 with a two-way labeling and normalized Laplacian $I - M_0$ such that:*

1. M_0 is PSD,
2. $I - M_0 \approx_\epsilon I - M^2$,
3. The algorithm uses space $O(\log N + \log(1/\epsilon))$, where N is the bit length of the input graph G .

A proof of Lemma 24 can be found in Appendix C.

4.2.2 Proof of Spectral Approximation

► **Lemma 25.** *Let G be an undirected multigraph with normalized Laplacian $I - M$, r be a positive integer and $\epsilon \in (0, 1)$. Let G_z be the output of Algorithm 1 with normalized Laplacian $I - M_z$. Then*

$$I - M_z \approx_{\epsilon} I - M^r$$

Proof. Let $b_z b_{z-1} \dots b_1 b_0$ be the binary representation of r . Recall that for the derandomized products in our algorithm we use a family of c -regular expanders \mathcal{H} from Theorem 20 such that for every $H \in \mathcal{H}$, $\lambda(H) \leq \mu = \epsilon/(32 \cdot z)$ (and hence $c = \text{poly}(1/\mu) = \text{poly}((\log r)/\epsilon)$).

We construct G_0 with normalized Laplacian $I - M_0$ as in Lemma 24 such that M_0 is PSD and $I - M_0 \approx_{\epsilon/(16 \cdot z)} I - M^2$. By Proposition 6 Part 1, and the fact that

$$\begin{aligned} \frac{\epsilon/(16 \cdot z)}{1 - \epsilon/(16 \cdot z)} &= \frac{\epsilon}{(16 \cdot z) - \epsilon} \\ &\leq \frac{\epsilon}{8 \cdot z}, \end{aligned}$$

we also have $I - M^2 \approx_{\epsilon/(8 \cdot z)} I - M_0$.

For each $i \in \{0, \dots, z\}$ let r_i be the integer with binary representation $b_z b_{z-1} \dots b_{z-i}$ and let $I - M_i$ be the normalized Laplacian of G_i . We will prove by induction on i that G_i is a $(4 \cdot \mu \cdot i)$ -approximation to $I - M_0^{r_i}$. Thus, G_{z-1} is a $4 \cdot \mu \cdot (z-1) \leq \epsilon/8$ -approximation to $I - M_0^{r_{z-1}}$.

The base case is trivial since $r_0 = 1$. For the induction step, suppose that $I - M_{i-1} \approx_{4 \cdot \mu \cdot (i-1)} I - M_0^{r_{i-1}}$. On iteration i , if $b_{z-i} = 0$, then $G_i = G_{i-1} \oplus_{\mathcal{H}} G_{i-1}$. So we have

$$\begin{aligned} I - M_i &\approx_{\mu} I - M_{i-1}^2 \\ &\approx_{4 \cdot \mu \cdot (i-1)} I - M_0^{2 \cdot r_{i-1}} \\ &= I - M_0^{r_i} \end{aligned}$$

where the first approximation uses Theorem 19 and the second uses Lemma 21. By Proposition 6 Part 2 this implies that $I - M_i$ approximates $I - M_0^{r_i}$ with approximation factor

$$\mu + 4 \cdot \mu \cdot (i-1) + 4 \cdot \mu^2 \cdot (i-1) \leq 4 \cdot \mu \cdot i$$

where we used the fact that $\mu < 1/(32 \cdot (i-1))$.

If $b_{z-i} = 1$, $G_i = (G_{i-1} \oplus_{\mathcal{H}} G_{i-1}) \oplus_{\mathcal{H}} G_0$. Let $I - M_{\text{ds}}$ be the normalized Laplacian of $G_{i-1} \oplus_{\mathcal{H}} G_{i-1}$. By the analysis above, $I - M_{\text{ds}}$ is a $(\mu + 4 \cdot \mu \cdot (i-1) + 4 \cdot \mu^2 \cdot (i-1))$ -approximation of $I - M_0^{2 \cdot r_{i-1}}$. By Theorem 19 and Lemma 22 we have

$$\begin{aligned} I - M_i &\approx_{\mu} I - \frac{1}{2} \cdot (M_{\text{ds}} M_0 + M_0 M_{\text{ds}}) \\ &\approx_{\mu + 4 \cdot \mu \cdot (i-1) + 4 \cdot \mu^2 \cdot (i-1)} I - M_0^{2 \cdot r_{i-1}} M_0 \\ &= I - M_0^{r_i} \end{aligned}$$

Applying Proposition 6 Part 2 and noting that $\mu \leq 1/(32 \cdot (i-1))$ we get

$$I - M_i \approx_{4 \cdot \mu \cdot i} I - M_0^{r_i}.$$

So we conclude that $I - M_{z-1} \approx_{\epsilon/8} I - M_0^{r_{z-1}}$. Furthermore, by Lemma 23 we have

$$I - M_0^{r_{z-1}} \approx_{\epsilon/8} I - M^{2 \cdot r_{z-1}}.$$

By Proposition 6 Part 2, and the fact that $\epsilon \leq 1$, this gives

$$I - M_{z-1} \approx_{\epsilon/3} I - M^{2 \cdot r_{z-1}}$$

If $b_0 = 0$ then $2 \cdot r_{z-1} = r$ and we are done. If $b_0 = 1$ then we apply one more plus one operation using our original graph G to form $G_z = G_{z-1} \oplus_{\mathcal{H}} G$ such that

$$\begin{aligned} I - M_z &\approx_{\mu} I - \frac{1}{2} \cdot (M_{z-1}M + MM_{z-1}) \\ &\approx_{\epsilon/3} I - M^{2 \cdot r_{z-1} + 1} \\ &= I - M^r. \end{aligned}$$

Applying Proposition 6 Part 2 then gives $I - M_z \approx_{\epsilon} I - M^r$. ◀

4.2.3 Analysis of Space Complexity

► **Lemma 26.** *Algorithm 1 can be implemented so that given an undirected multigraph G , a positive integer r , and $\epsilon \in (0, 1)$, it computes its output G_z in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$, where N is the bit length of the input graph G .*

Proof. We show how to compute Rot_{G_z} in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$. Let $b_z b_{z-1} \dots b_0$ be the binary representation of r . Following Algorithm 1, G_0 is constructed with normalized Laplacian $I - M_0 \approx_{\epsilon/(16 \cdot z)} I - M^2$. From Lemma 24, we know Rot_{G_0} can be computed in space $O(\log N + \log(16 \cdot z/\epsilon)) = O(\log N + \log(1/\epsilon) + \log \log r)$. Let d_1, \dots, d_n be the vertex degrees in G_0 and d_{\max} be the maximum degree.

The algorithm is presented to have z iterations, where on iteration $i \in [z - 1]$, if $b_{z-i} = 0$ the derandomized product is invoked once, and if $b_{z-i} = 1$, it is invoked twice. On iteration z it is either invoked once ($b_0 = 1$) or not at all ($b_0 = 0$). It will be simpler for us to think of each derandomized product happening in its own iteration. So we will consider $\tau = z + w = O(\log r)$ iterations where w is the number of ones in b_{z-1}, \dots, b_0 . On iterations $1, \dots, z - 1$, there are $z - 1$ derandomized square operations and w plus one operations. The final iteration will either have a plus one operation with the graph G (if $b_0 = 1$) or no operation.

We copy the bits of r into memory and expand them into τ bits as follows: for $i \in \{1, \dots, z - 1\}$ if $b_{z-i} = 0$, record a 0 (corresponding to a derandomized square) and if $b_{z-i} = 1$, record a 0 followed by a 1 (corresponding to a derandomized square followed by a plus one operation). Finish by just recording b_z at the end. Now we have τ bits t_1, \dots, t_{τ} in memory where for $i < \tau$, $t_i = 0$ if the i th derandomized product in our algorithm is a derandomized square and $t_i = 1$ if the i th derandomized product is a plus one with the graph G_0 . If $t_{\tau} = 0$, we do no derandomized product on the last iteration and if $t_{\tau} = 1$ we apply the plus one operation using G instead of G_0 as described in the algorithm.

We also re-number our graphs to be G_1, \dots, G_{τ} where G_i is the graph produced by following the derandomized products corresponding to t_1, \dots, t_i . For each $i \in [\tau]$ and $v \in [n]$, vertex v in graph G_i has degree $(2 \cdot c)^i \cdot d_v$ because each derandomized product multiplies every vertex degree by a factor of $2 \cdot c$.

Since our graphs can be irregular, the input to a rotation map may have a different length than its output. To simplify the space complexity analysis, when calling a rotation map, we will pad the edge labels to always have the same length as inputs and outputs to the rotation map. For each graph G_i , we pad its edge labels to have length $\ell_i = \lceil \log_2 d_{\max} \rceil + i \cdot \lceil \log_2(2 \cdot c) \rceil$.

Sublogarithmic-space complexity can depend on the model, so we will be explicit about the model we use. We compute the rotation map of each graph G_i on a multi-tape Turing machine with the following input/output conventions:

42:14 Deterministic Approximation of Random Walks in Small Space

- Input Description:
 - Tape 1 (read-only): Contains the input G , r , and ϵ with the head at the leftmost position of the tape.
 - Tape 2 (read-write): Contains the input to the rotation map (v_0, k_0) , where $v_0 \in [n]$ is a vertex of G_i , and k_0 is the label of an edge incident to v_0 padded to have total length ℓ_i . The tapehead is at the rightmost end of k_0 . The rest of the tape may contain additional data.
 - Tape 3: (read-write) Contains the bits t_1, \dots, t_τ with the head pointing at t_i .
 - Tapes 4+: (read-write): Blank worktapes with the head at the leftmost position.
- Output Description:
 - Tape 1: The head should be returned to the leftmost position.
 - Tape 2: In place of (v_0, k_0) , it should contain $(v_2, k_2) = \text{Rot}_{G_i}(v_0, k_0)$, where $v_2 \in [n]$, and k_2 is padded to have total length ℓ_i . The head should be at the rightmost position of k_2 and the rest of the tape should remain unchanged from its state at the beginning of the computation.
 - Tape 3: Contains the bits t_1, \dots, t_τ with the head pointing at t_i .
 - Tapes 4+: (read-write): Are returned to the blank state with the heads at the leftmost position.

Let $\text{Space}(G_i)$ be the space used on tapes other than tape 1 to compute Rot_{G_i} . We will show that $\text{Space}(G_i) = \text{Space}(G_{i-1}) + O(\log c)$. Recalling that $\text{Space}(G_0) = O(\log N + \log(1/\epsilon) + \log \log r)$ and unraveling the recursion gives

$$\begin{aligned} \text{Space}(G_\tau) &= O(\log N + \log(1/\epsilon) + \log \log r + \tau \cdot \log c) \\ &= O(\log N + \log(1/\epsilon) + \log \log r + \log r \cdot \log(\text{poly}(\log r)/\epsilon)) \\ &= O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r) \end{aligned}$$

as desired. Now we prove the recurrence on $\text{Space}(G_i)$. We begin with (v_0, k_0) on Tape 2 (possibly with additional data) and the tapehead at the far right of k_0 . We parse k_0 into $k_0 = (j_0, a_0, b)$ where j_0 is an edge label in $[(2 \cdot c)^{i-1} \cdot d_{v_0}]$ padded to have length ℓ_{i-1} , $a_0 \in [c]$, and $b \in \{0, 1\}$.

Note that $G_i = G_{i-1} \oplus_{\mathcal{H}} G'$ where for $i \neq \tau$, we have $G' = G_{i-1}$ if $t_{i-1} = 0$ and $G' = G_0$ when $t_{i-1} = 1$. We compute Rot_{G_i} according to Definition 18. We move the head left to the rightmost position of j_0 . If $b = 0$, we move the third tapehead to t_{i-1} and recursively compute $\text{Rot}_{G_{i-1}}(v_0, j_0)$ so that Tape 2 now contains (v_1, j_1, a_0, b) (with j_1 padded to have the same length as j_0). The vertex v_1 in the graph G_{i-1} has degree $d' = (2 \cdot c)^{i-1} \cdot d_{v_1}$ so we next compute $\text{Rot}_{H_{d'}}(j_1, a_0)$ so that (v_1, j_2, a_1, b) is on the tape. Finally we compute $\text{Rot}_{G'}(v_1, j_2)$ and flip b to finish with (v_2, j_3, a_1, \bar{b}) on the second tape. We then move the third tapehead to t_i . If $b = 1$ then we just swap the roles of G_{i-1} and G' above.

So computing Rot_{G_i} involves computing the rotation maps of G_{i-1} , $H_{d'}$, and G' each once. Note that each of the rotation map evaluations occur in succession and can therefore reuse the same space. Clearly $\text{Space}(G') \leq \text{Space}(G_{i-1})$ because either $G' = G_{i-1}$ or G' is either G_0 or G , both of whose rotation maps are subroutines in computing $\text{Rot}_{G_{i-1}}$. Computing $\text{Rot}_{H_{d'}}$ adds an overhead of at most $O(\log c)$ space to store the additional edge label a_0 and the bit b . So we can compute the rotation map of G_τ in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$. ◀

5 Corollaries

5.1 Random Walks

Our algorithm immediately implies Theorem 2, which we prove below.

Proof of Theorem 2. Let D be the diagonal degree matrix and $I - M$ be the normalized Laplacian of G . Let $v = D^{1/2}e_S$ where e_S is the characteristic vector of the set S . Let d_S be the sum of the degrees of vertices in S . Then using the fact that $I - M^r = D^{-1/2}(I - T^r)D^{1/2}$ where T is the transition matrix of G gives:

$$\begin{aligned} \frac{1}{d_S} \cdot v^T(I - M^r)v &= \frac{1}{d_S} \cdot e_S^T D^{1/2} D^{-1/2} (I - T^r) D^{1/2} D^{1/2} e_S \\ &= \frac{1}{d_S} \cdot e_S^T D e_S - e_S^T (T^r (D e_S / d_S)) \\ &= 1 - \Pr[V_r \in S | V_0 \in S] \\ &= \Phi_r(S) \end{aligned}$$

where the penultimate equality follows from the fact that $D e_S / d_S$ is the probability distribution over vertices in S where each vertex has mass proportional to its degree, i.e. the probability distribution $V_0 || (V_0 \in S)$. Multiplying this distribution by T^r gives the distribution of $V_r || (V_0 \in S)$. Multiplying this resulting distribution on the left by e_S^T , sums up the probabilities over vertices in S , which gives the probability that our random walk ends in S .

From Theorem 4, we can compute a matrix \tilde{L} such that $\tilde{L} \approx_\epsilon I - M^r$ in space $O(\log N + (\log r) \cdot \log(1/\epsilon) + (\log r) \cdot \log \log r)$. It follows from Proposition 6, Part 6 and the definition of spectral approximation that

$$(1 - \epsilon) \cdot \Phi_r(S) \leq \frac{1}{d_S} \cdot v^T \tilde{L} v \leq (1 + \epsilon) \cdot \Phi_r(S). \quad \blacktriangleleft$$

5.2 Odd Length Walks in Nearly Linear Time

Our approach to approximating odd length walks deterministically and space-efficiently also leads to a new result in the context of nearly linear-time (randomized) spectral sparsification algorithms. Specifically, we extend the following Theorem of Cheng, Cheng, Liu, Peng, and Teng [5].

► **Theorem 27 ([5]).** *There is a randomized algorithm that given an undirected weighted graph G with n vertices, m edges, and normalized Laplacian $I - M$, even integer r , and $\epsilon > 0$ constructs an undirected weighted graph \tilde{G} with normalized Laplacian \tilde{L} containing $O(n \log n / \epsilon^2)$ non-zero entries, in time $O(m \cdot \log^3 n \cdot \log^5 r / \epsilon^4)$, such that $\tilde{L} \approx_\epsilon I - M^r$ with high probability.*

Our approach to approximating odd length walks can be used to extend Theorem 27 to odd r .

► **Corollary 28.** *There is a randomized algorithm that given an undirected weighted graph G with n vertices, m edges, and normalized Laplacian $I - M$, odd integer r , and $\epsilon > 0$ constructs an undirected weighted graph \tilde{G} with normalized Laplacian \tilde{L} containing $O(n \log n / \epsilon^2)$ non-zero entries, in time $O(m \cdot \log^3 n \cdot \log^5 r / \epsilon^4)$, such that $\tilde{L} \approx_\epsilon I - M^r$ with high probability.*

Our proof of Corollary 28 uses Theorem 27 as a black box. So in fact, given G with normalized Laplacian $I - M$ and any graph \tilde{G} whose normalized Laplacian approximates $I - M^r$ for even r , we can produce an approximation to $I - M^{r+1}$ in time nearly linear in

the sparsities of G and \tilde{G} . To prove the corollary, we use the same method used in [18] and [6] for sparsifying two-step walks on undirected and directed graphs, respectively. The idea is that the graphs constructed from two-step walks can be decomposed into the union of *product graphs*: graphs whose adjacency matrices have the form xy^T for vectors $x, y \in \mathbb{R}^n$. We use the following fact from [6] that says that product graphs can be sparsified in time that is nearly-linear in the number of non-zero entries of x and y rather than the number of non-zero entries in xy^T , which may be much larger.

► **Lemma 29** (Adapted from [6] Lemma 3.18). *Let x, y be non-negative vectors with $\|x\|_1 = \|y\|_1 = r$ and let $\epsilon \in (0, 1)$. Furthermore, let s denote the total number of non-zero entries in x and y and let $L = \text{diag}(y) - \frac{1}{r} \cdot xy^T$. Then there is an algorithm that in time $O(s \cdot \log s / \epsilon^2)$ computes a matrix \tilde{L} with $O(s \cdot \log s / \epsilon^2)$ non-zeros such that \tilde{L} is a directed ϵ -approximation of L with high probability.*

After using Lemma 29 to sparsify each product graph in our decomposition, we then apply an additional round of graph sparsification.

► **Lemma 30** ([12]). *Given an undirected graph G with n vertices, m edges, and Laplacian L and $\epsilon > 0$, there is an algorithm that computes a graph \tilde{G} with Laplacian \tilde{L} containing $O(n \cdot \log n / \epsilon^2)$ non-zero entries in time $O(m \cdot \log^2 n / \epsilon^2)$ such that $\tilde{L} \approx_\epsilon L$ with high probability.*

Now we are able to prove Corollary 28. See Appendix D for the proof.

A Proof of Theorem 19

Proof. Note that $k \cdot G_1$ has the same transition matrix and normalized Laplacian as G_1 . So we can replace G_1 with $k \cdot G_1$ and assume $k = 1$ without loss of generality.

Since G_0 and G_1 have the same vertex degrees, we can write

$$I - \frac{1}{2} \cdot (M_0 M_1 + M_1 M_0) = I - D^{-1/2} \frac{1}{2} \cdot (T_0 T_1 + T_1 T_0) D^{1/2} \quad (1)$$

where T_0 and T_1 are the transition matrices of G_0 and G_1 , respectively.

Following the proofs in [21] and [16], we can write the transition matrix for the random walk on \tilde{G} as $\tilde{T} = \frac{1}{2} \cdot (PR_0 \tilde{B} R_1 Q + PR_1 \tilde{B} R_0 Q)$, where each matrix corresponds to a step in the definition of the derandomized product. The two terms correspond to $b = 0$ and $b = 1$ in the derandomized product and, setting $\bar{d} = \sum_{i \in [n]} d_i$,

- Q is a $\bar{d} \times n$ matrix that “lifts” a probability distribution over $[n]$ to one over $[\bar{d}]$ where the mass on each coordinate $i \in [n]$ is divided uniformly over the corresponding degree d_i . That is, $Q_{(u,i),v} = 1/d_i$ if $u = v$ and 0 otherwise where the rows of Q are ordered $(1, 1), (1, 2), \dots, (1, d_1), (2, 1), \dots, (2, d_2), \dots, (n, 1), \dots, (n, d_n)$.
- R_0 and R_1 are the $\bar{d} \times \bar{d}$ symmetric permutation matrices corresponding to the rotation maps of G_0 and G_1 , respectively. That is, entry $(u, i), (v, j)$ in R_a is 1 if $\text{Rot}_{G_a}(u, i) = (v, j)$ and 0 otherwise for $a \in \{0, 1\}$.
- \tilde{B} is a $\bar{d} \times \bar{d}$ symmetric block-diagonal matrix with n blocks where block i is the transition matrix for the random walk on $H_{d_i} \in \mathcal{H}$, the expander in our family with d_i vertices.
- $P = DQ^T$ is the $n \times \bar{d}$ matrix that maps any \bar{d} -vector to an n -vector by summing all the entries corresponding to edges incident to the same vertex in G_0 and G_1 . This corresponds to projecting a distribution on $[\bar{d}]$ back down to a distribution over $[n]$. $P_{v,(u,i)} = 1$ if $u = v$ and 0 otherwise where the columns of P are ordered $(1, 1), (1, 2), \dots, (1, d_1), (2, 1), \dots, (2, d_2), \dots, (n, 1), \dots, (n, d_n)$.

Likewise, we can write

$$(T_0 T_1 + T_1 T_0) = (PR_0 \tilde{J} R_1 Q + PR_1 \tilde{J} R_0 Q) \quad (2)$$

where \tilde{J} is a $\bar{d} \times \bar{d}$ symmetric block-diagonal matrix with n blocks where block i is J_i , the transition matrix for the complete graph on d_i vertices with a self loop on every vertex. That is, every entry of J_i is $1/d_i$.

We will show that

$$I_{\bar{d}} - \frac{1}{2} \cdot (R_0 \tilde{B} R_1 + R_1 \tilde{B} R_0) \approx_{\lambda} I_{\bar{d}} - \frac{1}{2} \cdot (R_0 \tilde{J} R_1 + R_1 \tilde{J} R_0).$$

From this the theorem follows by multiplying by $D^{-1/2} P$ on the left and $(D^{-1/2} P)^T = Q D^{1/2}$ on the right and applying Proposition 6 Part 3. Since $D^{-1/2} P Q D^{1/2} = I_n$, the left-hand side becomes

$$\begin{aligned} I_n - D^{-1/2} \tilde{T} D^{1/2} &= I_n - \tilde{D}^{-1/2} \tilde{T} \tilde{D}^{1/2} \\ &= I_n - \tilde{M} \end{aligned}$$

where $\tilde{D} = 2 \cdot c \cdot D$ is the diagonal matrix of vertex degrees of \tilde{G} . By Equations (1) and (2), the right-hand side becomes $I_n - \frac{1}{2}(M_0 M_1 + M_1 M_0)$.

By Lemma 8, each graph in \mathcal{H} is a λ -approximation of the complete graph on the same number of vertices. It follows that $I_{\bar{d}} - \tilde{B} \approx_{\lambda} I_{\bar{d}} - \tilde{J}$ because the quadratic form of a block diagonal matrix equals the sum of the quadratic forms of its blocks. By Lemma 13 and the fact that $I_{\bar{d}} - \tilde{J}$ is PSD, $I_{\bar{d}} - \tilde{B}$ is also a directed λ -approximation of $I_{\bar{d}} - \tilde{J}$. So for all vectors $x, y \in \mathbb{R}^{\bar{d}}$ we have

$$\begin{aligned} |x^T(\tilde{B} - \tilde{J})y| &\leq \frac{\lambda}{2} \cdot (x^T(I_{\bar{d}} - \tilde{J})x + y^T(I_{\bar{d}} - \tilde{J})y) \\ &\leq \frac{\lambda}{2} \cdot (x^T x + y^T y - 2x^T \tilde{J}y). \end{aligned}$$

The first inequality uses Lemma 11. We can add the absolute values on the left-hand side since the right-hand side is always nonnegative ($I_{\bar{d}} - \tilde{J}$ is PSD) and invariant to swapping x with $-x$. The second inequality follows from the fact that \tilde{J} is PSD and so

$$0 \leq (x - y)^T \tilde{J}(x - y) = x^T \tilde{J}x + y^T \tilde{J}y - 2 \cdot x^T \tilde{J}y.$$

Fix $v \in \mathbb{R}^{\bar{d}}$ and set $x = R_0 v$ and $y = R_1 v$. Recall that R_0 and R_1 are symmetric permutation matrices and hence $R_0^2 = R_1^2 = I_{\bar{d}}$. Also note that for all square matrices A and vectors x , $x^T A x = x^T (A + A^T)x/2$. Combining these observations with the above gives

$$\begin{aligned} \left| v^T \left(\frac{1}{2} \cdot (R_0(\tilde{B} - \tilde{J})R_1 + R_1(\tilde{B} - \tilde{J})R_0) \right) v \right| &= |v^T R_0(\tilde{B} - \tilde{J})R_1 v| \\ &\leq \frac{\lambda}{2} \cdot (v^T R_0^2 v + v^T R_1^2 v - 2v^T R_0 \tilde{J} R_1 v) \\ &= \lambda \cdot (v^T v - v^T R_0 \tilde{J} R_1 v) \\ &= \lambda \cdot v^T \left(I - \frac{1}{2} \cdot (R_0 \tilde{J} R_1 + R_1 \tilde{J} R_0) \right) v \end{aligned}$$

Rearranging the above shows that

$$I_{\bar{d}} - \frac{1}{2} \cdot (R_0 \tilde{B} R_1 + R_1 \tilde{B} R_0) \approx_{\lambda} I_{\bar{d}} - \frac{1}{2} \cdot (R_0 \tilde{J} R_1 + R_1 \tilde{J} R_0),$$

which proves the theorem. ◀

B Proof of Theorem 20

Proof. Let H' be a c' -regular expander on m vertices such that $n \leq m \leq 2n$, c' is a constant independent of n and $\lambda(H') \leq \lambda' < 1/4$. H' can be constructed using already known strongly explicit constructions such as [9, 20] followed by squaring the graph a constant number of times to achieve $\lambda' < 1/4$. We will construct H as follows: Pair off the first $(m - n)$ vertices with the last $(m - n)$ vertices in H' and merge each pair into a single vertex (which will then have degree $2 \cdot c'$). To make the graph regular, add c' self loops to all of the unpaired vertices. More precisely, given $u' \in [n]$ and $i' \in [c] = [2 \cdot c']$ we compute $\text{Rot}_H(u', i')$ as follows:

1. If $1 \leq u' \leq m - n$ [u' is a paired vertex]:
 - a. If $1 \leq i' \leq c'$, let $u = u'$, $i = i'$ [u' is the first vertex in pair]
 - b. else let $u = m - u'$, $i = i' - c'$ [u' is the second vertex in pair]
 - c. let $(v, j) = \text{Rot}_{H'}(u, i)$

42:20 Deterministic Approximation of Random Walks in Small Space

2. else (if $m - n < u' \leq n$) [u' is an unpaired vertex]
 - a. If $1 \leq i' \leq c'$, let $u = u'$, $i = i'$, and $(v, j) = \text{Rot}_H(u, j)$ [original edge]
 - b. else let $(v, j) = (u', i')$ [new self loop]
3. a. If $v \leq n$, let $(v', j') = (v, j)$
 - b. else let $v' = m - v$, $j' = j + c'$.
4. Output (v', j')

Next we show that $\lambda(H)$ is bounded below 1 by a constant. The theorem then follows by taking the $O(\log 1/\lambda)$ th power to drive $\lambda(H)$ below λ . This gives the graph degree $\text{poly}(1/\lambda)$.

Let A' be the adjacency matrix of H' and K' be the $m \times m$ all ones matrix. Since $\lambda(H') \leq \lambda'$, Lemma 8 implies that

$$\frac{1}{c'} \cdot (c' \cdot I - A') \approx_{\lambda'} \frac{1}{m} \cdot (m \cdot I - K').$$

Define B to be the $m \times n$ matrix such that $B_{u',u} = 1$ if and only if vertex $u' \in V(H')$ was merged into vertex $u \in V(H)$ or vertex $u \in V(H')$ was not merged and is labeled vertex u' in H . That is, $B_{u',u} = 1$ if and only if $u = u'$ or $n \leq u = m - u'$. Then the unnormalized Laplacian of the expander after the merging step is $B^T(c' \cdot I - A')B$. Adding self loops to a graph does not change its Laplacian. So applying Proposition 6 parts 3 and 6 we get

$$L(H) = \frac{1}{2c'} \cdot B^T(c' \cdot I - A')B \approx_{\lambda'} \frac{1}{2m} \cdot B^T(m \cdot I - K)B$$

Note that the righthand side is the normalized Laplacian of the graph U that results from starting with the complete graph on m vertices, merging the same pairs of vertices that are merged in H and adding m self loops to all of the unmerged vertices for regularity.

We finish the proof by showing that $\lambda(U) \leq 1/2$ and thus H is a $(\lambda' + 1/2 + \lambda'/2)$ -approximation of the complete graph by Proposition 6 Part 2 and Lemma 8. Recalling that $\lambda' < 1/4$ completes the proof.

U has at least m edges between every pair of vertices so we can write its transition matrix T_u as

$$T_u = \frac{1}{2} \cdot J_m + \frac{1}{2} \cdot E$$

where J_m is the transition matrix of the complete graph on m vertices with self loops on every vertex and E is the transition matrix for an m -regular multigraph. Since the uniform distribution is stationary for all regular graphs, $\vec{1}$ is an eigenvector of eigenvalue 1 for T_u , J_m , and E . Thus

$$\begin{aligned} \lambda(U) &= \sup_{v \perp \vec{1}} \frac{\|T_u v\|}{\|v\|} \\ &\leq \sup_{v \perp \vec{1}} \frac{\frac{1}{2} \cdot (\|J_m v\| + \|E v\|)}{\|v\|} \\ &\leq \frac{1}{2} \cdot 0 + \frac{1}{2} \cdot 1, \end{aligned}$$

which completes the proof. ◀

C Proof of Lemma 24

Proof. Let $\delta = 1/\lceil 4/\epsilon \rceil$ and $t = 1/\delta$, an integer. Let \mathcal{H} be a family of c -regular expanders of every size from Theorem 20, such that for every $H \in \mathcal{H}$, $\lambda(H) \leq \delta$ (and hence $c = \text{poly}(1/\delta)$).

Let $\tilde{G} = G \boxtimes_{\mathcal{H}} G$ be the derandomized square of G with normalized Laplacian $I - \tilde{M}$. Each vertex v in \tilde{G} has degree $\tilde{d}_v = 2 \cdot c \cdot d_v$, where d_v is the degree of v in G . We construct G_0 as follows: duplicate every edge of \tilde{G} to have multiplicity t and then for each vertex v , add \tilde{d}_v self loops. So for each vertex v in G_0 , v has degree $(t + 1) \cdot 2 \cdot c \cdot d_v$ and hence G_0 has the same stationary distribution as G . Note that we can write

$$M_0 = (t \cdot \tilde{M} + I)/(t + 1).$$

First we show that M_0 is PSD. From Theorem 19, we have $I - \tilde{M} \approx_{\delta} I - M^2$, so $I - \tilde{M} \preceq (1 + \delta) \cdot (I - M^2) \preceq (1 + \delta) \cdot I$, since M^2 is PSD. Thus $\tilde{M} \succeq -\delta \cdot I$ and

$$M_0 \succeq \frac{t \cdot (-\delta \cdot I) + I}{t + 1} \succeq 0.$$

Next we prove that $I - M_0 \approx_{\epsilon} I - M^2$

$$\begin{aligned} I - M_0 &= (t/(t + 1)) \cdot (I - \tilde{M}) \\ &= \left(\frac{1}{1 + \delta} \right) \cdot (I - \tilde{M}) \\ &\preceq I - M^2. \end{aligned}$$

Observe that since $I - \tilde{M} \approx_{\delta} I - M^2$, we also have

$$\begin{aligned} I - M_0 &= \left(\frac{1}{1 + \delta} \right) \cdot (I - \tilde{M}) \\ &\succeq \left(\frac{1 - \delta}{1 + \delta} \right) \cdot (I - M^2) \\ &\succeq (1 - \epsilon) \cdot (I - M^2). \end{aligned}$$

We can construct a two-way labeling of G in space $O(\log N)$ by arbitrarily numbering the edges incident to each vertex. Computing $\text{Rot}_{\tilde{G}}$ involves computing Rot_G twice and the rotation map of an expander in \mathcal{H} once. For a given vertex degree d in G , Rot_{H_d} can be computed in space $O(\log(d \cdot c)) = O(\log N + \log(1/\epsilon))$. Duplicating the edges and adding self loops for Rot_{G_0} adds at most $O(\log N + \log(1/\epsilon))$ overhead for a total of $O(\log N + \log(1/\epsilon))$ space. \blacktriangleleft

D Proof of Corollary 28

Proof. Theorem 27 says that we can compute a graph \tilde{G} with normalized Laplacian $I - \tilde{M}$ with $O(n \log n/\epsilon^2)$ non-zero entries, in time $O(m \cdot \log^3 n \cdot \log^5 r/\epsilon^4)$, such that $I - \tilde{M} \approx_{\epsilon/8} I - M^{r-1}$ with high probability. By Lemma 22 we have

$$I - \frac{1}{2} \cdot (\tilde{M}M + M\tilde{M}) \approx_{\epsilon/8} I - M^r. \tag{3}$$

Our goal is to sparsify the lefthand side. Note that since $I - \tilde{M}$ spectrally approximates $I - M^{r-1}$, the corresponding graphs must have the same stationary distribution and hence proportional vertex degrees. In other words there is a number k such that for all vertices

42:22 Deterministic Approximation of Random Walks in Small Space

$v \in [n]$ we have $\deg_{\tilde{G}}(v) = k \cdot \deg_G(v)$. We will think of the graph that adds one step to our walk as $k \cdot G$ rather than G because $k \cdot G$ and \tilde{G} have the same degrees and the normalized Laplacian of $k \cdot G$ is the same as the normalized Laplacian of G .

Let A and \tilde{A} be the adjacency matrices of $k \cdot G$ and \tilde{G} , respectively and let D be the diagonal matrix of vertex degrees. Let $Q = D - AD^{-1}\tilde{A}$ and note that Q is the Laplacian of a weighted directed graph. We will show how to compute a sparse directed approximation of Q and use this to show how to compute a sparse approximation to the lefthand side of Equation 3. Our approach is inspired by similar arguments from [18, 6]. We decompose Q into n product graphs as follows. For each $i \in [n]$ let

$$Q_i = \text{diag}(\tilde{A}_{i,:}) - \frac{1}{D_{i,i}} \cdot A_{:,i} \tilde{A}_{i,:}^T$$

where $\tilde{A}_{i,:}$ and $A_{:,i}$ denote the i th row of \tilde{A} and the i th column of A , respectively. Observe that Q_i is a directed Laplacian of a bipartite graph between the neighbors of vertex i in $k \cdot G$ and the neighbors of i in \tilde{G} and that $Q = \sum_{i \in [n]} Q_i$. Furthermore, each Q_i is a product graph and hence can be sparsified using Lemma 29. Set $x_i = A_{:,i}$, $y_i = \tilde{A}_{i,:}$, $r_i = D_{i,i}$, and let s_i be the total number of non-zero entries in x and y . Note that $\|x_i\|_1 = \|y_i\|_1 = r_i$ because $k \cdot G$ and \tilde{G} have the same vertex degrees. By Lemma 29, for each $i \in [n]$ we can compute a directed $\epsilon/8$ -approximation \tilde{Q}_i of Q_i containing $O(s_i \cdot \log s_i / \epsilon^2)$ entries in time $O(s_i \cdot \log s_i / \epsilon^2)$. Applying the lemma to each Q_i yields $\tilde{Q} = \sum_{i \in [n]} \tilde{Q}_i$, which contains $O(m \cdot \log m / \epsilon^2)$ non-zero entries and can be computed in time $O(m \cdot \log m / \epsilon^2)$ because $\sum_{i \in [n]} s_i = O(m)$. By Lemma 12 we have

$$\frac{1}{2} \cdot (\tilde{Q}_i + \tilde{Q}_i^T) \approx_{\epsilon/8} \frac{1}{2} \cdot (Q_i + Q_i^T)$$

for all $i \in [n]$ with high probability. It follows from Proposition 6 Part 5 that

$$\begin{aligned} \frac{1}{2} \cdot (\tilde{Q} + \tilde{Q}^T) &= \frac{1}{2} \cdot \sum_{i \in [n]} (\tilde{Q}_i + \tilde{Q}_i^T) \\ &\approx_{\epsilon/8} \frac{1}{2} \cdot \sum_{i \in [n]} (Q_i + Q_i^T) \\ &= \frac{1}{2} \cdot (Q + Q^T) \end{aligned}$$

with high probability. From Proposition 6 Part 3, we then get

$$\begin{aligned} D^{-1/2} \frac{1}{2} \cdot (\tilde{Q} + \tilde{Q}^T) D^{-1/2} &\approx_{\epsilon/8} D^{-1/2} \frac{1}{2} \cdot (Q + Q^T) D^{-1/2} \\ &= I - \frac{1}{2} \cdot (\tilde{M}M + M\tilde{M}) \end{aligned}$$

with high probability. Applying Lemma 30 we can re-sparsify the graph corresponding to $D^{-1/2} \frac{1}{2} \cdot (\tilde{Q} + \tilde{Q}^T) D^{-1/2}$ to produce a graph G' whose normalized Laplacian $I - M'$ has $O(n \cdot \log n / \epsilon^2)$ non-zero entries and $I - M' \approx_{\epsilon/8} D^{-1/2} \frac{1}{2} \cdot (\tilde{Q} + \tilde{Q}^T) D^{-1/2}$ with high probability. This takes additional time $O(m \cdot \log^2 n / \epsilon^2)$ due to Theorem 1.1 of [12]. Applying Proposition 6 Part 2 twice we get that $I - M' \approx_{\epsilon} I - M^r$ and the total running time for the procedure was $O(m \cdot \log^3 n \cdot \log^5 r / \epsilon^4)$. \blacktriangleleft

Two-Source Condensers with Low Error and Small Entropy Gap via Entropy-Resilient Functions

Abstract

In their seminal work, Chattopadhyay and Zuckerman (STOC'16) constructed a two-source extractor with error ε for n -bit sources having min-entropy $\text{polylog}(n/\varepsilon)$. Unfortunately, the construction's running-time is $\text{poly}(n/\varepsilon)$, which means that with polynomial-time constructions, only polynomially-small errors are possible. Our main result is a $\text{poly}(n, \log(1/\varepsilon))$ -time computable two-source condenser. For any $k \geq \text{polylog}(n/\varepsilon)$, our condenser transforms two independent (n, k) -sources to a distribution over $m = k - O(\log(1/\varepsilon))$ bits that is ε -close to having min-entropy $m - o(\log(1/\varepsilon))$. Hence, achieving entropy gap of $o(\log(1/\varepsilon))$.

The bottleneck for obtaining low error in recent constructions of two-source extractors lies in the use of resilient functions. Informally, this is a function that receives input bits from r players with the property that the function's output has small bias even if a bounded number of corrupted players feed adversarial inputs after seeing the inputs of the other players. The drawback of using resilient functions is that the error cannot be smaller than $\ln r/r$. This, in return, forces the running time of the construction to be polynomial in $1/\varepsilon$.

A key component in our construction is a variant of resilient functions which we call *entropy-resilient functions*. This variant can be seen as playing the above game for several rounds, each round outputting one bit. The goal of the corrupted players is to reduce, with as high probability as they can, the min-entropy accumulated throughout the rounds. We show that while the bias decreases only polynomially with the number of players in a one-round game, their success probability decreases *exponentially* in the entropy gap they are attempting to incur in a repeated game.

1 Introduction

The problem of extracting randomness from imperfect random sources can be traced back to von Neumann [45]. Ideally, and somewhat informally, a randomness extractor is an algorithm that produces, or extracts, truly random bits from an imperfect source of randomness. Going beyond that particular task, randomness extractors have found dozens of applications for error correcting codes, cryptography, combinatorics, and circuit lower bounds to name a few.

An imperfect source of randomness is modelled by a random variable X that, for convenience sake, is assumed to be supported on n -bit strings. The standard measure for the amount of randomness in X is its *min-entropy* [18], which is the maximum $k \geq 0$ for which one cannot guess X with probability larger than 2^{-k} . For any such k , we say that X is an (n, k) -source, or a k -source for short.

Ideally, a randomness extractor would have been defined as a function $\text{Ext}: \{0, 1\}^n \rightarrow \{0, 1\}^m$ with the property that for every random variable X with sufficiently high min-entropy, the output $\text{Ext}(X)$ is ε -close to the uniform distribution on $\{0, 1\}^m$ in the statistical distance, which we write as $\text{Ext}(X) \approx_\varepsilon U_m$. Unfortunately, such a function Ext , even for very high min-entropy $k = n - 1$ and, when set with a modest error guarantee $\varepsilon = 1/4$ and a single output bit $m = 1$, does not exist. In light of that, several types of randomness extractors, that relax in different ways the above ideal definition, have been introduced and studied in the literature. In this work, we focus on one such well-studied instantiation.

► **Definition 1** (Two-source extractors [18]). *A function $\text{Ext}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m$ is a two-source extractor for min-entropy k with error guarantee ε if for every pair of independent (n, k) -sources X, Y , the output distribution $\text{Ext}(X, Y) \approx_\varepsilon U_m$.*

The existence of a two-source extractor for any min-entropy $k = \Omega(\log(n/\varepsilon))$ with $m = 2k - O(\log(1/\varepsilon))$ output bits was proved in [18]. In the same paper, an explicit construction of a two-source extractor for min-entropy $k > n/2$ was obtained. Remarkably, despite much attention [13, 42, 12, 31] and progress on relaxed settings [6, 41, 33, 32, 34, 20], the problem of constructing two-source extractors even for min-entropy as high as $k = 0.1n$ with $m = 1$ output bits remained open for 30 years. To appreciate the difficulty of constructing two-source extractors, we remark that such constructions yield explicit constructions of Ramsey graphs, a notoriously hard problem in combinatorics [1, 38, 25, 19, 26, 3, 27, 39, 5, 6, 7, 23].

In their breakthrough result, Chattopadhyay and Zuckerman [17] were finally able to obtain an explicit two-source extractor for min-entropy $k = \text{polylog}(n/\varepsilon)$. Partially motivated by the problem of constructing Ramsey graphs, a line of followup works [24, 16, 21, 9, 22, 35, 36] focused on the case of constant error ε and was devoted for reducing the min-entropy requirement as a function of n . The state of the art result in this line of work is due to Li [36] and requires min-entropy $\frac{\log n \cdot \log \log n}{\log \log \log n} \cdot \text{poly}(1/\varepsilon)$.

1.1 Resilient Functions – The Barrier for Obtaining Extractors With Low Error

Unfortunately, despite the fact that the dependence of the min-entropy of the Chattopadhyay-Zuckerman extractor on ε is polynomially-close to optimal, the running-time of their construction depends polynomially on $1/\varepsilon$ rather than the desired $\text{polylog}(1/\varepsilon)$ dependence. The same holds for all subsequent constructions. That is, these constructions are not strongly polynomial-time and, in particular, the error guarantee cannot be taken to be sub-polynomial in n while maintaining running-time $\text{poly}(n)$. This stands in contrast to classical extractors for high min-entropy [18, 42, 13, 31] that are strongly polynomial-time, and can support exponentially-small error.

Informally speaking, the reason for this undesired dependence of the running-time on ε lies in the use of a so-called *resilient function* [11]. A q -resilient function $f: \{0, 1\}^r \rightarrow \{0, 1\}$ can be thought of as an r -player game. If all players feed uniform and independent inputs to f , the output distribution has small bias, and, furthermore, this property is retained even if any q players decide to deviate from the rules of the game and choose their inputs as a function of all other inputs to f .

Majority on r input bits is an example of a q -resilient function with $q = O(\sqrt{r})$. Ajtai and Linial proved, using the probabilistic method, the existence of a q -resilient function for $q = O(\frac{r}{\log^2 r})$ [2]. The KKL Theorem [30] implies that the Ajtai-Linial function is tight up to a $\log r$ factor. Chattopadhyay and Zuckerman [17] constructed a derandomized version of the Ajtai-Linial function with $q = r^{1-\delta}$, for any constant $\delta > 0$. Their construction has further desirable properties. In a subsequent work, Meka obtained a derandomized version of the Ajtai-Linial function with the same parameters as the randomized construction [37]. However, no matter what function is chosen, [30] showed that there is always a single corrupted player that has influence $p = \Omega(\frac{\log r}{r})$, i.e., with probability p over the input fed by the other players, the single corrupted player can fully determine the result.

Almost all constructions of randomness extractors following [17] can be divided into two steps. First, the two n -bit sources X, Y are “transformed” to a single r -bit source $Z = h(X, Y)$ with some structure, called a *non-oblivious bit-fixing source*. A resilient function $f: \{0, 1\}^r \rightarrow \{0, 1\}$ is then applied to Z so to obtain the output $\text{Ext}(X, Y) = f(h(X, Y))$. In all works, the function h is based on non-malleable extractors or on related primitives such as correlation breakers. As mentioned above, the use of the resilient function implies that even a single corrupted player has influence $\Omega(\frac{\log r}{r})$ and so to obtain an error guarantee ε , the number of players r must be taken larger than $1/\varepsilon$. This results in running-time $\Omega(1/\varepsilon)$.¹

1.2 Entropy-Resilient Functions

To obtain our condenser, we extend the notion of resilient functions to functions outputting many bits. Informally speaking, instead of considering an r -player game in which the bad players try to bias the output, we study a repeated game version in which the r players play for m rounds. The bad players attempt to decrease, with as high probability as they can, the min-entropy of the m -bit outcome (and we will even allow the bad players to cast their votes after the good players played all rounds).

Recall that, by [30], when $m = 1$, even a single player can bias the result by $\Omega(\frac{\log r}{r})$. Put differently, viewing this bias as the error of a deterministic extractor, the error is bound to be at least polynomially-small in the number of players. Our key insight is that when m becomes large, the probability that the bad players can reduce g bits of entropy from the output (creating an “entropy gap” of g) is *exponentially small* in g . We further show that this holds for a specific function f , induced by the Ajtai-Linial function, even when the honest players are only t -wise independent (for $t = \text{polylog}(r/\varepsilon)$). Our analysis uses and extends ideas from the work of Chattopadhyay and Zuckerman [17].

¹ There is one exception to the above scheme. In [8], it is shown that if very strong t -non-malleable extractors can be explicitly constructed then the function f can be replaced with the parity function (which is not resilient at all) and low error two-source extractors with low min-entropy requirement can be obtained. However, it is not known how to explicitly construct such t -non-malleable extractors.

1.3 The Two-Source Condensers We Obtain

The main contribution of this work is an explicit construction of a two-source *condenser* with low error and small entropy gap, outputting almost all of the entropy from one source.

► **Definition 2** (Two-source condensers). *A function $\text{Cond}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m$ is a two-source condenser for min-entropy k with min-entropy gap g and error guarantee ε if for every pair of independent (n, k) -sources, $\text{Cond}(X, Y)$ is ε -close to an $(m, m - g)$ -source.*

Note that a two-source extractor is a two-source condenser with entropy gap $g = 0$. Thus, condensers can be seen as a relaxation of extractors in which some, hopefully small, “gap” of min-entropy in the output distribution is allowed. Despite having a weaker guarantee, condensers play a key role in the construction of many types of randomness extractors, including two-source extractors [9], their variants [42, 6, 47, 41, 32], and seeded-extractors [28]. Most related to our work is a paper by Rao [40] that, for every $\delta > 0$, constructed a $\text{poly}(n, \log(1/\varepsilon))$ -time computable two-source condenser² for min-entropy $k = \delta n$ having $m = \Omega(\delta n)$ output bits with entropy gap $g = \text{poly}(1/\delta, \log(1/\varepsilon))$.

In this work, we obtain a strongly polynomial-time construction of a two-source condenser with low error and small min-entropy gap.

► **Theorem 3** (Main result). *For all integers n, k and every $\varepsilon > 0$ such that $n \geq k \geq \text{polylog}(\frac{n}{\varepsilon})$, there exists a $\text{poly}(n, \log(1/\varepsilon))$ -time computable two-source condenser*

$$\text{Cond}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m$$

for min-entropy k , with error guarantee ε , min-entropy gap $g = o(\log \frac{1}{\varepsilon})$, and $m = k - O(\log(1/\varepsilon))$ output bits.

Note that the entropy gap g is independent of the entropy k and scales *sub-logarithmically* with $1/\varepsilon$. We prove Theorem 3, whose formal statement is given in Theorem 31, in two steps. First, we construct a two-source condenser with the same guarantees as provided by Theorem 3, though only with $m = k^\alpha$ output bits, where $0 < \alpha < 1$ is some small universal constant (see Theorem 27). This part of the construction is based on our study of entropy-resilient functions (Section 3) and on the adaptation of the Chattopadhyay-Zuckerman construction for entropy-resilient functions. To reduce the huge entropy-loss we incur (i.e., to increase the output length from k^α to $k - O(\log(1/\varepsilon))$), in the second step, we construct a seedless condenser for block-sources—a result that we believe is of independent interest on which we now elaborate.

1.4 Seedless Condensers for a Single Block-Source

A (k_1, k_2) -*block-source* is a pair of random variables X_1, X_2 that, although may be dependent, have the following guarantee. First, X_1 is a k_1 -source, and second, conditioned on any fixing of X_1 , the random variable X_2 has min-entropy k_2 . Throughout this section, we denote the length of X_1 by n_1 and the length of X_2 by n_2 . Informally, the notion of a block-source “lies between” a single source and two independent sources. Indeed, any (k_1, k_2) -block-source is a $(k_1 + k_2)$ -source. Moreover, if X_1 is a k_1 -source and X_2 is an independent k_2 -source then X_1, X_2 is a (k_1, k_2) -block-source.

² To the matter of fact, Rao entitled his construction a “two-source almost extractor” – a suitable name given its small entropy gap.

Block-sources are key to almost all constructions of seeded extractors as well as to the construction of Ramsey graphs. As mentioned above, there is no one-source extractor, whereas two-source extractors exist even for very low min-entropy. Despite being more structured than a general source, it is a well-known fact that there is no extractor for a single block-source (with non-trivial parameters).

A key component that allows us to increase the output length of our condenser discussed above is a seedless condenser for a single block-source. Let X_1, X_2 be a (k_1, k_2) -block-source. Write $g = n_2 - k_2$ for the entropy gap of X_2 . For any given $\varepsilon > 0$, we show how to *deterministically* transform X_1, X_2 to a single m -bit random variable, where $m = k_1 - g - O(\log(1/\varepsilon))$, that is ε -close to having min-entropy $m - g - 1$. That is, informally, we are able to condense X_1 roughly to its entropy content k_1 using (the dependent random variable) X_2 while inheriting the entropy gap of X_2 both in the resulted entropy gap and entropy loss. We stress that this transformation is deterministic. This demonstrates that despite the well-known fact that a block-source extractor does not exist, a block-source condenser does. For a formal treatment, see Section 5.

1.5 A Three-Source Extractor

An immediate implication of Theorem 3 are low error three-source extractors supporting min-entropies $k_1 = k_2 = \text{polylog}(n/\varepsilon)$ and $k_3 = \Omega(\log(1/\varepsilon))$. This is achieved by feeding our condenser's output $Y = \text{Cond}(X_1, X_2)$ as a seed to a seeded extractor that supports small entropies (see, e.g., Theorem 10), outputting $\text{Ext}(X_3, Y)$.

► **Corollary 4.** *For all integers n, k, k' and every $\varepsilon > 0$ such that $n \geq k \geq \text{polylog}(\frac{n}{\varepsilon})$ and $n \geq k' \geq \Omega(\log \frac{1}{\varepsilon})$ there exists a $\text{poly}(n, \log(1/\varepsilon))$ -time computable three-source extractor*

$$3\text{Ext}: \{0, 1\}^n \times \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m$$

for min-entropies k, k, k' and error guarantee ε , where $m = k' - O(\log(1/\varepsilon))$.

Proof. Set $\varepsilon' = \varepsilon^2$, let $k' \geq 2 \log(1/\varepsilon') + O(1)$ and let $\text{Ext}: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ be the (k', ε') -strong-seeded-extractor guaranteed to us by Theorem 10, where $m = k' - 2 \log(1/\varepsilon) - O(1)$ and $d = O(\log n \log(n/\varepsilon'))$.

Let k be large enough for $\text{Cond}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^d$ given to us by Theorem 31 to output d bits with error $\varepsilon/2$ and entropy gap $g = o(\log(1/\varepsilon))$, so indeed $k \geq \text{polylog}(\frac{n}{\varepsilon})$.

Denote $Y = \text{Cond}(X_1, X_2)$, so Y is $(\varepsilon/2)$ -close to some random variable Y' having min-entropy at least $d - g$. Then:

$$\begin{aligned} |\text{Ext}(X_3, Y) - U_m \times Y| &\leq |\text{Ext}(X_3, Y') - U_m \times Y'| + \frac{\varepsilon}{2} \\ &= \sum_{y \in \text{supp}(Y')} \Pr[Y' = y] \cdot |\text{Ext}(X_3, y) - U_m| + \frac{\varepsilon}{2} \\ &\leq \sum_{y \in \{0, 1\}^d} 2^{-(d-g)} \cdot |\text{Ext}(X_3, y) - U_m| + \frac{\varepsilon}{2} \\ &\leq 2^g \sum_{y \in \{0, 1\}^d} 2^{-d} |\text{Ext}(X_3, y) - U_m| + \frac{\varepsilon}{2} \\ &= 2^g \cdot |\text{Ext}(X_3, U_d) - U_m \times U_d| + \frac{\varepsilon}{2} \leq 2^g \varepsilon' + \frac{\varepsilon}{2} \leq \varepsilon, \end{aligned}$$

thereby also showing that $3\text{Ext}(X_1, X_2, X_3) = \text{Ext}(X_3, Y)$ is strong in Y . ◀

When ε is sub-polynomial in n (which is an interesting regime of parameters because then the two-source extractor of [17] is not polynomial-time computable) Corollary 4 improves upon known three-source extractors that either require all three-sources to have min-entropy $\text{poly}(\frac{n}{\varepsilon})$ [34] or require, for any parameter of choice $\delta > 0$, min-entropies δn , $\text{poly}(\frac{1}{\delta}) \log(\frac{n}{\varepsilon})$, $\text{poly}(\frac{1}{\delta}) \log(\frac{\log n}{\varepsilon})$ [20].

We remark that the proof of Corollary 4 goes through because the tiny entropy gap g of $Y = \text{Cond}(X_1, X_2)$ (where $g = o(\log \frac{1}{\varepsilon})$) allows us to use Y as a replacement to a truly uniform seed with only a minor loss in parameters. We believe this should also be true in other circumstances where random variables with a negligible entropy gap can replace uniform random variables. A recent example to this is the use of samplers with multiplicative error instead of standard samplers in [9].

To conclude, we believe that the use of entropy-resilient functions as a tool to extract almost all the entropy from bit-fixing sources while suffering only a small error is both natural and interesting on its own. We hope the tools and constructions developed in this paper will be of further use, possibly for constructing low error two-source extractors. In particular, we have seen in Corollary 4 that by using an independent third source and outputting $\text{Ext}(X_3, \text{Cond}(X_1, X_2))$ we get an excellent three-source extractor. An open problem left by our work is whether outputting $\text{Ext}(X_2, \text{Cond}(X_1, X_2))$ gives a low-error two-source extractor. We remark that a similar idea has been used in previous constructions [34, 10] and elsewhere. We were not able to prove that $\text{Ext}(X_2, \text{Cond}(X_1, X_2))$ gives a low-error two-source extractor and we leave this as an intriguing open problem.

2 Preliminaries

We use $\log(x)$ for $\log_2(x)$. For an integer n , we denote by $[n]$ the set $\{1, \dots, n\}$. The density of a subset $B \subseteq A$ is denoted by $\mu(B) = \frac{|B|}{|A|}$.

2.1 Random Variables, Min-Entropy

The *statistical distance* between two distributions X and Y over the same domain Ω is defined by $\text{SD}(X, Y) = \max_{A \subseteq \Omega} (\Pr[X \in A] - \Pr[Y \in A])$. If $\text{SD}(X, Y) \leq \varepsilon$ we say X is ε -close to Y and denote it $X \approx_\varepsilon Y$. We denote by U_n the random variable distributed uniformly over $\{0, 1\}^n$.

For a function $f: \Omega_1 \rightarrow \Omega_2$ and a random variable X distributed over Ω_1 , $f(X)$ is the random variable distributed over Ω_2 obtained by choosing $x \sim X$ and outputting $f(x)$. For every $f: \Omega_1 \rightarrow \Omega_2$ and two random variables X, Y over Ω_1 it holds that $\text{SD}(f(X), f(Y)) \leq \text{SD}(X, Y)$.

The *min-entropy* of a random variable X is defined by

$$H_\infty(X) = \min_{x \in \text{supp}(X)} \log \frac{1}{\Pr[X = x]}.$$

A random variable X is an (n, k) -source if X is distributed over $\{0, 1\}^n$ and has min-entropy at least k . When n is clear from the context we sometimes omit it and simply say that X is a k -source.

2.2 Limited Independence

► **Definition 5.** A distribution X over $\{0, 1\}^n$ is called (t, γ) -wise independent if the restriction of X to every t coordinates is γ -close to U_t .

► **Lemma 6** ([4]). Let $X = X_1, \dots, X_n$ be a distribution over $\{0, 1\}^n$ that is (t, γ) -wise independent. Then, X is $(n^t \gamma)$ -close to a t -wise independent distribution.

2.3 Seeded Extractors

► **Definition 7** (Seeded extractors). *A function*

$$\text{Ext}: \{0,1\}^n \times \{0,1\}^d \rightarrow \{0,1\}^m$$

is a (k, ε) -seeded-extractor if the following holds. For every (n, k) -source X , the output $\text{Ext}(X, Y) \approx_\varepsilon U_m$, where Y is uniformly distributed over $\{0,1\}^d$ and is independent of X . Further, Ext is a (k, ε) -strong-seeded-extractor if $(\text{Ext}(X, Y), Y) \approx_\varepsilon (U_m, Y)$.

► **Theorem 8** ([28]). *There exists a universal constant $c_{\text{GUV}} \geq 2$ for which the following holds. For every integers $n \geq k$ and $\varepsilon > 0$ there exists a $\text{poly}(n, \log(1/\varepsilon))$ -time computable (k, ε) -strong-seeded-extractor*

$$\text{Ext}: \{0,1\}^n \times \{0,1\}^d \rightarrow \{0,1\}^m$$

with seed length $d = c_{\text{GUV}} \log(n/\varepsilon)$ and $m = k/2$ output bits.

Extractors can be used for sampling using weak sources.

► **Theorem 9** ([46]). *Let $\text{Ext}: \{0,1\}^n \times \{0,1\}^d \rightarrow \{0,1\}^m$ be a (k_1, ε) -seeded-extractor. Identify $\{0,1\}^d$ with $[2^d]$ and let $S(X) = \{\text{Ext}(X, 1), \dots, \text{Ext}(X, 2^d)\}$. Then, for every (n, k_2) -source X and any set $T \subseteq \{0,1\}^m$,*

$$\Pr_{x \sim X} \left[\left| \frac{|S(x) \cap T|}{2^d} - \mu(T) \right| > \varepsilon \right] \leq 2^{-(k_2 - k_1)}.$$

The following extractor allows us to extract all the min-entropy, at the cost of a larger seed-length.

► **Theorem 10** ([28]). *There exists a universal constant c such that the following holds. For all integers $n \geq k$ and any $\varepsilon > 0$ such that $k \geq 2 \log(1/\varepsilon) + O(1)$, there exists a $\text{poly}(n, \log(1/\varepsilon))$ -time computable (k, ε) -strong-seeded-extractor*

$$\text{Ext}: \{0,1\}^n \times \{0,1\}^d \rightarrow \{0,1\}^m$$

with seed length $d = c \log n \cdot \log \frac{n}{\varepsilon}$ and $m = k - 2 \log \frac{1}{\varepsilon} - O(1)$ output bits.

2.4 Two-Source Condensers

► **Definition 11** (Condensers). *A function*

$$\text{Cond}: \{0,1\}^{n_1} \times \{0,1\}^{n_2} \rightarrow \{0,1\}^m$$

is an $((n_1, k_1), (n_2, k_2)) \rightarrow_\varepsilon (m, k' = m - g)$ condenser if the following holds. For every (n_1, k_1) -source X_1 and an independent (n_2, k_2) -source X_2 , the output $\text{Cond}(X_1, X_2)$ is ε -close to an (m, k') -source. We refer to ε as the error guarantee and to g as the entropy gap of Cond .

► **Definition 12** (Strong condensers). *A function*

$$\text{Cond}: \{0,1\}^{n_1} \times \{0,1\}^{n_2} \rightarrow \{0,1\}^m$$

is a $((n_1, k_1), (n_2, k_2)) \rightarrow_{\varepsilon_1, \varepsilon_2} (m, k')$ -strong-condenser (in the first source) if the following holds. For every (n_1, k_1) -source X_1 and an independent (n_2, k_2) -source X_2 , with probability $1 - \varepsilon_1$ over $x_1 \sim X_1$, the output $\text{Cond}(x_1, X_2)$ is ε_2 -close to an (m, k') -source.

Similarly, one can define, in the natural way, a condenser that is strong in the second source.

2.5 Non-Malleable Extractors

► **Definition 13.** A function $\text{nmExt}: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is a (k, ε) t -non-malleable extractor, if for every (n, k) -source X , for every independent random variable Y that is uniform over $\{0, 1\}^d$ and every functions $f_1, \dots, f_t: \{0, 1\}^d \rightarrow \{0, 1\}^d$ with no fixed-points³ it holds that:

$$(\text{nmExt}(X, Y), \text{nmExt}(X, f_1(Y)), \dots, \text{nmExt}(X, f_t(Y), Y)) \approx_\varepsilon (U_m, \text{nmExt}(X, f_1(Y)), \dots, \text{nmExt}(X, f_t(Y), Y)).$$

We will need the following lemma concerning the existence of a set of good seeds of a non-malleable extractor, given in [17].

► **Lemma 14** ([17]). Let $\text{nmExt}: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ be a (k, ε) t -non-malleable extractor. Let X be any (n, k) -source. Let BAD be the set defined by

$$\text{BAD} = \{r \in [D] \mid \exists \text{ distinct } r_1, \dots, r_t \in [D], \forall i \in [t] \ r_i \neq r, |(\text{nmExt}(X, r), \text{nmExt}(X, r_1), \dots, \text{nmExt}(X, r_t)) - (U_m, \text{nmExt}(X, r_1), \dots, \text{nmExt}(X, r_t))| > \sqrt{\varepsilon}\}.$$

Then, $\mu(\text{BAD}) \leq \sqrt{\varepsilon}$. We refer to the set $[D] \setminus \text{BAD}$ as the set of good seeds (with respect to the underlying distribution of X).

► **Lemma 15.** Let X_1, \dots, X_t be random variables over $\{0, 1\}^m$. Further suppose that for any $i \in [t]$,

$$(X_i, \{X_j\}_{j \neq i}) \approx_\varepsilon (U_m, \{X_j\}_{j \neq i}).$$

Then, $(X_1, \dots, X_t) \approx_{t\varepsilon} U_{tm}$.

Finally, good explicit constructions of t -non-malleable extractors exist. The following choice of parameters will be sufficient for us.

► **Theorem 16** ([15, 22, 35]). There exists a universal constant $c_{\text{nm}} \geq 2$ such that for all integers n, k, t , and every $\varepsilon > 0$ such that $n \geq k \geq c_{\text{nm}} t^2 \log^2(n/\varepsilon)$, there exists a $\text{poly}(n, \log(1/\varepsilon))$ -time computable (k, ε) t -non-malleable extractor

$$\text{nmExt}: \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$$

with $m = \frac{k}{3t}$ output bits and seed length $d = c_{\text{nm}} t^2 \log^2(n/\varepsilon)$.

2.6 Fooling AC Circuits

A Boolean circuit is an $\text{AC}[d, s]$ circuit if it has depth d , size s and unbounded fan-in. We say that a circuit C with n input bits is ε -fooled by a distribution D if $\text{SD}(C(D), D(U_n)) \leq \varepsilon$.

Harsha and Srinivasan [29], improving upon Braverman's seminal result [14] (see also [44]) proved:

► **Theorem 17** ([29]). There exists a constant $c > 0$ such that the following holds. For every integers s, d, t , any $\text{AC}[d, s]$ circuit is ε -fooled by any t -wise independent distribution, where $\varepsilon = 2^{-\frac{t}{(\log s)^{c \cdot d}}}$.

³ That is, for every i and every x , we have $f_i(x) \neq x$.

We need a slight generalization of Theorem 17:

► **Lemma 18.** *There exists a constant $c > 0$ such that the following holds for every integers n, m, d, s , where $m \leq s$. Let $C: \{0, 1\}^n \rightarrow \{0, 1\}^m$ be an $\text{AC}[d, s]$ circuit. Then, C is ε -fooled by any t -wise independent distribution, where $\varepsilon = 2^{m - \frac{t}{(\log s)^{c \cdot d}}}$.*

Proof. Fix some $z \in \{0, 1\}^m$ and consider the circuit $C_z: \{0, 1\}^n \rightarrow \{0, 1\}$ that given an input $x \in \{0, 1\}^n$ checks whether $C(x) = z$. C_z can be constructed by adding an AND gate and m comparators on top of C , so clearly C_z is an $\text{AC}[d + 2, s']$ circuit for $s' = s + O(m)$. By Theorem 17, every t -wise distribution ε' -fools C_z , where

$$\varepsilon' = 2^{-\frac{t}{(\log s')^{c' \cdot (d+2)}}} \leq 2^{-\frac{t}{(\log s)^{c \cdot d}}}$$

for some universal constants $c, c' > 0$ (using the fact that $m \leq s$). That is, for every t -wise distribution D and $z \in \{0, 1\}^m$, $\text{SD}(C_z(D), C_z(U_n)) \leq \varepsilon'$. Now,

$$\begin{aligned} \varepsilon = \text{SD}(C(D), C(U_n)) &= \frac{1}{2} \sum_{z \in \{0, 1\}^m} |\Pr[C(D) = z] - \Pr[C(U_n) = z]| \\ &= \sum_{z \in \{0, 1\}^m} \frac{1}{2} |\mathbb{E}[C_z(D)] - \mathbb{E}[C_z(U_n)]| \leq 2^m \varepsilon', \end{aligned}$$

as desired. ◀

3 Entropy-Resilient Functions

► **Definition 19** (Non-oblivious sources). *Let $\Sigma = \{0, 1\}^m$. A (q, t) -non-oblivious Σ -fixing source $X = (X_1, \dots, X_r)$ is a random variable over $\Sigma^r = \{0, 1\}^{rm}$ for which there exists a set $R_{\text{bad}} \subseteq [r]$ of cardinality $q' \leq q$ such that:*

- *The joint distribution of $\{(X_i)_j \mid i \in [r] \setminus R_{\text{bad}}, j \in [m]\}$, denoted by G_X , is t -wise independent over $\{0, 1\}^{(r-q')m}$; and*
- *Each of the random variables in $B_X \triangleq \{(X_i)_j\}$ with $i \in R_{\text{bad}}$ and $j \in [m]$ may depend arbitrarily on all other random variables in G_X and B_X .*

If $t = (r - q')m$ we say X is a q -non-oblivious Σ -fixing source. If $m = 1$ we say X is a bit-fixing source and the definition coincides with the standard definition of non-oblivious bit-fixing sources [11]. When X is clear from context, we write G and B for G_X and B_X , respectively.

► **Definition 20** (Entropy-resilient functions). *Let $\Sigma = \{0, 1\}^m$. A function $f: \Sigma^r \rightarrow \Sigma$ is a (q, t, g, ε) -entropy-resilient function if for every (q, t) -non-oblivious Σ -fixing source X over Σ^r , the output $f(X)$ is ε -close to an $(m, m - g)$ -source. If $g = 0$ we say f is (q, t, ε) -resilient.*

3.1 Functions With One Output Bit

► **Definition 21.** *Let $f: \{0, 1\}^r \rightarrow \{0, 1\}$ be an arbitrary function. Let X be a (q, t) -non-oblivious bit-fixing source over $\{0, 1\}^r$. Define $E(f)$ to be the event in which the bits tossed by the good players do not determine the value of the function f . We define the influence of the bad players by $I(f) = \Pr[E(f)]$.*

43:10 Two-Source Condensers with Low Error and Small Entropy Gap

Balanced resilient functions can be seen as deterministic extractors against non-oblivious bit-fixing sources outputting one bit. Chattopadhyay and Zuckerman [17], followed by an improvement by Meka [37], derandomized the Ajtai-Linial function [2] and obtained an explicit construction of an almost-balanced resilient function which is also computable by monotone AC^0 circuits.

► **Theorem 22** ([17, 37]). *For every constant $0 < \delta < 1$, there exists a constant $c_\delta \geq 1$ such that for every constant $c \geq c_\delta$ and integer r there exists a monotone function $\text{Res}: \{0, 1\}^r \rightarrow \{0, 1\}$ such that for every $t \geq c \log^4 r$,*

- *For every (q, t) -non-oblivious bit-fixing source X , $I(\text{Res}) \leq c \cdot \frac{q}{r^{1-\delta}}$.*
- *For every t -wise independent distribution D , $\text{bias}(\text{Res}(D)) \leq r^{-1/c}$.*

The function Res is computable by a uniform depth 3 monotone circuit of size r^c . Further, the function $c_\delta(\delta)$ is continuous and monotonically decreasing.

Throughout the paper we make use of the following corollary.

► **Corollary 23.** *For every constant $0 < \gamma < 1$ there exist constants $0 < \alpha < \beta < 1$ such that for every integer r there exists a function $\text{Res}: \{0, 1\}^r \rightarrow \{0, 1\}$ which for every $t \geq \frac{1}{\beta} \log^4 r$ satisfies: For every $(r^{1-\gamma}, t)$ -non-oblivious bit-fixing source X ,*

$$I(\text{Res}) \leq \frac{1}{\beta} \cdot r^{-\alpha},$$

$$\text{bias}(\text{Res}(X) \mid \neg E(\text{Res})) \leq \frac{3}{\beta} \cdot r^{-\alpha}.$$

The function Res is computable by a uniform depth 3 monotone circuit of size $r^{\frac{1}{\beta}}$.

Proof. Using the notations of Theorem 22, assume that for every η , $c_\eta > \frac{1}{2\eta}$ (if not, we can always increase c_η). Given $\gamma > 0$, set δ to be the constant satisfying the equation $f(\delta) = \delta - \gamma + \frac{1}{2c_\delta} = 0$. Such a δ exists, as $f(\delta) \leq 2\delta - \gamma$ and therefore $f(\delta) < 0$ when δ approaches 0, and $f(\delta) > 0$ when δ approaches γ . Note that by our choice of δ , it holds that

$$\delta < \gamma = \delta + \frac{1}{2c_\delta} < \delta + \frac{1}{c_\delta}.$$

Set $\alpha = \gamma - \delta > 0$ and $\beta = \frac{1}{c_\delta}$. Note that indeed $\beta > \alpha$.

By Theorem 22, applied with the constant δ , it holds that $I(\text{Res}) \leq c_\delta \frac{r^{1-\gamma}}{r^{1-\delta}} = \frac{1}{\beta} r^{-\alpha}$. Further, $\text{bias}(\text{Res}(D)) \leq r^{-\beta}$.

Following similar arguments as in [17], we have that $\text{bias}(\text{Res}(X)) \leq \frac{1}{\beta} r^{-\alpha} + r^{-\beta}$, so

$$\text{bias}(\text{Res}(X) \mid \neg E(\text{Res})) \leq \frac{\frac{1}{\beta} r^{-\alpha} + r^{-\beta}}{1 - \frac{1}{\beta} r^{-\alpha}} \leq \frac{3}{\beta} r^{-\alpha}. \quad \blacktriangleleft$$

3.2 Functions With Multiple Output Bits

The output bit of a (q, t, ε) -resilient function $f: \{0, 1\}^r \rightarrow \{0, 1\}$ applied to a (q, t) -non-oblivious bit-fixing source is indeed ε -close to uniform, but, as shown by [30] even when $q = 1$, ε cannot be smaller than $\frac{\ln r}{r}$ (and the simpler bound $\varepsilon \geq \frac{1}{r}$ is almost trivial). We show that when we output many bits, and allow $o(\log \frac{1}{\varepsilon})$ entropy gap, we may obtain much smaller error. We do that by exhibiting an entropy-resilient function based on a parallel application of the (derandomized version of the) Ajtai-Linial function.

A construction of an entropy-resilient function. Given a constant $0 < \gamma < 1$ and integers $r \geq m$ let $\text{Res}: \{0, 1\}^r \rightarrow \{0, 1\}$ be the function guaranteed by Corollary 23 with respect to γ . Define $\Sigma = \{0, 1\}^m$ and $\text{EntRes}: \Sigma^r \rightarrow \Sigma$ as follows. On input $x \in \Sigma^r$,

$$\text{EntRes}(x) = (\text{Res}(x^{(1)}), \dots, \text{Res}(x^{(m)})),$$

where x_i stands for the i -th column of x , when we view x as a $r \times m$ table.

► **Theorem 24.** *For every constant $0 < \gamma < 1$ there exist constants $0 < \alpha < 1$ and $c' \geq 1$ such that the following holds. For every integers $r, m \leq r^{\alpha/2}$, every $\varepsilon > 0$, and for every integer $t \geq m \cdot (\log r)^{c'}$, the function $\text{EntRes}: \Sigma^r \rightarrow \Sigma$ is $(q = r^{1-\gamma}, t, g, \varepsilon)$ -entropy-resilient with entropy gap $g = o(\log(1/\varepsilon))$.*

The proof of Theorem 24 is done in two steps. First, in Section 3.2.1, we analyze the theorem for the special case in which the distribution G_X of the given non-oblivious Σ -fixing source X is uniform. Then, based on that result, in Section 3.2.2 we prove Theorem 24.

3.2.1 The Uniform Case

In this section, we prove the following lemma.

► **Lemma 25.** *Keeping the notations of Theorem 24, the function $\text{EntRes}: \Sigma^r \rightarrow \Sigma$ is $(q = r^{1-\gamma}, g, \varepsilon)$ -entropy-resilient with entropy gap*

$$g = c_{\text{ent}_1} \frac{\ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + c_{\text{ent}_2} \ln r} = o(\log(1/\varepsilon))$$

for some universal constant $c_{\text{ent}_1} > 0$ and a constant $c_{\text{ent}_2} > 0$ that depends only on γ .

Proof of Lemma 25. Let X be a $(q = r^{1-\gamma})$ -non-oblivious Σ -fixing source. Let $R_{\text{bad}} \subseteq [r]$ be the set of bad players, and E_i the event that the values of the good players in $X^{(i)}$ do not determine the value of Res . Note that we shall also denote E_i as an indicator for that event.

By Corollary 23, there exists constants $0 < \alpha < \beta < 1$ such that $\Pr[E_i = 1] \leq \frac{1}{\beta} \cdot r^{-\alpha}$ for every $i \in [m]$. Observe that the random variables E_1, \dots, E_m are independent, as the value of E_i depends only on the values of the good players in the i -th column, and by assumption all these values are independent of the corresponding values in the other columns. Write $\mu = m \cdot \frac{1}{\beta} \cdot r^{-\alpha}$ and note that since $m \leq r^{\alpha/2}$, $\mu < 1$. Set

$$c = \frac{4 \ln \frac{1}{\varepsilon}}{\mu} \cdot \frac{1}{\ln \frac{1}{\mu}}$$

and observe that $c > 1$. By the Chernoff bound,

$$\Pr \left[\sum_{i=1}^m E_i > c\mu \right] \leq \left(\frac{e^{c-1}}{c^c} \right)^\mu \leq e^{-\frac{1}{2}\mu c \ln c} \leq \varepsilon,$$

where the last inequality follows from the fact that $c \ln c \geq \frac{2 \ln \frac{1}{\varepsilon}}{\mu}$.

By Corollary 23, for every $i \in [m]$,

$$\text{bias}(\text{Res}(X_i) \mid E_i = 0) \leq \frac{3}{\beta} \cdot r^{-\alpha}.$$

43:12 Two-Source Condensers with Low Error and Small Entropy Gap

Assume that the event $\sum_{i=1}^m E_i \leq c\mu$ holds, and let $I \subseteq [m]$, $|I| \geq m - c\mu$ be the set of good columns I for which $E_i = 0$. For every $w \in \{0,1\}^m$, since the random variables $\{\text{EntRes}(X)_i\}_{i \in I}$ are independent, we have:

$$\begin{aligned} \Pr[\text{EntRes}(X) = w] &\leq \Pr[\text{EntRes}(X)_I = w_I] \leq \left(\frac{1}{2} + \frac{3}{\beta} \cdot r^{-\alpha}\right)^{m-c\mu} \\ &\leq 2^{-m+c\mu} e^{\frac{6}{\beta} r^{-\alpha} m} \leq 2^{-m+c\mu} 2^{10\mu}. \end{aligned}$$

Now, we have

$$c\mu + 10\mu \leq 2c\mu \leq \frac{8 \ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + \ln \frac{1}{\mu}} \leq \frac{8 \ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + \frac{4}{\alpha} \ln r} = o\left(\log \frac{1}{\varepsilon}\right).$$

We have shown that except with probability ε , the output $\text{EntRes}(X)$ has min-entropy $m - o(\log(1/\varepsilon))$, as desired. More specifically, the min-entropy in the good columns alone is at least $m - o(\log(1/\varepsilon))$, and we stress that the good columns are not fixed but depend on the sample itself. \blacktriangleleft

3.2.2 The Bounded-Independence Case – Proof of Theorem 24

Throughout this section, we use the same notations as in Lemma 25. We are given X that is a (q, t) -non-oblivious Σ -fixing source. We use a similar approach to the one taken in [17]. For the sake of the proof, we:

- Let GU be the distribution in which the good players are jointly uniform, and the bad players are arbitrary.
- Define a small-depth circuit C' that is related to EntRes so that $H_\infty(\text{EntRes}(X)) \geq H_\infty(C'(X))$.

We will show that $C'(X)$ and $C'(GU)$ are statistically close to each other. Finally, the results of Section 3.2.1 proves that except for a small probability, $H_\infty(C'(GU)) \geq m - o(\log(1/\varepsilon))$.

Proof of Theorem 24. Fix a (q, t) -non-oblivious Σ -fixing source X . Let GU be the distribution where the good players are jointly uniform, and the bad players are arbitrary. We construct a circuit $C': \{0,1\}^{rm} \rightarrow \{0,1\}^m$ such that:

$$(C'(x))_i = \begin{cases} \text{EntRes}(x)_i & \text{If } E_i(x) = 0, \\ 0 & \text{Otherwise.} \end{cases}$$

Recall that E_i is *fully determined* by the good players, and so does $\text{EntRes}(X)_i$ when $E_i = 0$. Hence, C' is fully determined by the good players.

We can write a small-depth circuit computing C' . Let C be the depth-3 size $r^{1/\beta}$ circuit that computes the function $\text{Res}: \{0,1\}^r \rightarrow \{0,1\}$ as guaranteed by Theorem 22. Construct a circuit for C' as follows:

- For $i \in [m]$ and $b \in \{0,1\}$ let $C_{i,b}$ be a copy of C where we wire $(x_i)_j$ for every good player $j \in [r]$, and the value b for every bad player.
- The top part contains m comparators, outputting the output of $C_{i,0}$ if the output of $C_{i,0}$ is the same as the output of $C_{i,1}$, and 0 otherwise.

The circuit has depth 4 and size $s'' = O(mr^{1/\beta})$ and its correctness is guaranteed by the fact that Res is monotone (so it is sufficient to consider the case where the bad players voted unanimously).

By Lemma 18, $SD(C'(GU), C'(X)) \leq 2^{m - \frac{t}{(\log(mr))^{c''}}}$ for some large enough universal constant $c'' > 0$. For every $w \in \{0, 1\}^m$:

$$\begin{aligned} \Pr[\text{EntRes}(X) = w] &\leq \Pr[\text{EntRes}(X)_I = w_I] = \Pr[C'(X)_I = w_I] \\ &\leq \Pr[C'(GU)_I = w_I] + 2^{m - \frac{t}{(\log(mr))^{c''}}} \\ &\leq 2^{-m + \frac{8 \ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + \frac{4}{\alpha} \ln r}} + 2^{m - \frac{t}{(\log(mr))^{c''}}}, \end{aligned}$$

where in the last inequality we have used Lemma 25. We can set the constant c' stated in the theorem to be larger than c'' and get that

$$\Pr[\text{EntRes}(X) = w] \leq 2 \cdot 2^{-m + \frac{8 \ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + \frac{4}{\alpha} \ln r}}.$$

To conclude, note that the above holds with probability at least $1 - \varepsilon$, and then $\text{EntRes}(X)$ has min-entropy at least $-1 + m - \frac{8 \ln \frac{1}{\varepsilon}}{\ln \ln \frac{1}{\varepsilon} + \frac{4}{\alpha} \ln r} = m - o(\log(1/\varepsilon))$, as desired. ◀

4 Low Error Two-Source Condensers With High Entropy Loss

Chattopadhyay and Zuckerman [17] showed a reduction from two independent sources to non-oblivious bit-fixing sources. In Section 4.1 we extend this to many output bits and show a reduction from two independent sources to non-oblivious Σ -fixing sources. Our reduction is similar to the one in [17], and here:

- We let the non-malleable extractors output m bits rather than a single bit, obtaining a non-oblivious Σ -fixing source for $\Sigma = \{0, 1\}^m$.
- Correspondingly, we apply our entropy-resilient function EntRes whereas in [17] the function Res is applied.

In Section 4.2 we use this together with the results of Section 3 to get a low error two-source condenser with many output bits, yet still far from getting almost all of the possible entropy from the two sources.

4.1 From Two Independent Sources to a Non-Oblivious Σ -Fixing Source

In this section, we revisit the [17] transformation of two independent sources to a non-oblivious bit-fixing source (i.e., with $m = 1$), and extend it to sources with several bits. Throughout this section, we refer to $c_{\text{GUV}}, c_{\text{nm}}$ as the constants that appear in Theorem 8 and Theorem 16, respectively.

► **Theorem 26.** *For every integers n, t, m, k , with $n \geq k \geq (tm \log n)^5$ and set $\Sigma = \{0, 1\}^m$, there exists a poly(n)-time computable function $\text{TwoSourcesToNOF}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \Sigma^t$, where $r = n^{2c_{\text{GUV}}}$ such that the following holds. Let X_1, X_2 be a pair of independent (n, k) -sources. Then, with probability at least $1 - 2^{-k/2}$ over $x_2 \sim X_2$, the output*

$$\text{TwoSourcesToNOF}(X_1, x_2)$$

is (n^{-mt}) -close to an $(r^{1 - \frac{1}{4c_{\text{GUV}}}}, t)$ -non-oblivious Σ -fixing source.

43:14 Two-Source Condensers with Low Error and Small Entropy Gap

Proof. We start by setting the following parameters:

Setting of parameters.

- Set $\varepsilon_{\text{GUV}} = \frac{1}{n}$.
- Set $d_{\text{GUV}} = c_{\text{GUV}} \log\left(\frac{n}{\varepsilon_{\text{GUV}}}\right) = 2c_{\text{GUV}} \log n$.
- Set $\varepsilon_{\text{nm}} = 2^{-4mt(d_{\text{GUV}} + \log m)}$.
- Set $d_{\text{nm}} = c_{\text{nm}} t^2 \log^2\left(\frac{n}{\varepsilon_{\text{nm}}}\right)$.

Note that $\varepsilon_{\text{nm}} = 2^{-\Theta(mt \log n)}$ and that $d_{\text{nm}} = \Theta(t^4 m^2 \log^2 n)$.

Building blocks. For the construction of `TwoSourcesToNOF`, we make use of the following ingredients:

- Let `Ext`: $\{0, 1\}^n \times \{0, 1\}^{d_{\text{GUV}}} \rightarrow \{0, 1\}^{d_{\text{nm}}}$ be the $(k/2, \varepsilon_{\text{GUV}})$ -strong-seeded-extractor, guaranteed by Theorem 8. One can verify that $k/2 \geq 2d_{\text{nm}}$ as required by Theorem 8.
- Let `nmExt`: $\{0, 1\}^n \times \{0, 1\}^{d_{\text{nm}}} \rightarrow \{0, 1\}^m$ be the $(k, \varepsilon_{\text{nm}})$ t -non-malleable extractor, guaranteed by Theorem 16. Note that $k \geq 3tm$ so the hypothesis of Theorem 16 is met with our choice of parameters.

The construction. We identify $[r]$ with $\{0, 1\}^{d_{\text{GUV}}}$. On inputs $x_1, x_2 \in \{0, 1\}^n$, we define `TwoSourcesToNOF`(x_1, x_2) to be the $r \times m$ matrix whose i -th row is given by

$$\text{TwoSourcesToNOF}(x_1, x_2)_i = \text{nmExt}(x_1, \text{Ext}(x_2, i)).$$

Analysis. Write $D_{\text{nm}} = 2^{d_{\text{nm}}}$ and identify $[D_{\text{nm}}]$ with $\{0, 1\}^{d_{\text{nm}}}$. Let $G \subseteq [D_{\text{nm}}]$, $|G| \geq (1 - \sqrt{\varepsilon_{\text{nm}}})D_{\text{nm}}$, be the set of good seeds guaranteed by Lemma 14. By Lemma 15, for any distinct $r_1, \dots, r_t \in G$,

$$(\text{nmExt}(X_1, r_1), \dots, \text{nmExt}(X_1, r_t)) \approx_{t\sqrt{\varepsilon_{\text{nm}}}} U_{tm}.$$

Let $S(X_2) = \{\text{Ext}(X_2, 1), \dots, \text{Ext}(X_2, 2^{d_{\text{nm}}})\}$. By Theorem 9,

$$\Pr_{x_2 \sim X_2} [|S(x_2) \cap G| \leq (1 - \sqrt{\varepsilon_{\text{nm}}} - \varepsilon_{\text{GUV}}) \cdot r] \leq 2^{-k/2}.$$

We say that $x_2 \in \text{supp}(X_2)$ is good if it induces a good sample, that is if $|S(x_2) \cap G| > (1 - \sqrt{\varepsilon_{\text{nm}}} - \varepsilon_{\text{GUV}})r$. Fix a good x_2 and let $Z = \text{TwoSourcesToNOF}(X_1, x_2)$. In the good seeds, every t elements of Z are $(t\sqrt{\varepsilon_{\text{nm}}})$ -close to uniform, and there are at most $q \leq (\sqrt{\varepsilon_{\text{nm}}} + \varepsilon_{\text{GUV}})r$ bad rows. Applying Lemma 6, we get that Z is $\zeta = t\sqrt{\varepsilon_{\text{nm}}}(rm)^{mt}$ -close to a (q, t) -non-oblivious bit-fixing source. By our choice of ε_{nm} ,

$$\zeta = 2^{-2mt(d_{\text{GUV}} + \log m)} 2^{mt \log(rm)} \leq 2^{-mt \log r} \leq n^{-mt}.$$

Further,

$$q \leq (\sqrt{\varepsilon_{\text{nm}}} + \varepsilon_{\text{GUV}})r \leq 2\varepsilon_{\text{GUV}}r = 2r^{-\frac{1}{2c_{\text{GUV}}}} \leq r^{1 - \frac{1}{4c_{\text{GUV}}}}.$$

We now analyse the running-time. We first apply `Ext` to compute $S(x_2)$, which takes time $\text{poly}(n, \log(1/\varepsilon_{\text{GUV}})) = \text{poly}(n)$. Then, applying each `nmExt` takes $\text{poly}(n, \log(1/\varepsilon_{\text{nm}})) = \text{poly}(n, m, t, d_{\text{GUV}}) = \text{poly}(n)$ time and we do it for $r = \text{poly}(n)$ times. Overall, the running time is $\text{poly}(n)$, as required. In particular, as $n \geq k \geq m$, the running time is also poly-logarithmic in the errors of the construction, $2^{-k/2}$ and n^{-mt} . ◀

4.2 Low Error Condensers With High Entropy Loss

► **Theorem 27.** *There exists a universal constant $c \geq 1$ such that the following holds. For every integers n, k, m and every $\varepsilon > 0$ such that $n \geq k \geq (m \log(n/\varepsilon))^c$ there exists a poly(n)-time computable $((n, k), (n, k)) \rightarrow_{\varepsilon, 2^{-k/2}} (m, m - g)$ -condenser*

$$\text{Cond}' : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m,$$

that is strong in the second source, with entropy gap $g = o(\log(1/\varepsilon))$.

Proof. We start by describing the construction of our condenser Cond' and then turn to the analysis. As usual, we let c_{GUV} be the constant that is given by Theorem 8.

Setting of parameters.

- Set $\gamma = \frac{1}{4c_{\text{GUV}}}$ and let $0 < \alpha < \beta < 1$ and c' be the constants from Theorem 24 with respect to this γ .
- Set $r = n^{2c_{\text{GUV}}}$.
- Set $t = m \cdot (\log(r/\varepsilon))^{c'}$.
- Set c , the constant stated in this theorem, to $c = \max(10c', 2/\alpha)$.

Building blocks.

- Let $\text{TwoSourcesToNOF} : \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^{r \times m}$ be the function that is given by Theorem 26. We are about to apply TwoSourcesToNOF to (n, k) -sources, and indeed k is large enough to satisfy the hypothesis of Theorem 26.
- Let $\text{EntRes} : \{0, 1\}^{r \times m} \rightarrow \{0, 1\}^m$ be the function from Theorem 24 when set with the parameter γ as defined above. Note that the hypothesis of Theorem 24 holds, as since $c \geq 2/\alpha$ we have that $m < r^{\alpha/2}$, and t is large enough.

The construction. On inputs $x_1, x_2 \in \{0, 1\}^n$, we define

$$\text{Cond}'(x_1, x_2) = \text{EntRes}(\text{TwoSourcesToNOF}(x_1, x_2)).$$

Analysis. Clearly, EntRes is computable in $\text{poly}(m, r) = \text{poly}(n)$ time. Let X_1, X_2 be a pair of independent (n, k) -sources. By Theorem 26, except with probability $2^{-k/2}$ over $x_2 \sim X_2$, the output $\text{TwoSourcesToNOF}(X_1, x_2)$ is n^{-mt} -close to an $(r^{1-\gamma}, t)$ -non-oblivious bit-fixing source. For every x_2 for which this event holds, the output $\text{EntRes}(\text{TwoSourcesToNOF}(X_1, x_2))$ is $(n^{-mt} + \varepsilon)$ -close to an $(m, m - o(\log(1/\varepsilon)))$ -source, and $n^{-mt} \leq \varepsilon$. ◀

5 Deterministically Condensing a Single Block-Source

A distribution (X, Y) is a blockwise source if both X has sufficient min-entropy and also for every $x \in \text{supp}(X)$, $(Y | X = x)$ has sufficient min-entropy. In this section we show how to deterministically condense a blockwise source into a source having very small entropy gap, using the connection between condensers with small entropy gap and samplers with multiplicative error and ideas from [43]. In the next section we will use it to significantly increase the output length of the condenser from Section 4.2.

► **Lemma 28** (Deterministically condensing a blockwise source). *Let X be an (n, k) -source. Let Y be a d -bit random variable (that may depend on X) such that for every $x \in \text{supp}(X)$, the random variable $(Y | X = x)$ is ε_{B} -close to a $(d, d - g)$ -source.*

Let $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ be a $(k_{\text{Ext}}, \varepsilon_{\text{Ext}})$ -seeded-extractor. Suppose $k \geq k_{\text{Ext}} + \log(1/\varepsilon_{\text{Ext}})$. Then, $\text{Ext}(X, Y)$ is $(2^{g+2}\varepsilon_{\text{Ext}} + 2\varepsilon_{\text{B}})$ -close to an $(m, m - g - 1)$ -source.

43:16 Two-Source Condensers with Low Error and Small Entropy Gap

Proof. Fix any $T \subseteq \{0, 1\}^m$. Define the set

$$\text{OverHit}_T = \left\{ x \in \{0, 1\}^n : \Pr_{y \sim U_d} [\text{Ext}(x, y) \in T] > \mu(T) + \varepsilon_{\text{Ext}} \right\}.$$

▷ **Claim 29.** $|\text{OverHit}_T| < 2^{k_{\text{Ext}}}$.

Proof. Suppose towards a contradiction that $|\text{OverHit}_T| \geq 2^{k_{\text{Ext}}}$ and let B denote the random variable that is uniform over the set OverHit_T . Since B has min-entropy at least k_{Ext} , the output $\text{Ext}(B, U_d)$ is ε_{Ext} -close to uniform, and therefore $\Pr_{x \sim B, y \sim U_d} [\text{Ext}(x, y) \in T] \leq \mu(T) + \varepsilon_{\text{Ext}}$. This stands in contradiction to the definition of B . ◁

Now,

$$\Pr[\text{Ext}(X, Y) \in T] \leq \Pr[\text{Ext}(X, Y) \in T \mid X \notin \text{OverHit}_T] + \Pr[X \in \text{OverHit}_T].$$

By Claim 29, $\Pr[X \in \text{OverHit}_T] \leq 2^{k_{\text{Ext}} - k}$. Also, for every $x \notin \text{OverHit}_T$ let

$$GY_x = \left\{ y \in \{0, 1\}^d : \text{Ext}(x, y) \in T \right\}.$$

By definition, $\mu(GY_x) \leq \mu(T) + \varepsilon_{\text{Ext}}$. Also, $Y \mid (X = x)$ is ε_B -close to some random variable Y'_x having support size at least 2^{d-g} . Therefore,

$$\begin{aligned} \Pr_{y \sim (Y \mid X=x)} [\text{Ext}(x, y) \in T] &= \Pr_{y \sim (Y \mid X=x)} [y \in GY_x] \leq \varepsilon_B + \Pr[Y'_x \in GY_x] \\ &\leq \varepsilon_B + \frac{|GY_x|}{2^{d-g}} \leq \varepsilon_B + 2^g(\mu(T) + \varepsilon_{\text{Ext}}). \end{aligned}$$

Thus,

$$\begin{aligned} \Pr[\text{Ext}(X, Y) \in T] &\leq \Pr[\text{Ext}(X, Y) \in T \mid X \notin \text{OverHit}_T] + \Pr[X \in \text{OverHit}_T] \\ &\leq 2^g \mu(T) + 2^g \varepsilon_{\text{Ext}} + \varepsilon_B + 2^{k_{\text{Ext}} - k} \leq 2^g \mu(T) + (2^g + 1) \varepsilon_{\text{Ext}} + \varepsilon_B. \end{aligned}$$

But,

▷ **Claim 30.** Let Z be a random variable over n -bit strings such that for every $T \subseteq \{0, 1\}^n$, $\Pr[Z \in T] \leq 2^g \mu(T) + \varepsilon$. Then, Z is 2ε -close to an $(n, n - g - 1)$ -source.

Proof. Set $H = \{x : \Pr[Z = x] > 2^{-(n-g-1)}\}$. On the one hand,

$$\Pr[Z \in H] = \sum_{x \in H} \Pr[Z = x] \geq 2^{g+1} \mu(H).$$

On the other hand, by our assumption, $\Pr[Z \in H] \leq 2^g \mu(H) + \varepsilon$. Together, we get that $2^g \mu(H) \leq \varepsilon$. Thus, $\Pr[Z \in H] \leq 2\varepsilon$. As H are all the heavy elements, we conclude that Z is 2ε -close to a distribution with $n - g - 1$ min-entropy. ◁

We can therefore summarize that $\text{Ext}(X, Y)$ is $(2^{g+2} \varepsilon_{\text{Ext}} + 2\varepsilon_B)$ -close to an $(m, m - g - 1)$ -source. ◀

6 Low Error Two-Source Condensers

In this section we will construct our low error condenser, with small entropy gap outputting many bits, by exploiting the block-wise structure of our previous construction. Roughly speaking, we are close to a scenario in which X_2 has sufficient min-entropy and also for every fixing of $x_2 \in \text{supp}(X_2)$, the random variable $\text{Cond}'(X_1, x_2)$ is close to uniform. The result of Section 5 can then be applied – allowing us to extract almost all the entropy from one of the sources. To that end, we prove the following theorem, which readily implies Theorem 3.

► **Theorem 31 (Main theorem).** *There exists a universal constant $c \geq 1$ such that the following holds. For every integers $n \geq k$ and every $\varepsilon > 0$ such that $k \geq \log^c(n/\varepsilon)$ there exists a poly($n, \log(1/\varepsilon)$)-time computable $((n, k), (n, k)) \rightarrow_\varepsilon (m, m-g)$ two-source condenser*

$$\text{Cond}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^m$$

with $m = k - 5 \log(1/\varepsilon) - O(1)$ and $g = o(\log(1/\varepsilon))$.

Proof. We start by setting some parameters.

Parameters.

- Set $\varepsilon_{\text{Cond}'} = \varepsilon/8$.
- Set $\varepsilon_{\text{Ext}} = \varepsilon^2/32$.
- Set $k_{\text{Ext}} = k - \log(2/\varepsilon)$.
- Set $d_{\text{Ext}} = c' \log n \cdot \log(n/\varepsilon_{\text{Ext}})$ where c' is the constant that is given by Theorem 10.

For the construction we make use of the following building blocks.

- Let $\text{Ext}: \{0, 1\}^n \times \{0, 1\}^{d_{\text{Ext}}} \rightarrow \{0, 1\}^m$ be the $(k_{\text{Ext}}, \varepsilon_{\text{Ext}})$ -strong-seeded-extractor that is given by Theorem 10. By that theorem, $m = k_{\text{Ext}} - 2 \log(1/\varepsilon_{\text{Ext}}) - O(1)$.
- Let $\text{Cond}': \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}^{d_{\text{Ext}}}$ be the $((n, k), (n, k)) \rightarrow_{\varepsilon_{\text{Cond}'}, 2^{-k/2}} (d_{\text{Ext}}, d_{\text{Ext}} - g')$ -condenser, strong in the second source, that is given by Theorem 27, with $g' = o(\log(1/\varepsilon_{\text{Cond}'}))$. Note that our choice of parameters satisfies the hypothesis of Theorem 27 for a large enough constant c .

The construction. On inputs $x_1, x_2 \in \{0, 1\}^n$, we define

$$\text{Cond}(x_1, x_2) = \text{Ext}(x_2, \text{Cond}'(x_1, x_2)).$$

Analysis. Let X_1, X_2 be a pair of independent (n, k) -sources. By Theorem 27, with probability at least $1 - 2^{-k/2}$ over $x_2 \sim X_2$, the random variable $\text{Cond}'(X_1, x_2)$ is $\varepsilon_{\text{Cond}'}$ -close to a $(d, d - g')$ -source. Lemma 28 implies that $\text{Ext}(X_2, \text{Cond}'(X_1, X_2))$ is $2^{-k/2} + (2^{g'+2}\varepsilon_{\text{Ext}} + 2\varepsilon_{\text{Cond}'})$ -close to an $(m, m - g' - 1)$ -source.

By our choice of parameters, $2^{-k/2} + 2^{g'+1}\varepsilon_{\text{Ext}} + 2\varepsilon_{\text{Cond}'} \leq \varepsilon$. Note that $k - m = \log(2/\varepsilon) + 2 \log(1/\varepsilon_{\text{Ext}}) = 5 \log(1/\varepsilon) + O(1)$. The running-time of the construction readily follows from the running-times of Cond' and Ext . ◀

Abstract

A number of recent works have considered the *trace reconstruction problem*, in which an unknown source string $x \in \{0, 1\}^n$ is transmitted through a probabilistic channel which may randomly delete coordinates or insert random bits, resulting in a *trace* of x . The goal is to reconstruct the original string x from independent traces of x . While the asymptotically best algorithms known for worst-case strings use $\exp(O(n^{1/3}))$ traces [8, 21], several highly efficient algorithms are known [23, 13] for the *average-case* version of the problem, in which the source string x is chosen uniformly at random from $\{0, 1\}^n$. In this paper we consider a generalization of the above-described average-case trace reconstruction problem, which we call *average-case population recovery in the presence of insertions and deletions*. In this problem, rather than a single unknown source string there is an unknown distribution over s unknown source strings $x^1, \dots, x^s \in \{0, 1\}^n$, and each sample given to the algorithm is independently generated by drawing some x^i from this distribution and returning an independent trace of x^i . Building on the results of [23] and [13], we give an efficient algorithm for the average-case population recovery problem in the presence of insertions and deletions. For any support size $1 \leq s \leq \exp(\Theta(n^{1/3}))$, for a $1 - o(1)$ fraction of all s -element support sets $\{x^1, \dots, x^s\} \subset \{0, 1\}^n$, for every distribution \mathcal{D} supported on $\{x^1, \dots, x^s\}$, our algorithm can efficiently recover \mathcal{D} up to total variation distance at most ε with high probability, given access to independent traces of independent draws from \mathcal{D} . The running time of our algorithm is $\text{poly}(n, s, 1/\varepsilon)$ and its sample complexity is $\text{poly}(s, 1/\varepsilon, \exp(\log^{1/3} n))$. This polynomial dependence on the support size s is in sharp contrast with the *worst-case* version of the problem (when x^1, \dots, x^s may be any strings in $\{0, 1\}^n$), in which the sample complexity of the most efficient known algorithm [3] is doubly exponential in s .

1 Introduction

Background: Worst-case and average-case trace reconstruction. In the problem of *trace reconstruction in the presence of insertions and deletions*, there is an unknown and arbitrary n -bit source string $x \in \{0, 1\}^n$ and the goal is to reconstruct x given access to independent *traces* of x . A *trace* of x is a copy that has been passed through a noise channel which independently removes each bit of x with some probability q (the *deletion rate*) and also independently inserts random bits according to some *insertion rate* q' .¹ Intuitively, the insertion-deletion channel (or even just the deletion channel with no insertions) is challenging to deal with because it is difficult to determine which coordinate of the source string (if any, if insertions are possible) is responsible for a given coordinate of a received trace.

The insertion/deletion trace reconstruction problem is motivated by connections to recovery problems arising in biology (see e.g. [2, 6, 1]) and has been the subject of considerable research, especially in recent years. The worst-case version of this problem, in which the source string x can be an arbitrary element of $\{0, 1\}^n$, appears to be quite difficult even for small constant noise rates. In early work [4] gave an efficient algorithm that succeeds in the deletion-only model if the deletion rate q is quite low, at most $O(1/n^{1/2+\epsilon})$. Also in the deletion-only model, [14] showed that $\exp(\tilde{O}(\sqrt{n}))$ many traces suffice for any constant deletion rate q bounded away from 1. More recently, this result was improved in simultaneous and independent works of [8] and [21], each of which showed that for any constant insertion and deletion rates q, q' , $\exp(O(n^{1/3}))$ traces suffice to reconstruct any $x \in \{0, 1\}^n$. These algorithms, which run in $\exp(O(n^{1/3}))$ time, give the best results to date for the worst-case problem. (On the lower bound side, recent work of [12] obtained an $\tilde{\Omega}(n^{5/4})$ lower bound on the number of traces required from the deletion channel, improving an earlier $\Omega(n)$ lower bound due to [19]. Later work of [5] improved this lower bound to $\tilde{\Omega}(n^{3/2})$.)

Since the worst-case trace reconstruction problem seems to be quite difficult, and since the assumption that the source string x is completely arbitrary may be overly pessimistic in various contexts, it is natural to consider an *average-case* version of the problem in which the source string x is assumed to be drawn uniformly at random from $\{0, 1\}^n$. This average-case problem has been intensively studied, and interestingly it turns out to be significantly easier than the worst-case problem. [4] showed that for most source strings x , in the deletion-only setting only $O(\log n)$ traces suffice for deletion rates q as large as $O(1/\log n)$. [16] considered the insertion/deletion noise channel and obtained an $O(\log n)$ -trace average-case algorithm for noise rates up to $O(1/\log^2 n)$, which was later improved to $O(1/\log n)$ in [25]. [14] were the first to give an efficient (using $\text{poly}(n)$ traces) average-case algorithm, for the deletion-only model, that succeeds for some constant deletion rate (their algorithm could handle deletion rates up to about $q = 0.07$). Building on the worst-case results of [8] and [21], a number of significantly stronger average-case results have recently been established. [23] gave an average-case algorithm for the deletion-only problem which uses $\exp(O(\log^{1/2} n))$ many traces for any deletion rate $q < 1/2$. Improving on this, [13] gave an average-case algorithm which can handle both insertions and deletions at any constant rate and uses only $\exp(O(\log^{1/3} n))$ many traces. (A simple reduction shows that any improvement on this sample complexity for the average-case problem would imply an improvement of the $\exp(O(n^{1/3}))$ -trace worst-case algorithms of [8] and [21].)

¹ A detailed description of the channel is given in Section 2. Augmented variants of this insertion/deletion noise model can also be considered, for example allowing for bit-flips as well as insertions and deletions, but unlike deletions and insertions bit-flips can typically be handled in a straightforward fashion. In this paper we confine our attention to the insertion/deletion channel.

Beyond trace reconstruction: Population recovery from the deletion channel. Inspired by a related problem known as *population recovery*, recent work of [3] has considered a challenging extension of the trace reconstruction problem. Population recovery is the problem of learning an unknown *distribution* over an unknown set of n -bit strings, given access to independent draws from the distribution that have been independently corrupted according to some noise channel. Most research in population recovery has focused on two noise models, namely the *bit-flip* noise channel (in which each coordinate is independently flipped with some fixed probability) and the *erasure* noise channel (in which each coordinate is independently replaced by ‘?’ with some fixed probability), both of which have been intensively studied, see e.g. [10, 26, 24, 9, 20, 18, 7, 9]. [3] considered the problem of *population recovery from the deletion channel*. This is a generalization of the deletion-channel trace reconstruction problem: now there is an unknown distribution over s unknown source strings $x^1, \dots, x^s \in \{0, 1\}^n$, and each sample provided to the learner is obtained by first drawing a string x^i from this distribution and then passing it through the deletion noise channel. It is clear that this problem is at least as difficult as the trace reconstruction problem (which is the $s = 1$ case), and indeed having multiple source strings turns out to pose significant new challenges. [3] considered the worst-case version of this problem, and showed that any distribution \mathcal{D} over any set of s unknown source strings can be recovered to total variation distance ε given $2\sqrt{n} \cdot (\log n)^{O(s)} / \varepsilon^2$ many traces from the deletion channel. [3] also gave a lower bound, showing that for any $s \leq n^{0.49}$ at least $n^{\Omega(s)}$ many traces are required. Population recovery-type problems have also been studied in the computational biology literature, specifically for DNA storage (see e.g. [22, 27]). In these settings, the population of strings corresponds to a collection of DNA sequences.

Summarizing, while population recovery from the deletion channel is a natural problem, the above results (and the fact that it is at least as difficult as trace reconstruction) indicate that it is also a hard one. Thus it is natural to investigate *average-case* versions of this problem; this is the subject of the current work.

1.1 Our result: Average-case population recovery in the insertion / deletion model

In the average-case model we consider, there is a given *population size* $s \geq 1$, i.e. there is a set x^1, \dots, x^s of s strings which are assumed to be drawn independently and uniformly from $\{0, 1\}^n$. Associated with this population is an *arbitrary* vector of non-negative probability values p_1, \dots, p_s , where p_i is the probability that the distribution \mathcal{D} puts on string x^i . Thus in our model the support of the distribution is “average-case” but the actual distribution over that support is “worst-case.”

Building on the work of [13], our main result is a highly efficient algorithm for average-case population recovery in the presence of insertions and deletions. We show that even for extremely large population sizes s (up to $\exp(\Theta(n^{1/3}))$), the average-case population recovery problem can be solved by a highly efficient algorithm which has running time polynomial in n (the length of unknown strings), s (the population size), and $1/\varepsilon$ (where ε is the total variation distance between \mathcal{D} and the distribution returned by the algorithm). The sample complexity of our algorithm is polynomial in s , $1/\varepsilon$, and $\exp(\log^{1/3} n)$. Thus our algorithm extends the average-case trace reconstruction results of [13] to the more challenging setting of s -string population recovery with essentially the best possible dependence on the new parameters s and $1/\varepsilon$ (which are not present in the original trace reconstruction problem but are inherent in the population recovery problem).

In more detail, we prove the following theorem (the exact definition of a random trace drawn from the insertion/deletion noise channel $\mathcal{C}_{q,q'}(\mathcal{D})$ will be given in Section 2):

► **Theorem 1.** *Fix any two constants $q, q' \in [0, 1)$ as deletion and insertion rates, respectively. There is an algorithm A with the following property: Let $\delta_{hard} \geq \exp(-\Theta(n^{1/3}))$ be a fraction of hard support sets, let $\delta_{fail} \geq \exp(-\Theta(n^{1/3}))$ be a failure probability, let $\varepsilon \geq \exp(-\Theta(n^{1/3}))$ be an accuracy parameter, let $1 \leq s \leq \exp(\Theta(n^{1/3}))$ be a support size, and let x^1, \dots, x^s be a support set (viewed as an ordered list of strings in $\{0, 1\}^n$). For at least a $(1 - \delta_{hard})$ -fraction of all 2^{ns} many possible s -element support sets, it is the case that for any probability distribution \mathcal{D} supported on $\{x^1, \dots, x^s\}$, given $n, s, \varepsilon, \delta_{hard}, \delta_{fail}$, and access to $\mathcal{C}_{q,q'}(\mathcal{D})$, algorithm A uses $\text{poly}(s, 1/\varepsilon, \exp(\log^{1/3} n), \exp(\log^{1/3}(1/\delta_{hard})), \log(1/\delta_{fail}))$ random traces from $\mathcal{C}_{q,q'}(\mathcal{D})$, runs in time $\text{poly}(n, s, 1/\varepsilon, 1/\delta_{hard}, \log(1/\delta_{fail}))$ and has the following property: with probability at least $1 - \delta_{fail}$ it outputs a hypothesis distribution \mathcal{D}' over $\{0, 1\}^n$ such that $d_{TV}(\mathcal{D}, \mathcal{D}') \leq \varepsilon$.*

Discussion. Taken together with the recent results of [3], Theorem 1 shows that the average-case and worse-case versions of population recovery in the presence of insertions and deletions have dramatically different complexities. The best known algorithm for the population size- s worst-case population recovery problem [3] has a doubly exponential dependence on s ; even for s constant this sample complexity is significantly worse than the best known sample complexity for the $s = 1$ worst-case trace reconstruction problem, which is $\exp(\Theta(n^{1/3}))$ by [8, 21]. The $n^{\Omega(s)}$ sample complexity lower bound given in [3] shows that an exponential dependence on s is inherent for worst-case population recovery. In contrast, Theorem 1 shows that a *polynomial* sample complexity (and running time) dependence on s is achievable for the average-case problem, and that passing from $s = 1$ to larger values of s does not incur much increase in complexity for the average-case problem.

In independent work, [17] studied a different generalization of trace reconstruction which they called *matrix reconstruction*. Instead of reconstructing a string by sampling traces where each character of the string has some probability of being deleted, the goal in *matrix reconstruction* is to reconstruct a matrix by sampling traces where each row and column of the matrix has some probability of being deleted. They used similar techniques to those used in this paper.

1.2 Our techniques

A natural way to approach our problem is to attempt to reduce it to the $s = 1$ case, which as described above is just the average-case trace reconstruction problem which was solved by [13]. However, two challenges arise in carrying out such a reduction. The first challenge is that the analysis of [13] only gives an algorithm which succeeds on a $1 - \Theta(1/n)$ fraction of all source strings $x \in \{0, 1\}^n$. So if the population size s is much larger than n , then a random population of s source strings will with high probability contain $\Theta(s/n)$ many “hard-to-reconstruct” strings. It is not clear how to proceed if these hard-to-reconstruct strings have significant weight under the distribution \mathcal{D} (which they may, since the distribution \mathcal{D} over the s source strings is assumed to be completely arbitrary).

We get around this challenge by showing that for any arbitrarily small δ , the algorithm of [13] can be extended in a black-box way to succeed on any $1 - \delta$ fraction of all source strings $x \in \{0, 1\}^n$ (at the cost of a modest increase in running time and sample complexity depending on the value of δ). By taking $\delta \ll 1/s$, with high probability the random population will consist entirely of source strings x^i each of which could be reconstructed in isolation if we were given only traces coming from x^i .

The second (main) challenge, of course, is that we are not given traces from each individual string x^i in isolation, but rather we are given a mixture of traces from all s strings x^1, \dots, x^s . The main contribution of our work is a clustering procedure which lets us (with high probability over a population of s random source strings) correctly group together traces that came from the same source string. Given the ability to do such clustering, we can indeed use the [13] algorithm on each obtained cluster to identify each of the source strings which has non-negligible weight under the distribution \mathcal{D} , and given the identity of these source strings that each trace came from, it is straightforward to output a high-accuracy hypothesis for the unknown distribution \mathcal{D} over these strings.

The core clustering procedure which we develop is a simple algorithm which we call A_{cluster} (see Algorithm 1 in Section 4). This algorithm takes two traces a and b as input, and outputs either “same” or “different.” Its performance guarantee is the following: If a and b were generated as two independent traces from *the same* randomly chosen source string \mathbf{x} , then with high probability A_{cluster} outputs “same,” whereas if a, b were generated as two traces coming from *two independent* uniform random source strings \mathbf{x}^1 and \mathbf{x}^2 respectively, then with high probability A_{cluster} outputs “different.” (See Theorem 5 for a detailed statement.)

The idea underlying A_{cluster} is as follows. Given a trace a (which we view as a string over $\{-1, 1\}$), imagine breaking it up into contiguous segments (which we call “blocks”) and summing the ± 1 bits within each block, and let $\text{sum}(a, i)$ denote the sum of the bits in the i -th block. We do the same for the trace b and obtaining a value $\text{sum}(b, i)$ from the i -th block of b . The high-level idea is that, for a suitable choice of the block size, in general there will be significant overlap between the positions in $\{1, \dots, n\}$ (of the source string) that gave rise to the elements of the i -th block of a and the i -th block of b . As a result,

- On the one hand, if a and b came from the same source \mathbf{x} , then there will be significant cancellation in the difference $\text{sum}(a, i) - \text{sum}(b, i)$ and this difference will tend to be “small” in magnitude.
- On the other hand, if a and b came from independent source strings \mathbf{x}^1 and \mathbf{x}^2 , then there will be no such cancellation and the difference $\text{sum}(a, i) - \text{sum}(b, i)$ will not be so “small” in magnitude.

Therefore by checking the magnitude of $\text{sum}(a, i) - \text{sum}(b, i)$ across many different blocks i , it is possible to determine with high confidence whether or not a and b came from the same source string or not.

2 Preliminaries

We write $[n] = \{1, \dots, n\}$ for a positive integer n . We index strings $x \in \{0, 1\}^n$ as $x = (x_1, \dots, x_n)$. We use **bold font** to denote random variables (which may be real-valued, integer-valued, $\{0, 1\}^*$ -valued, etc.).

We consider an insertion-deletion noise channel $\mathcal{C}_{q, q'}$ defined as by [13]. Given a *deletion rate* q and an *insertion rate* q' , both in $[0, 1)$, the insertion-deletion channel $\mathcal{C}_{q, q'}$ acts on an $x \in \{0, 1\}^n$ as follows: First, for each $j \in [n]$, $\mathbf{G}_j(q') - 1$ many independent and uniform bits from $\{0, 1\}$ are inserted before the j -th bit of x , where $\mathbf{G}_1(q'), \dots, \mathbf{G}_n(q')$ are i.i.d. geometric random variables satisfying

$$\Pr[\mathbf{G}_j(q') = \ell] = (q')^{\ell-1}(1 - q')$$

(i.e. each $\mathbf{G}_j(q')$ is distributed as $\text{Geometric}(1 - q')$). Then each bit of the resulting string is independently deleted with probability q . The resulting string is the output from $\mathcal{C}_{q, q'}(x)$, and we write “ $\mathbf{y} \sim \mathcal{C}_{q, q'}(x)$ ” to indicate that \mathbf{y} is a random trace generated from x in this way. If \mathcal{D} is a distribution over n -bit strings, we write “ $\mathbf{y} \sim \mathcal{C}_{q, q'}(\mathcal{D})$ ” to indicate that \mathbf{y} is obtained by first drawing $\mathbf{x} \sim \mathcal{D}$ and then drawing $\mathbf{y} \sim \mathcal{C}_{q, q'}(\mathbf{x})$.

3 Achieving an arbitrarily small fraction of “hard” strings in average-case trace reconstruction

Fix any constants $q, q' \in [0, 1)$ as deletion and insertion rates, respectively. We will use asymptotic notation such as $O(\cdot)$ and $\Theta(\cdot)$ to hide constants that depend on q and q' .

The main result of [13] is an algorithm which successfully performs trace reconstruction on at least $(1 - O(1/n))$ -fraction of all n -bit strings (which is $1 - M/n$ for some constant $M = M(q, q')$ that only depends on q and q'). In more detail, their main result is the following:

► **Theorem 2.** *Fix any constants $q, q' \in [0, 1)$. There is a deterministic algorithm $A_{\text{average-case}}$ with the following property: It is given (1) a confidence parameter $\delta > 0$, (2) the length n of an unknown string $x \in \{0, 1\}^n$ and (3) access to $\mathcal{C}_{q, q'}(x)$, uses*

$$\exp\left(O\left(\log^{1/3} n\right)\right) \cdot \log(1/\delta) \quad (1)$$

traces drawn from $\mathcal{C}_{q, q'}(x)$, and runs in time $\text{poly}(n, \log(1/\delta))$. For at least $(1 - O(1/n))$ -fraction of all strings $x \in \{0, 1\}^n$,² it is the case that, algorithm $A_{\text{average-case}}(\delta, n, \mathcal{C}_{q, q'}(x))$ outputs the string x with probability at least $1 - \delta$ (over the randomness of traces drawn from $\mathcal{C}_{q, q'}(x)$).

Note that in the above theorem the fraction of “hard” strings $x \in \{0, 1\}^n$ on which the [13] algorithm does not succeed is $\Theta(1/n)$. In our setting, to achieve results for general population sizes s , we may require the fraction of “hard” strings on which the reconstruction algorithm does not succeed to be smaller than this; to see this, suppose for example that we are considering a population of size $s = n^2$. If a $\Theta(1/n)$ fraction of strings are “hard” and n^2 strings are chosen uniformly at random to form the support of our distribution \mathcal{D} , then we would expect $\Theta(n)$ many hard strings to be present in the support set (i.e. the population) of n^2 strings. If the unknown distribution over the n^2 strings (which, recall, may be any distribution over that support) puts a significant amount of its probability mass on these hard strings, then it may not be possible to successfully recover the population.

In this section we show that the fraction of strings in $\{0, 1\}^n$ that are “hard” can be driven down from $\Theta(1/n)$ to an arbitrarily small fraction in the [13] result, at the cost of a corresponding modest increase in the sample complexity and running time of the algorithm. (As suggested by the discussion given above, such an extension is crucial for us to be able to handle populations of size $s = \omega(n)$.) It may be possible to verify this directly via a careful reworking of the [13] proof, but that proof is involved and such a verification would be quite tedious. Instead we give a simple and direct argument which uses Theorem 2 in a black-box way to prove the following generalization of it, in which only an arbitrarily small fraction of strings are hard to reconstruct:

► **Theorem 3.** *Fix any constants $q, q' \in [0, 1)$. There is a deterministic algorithm $A'_{\text{average-case}}$ with the following property: It is given (1) $\tau > 0$ as the desired fraction of hard strings, (2) a confidence parameter δ , (3) the length n of the unknown string $x \in \{0, 1\}^n$ and (4) access to $\mathcal{C}_{q, q'}(x)$. It uses*

$$\exp\left(O\left(\left(\log \max\{n, 1/\tau\}\right)^{1/3}\right)\right) \cdot \log(1/\delta)$$

² Theorem 1 of [13] only claims a $1 - o_n(1)$ fraction of strings x , but the proof shows that the fraction is $1 - O_{q, q'}(1/n)$; see e.g. the discussion at the beginning of Section 1.3 of [13].

many traces drawn from $\mathcal{C}_{q,q'}(x)$, and runs in time $\text{poly}(\max\{n, 1/\tau\}, \log(1/\delta))$. For at least $1 - \tau$ fraction of all strings $x \in \{0, 1\}^n$, it is the case that algorithm $A'_{\text{average-case}}(\tau, \delta, n, \mathcal{C}_{q,q'}(x))$ outputs the string x with probability at least $1 - \delta$.

We note that the sample complexity of Theorem 3 interpolates smoothly between the average-case result of [13], in which a $\tau = \Theta(1/n)$ fraction of strings are hard, and the worst-case results of [8, 21], in which no strings in $\{0, 1\}^n$ (equivalently, at most a $\tau = 1/2^{n+1}$ fraction of strings) are hard.

The high-level idea underlying Theorem 3 is very simple: By padding the input string x (which should be thought of as uniformly random over $\{0, 1\}^n$) with random bits, it is possible to obtain a uniformly random N -bit string, and by running algorithm $A_{\text{average-case}}$ over this string of length N , with probability $1 - \Theta(1/N)$ it is possible to reconstruct this N -bit string, from which the original input string x can be reconstructed. Taking N to be suitably large this yields the desired result. We give a detailed proof below.

Let M be the constant hidden in the $O(1/n)$ in Theorem 2. We note that if $\tau \geq M/n$ then we may simply use $A_{\text{average-case}}$, so we henceforth assume that $\tau < M/n$.

The algorithm. Algorithm $A'_{\text{average-case}}(\tau, \delta, n, \mathcal{C}_{q,q'}(x))$ works by running an auxiliary algorithm $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$ (which always outputs an n -bit string) $O(\log(1/\delta))$ many times. If at least $9/16$ of the $O(\log(1/\delta))$ runs of A^* yield the same n -bit string then this is the output of $A'_{\text{average-case}}$, and otherwise $A'_{\text{average-case}}$ outputs “failure.” Below we will show that for at least $1 - \tau$ fraction of all strings $x \in \{0, 1\}^n$, $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$ outputs the correct string x with probability at least $5/8$. It follows from the Chernoff bound that $A'_{\text{average-case}}$ achieves the desired $1 - \delta$ success probability.

We turn to describing and analyzing $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$, which works as follows:

1. It draws a string \mathbf{z} uniformly from $\{0, 1\}^{N-n}$ (the value of $N > n$ will be specified later).
2. Let $m = m(N)$ be the following parameter:

$$m(N) = \exp\left(O\left(\log^{1/3} N\right)\right) \cdot \log(1/\delta'),$$

where $\delta' = 1/8$. This is the number of traces needed by $A_{\text{average-case}}$ to achieve confidence parameter δ' on strings of length N (as in (1)). For m times, algorithm A^* independently repeats the following: at the i -th repetition it draws a string $\mathbf{y}^{(i)} \sim \mathcal{C}_{q,q'}(x)$, constructs a string $\mathbf{y}'^{(i)}$ that is distributed according to $\mathcal{C}_{q,q'}(\mathbf{z})$, and constructs $\mathbf{a}^{(i)} := \mathbf{y}^{(i)} \circ \mathbf{y}'^{(i)}$ which is the concatenation of $\mathbf{y}^{(i)}$ and $\mathbf{y}'^{(i)}$.

3. Finally, it uses the m strings $\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(m)}$ to run algorithm $A_{\text{average-case}}$ with length N and confidence parameter δ' . Let $w \in \{0, 1\}^N$ be the string that $A_{\text{average-case}}$ returns. The output of A^* is $w_1 w_2 \dots w_n$, the first n characters of w .

Proof of correctness. We first observe that (as an immediate consequence of the definition of the noise channel $\mathcal{C}_{q,q'}$) each string $\mathbf{a}^{(i)} = \mathbf{y}^{(i)} \circ \mathbf{y}'^{(i)}$ generated as in Step 2 of $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$ is distributed precisely as a draw from $\mathcal{C}_{q,q'}(x \circ \mathbf{z})$. By the choice of $m = m(N)$ in Step 2, the strings $\mathbf{a}^{(1)}, \dots, \mathbf{a}^{(m)}$ constitute precisely the required traces for a run of $A_{\text{average-case}}$ on the N -bit string $x \circ \mathbf{z}$.

Let us say that the strings in $\{0, 1\}^N$ which $A_{\text{average-case}}$ (with parameters δ' and N) correctly reconstructs with probability at least $1 - \delta'$ are *good* strings, and that the other strings in $\{0, 1\}^N$ are *bad* strings. By Theorem 2, at most an (M/N) -fraction of all strings in $\{0, 1\}^N$ are bad. The value of N is set to $N := 4M/\tau$,³ so $M/N = \tau/4$, and it is the case

³ Note that $N \geq 4n$ using $\tau < M/n$, so $N - n > 0$ and indeed Step 1 makes sense.

that at most a $\tau/4$ fraction of strings in $\{0, 1\}^N$ are bad. For each $x \in \{0, 1\}^n$, let γ_x denote the fraction of strings $z \in \{0, 1\}^{N-n}$ such that $x \circ z$ is bad. The average over all $x \in \{0, 1\}^n$ of γ_x is at most $\tau/4$, and consequently at most a τ fraction of strings x have $\gamma_x \geq 1/4$.

▷ **Claim 4.** If $x \in \{0, 1\}^n$ has $\gamma_x < 1/4$, then $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$ outputs x with probability at least $5/8$.

Proof. The probability that $z \sim \{0, 1\}^{N-n}$ such that $x \circ z$ is good is at least $3/4$. If $x \circ z$ is good then with probability at least $1 - \delta' = 7/8$ the output of $A_{\text{average-case}}$ as run in Step 3 is the string $x \circ z$ and hence the output of A^* is x . The claim follows since $(3/4) \cdot (7/8) > 5/8$. ◀

Hence for at least a $(1 - \tau)$ -fraction of $x \in \{0, 1\}^n$, a run of $A^*(\tau, n, \mathcal{C}_{q,q'}(x))$ outputs x with probability at least $5/8$. For any such x , a simple Chernoff bound shows that with probability at least $1 - \delta$, at least $9/16$ of the $O(\log(1/\delta))$ many independent runs of A^* will output x . This concludes the proof of Theorem 3. ◀

4 The core clustering result

In this section we state and prove the key clustering result that is used in the main algorithm. Intuitively, it gives an efficient procedure with the following performance guarantee: Given two traces, the procedure can determine with high probability whether the two traces were both obtained as traces from the same uniform random string $\mathbf{x} \sim \{0, 1\}^n$, or the two traces were obtained from two independent uniform random strings $\mathbf{x}^1, \mathbf{x}^2 \sim \{0, 1\}^n$.

In more detail, the main result of this section is the following theorem:

► **Theorem 5.** Fix any constants $q, q' \in [0, 1)$. There is a deterministic algorithm A_{cluster} with the following performance guarantee: It is given a positive integer n and a pair of binary strings z and z' . Let $\delta_{\text{cluster}} := \exp(-\Theta(n^{1/3}))$. Then $A_{\text{cluster}}(n, z, z')$ runs in time $O(n)$ and satisfies the following two properties:

1. Suppose that \mathbf{x} is uniform random over $\{0, 1\}^n$ and \mathbf{z}, \mathbf{z}' are independent draws from $\mathcal{C}_{q,q'}(\mathbf{x})$. Then with probability at least $1 - \delta_{\text{cluster}}$, algorithm $A_{\text{cluster}}(n, \mathbf{z}, \mathbf{z}')$ outputs “same.”
2. Suppose that $\mathbf{x}^1, \mathbf{x}^2$ are independent uniform random strings over $\{0, 1\}^n$, $\mathbf{z} \sim \mathcal{C}_{q,q'}(\mathbf{x}^1)$ and $\mathbf{z}' \sim \mathcal{C}_{q,q'}(\mathbf{x}^2)$. Then with probability at least $1 - \delta_{\text{cluster}}$, $A_{\text{cluster}}(n, \mathbf{z}, \mathbf{z}')$ outputs “different.”

4.1 Proof of Theorem 5

For convenience, we consider strings over $\{-1, 1\}$ instead of $\{0, 1\}$ in the rest of this section. We need the following technical lemma:

► **Lemma 6.** Let $\tau \in (0, 1]$ be a constant. Then there exist three positive constants c_1, c_2 and c_3 (that only depend on τ) such that the following property holds. For all positive integers m and m' such that $m' \leq (1 - \tau)m$ and m is sufficiently large, letting $\mathbf{X}_1, \dots, \mathbf{X}_m$ be independent and uniform random variables over $\{-1, 1\}$, we have

$$\Pr\left[|\mathbf{X}_1 + \dots + \mathbf{X}_m| \geq c_1\sqrt{m}\right] \geq c_2 + c_3 \quad \text{and} \quad \Pr\left[|\mathbf{X}_1 + \dots + \mathbf{X}_{m'}| \geq c_1\sqrt{m}\right] \leq c_2 - c_3.$$

Proof. The Berry-Esseen theorem (see e.g. [11]) establishes closeness between the cdf of a sum of “well-behaved” independent random variables (such as $\mathbf{X}_1, \dots, \mathbf{X}_m$) and the cdf of a Normal distribution with the same mean and variance. By the Berry-Esseen theorem, the probability of $|\mathbf{X}_1 + \dots + \mathbf{X}_m| \geq c_1\sqrt{m}$ is within an additive $\pm o_m(1)$ of the corresponding probability of $|\mathbf{G}_1| \geq c_1\sqrt{m}$, where $\mathbf{G}_1 \sim \mathcal{N}(0, m)$.

We first consider the case that m' is not too small compared to m , say $m' > m^{1/3}$. In this case the Berry-Esseen theorem implies that the probability of $|\mathbf{X}_1 + \dots + \mathbf{X}_{m'}| \geq c_1\sqrt{m}$ is also within an additive $\pm o_m(1)$ of the corresponding probability for Gaussian random variables, which is now $\Pr[|\mathbf{G}_2| \geq c_1\sqrt{m}]$ with $\mathbf{G}_2 \sim \mathcal{N}(0, m')$. So in this case Lemma 6 is an immediate consequence of an analogous statement for Gaussian random variables,

$$\Pr\left[|\mathbf{G}_1| \geq c_1\sqrt{m}\right] \geq c_2 + c_3 \quad \text{and} \quad \Pr\left[|\mathbf{G}_2| \geq c_1\sqrt{m}\right] \leq c_2 - c_3, \tag{2}$$

where $\mathbf{G}_1 \sim \mathcal{N}(0, m)$ and $\mathbf{G}_2 \sim \mathcal{N}(0, m')$. The first probability in (2) is the probability that a Gaussian’s magnitude exceeds its mean by at least c_1 standard deviations, while the second probability in (2) is the probability that a Gaussian’s magnitude exceeds its mean by at least $c_1/\sqrt{1-\tau}$ standard deviations. Given this, for suitable c_1, c_2, c_3 depending only on τ , the inequalities (2) are a straightforward consequence of the following standard bounds on the cdf of a Gaussian $\mathbf{G} \sim \mathcal{N}(0, \sigma^2)$ [[11], Section 7.1]:

$$\left(\frac{1}{x} - \frac{1}{x^3}\right) \cdot \frac{e^{-x^2/2}}{\sqrt{2\pi}} \leq \Pr[\mathbf{G} \geq x\sigma] \leq \frac{1}{x} \cdot \frac{e^{-x^2/2}}{\sqrt{2\pi}}, \quad \text{for all } x > 0.$$

Finally we consider the case that m' is very small compared to m , say $m' \leq m^{1/3}$. In this case, by the Berry-Esseen theorem we have that $\Pr[|\mathbf{X}_1 + \dots + \mathbf{X}_m| \geq c_1\sqrt{m}]$ is $\pm o_m(1)$ -close to the probability that a Gaussian’s magnitude exceeds its mean by c_1 standard deviations, which is at least some absolute constant, while $\Pr[|\mathbf{X}_1 + \dots + \mathbf{X}_{m'}| \geq c_1\sqrt{m}]$ is zero for sufficiently large m , because $m' \leq m^{1/3} < c_1\sqrt{m}$ for m sufficiently large. This finishes the proof of Lemma 6. \blacktriangleleft

Recall that constants $q, q' \in [0, 1)$ denote the deletion probability and insertion probability respectively. Let $p, p' \in (0, 1]$ be $p = 1 - q$ and $p' = 1 - q'$. Then the expected length of a string drawn from $\mathcal{C}_{q,q'}(x)$ with $x \in \{-1, 1\}^n$ is $np/p' = \alpha n$, where $\alpha := p/p'$ is a positive constant.

Given a string $x \in \{-1, 1\}^n$, we start by describing an equivalent way of drawing $z \sim \mathcal{C}_{q,q'}(x)$. We say a string r over $[n] \cup \{*\}$ is an n -*pattern* if every $i \in [n]$ appears in r at most once and integers appear in r in ascending order. We write $\mathcal{R}_{n,q,q'}$ to denote the following distribution over n -patterns. To draw $\mathbf{r} \sim \mathcal{R}_{n,q,q'}$ we start with $r^{(0)} = (1, 2, \dots, n)$. Then for each $j \in [n]$, $\mathbf{G}_j(q') - 1$ many $*$ ’s are inserted before the j -th entry (with value j) of $r^{(0)}$ to obtain $\mathbf{r}^{(1)}$. Finally each entry of $\mathbf{r}^{(1)}$ is independently deleted with probability q to obtain the final string \mathbf{r} . Using $\mathcal{R}_{n,q,q'}$, drawing $z \sim \mathcal{C}_{q,q'}(x)$ can be done equivalently as follows:

1. Draw an n -pattern $\mathbf{r} \sim \mathcal{R}_{n,q,q'}$.
2. For each index $i \in [n]$ that appears in \mathbf{r} , replace it by x_i in \mathbf{r} .
3. Replace each $*$ in \mathbf{r} with an independent and uniform draw from $\{-1, 1\}$.

Next we introduce a number of parameters and constants that will be used in the clustering algorithm A_{cluster} . Two parameters \tilde{s} and t used in the algorithm are

$$t := n^{2/3} \quad \text{and} \quad \tilde{s} = \left\lfloor \frac{\alpha n}{4t} \right\rfloor = \Theta(n^{1/3})$$

so that $2\tilde{s}t \leq \alpha n/2$. Three constants β, γ and δ are defined as c_1, c_2 and c_3 in Lemma 6 with τ set to be the following constant in $(0, 1)$: $\tau = 0.7pp'$. For each $\ell \in [\tilde{s}]$, we let I_ℓ denote the following set of integers:

$$I_\ell = [(2\ell - 2)t + 1, (2\ell - 1)t] \cap \mathbb{Z}. \quad (3)$$

Given a string z over $\{-1, 1\}$ (or an n -pattern r), we will refer to entries z_i of z (or r_i of r) over $i \in I_\ell$ as the ℓ -th *block* of z (or r). So each block consists of t entries and two consecutive blocks are separated by a gap of t entries. Given an n -pattern r and an integer ℓ , we write $B_\ell(r) \subset [n]$ to denote the set of $i \in [n]$ that appears in the ℓ -th block of r .

The algorithm A_{cluster} is described in Algorithm 1. Before stating the key technical lemma (Lemma 7) and using it to prove Theorem 5, we give some intuition for the algorithm A_{cluster} .

■ **Algorithm 1** Description of the clustering algorithm A_{cluster} .

Algorithm $A_{\text{cluster}}(n, z, z')$

Input: A positive integer n and two strings z and z' over $\{-1, 1\}$.

Output: “Same” or “different.”

1. For each $\ell \in [\tilde{s}]$, set Z_ℓ to be the sum of z_i over $i \in I_\ell$, with $z_i = 0$ when $i > |z|$.
2. For each $\ell \in [\tilde{s}]$, set Z'_ℓ to be the sum of z'_i over $i \in I_\ell$, with $z'_i = 0$ when $i > |z'|$.
3. Count the number of $\ell \in [\tilde{s}]$ such that $|Z_\ell - Z'_\ell| \geq \beta\sqrt{2t}$.
4. If the number of such ℓ is at least $\gamma\tilde{s}$, return “different;” otherwise, return “same.”

Recall the two cases in Theorem 5. We start with the easier second case, where \mathbf{x}^1 and \mathbf{x}^2 are drawn from $\{-1, 1\}^n$ uniformly and independently, $z \sim \mathcal{C}_{q,q'}(\mathbf{x}^1)$ and $z' \sim \mathcal{C}_{q,q'}(\mathbf{x}^2)$. First it is easy to show (see property (0) of Lemma 7) that $|z|, |z'| \geq \alpha n/2$ with very high probability. When this happens, Z_ℓ is the sum of t independent and uniform random variables over $\{-1, 1\}$ and the same holds for Z'_ℓ . Moreover, Z_ℓ and Z'_ℓ are independent of each other since \mathbf{x}^1 and \mathbf{x}^2 are drawn independently and thus, $Z_\ell - Z'_\ell$ can be equivalently written as the sum of $2t$ independent and uniform variables over $\{-1, 1\}$. Furthermore, the \tilde{s} random variables $Z_\ell - Z'_\ell$ over $\ell \in [\tilde{s}]$ are independent. Thus, it follows from Lemma 6 and our choices of β, γ and δ that the probability of each $|Z_\ell - Z'_\ell| \geq \beta\sqrt{2t}$ is at least $\gamma + \delta$ and with very high probability, the number of such $\ell \in [\tilde{s}]$ is at least $\gamma\tilde{s}$, in which case the algorithm returns “different” as desired.

In the first case of Theorem 5, we draw \mathbf{x} from $\{-1, 1\}^n$ uniformly and then draw z, z' from $\mathcal{C}_{q,q'}(\mathbf{x})$ independently. Equivalently one can view the process as first drawing two n -patterns \mathbf{r} and \mathbf{r}' independently from $\mathcal{R}_{n,q,q'}$ and \mathbf{x} from $\{-1, 1\}^n$. The string z (or z') is then obtained by replacing each $i \in [n]$ in \mathbf{r} (or \mathbf{r}') by \mathbf{x}_i and each $*$ by an independent draw from $\{-1, 1\}$. Again we assume that $|\mathbf{r}|, |\mathbf{r}'| \geq \alpha n/2$, which happens with high probability. When this is the case, each of Z_ℓ and Z'_ℓ for $\ell \in [\tilde{s}]$ remains the sum of t independent uniform random variables over $\{-1, 1\}$. However, when an index $i \in [n]$ appears in the ℓ -th block of both \mathbf{r}, \mathbf{r}' , then \mathbf{x}_i appears in both sums Z_ℓ, Z'_ℓ and gets cancelled out in their difference $Z_\ell - Z'_\ell$.

Our main technical lemma shows that with very high probability over draws \mathbf{r} and \mathbf{r}' from $\mathcal{R}_{n,q,q'}$, the following two properties hold: (1) $|B_\ell(\mathbf{r}) \cap B_\ell(\mathbf{r}')| \geq \tau t$ for every $\ell \in [\tilde{s}]$, i.e., there are at least τt many integers that appear in the ℓ -th block of both \mathbf{r} and \mathbf{r}' ; and (2) No index $i \in [n]$ appears in two different blocks of \mathbf{r} and \mathbf{r}' (i.e., it cannot be the case that both $i \in B_\ell(\mathbf{r})$ and $i \in B_{\ell'}(\mathbf{r}')$ with $\ell \neq \ell'$; intuitively the reason why we leave a gap of t entries between two consecutive blocks is to achieve this property). Fixing such a pair of n -patterns r and r' , property (1) implies that each $Z_\ell - Z'_\ell$ can be written as the sum of

at most $(1 - \tau)2t$ many independent $\{-1, 1\}$ -variables; given this, it follows directly from Lemma 6 that the probability of each $|\mathbf{Z}_\ell - \mathbf{Z}'_\ell| \geq \beta\sqrt{2t}$ is at most $\gamma - \delta$. Furthermore (2) implies that the \tilde{s} variables $\mathbf{Z}_\ell - \mathbf{Z}'_\ell$ over $\ell \in [\tilde{s}]$ are independent. This lets us easily infer that the number of ℓ such that $|\mathbf{Z}_\ell - \mathbf{Z}'_\ell| \geq \beta\sqrt{2t}$ is less than $\gamma\tilde{s}$ with very high probability, in which case the algorithm returns “same” as desired.

As discussed above, the main technical lemma we require is as follows:

► **Lemma 7.** *Let \mathbf{r}, \mathbf{r}' be two n -patterns drawn independently from $\mathcal{R}_{n,q,q'}$. Then with probability at least $1 - \exp(-\Omega(n^{1/3}))$, the following three properties all hold:*

- (0): $|\mathbf{r}|, |\mathbf{r}'| \geq \alpha n/2$.
- (1): $|B_\ell(\mathbf{r}) \cap B_\ell(\mathbf{r}')| \geq \tau t$ for all $\ell \in [\tilde{s}]$.
- (2): If an $i \in [n]$ appears in both $B_\ell(\mathbf{r})$ and $B_{\ell'}(\mathbf{r}')$ for some $\ell, \ell' \in [\tilde{s}]$, then we have $\ell = \ell'$.

The detailed proof of Lemma 7 is given in Appendix A; here we give some intuition.

To prove Lemma 7, we show that $\mathbf{r}, \mathbf{r}' \sim \mathcal{R}_{n,q,q'}$ satisfy each of the three properties with probability at least $1 - \exp(-\Omega(n^{1/3}))$; the lemma follows from a union bound. Property (0) follows from tail bounds on sums of independent Geometric random variables and from standard Chernoff bounds (see Claim 12) for insertions and deletions, respectively. Indeed property (0) holds with probability $1 - \exp(-\Omega(n))$.

Properties (1) and (2) follow from Lemma 13 in Appendix A. To state the lemma, recall that we write $\mathbf{r}^{(1)}$ to denote the string over $[n] \cup \{*\}$ obtained after insertions during the generation of $\mathbf{r} \sim \mathcal{R}_{n,q,q'}$. For each $i \in [n]$, we use \mathbf{Y}_i to denote the number of characters before i in $\mathbf{r}^{(1)}$ that survive deletions; note that \mathbf{Y}_i is the number of characters that appear before i in \mathbf{r} if i survives in \mathbf{r} , but \mathbf{Y}_i is well defined even if i was deleted. By definition, we have $\mathbf{E}[\mathbf{Y}_i] = ((i/p') - 1)p$. Lemma 13 shows that for constant $c \in (0, 1)$, with probability $1 - \exp(-\Omega(n^{1/3}))$, $|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \leq ct$. Lemma 13 again follows from tail bounds on sums of independent Geometric random variables and from standard Chernoff bounds. We define \mathbf{Y}'_i similarly for \mathbf{r}' and the same statement also holds for \mathbf{Y}'_i .

Property (2) follows directly from Lemma 13, since for an $i \in [n]$ to appear in two different blocks, it must be the case that $|\mathbf{Y}_i - \mathbf{Y}'_i| \geq t$ and thus, either $|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \geq t/2$ or $|\mathbf{Y}'_i - \mathbf{E}[\mathbf{Y}'_i]| \geq t/2$ (as we have $\mathbf{E}[\mathbf{Y}'_i] = \mathbf{E}[\mathbf{Y}_i]$), which happens with probability at most $\exp(-\Omega(n^{1/3}))$ by Lemma 13.

To prove property (1) for $\ell \in [\tilde{s}]$, we focus on the following interval of indices in $[n]$:

$$I_\ell^{(0)} := \left[\frac{p'}{p}(2\ell - 1.9)t + 1, \frac{p'}{p}(2\ell - 1.1)t \right] \cap \mathbb{Z},$$

and show that with probability at least $1 - \exp(-\Omega(n^{1/3}))$, we have both

- (a) At least $\tau t = 0.7tp'$ indices in $I_\ell^{(0)}$ survive in both \mathbf{r} and \mathbf{r}' ; and
- (b) Every $i \in I_\ell^{(0)}$ that survives in both \mathbf{r} and \mathbf{r}' lies in both $B_\ell(\mathbf{r})$ and $B_\ell(\mathbf{r}')$.

Item (a) follows from a Chernoff bound: the length of $I_\ell^{(0)}$ is $0.8tp'/p$ and every element survives independently in both strings with probability p^2 . Letting i_0, i_1 be the left and right ends of $I_\ell^{(0)}$, item (b) holds when $\mathbf{Y}_{i_0}, \mathbf{Y}'_{i_0}, \mathbf{Y}_{i_1}, \mathbf{Y}'_{i_1}$ do not shift too far ($0.1t$) away from their expectations which happens with probability at least $1 - \exp(-\Omega(n^{1/3}))$ by Lemma 13.

Finally we use Lemma 7 to prove Theorem 5:

Proof of Theorem 5. We start with the second case in which $\mathbf{x}^1, \mathbf{x}^2$ are independent uniform random strings over $\{0, 1\}^n$, $\mathbf{z} \sim \mathcal{C}_{q,q'}(\mathbf{x}^1)$ and $\mathbf{z}' \sim \mathcal{C}_{q,q'}(\mathbf{x}^2)$. By our discussion earlier, \mathbf{z} and \mathbf{z}' can be generated equivalently by first drawing $\mathbf{r}, \mathbf{r}' \sim \mathcal{R}_{n,q,q'}$, then drawing $\mathbf{x}^1, \mathbf{x}^2$,

and finally deriving \mathbf{z} (or \mathbf{z}') from \mathbf{r} (or \mathbf{r}') using \mathbf{x}^1 (or \mathbf{x}^2) as well as independent random bits for the $*$'s. By Lemma 7, \mathbf{r} and \mathbf{r}' satisfy all three properties with probability at least $1 - \exp(-\Omega(n^{1/3}))$. Fixing r and r' that satisfy all three properties (for the first case we only need property (0)), we show that $A_{\text{cluster}}(n, \mathbf{z}, \mathbf{z}')$ returns “different” with probability at least $1 - \exp(-\Omega(n^{1/3}))$ conditioning on $\mathbf{r} = r$ and $\mathbf{r}' = r'$; the lemma for this case then follows.

To this end, it follows from property (0) that each $\mathbf{Z}_\ell - \mathbf{Z}'_\ell$ is a sum of $2t$ independent uniform random variables over $\{-1, 1\}$ and thus, each $\ell \in [\tilde{s}]$ satisfies $|\mathbf{Z}_\ell - \mathbf{Z}'_\ell| \geq \beta\sqrt{2t}$ with probability at least $\gamma + \delta$. Moreover, the \tilde{s} variables $\mathbf{Z}_\ell - \mathbf{Z}'_\ell$ are independent. It follows from a Chernoff bound (and that δ is a positive constant) that A_{cluster} returns “different” with probability $1 - \exp(-\Omega(\tilde{s})) = 1 - \exp(-\Omega(n^{1/3}))$.

For the second case we can similarly generate \mathbf{z}, \mathbf{z}' by first drawing $\mathbf{r}, \mathbf{r}' \sim \mathcal{R}_{n,q,q'}$, then drawing \mathbf{x} , and finally deriving \mathbf{z}, \mathbf{z}' from \mathbf{r}, \mathbf{r}' using the same \mathbf{x} and independent random bits for the $*$'s. Again it follows from Lemma 7 that \mathbf{r}, \mathbf{r}' satisfy all three properties with probability $1 - \exp(-\Omega(n^{1/3}))$. Fixing r, r' that satisfy all three properties, we show that $A_{\text{cluster}}(n, \mathbf{z}, \mathbf{z}')$ returns “same” with probability $1 - \exp(-\Omega(n^{1/3}))$, conditioning on $\mathbf{r} = r$ and $\mathbf{r}' = r'$; the lemma for this case then follows.

For this purpose, properties (0) and (1) imply that each $\mathbf{Z}_\ell - \mathbf{Z}'_\ell$ is the sum of at most $(1 - \tau)2t$ many independent uniform random variables over $\{-1, 1\}$. Lemma 6 implies that the probability of $|\mathbf{Z}_\ell - \mathbf{Z}'_\ell| \geq \beta\sqrt{2t}$ is at most $\gamma - \delta$. Moreover, property (2) implies that these \tilde{s} variables $\mathbf{Z}_\ell - \mathbf{Z}'_\ell$ are independent. It similarly follows from a Chernoff bound that A_{cluster} returns “same” with probability $1 - \exp(-\Omega(\tilde{s})) = 1 - \exp(-\Omega(n^{1/3}))$. ◀

5 Putting the pieces together: Proof of Theorem 1

In this section we combine the main results from earlier sections, Theorem 3 from Section 3 and Theorem 5 from Section 4, together with standard results on learning discrete distributions, to prove Theorem 1.

5.1 Learning discrete distributions

We recall the following folklore result on learning a discrete distribution from independent samples:

► **Theorem 8.** *Fix $\gamma, \kappa > 0, N \in \mathbb{N}$. Let \mathcal{P} be an unknown probability distribution over the discrete set $\{1, \dots, N\}$, and let $\mathbf{S} = \{\mathbf{i}_1, \dots, \mathbf{i}_m\}$ be independent draws from \mathcal{P} , where $m = O((N/\kappa^2) \cdot \log(1/\gamma))$. Let $\hat{\mathcal{P}}_{\mathbf{S}}$ denote the empirical probability distribution over $[N]$ corresponding to \mathbf{S} . Then with probability at least $1 - \gamma$ over the draw of \mathbf{S} , the variation distance $d_{\text{TV}}(\hat{\mathcal{P}}_{\mathbf{S}}, \mathcal{P})$ is at most κ .*

We will need a corollary which says that removing low-frequency elements has only a negligible effect:

► **Corollary 9.** *Let \mathcal{P}, m and \mathbf{S} be as above. Let \mathbf{S}' be the subset of \mathbf{S} obtained by removing each element j whose frequency in \mathbf{S} is at most $\kappa/(2N)$, and let $\hat{\mathcal{P}}_{\mathbf{S}'}$ denote the empirical distribution over $[N]$ corresponding to \mathbf{S}' . Then with probability at least $1 - \gamma$ over the draw of \mathbf{S}' , $d_{\text{TV}}(\hat{\mathcal{P}}_{\mathbf{S}'}, \mathcal{P})$ is at most κ .*

Proof. By Theorem 8, with probability at least $1 - \delta$ the hypothesis $\hat{\mathcal{P}}_{\mathbf{S}}$ from Theorem 8 is $\kappa/2$ -close to \mathcal{P} . The corollary follows since the variation distance between $\hat{\mathcal{P}}_{\mathbf{S}}$ and $\hat{\mathcal{P}}_{\mathbf{S}'}$ is at most $N \cdot \kappa/(2N) = \kappa/2$. ◀

■ **Algorithm 2** Description of the main algorithm A .

Algorithm $A(n, s, \varepsilon, \delta_{\text{hard}}, \delta_{\text{fail}}, \mathcal{C}_{q,q'}(\mathcal{D}))$, with constants $q, q' \in [0, 1]$ as deletion and insertion rates.

Input: String length n , support size $s \leq \exp(\Theta(n^{1/3}))$, accuracy parameter $\varepsilon \geq \exp(-\Theta(n^{1/3}))$, fraction of hard support sets $\delta_{\text{hard}} \geq \exp(-\Theta(n^{1/3}))$, failure probability $\delta_{\text{fail}} \geq \exp(-\Theta(n^{1/3}))$, and access to $\mathcal{C}_{q,q'}(\mathcal{D})$ where \mathcal{D} is a probability distribution over s strings in $\{0, 1\}^n$.

Output: Either a probability distribution \mathcal{D}' or “fail.”

1. Draw T traces $\mathbf{y}^1, \dots, \mathbf{y}^T$ from $\mathcal{C}_{q,q'}(\mathcal{D})$, where

$$T = \frac{s}{\varepsilon^2} \cdot \exp\left(\Theta\left(\left(\log \max\left\{n, \frac{2s}{\delta_{\text{hard}}}\right\}\right)^{1/3}\right)\right) \cdot \log\left(\frac{3s}{\delta_{\text{fail}}}\right).$$

2. For each pair of traces $\mathbf{y}^i, \mathbf{y}^j$ with $1 \leq i < j \leq T$, run $A_{\text{cluster}}(n, \mathbf{y}^i, \mathbf{y}^j)$ from Section 4. If the $\binom{T}{2}$ -many outcomes of A_{cluster} (corresponding to $\binom{T}{2}$ many answers of “same” or “different”) do not correspond to a disjoint union of cliques then halt and output “fail,” otherwise continue.
3. Let the resulting clusters / cliques be denoted C_1, \dots, C_r , so $C_1 \sqcup \dots \sqcup C_r$ is a partition of the set $\{\mathbf{y}^1, \dots, \mathbf{y}^T\}$ of traces.^a Call C_i *large* if it contains at least $T \cdot (\varepsilon/(2s))$ many elements. Let $C'_1, \dots, C'_{r'}$ denote the large clusters for some $r' \leq r$, and let $C'_{\text{total}} = \sum_i |C'_i|$.
4. For each large multiset C'_i , run $A'_{\text{average-case}}$ from Section 3 using n and strings from C'_i , in which τ is set to $\delta_{\text{hard}}/(2s)$ and δ is set to $\delta_{\text{fail}}/(3s)$. Let z^i be the output of $A'_{\text{average-case}}$ on this input.
5. Distribution \mathcal{D}' that A outputs is supported on $z^1, \dots, z^{r'}$ and puts weight $|C'_i|/C'_{\text{total}}$ on z^i .

^a Strictly speaking, each C_i is a multiset.

5.2 Proof of Theorem 1

Algorithm A is given in Algorithm 2. Its proof of correctness is given below.

Proof. Suppose that the true underlying support of \mathcal{D} is $\mathcal{X} = (x^1, \dots, x^s)$ (as an ordered list). We consider s instances of algorithm $A'_{\text{average-case}}$ from Section 3, where each instance has parameters n , $\tau = \delta_{\text{hard}}/(2s)$ and $\delta = \delta_{\text{fail}}/(3s)$, and the i -th one runs on T^* many traces drawn from $\mathcal{C}_{q,q'}(x^i)$, where

$$T^* = \exp\left(\Theta\left(\left(\log \max\left\{n, \frac{2s}{\delta_{\text{hard}}}\right\}\right)^{1/3}\right)\right) \cdot \log\left(\frac{3s}{\delta_{\text{fail}}}\right)$$

as specified in Section 3 (so we have $T = (s/\varepsilon^2) \cdot T^*$). We say that \mathcal{X} is a *hard support* if either

- (a) At least one string x^i , $i \in [s]$, is hard for algorithm $A'_{\text{average-case}}$; or
- (b) After drawing T traces from $\mathcal{C}_{q,q'}(x^{(i)})$ for each $i \in [s]$, A_{cluster} fails on one of these $\binom{sT}{2}$ many pairs of traces with probability at least $\delta_{\text{fail}}/3$.

We consider a random support $\mathcal{X} = (x^1, \dots, x^s)$ drawn from $\{0, 1\}^n$ independently and uniformly. Theorem 3 says the probability of a uniform random string being hard for $A'_{\text{average-case}}$ is at most $\delta_{\text{hard}}/(2s)$. A union bound says the probability our support

satisfies (a) is at most $\delta_{\text{hard}}/2$. On the other hand, for each support \mathcal{X} , we let $\lambda(\mathcal{X})$ denote the probability that A_{cluster} fails on at least one of the $\binom{sT}{2}$ pairs. Theorem 5 implies $\mathbf{E}_{\mathcal{X}}[\lambda(\mathcal{X})] \leq \binom{sT}{2} \cdot \delta_{\text{cluster}} \leq (\delta_{\text{fail}}/3) \cdot \delta_{\text{hard}}/2$, where the last inequality follows by setting the constant hidden in the $\Theta(n^{1/3})$ of upper and lower bounds for $s, \varepsilon, \delta_{\text{hard}}$ and δ_{fail} to be sufficiently small (compared to the constant hidden in δ_{cluster}). By Markov, a random support satisfies (b) with probability at most $\delta_{\text{hard}}/2$. A union bound on (a) and (b) says the probability of a random support being hard is at most δ_{hard} .

If \mathcal{D}' is a probability distribution where $d_{\text{TV}}(\mathcal{D}, \mathcal{D}') \leq \varepsilon$, then we say that \mathcal{D}' is ε -accurate. It suffices to show that for a support \mathcal{X} that is not hard and an arbitrary distribution \mathcal{D} on that support set, the probability that our algorithm A fails to output an ε -accurate distribution \mathcal{D}' is at most δ_{fail} .

Our algorithm has three points of failure. In Step 2, it could fail to cluster the T traces correctly. Given the correct clustering in Step 2, it could fail to learn the underlying string for some cluster in Step 4. Finally, given the correct support, it could fail to output an ε -accurate distribution \mathcal{D}' in Step 5.

By the definition of hard supports we have that Step 2 returns an incorrect clustering with probability at most $\delta_{\text{fail}}/3$. Given a correct clustering in Step 2, each large C'_i will have at least $T \cdot (\varepsilon/2s) = T^*/\varepsilon \geq T^*$ elements. Since no x^i is hard for $A'_{\text{average-case}}$, by Theorem 3 the probability any instance of $A'_{\text{average-case}}$ fails is at most $\delta_{\text{fail}}/(3s)$. By a union bound, the probability of a Step 4 error is at most $\delta_{\text{fail}}/3$.

Since $T \geq \Omega((s/\varepsilon^2) \cdot \log(3/\delta_{\text{fail}}))$ and the large clusters are defined to have size at least a $\varepsilon/2s$ fraction of the number of traces, then by Corollary 9 with $N = s$, $\kappa = \varepsilon$, $\gamma = \delta_{\text{fail}}/3$, and $m = T$, given the correct support the probability that Step 5 fails to output an ε -accurate probability distribution is at most $\delta_{\text{fail}}/3$. By a union bound, the probability of failure on a support that is not hard is at most δ_{fail} .

By Theorem 5 Step 2 takes time $O(nT^2)$. By Theorem 3 Step 4 takes time $\text{poly}(n, s/\delta_{\text{hard}}, \log(1/\delta_{\text{fail}}))$. Step 5 takes time $O(s)$ to compute the weights used in \mathcal{D}' . Therefore, the overall running time of the algorithm is $\text{poly}(n, s, 1/\varepsilon, 1/\delta_{\text{hard}}, \log(1/\delta_{\text{fail}}))$. The theorem follows since the sample complexity T is at most $\text{poly}(s, 1/\varepsilon, \exp(\log^{1/3} n), \exp(\log^{1/3}(1/\delta_{\text{hard}})), \log(1/\delta_{\text{fail}}))$. ◀

A

 Deferred proof of Lemma 7

We recall Lemma 7:

Lemma 7 (restated). *Let \mathbf{r}, \mathbf{r}' be two n -patterns drawn independently from $\mathcal{R}_{n,q,q'}$. Then with probability at least $1 - \exp(-\Omega(n^{1/3}))$, the following three properties all hold:*

- (0): $|\mathbf{r}|, |\mathbf{r}'| \geq \alpha n/2$.
- (1): $|B_\ell(\mathbf{r}) \cap B_\ell(\mathbf{r}')| \geq \tau t$ for all $\ell \in [\tilde{s}]$.
- (2): If an $i \in [n]$ appears in both $B_\ell(\mathbf{r})$ and $B_{\ell'}(\mathbf{r}')$ for some $\ell, \ell' \in [\tilde{s}]$, then we have $\ell = \ell'$.

We will use the following tail bounds for sums of independent geometric random variables, which are special cases of results proved by [15].

► **Theorem 10** (Theorems 2.1 and 3.1 in [15]). *Let $p' \in (0, 1]$, and $\mathbf{X}_1, \dots, \mathbf{X}_n$ be independent Geometric(p') random variables. Let $\mathbf{X} = \sum_{i \in [n]} \mathbf{X}_i$ and $\mu = \mathbf{E}[\mathbf{X}] = n/p'$. Then the following holds:*

1. For any $\lambda \geq 1$, we have

$$\Pr[X \geq \lambda\mu] \leq \exp(-p'\mu(\lambda - 1 - \ln \lambda)).$$

2. For any $0 < \lambda \leq 1$, we have

$$\Pr[X \leq \lambda\mu] \leq \exp(-p'\mu(\lambda - 1 - \ln \lambda)).$$

Note that $\lambda - 1 - \ln \lambda \geq 0$ for all $\lambda > 0$, with equality only at $\lambda = 1$. We first derive a simpler expression for the tail bounds, using the following claim:

▷ **Claim 11.** Let $f : (-1, \infty) \rightarrow \mathbb{R}$ be defined as $f(x) = x - \ln(1 + x)$. The following properties hold: (i) $f(0) = 0$; (ii) $f(x) > x^2/4$ for all $x \in (-1, 1] \setminus \{0\}$; and (iii) $f(x) \geq x/4$ for all $x \geq 1$.

Proof. The claim follows from elementary calculus. For item (ii) it can be shown that $g(x) = f(x) - x^2/4$ attains its minimum value 0 at $x = 0$ and is strictly convex in $(-1, 1]$. For item (iii) it is easy to verify that $h(x) = f(x) - x/4$ satisfies $h'(x) > 0$ for all $x \geq 1$, and hence its minimum value is $h(1) \geq 0.05$. ◁

Letting $x = \lambda - 1$ in Theorem 10, this claim allows us to replace the $\lambda - 1 - \ln \lambda$ term in the exponent of the tail bounds by either $(\lambda - 1)^2/4$ or $(\lambda - 1)/4$, depending on whether $\lambda < 2$ or $\lambda \geq 2$.

Now, we state and prove a few claims that will be useful for proving Lemma 7. The first claim states that property (0) in Lemma 7 holds with probability at least $1 - \exp(-\Omega(n))$.

▷ **Claim 12.** With probability at least $1 - \exp(-\Omega(n))$, $\mathbf{r} \sim \mathcal{R}_{n,q,q'}$ satisfies that $|\mathbf{r}^{(1)}| \geq \alpha n/2$.

Proof. Let $\mathbf{r}^{(1)}$ be the random string defined earlier in the generation of $\mathbf{r} \sim \mathcal{R}_{n,q,q'}$. As $|\mathbf{r}^{(1)}|$ is a sum of n independent Geometric(p') random variables, we have $\mu = \mathbf{E}[|\mathbf{r}^{(1)}|] = n/p'$. Invoking Theorem 10 with $\lambda = 3/4$ and Part (1) of Claim 11 with $x = \lambda - 1$, the probability of $|\mathbf{r}^{(1)}| < 3n/(4p')$ is $\exp(-\Omega(n))$.

Fixing any realization $r^{(1)}$ of $\mathbf{r}^{(1)}$ with $|r^{(1)}| \geq 3n/(4p')$, it follows from the standard Chernoff bound that the probability of $|\mathbf{r}| < \alpha n/2 \leq (2p)/3 \cdot |r^{(1)}|$ is at most $\exp(-\Omega(n))$. This finishes the proof. ◁

Fix an $i \in [n]$. Let \mathbf{Y}_i^* be the random variable denoting the number of characters before i in $\mathbf{r}^{(1)}$ (after insertions). Recall that \mathbf{Y}_i denotes the number of characters before i in $\mathbf{r}^{(1)}$ that survive deletions; note that \mathbf{Y}_i is well-defined even if i is deleted. Then $\mathbf{E}[\mathbf{Y}_i^*] = (i/p') - 1$, and $\mathbf{E}[\mathbf{Y}_i] = p \cdot \mathbf{E}[\mathbf{Y}_i^*] = ((i/p') - 1)p$.

► **Lemma 13.** *For any $i \in [n]$, the probability that $|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \geq 0.05t$ is at most $\exp(-\Omega(n^{1/3}))$.*

Proof. Let $\varepsilon = 0.05$ in the proof. We have

$$|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \leq |\mathbf{Y}_i - p\mathbf{Y}_i^*| + |p\mathbf{Y}_i^* - p\mathbf{E}[\mathbf{Y}_i^*]| = |\mathbf{Y}_i - p\mathbf{Y}_i^*| + p \cdot |\mathbf{Y}_i^* - \mathbf{E}[\mathbf{Y}_i^*]|.$$

We first show that $|\mathbf{Y}_i^* - \mathbf{E}[\mathbf{Y}_i^*]| \leq \varepsilon t/(2p)$ with probability at least $1 - \exp(-\Omega(n^{1/3}))$. Next conditioning on any fixed realization $r^{(1)}$ of $\mathbf{r}^{(1)}$ with $|\mathbf{Y}_i^* - \mathbf{E}[\mathbf{Y}_i^*]| \leq \varepsilon t/(2p)$ (in particular this implies that $\mathbf{Y}_i^* = O(n)$) we show that $|\mathbf{Y}_i - p\mathbf{Y}_i^*| \leq \varepsilon t/2$ with probability at least $1 - \exp(-\Omega(n^{1/3}))$. The lemma then follows by combining these two steps. Given that the second step follows from the Hoeffding bound (with $\mathbf{Y}_i^* = O(n)$ and $t = n^{2/3}$), we focus on the first part in the rest of the proof.

First we analyze the lower tail, i.e., the probability of $\mathbf{Y}_i^* - \mathbf{E}[\mathbf{Y}_i^*] \leq -\varepsilon t/(2p)$. Because $\mathbf{Y}_i^* \geq 0$ we may assume $\mathbf{E}[\mathbf{Y}_i^*] > \varepsilon t/(2p)$ (otherwise $\mathbf{Y}_i^* \geq \mathbf{E}[\mathbf{Y}_i^*] - \varepsilon t/(2p)$ trivially). Let

$$\lambda = 1 - \frac{\varepsilon t}{2p\mathbf{E}[\mathbf{Y}_i^*]} \quad \text{and} \quad x = \lambda - 1 = -\frac{\varepsilon t}{2p\mathbf{E}[\mathbf{Y}_i^*]},$$

so that $\lambda\mathbf{E}[\mathbf{Y}_i^*] = \mathbf{E}[\mathbf{Y}_i^*] - \varepsilon t/(2p)$. By Theorem 10 and Part (1) of Claim 11, we have

$$\Pr \left[\mathbf{Y}_i^* \leq \mathbf{E}[\mathbf{Y}_i^*] - \frac{\varepsilon t}{2p} \right] \leq \exp \left(-\Omega \left(\mathbf{E}[\mathbf{Y}_i^*] \cdot \frac{t^2}{\mathbf{E}[\mathbf{Y}_i^*]^2} \right) \right) \leq \exp \left(-\Omega \left(\frac{t^2}{n} \right) \right) = \exp(-\Omega(n^{1/3})).$$

For the second inequality, we used the fact that $\mathbf{E}[\mathbf{Y}_i^*] = O(n)$. Similarly, we analyze the upper tail. Let

$$\lambda = 1 + \frac{\varepsilon t}{2p\mathbf{E}[\mathbf{Y}_i^*]} \quad \text{and} \quad x = \lambda - 1 = \frac{\varepsilon t}{2p\mathbf{E}[\mathbf{Y}_i^*]}.$$

If $\lambda \leq 2$, Theorem 10 and Part (1) of Claim 11 imply that

$$\Pr \left[\mathbf{Y}_i^* \geq \mathbf{E}[\mathbf{Y}_i^*] + \frac{\varepsilon t}{2p} \right] \leq \exp \left(-\Omega \left(\mathbf{E}[\mathbf{Y}_i^*] \cdot \frac{t^2}{\mathbf{E}[\mathbf{Y}_i^*]^2} \right) \right) \leq \exp \left(-\Omega \left(\frac{t^2}{n} \right) \right) = \exp(-\Omega(n^{1/3})).$$

On the other hand, if $\lambda \geq 2$, then $x \geq 1$. By Theorem 10 and Part (2) of Claim 11, we have

$$\Pr \left[\mathbf{Y}_i^* \geq \mathbf{E}[\mathbf{Y}_i^*] + \frac{\varepsilon t}{2p} \right] \leq \exp \left(-\Omega \left(\mathbf{E}[\mathbf{Y}_i^*] \cdot \frac{t}{\mathbf{E}[\mathbf{Y}_i^*]} \right) \right) \leq \exp(-\Omega(t)) = \exp(-\Omega(n^{2/3})).$$

This finishes the proof of the lemma. ◀

We are ready to prove Lemma 7.

Proof of Lemma 7. We work on the three events separately and apply a union bound at the end.

(0): It follows from Claim 12 that property (0) holds with probability at least $1 - \exp(-\Omega(n))$.

(1): Fix $\ell \in [\tilde{s}]$. Recall that $I_\ell = [(2\ell - 2)t + 1, (2\ell - 1)t] \cap \mathbb{Z}$. Let

$$I_\ell^{(0)} := \left[\frac{p'}{p}(2\ell - 1.9)t + 1, \frac{p'}{p}(2\ell - 1.1)t \right] \cap \mathbb{Z}.$$

Then $I_\ell^{(0)} \subset [n]$. We will show that with probability at least $1 - \exp(-\Omega(n^{1/3}))$, both properties below hold:

- (a) At least $0.7tpp'$ elements in $I_\ell^{(0)}$ survive in both \mathbf{r} and \mathbf{r}' ;
- (b) If an element $i \in I_\ell^{(0)}$ survives in both \mathbf{r} and \mathbf{r}' , then $i \in B_\ell(\mathbf{r}) \cap B_\ell(\mathbf{r}')$.

Given that (a) and (b) together imply property (1), we have that property (1) holds for $\ell \in [\tilde{s}]$ with probability at least $1 - \exp(-\Omega(n^{1/3}))$. A union bound over all $\ell \in [\tilde{s}]$ implies that property (1) holds for all $\ell \in [\tilde{s}]$ with probability at least $1 - \tilde{s} \cdot \exp(-\Omega(n^{1/3})) = 1 - \exp(-\Omega(n^{1/3}))$.

So it suffices to show that (a) and (b) happen with probability at least $1 - \exp(-\Omega(n^{1/3}))$. For (a), it follows from a standard Chernoff bound that (a) holds with probability at least $1 - \exp(-\Omega(n^{2/3}))$. For (b), let i_0 and i_1 be the left and right endpoints of $I_\ell^{(0)}$, respectively. Let $\mathbf{Y}_{i_0}, \mathbf{Y}_{i_1}$ ($\mathbf{Y}'_{i_0}, \mathbf{Y}'_{i_1}$) be as defined earlier with respect to \mathbf{r} (\mathbf{r}'). Note that $\mathbf{E}[\mathbf{Y}_{i_0}] = ((i_0/p') - 1)p$ and $\mathbf{E}[\mathbf{Y}_{i_1}] = ((i_1/p') - 1)p$. Then by Lemma 13 (and a union bound), with probability at least $1 - 4\exp(-\Omega(n^{1/3}))$, we have:

$$\mathbf{Y}_{i_0} \geq \mathbf{E}[\mathbf{Y}_{i_0}] - 0.05t > (2\ell - 2)t \quad \text{and} \quad \mathbf{Y}_{i_1} \leq \mathbf{E}[\mathbf{Y}_{i_1}] + 0.05t < (2\ell - 1)t,$$

and the same holds for \mathbf{Y}'_{i_0} and \mathbf{Y}'_{i_1} . When all these events occur, then clearly all characters in $I_\ell^{(0)}$ that survive in \mathbf{r}, \mathbf{r}' are in I_ℓ in both n -patterns. This finishes the analysis of property (1).

- (2): Suppose a character $i \in [n]$ appears in $B_\ell(\mathbf{r})$ and $B_{\ell'}(\mathbf{r}')$ for some $\ell \neq \ell'$. Let $\mathbf{Y}_i, \mathbf{Y}'_i$ denote the number of characters before i in \mathbf{r}, \mathbf{r}' respectively. Then $\mathbf{E}[\mathbf{Y}_i] = \mathbf{E}[\mathbf{Y}'_i]$. As any two distinct blocks are separated by at least t positions in the n -patterns, we have $|\mathbf{Y}_i - \mathbf{Y}'_i| \geq t$. Triangle inequality implies that $|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \geq t/2$ or $|\mathbf{Y}'_i - \mathbf{E}[\mathbf{Y}'_i]| \geq t/2$. Assume without loss of generality that $|\mathbf{Y}_i - \mathbf{E}[\mathbf{Y}_i]| \geq t/2 > 0.05t$. Instantiating Lemma 13, we conclude that this event happens with probability at most $n \cdot \exp(-\Omega(n^{1/3}))$ which remains $\exp(-\Omega(n^{1/3}))$.

The lemma follows from a union bound. ◀

Improved Pseudorandom Generators from Pseudorandom Multi-Switching Lemmas

Abstract

We give the best known pseudorandom generators for two touchstone classes in unconditional derandomization: small-depth circuits and sparse \mathbb{F}_2 polynomials. Our main results are an ε -PRG for the class of size- M depth- d AC^0 circuits with seed length $\log(M)^{d+O(1)} \cdot \log(1/\varepsilon)$, and an ε -PRG for the class of S -sparse \mathbb{F}_2 polynomials with seed length $2^{O(\sqrt{\log S})} \cdot \log(1/\varepsilon)$. These results bring the state of the art for unconditional derandomization of these classes into sharp alignment with the state of the art for computational hardness for all parameter settings: improving on the seed lengths of either PRG would require breakthrough progress on longstanding and notorious circuit lower bounds.

The key enabling ingredient in our approach is a new *pseudorandom multi-switching lemma*. We derandomize recently-developed *multi-switching lemmas*, which are powerful generalizations of Håstad’s switching lemma that deal with *families* of depth-two circuits. Our pseudorandom multi-switching lemma – a randomness-efficient algorithm for sampling restrictions that simultaneously simplify all circuits in a family – achieves the parameters obtained by the (full randomness) multi-switching lemmas of Impagliazzo, Matthews, and Paturi [39] and Håstad [35]. This optimality of our derandomization translates into the optimality (given current circuit lower bounds) of our PRGs for AC^0 and sparse \mathbb{F}_2 polynomials.

1 Introduction

Switching lemmas. Switching lemmas, first established in a series of breakthrough works in the 1980s [4, 29, 71, 34], are fundamental results stating that depth-two circuits (ORs of ANDs or vice versa) simplify dramatically when they are “hit with a random restriction.” They are a powerful technique in circuit complexity, and are responsible for a remarkable suite of hardness results concerning small-depth Boolean circuits (AC^0). Switching lemmas

are at the heart of several near-optimal bounds on AC^0 circuits, such as essentially optimal correlation bounds against the PARITY function [39, 35] and the worst-case and average-case depth hierarchy theorems of [34, 59, 36]. Indeed, comparably strong results are lacking (and are major open problems) for seemingly small extensions of AC^0 , such as AC^0 augmented with parity or mod- p gates, for which switching lemmas do not apply; this gap highlights the importance of switching lemmas as a proof technique.

Switching lemmas are versatile as well as powerful: many results in circuit complexity rely on sophisticated variants and generalizations of the “standard” switching lemmas. Recent examples include the aforementioned correlation bounds and average-case depth hierarchy theorems, as well as powerful lower bounds on the circuit complexity of the CLIQUE problem [12, 57], lower bounds on the small-depth circuit complexity of ST-CONNECTIVITY [25], and lower bounds against AC^0 formulas [58]. Beyond the immediate arena of circuit lower bounds, switching lemmas are also important tools in diverse areas including propositional proof complexity [54, 43, 55, 37], computational learning theory [44], the design of circuit satisfiability algorithms [13, 39], and coding theory [23, 10].

This paper is about the role of switching lemmas in the study of *unconditional pseudorandomness*. Switching lemmas have a long history in this area; indeed, arguably the first work in unconditional derandomization, the seminal paper of Ajtai and Wigderson [6], was based on a *pseudorandom* switching lemma, which they used to give the first non-trivial pseudorandom generator for AC^0 . (Interestingly, after many subsequent developments described in detail in Section 2, we come full circle in this paper and use the [6] framework to give a new pseudorandom generator for AC^0 that is essentially best possible without improving longstanding circuit lower bounds.) One key contribution that we make in this paper is to bring together two important generalizations of standard switching lemmas, one quite old and one very new:

- (i) *pseudorandom* switching lemmas (originating in [6]), which employ pseudorandom rather than “fully random” restrictions, and
- (ii) recently developed *multi-switching lemmas* [39, 35] which simultaneously simplify all of the depth-two circuits in a family of such circuits, rather than a single depth-two circuit as is the case for standard switching lemmas.

Let us discuss each of these generalizations in turn.

Pseudorandom switching lemmas. The (truly) random restrictions that are used in standard switching lemmas make a coordinatewise-independent random choice for each input variable x_1, \dots, x_n of whether to map it to 0, to 1, or to leave it unassigned (map it to *); standard switching lemmas show that a depth-two circuit simplifies dramatically with very high probability when it is hit with such a random restriction. Such “truly random” restrictions are inherently incompatible with unconditional derandomization, which naturally motivates the notion of a *pseudorandom* switching lemma. Such a result defines a much smaller probability space of “pseudorandom” restrictions, and proves that a restriction drawn randomly from this space also has the effect of simplifying a depth-two circuit with high probability. While pseudorandom switching lemmas have been the subject of much research since they were first introduced by Ajtai and Wigderson [6, 5, 24, 3, 32, 39, 31, 65, 30], and have been applied in a range of different ways in unconditional derandomization, they are not yet fully understood.

The designer of a pseudorandom switching lemma faces an inherent tension between achieving strong parameters – intuitively, having a depth-two circuit simplify as much as possible while keeping a large fraction of variables alive – and using as little randomness as

possible. Prior to the work of Trevisan and Xue [65], known pseudorandom switching lemmas fell short of achieving the parameters of Håstad’s influential “full randomness” switching lemma [34]. In particular, a parameter of central importance in essentially all applications of switching lemmas is the probability that a given coordinate x_i remains alive under a random (or pseudorandom) restriction; this is often referred to as the “*-probability” and denoted by p . A crucial quantitative advantage of Håstad’s switching lemma over previous works is that it can be applied even when p is as large as $\Omega(1/\log n)$ for $\text{poly}(n)$ -size depth-two circuits – in contrast, the earlier works of [4, 29, 71] required $p = n^{-\Omega(1)}$ – and yields a very strong conclusion, namely that with high probability the restricted circuit collapses to a shallow decision tree¹. (For example, while the recent pseudorandom switching lemma of [31] is able to achieve a relatively large p , the conclusion of that switching lemma is that the restricted depth-two circuit can w.h.p. be sandwiched by depth-two circuits with small bottom fan-in, which is weaker than the aforementioned decision tree conclusion.)

Trevisan and Xue [65] give a *pseudorandom* switching lemma that is highly randomness efficient and yet achieves the parameters of Håstad’s fully random switching lemma (i.e. [65] achieves the same simplification, collapsing to a shallow decision tree, that follows from [34], with the same *-parameter p as [34]). The key conceptual ingredient enabling this is a beautiful idea of “fooling the proof” of the Håstad’s switching lemma, exploiting its “computational simplicity”. Trevisan and Xue leverage their pseudorandom switching lemma to construct a new pseudorandom generator for AC^0 , obtaining the first improvement of Nisan’s celebrated PRG [52] in over two decades. We elaborate on Trevisan and Xue’s ideas and how they obtain their PRG later in Section 2.1.

Multi-switching lemmas. The switching lemma shows that any width- k CNF formula collapses to a shallow decision tree with high probability under a random restriction. Via a simple union bound it is of course possible to extend this result to say that a family of width- k CNF formulas will all collapse to a shallow decision tree with high probability under a random restriction; but this naive approach leads to a quantitative loss in parameters if the argument is iterated, as it typically is, $d - 1$ times to analyze a depth- d circuit. (The exact nature of this quantitative loss is important but somewhat subtle; see Section 3 for a detailed explanation.)

Via an ingenious extension of the ideas underlying the original switching lemma, Håstad [35] developed “multi-switching lemmas” that essentially bypass this quantitative loss in parameters that results from iterating a naive union bound (see also the work of Impagliazzo, Matthews, and Paturi [39] for closely related results). Roughly speaking, [35] shows that a *family* of width- k CNF formulas will with high probability have a shallow *common partial decision tree*. Without explaining this structure in detail here (again see Section 3 for a detailed explanation), this makes it possible to iterate the argument and tackle depth- d circuits without incurring a quantitative loss in parameters. The savings thus achieved is the key new ingredient that allowed [39, 35] to achieve essentially optimal correlation bounds for AC^0 against the PARITY function, capping off a long line of work [4, 71, 34, 19, 8, 13]. These ideas have also been leveraged to achieve new algorithmic results such as better-than-brute-force satisfiability algorithms and distribution-free PAC learning algorithms for AC^0 [13, 39, 60].

¹ The first published version of the switching lemma with a decision tree conclusion is due to Cai [19]; several authors subsequently noted that Håstad’s argument also yields such a conclusion.

A pseudorandom multi-switching lemma. A core technical contribution of this paper is to bring together these two lines of work, on pseudorandom switching lemmas and on multi-switching lemmas. Since the precise statement of our pseudorandom multi-switching lemma, Theorem 14, is somewhat involved we defer it to Section 4 and here merely make some remarks about it. In the spirit of Trevisan and Xue’s derandomization of the original switching lemma, to obtain Theorem 14 we “fool the proof” of Håstad’s multi-switching lemma [35], exploiting its “computational simplicity”. This enables us to achieve optimal parameters in the same sense as [65], namely, that it establishes the same dramatic simplification – now of the family \mathcal{F} of depth-two circuits – as [35], and while only requiring the same ϵ -probability p as [35]. Our pseudorandom switching lemma is highly efficient in its use of randomness; this randomness efficiency is crucial in the constructions of our pseudorandom generators for AC^0 circuits and sparse \mathbb{F}_2 polynomials using Theorem 14, which we now describe in the next section.²

2 PRGs for AC^0 and sparse \mathbb{F}_2 polynomials

We employ our pseudorandom multi-switching lemma to give the best known pseudorandom generators for two canonical classes in unconditional derandomization: AC^0 circuits and sparse \mathbb{F}_2 polynomials. As we describe in this section, our results bring the state of the art for unconditional derandomization of these classes into sharp alignment with the state of the art for computational hardness: improving on the seed lengths of either PRG would require breakthrough progress on longstanding and notorious circuit lower bounds. In this sense, our results are in the same spirit as those of Imagliazzo, Meka, and Zuckerman [40], which gave optimal (assuming current circuit lower bounds) pseudorandom generators for various classes of Boolean formulas and branching programs; however, our techniques are very different from those of [40].

2.1 PRGs for AC^0 circuits

The class of small-depth Boolean circuits (AC^0) is a class of central interest in unconditional derandomization, and has been the subject of intensive research in this area over the past 30 years [6, 45, 52, 53, 50, 49, 41, 64, 66, 11, 56, 18, 42, 26, 2, 1, 62, 47, 28, 32, 31, 65, 30, 63, 33, 21]. This highly successful line of work on derandomizing AC^0 has generated a wealth of ideas and techniques that have become mainstays in the field of pseudorandomness. A prominent example is Nisan’s celebrated PRG for AC^0 circuits [52], which introduced ideas that enriched the surprising connections between pseudorandomness and computational hardness [14, 70, 53]. The *hardness-versus-randomness paradigm* asserts, qualitatively, that strong explicit PRGs exist if and only if strong explicit circuit lower bounds exist. In the context of unconditional derandomization (the subject of this work), this strongly motivates the goal of constructing, for every circuit class \mathcal{C} , unconditional PRGs for \mathcal{C} that are best possible given the current best lower bounds for \mathcal{C} . In other words, this is the goal of achieving a *quantitatively optimal hardness to randomness conversion* for \mathcal{C} , converting “all the hardness” in our lower bounds for \mathcal{C} into pseudorandomness for \mathcal{C} .

² While our focus in this work is on unconditional derandomization, we briefly mention that recent work of Ball et al. [10] establishes a new connection between pseudorandom switching lemmas and *non-malleable codes* in coding theory [27]. Using this connection, [10] are able to leverage the randomness efficiency of [65]’s pseudorandom switching lemma in their design of new non-malleable codes for small-depth circuits. We leave the possibility of applying our techniques to obtain further-improved non-malleable codes as an interesting avenue for future work.

For \mathcal{C} being the class of n -variable size- M depth- d AC^0 circuits this amounts to constructing PRGs with seed length $\log^{d-1}(Mn) \log(1/\varepsilon)$: such seed length is best possible without improving longstanding AC^0 lower bounds that date back to the 1980s [34]. (More precisely, it is well known, see e.g. [65], that achieving seed length say $\log^{d-1.01}(Mn) \log(1/\varepsilon)$ would yield $\exp(\omega(n^{1/(d-1)}))$ size lower bounds against depth- d AC^0 circuits, which is a barrier that has stood for over 30 years even in the $d = 3$ case.) We give the first construction of a PRG that achieves this seed length up to an *additive* absolute constant in the exponent of $\log(Mn)$:

► **Theorem 1** (PRG for AC^0 circuits). *For every $d \geq 2$, $M \in \mathbb{N}$ and $\varepsilon > 0$, there is an ε -PRG for the class of n -variable size- M depth- d circuits with seed length $\log^{d+O(1)}(Mn) \log(1/\varepsilon)$.*

2.1.1 Background and prior PRGs for AC^0 circuits

As noted above there has been a significant body of work on PRGs for AC^0 circuits, spanning over 30 years. In this section we give a brief overview of the history and prior state-of-the-art for this touchstone problem in unconditional derandomization.

Ajtai–Wigderson and Nisan. Ajtai and Wigderson, in their seminal work [6] pioneering the study of unconditional derandomization, constructed the first non-trivial PRG for AC^0 circuits with an $n^{o(1)}$ seed length; we will discuss their techniques in detail later. [6]’s seed length was improved significantly in the celebrated work of Nisan [52], using what is now known as the Nisan–Wigderson framework [53], which provides a generic template for converting correlation bounds against a circuit class to PRGs for a closely related class (in the case of AC^0 these two classes essentially coincide). Via this approach Nisan showed how correlation bounds for AC^0 against the PARITY function [34] yield a PRG with seed length $\log^{2d+O(1)}(Mn/\varepsilon)$.

We remark that the generality of the Nisan–Wigderson framework comes at a quantitative price: it is straightforward to verify that a seed length of $(\log^d(Mn) + \log(1/\varepsilon))^2$ is the best that can be achieved via this framework given current AC^0 circuit lower bounds (see e.g. [65, 33]). This is roughly quadratically worse than the sought-for $\log^{d-1}(Mn) \log(1/\varepsilon)$, the best that can be achieved assuming *only* current AC^0 circuit lower bounds.

Bounded independence fools AC^0 . Nisan’s seed length for AC^0 circuits stood unmatched for more than two decades. However, in this interim period there was significant progress on showing that distributions with bounded independence fool AC^0 , a well-known conjecture posed by Linial and Nisan [45]. Braverman’s breakthrough result [18] showed that polylog(n)-wise independence fools AC^0 , which (along with standard constructions of k -wise independent distributions) gave a PRG with seed length $\log^{O(d^2)}(Mn/\varepsilon)$; this was subsequently sharpened to $\log^{3d+O(1)}(Mn/\varepsilon)$ by Tal [63]. Recently, Harsha and Srinivasan [33] further improved the seed length of Braverman’s generator to $\log^{3d+O(1)}(Mn) \log(1/\varepsilon)$, which is notable for its optimal dependence on the error parameter ε .

The work of Trevisan and Xue. Recent work of Trevisan and Xue [65] makes a significant advance towards achieving seed length $\log^{d-1}(Mn) \log(1/\varepsilon)$: their work circumvents the “quadratic loss” associated with the Nisan–Wigderson framework with a PRG of seed length $\log^{d+O(1)}(Mn/\varepsilon)$. This is the first PRG to achieve a $\log^{d+O(1)}(Mn)$ dependence, an exponent that is within an *additive* absolute constant of the sought-for $\log^{d-1}(Mn)$, and is also the first strict improvement on Nisan’s seed length in more than two decades. (Note however, that like Nisan’s PRG the dependence on ε is suboptimal: $\log^{d+O(1)}(1/\varepsilon)$ instead of $\log(1/\varepsilon)$.)

Rather than going through the Nisan–Wigderson framework – which, as noted above, carries with it an associated quantitative loss in parameters – Trevisan and Xue construct their PRG by *derandomizing the proof* of AC^0 lower bounds, “opening up the black-box” of AC^0 lower bounds, so to speak. At a high level, [65] adopts the strategy employed in the early work of Ajtai and Wigderson [6]. We describe this strategy in detail in the full version of this paper, but roughly speaking, Ajtai and Wigderson introduced a powerful and generic framework for constructing PRGs from pseudorandom switching lemmas. In [6], they instantiated this framework with a derandomization of Ajtai’s switching lemma [4] – which underlies his proof of the first superpolynomial lower bounds against AC^0 – to obtain the first non-trivial PRG for AC^0 . Trevisan and Xue obtain their PRG by revisiting this early framework of [6], instantiating it with their derandomization of Håstad’s switching lemma [34]. (And as we will soon discuss, in this work we obtain our PRG by instantiating the [6] framework with our derandomization of the [35] multi-switching lemmas.)

PRGs via polarizing random walks. Finally, in recent exciting work Chattopadhyay, Hatami, Hosseini, and Lovett [21] have introduced an elegant new framework for obtaining pseudorandom generators which has consequences for fooling AC^0 . Their framework is based on a notion of “fractional” pseudorandom generators, which are used as steps in a random walk which ultimately yields a (standard) pseudorandom generator. [21] show that if a class \mathcal{C} is closed under restrictions and has sufficiently strong Fourier concentration on low-degree coefficients, then almost k -wise independence suffice to yield a fractional PRG, which their random walk approach can then convert into a standard PRG against \mathcal{C} . Using Tal’s sharp bounds [63] on the Fourier concentration of AC^0 , they obtain a seed length of $O(\log(n/\varepsilon)(\log(\log(n)/\varepsilon)) \log^{2d-2} M)$ for size- M depth- d circuits.

2.1.2 Our PRG and approach

To summarize, prior to our work there were three incomparable best known PRGs for AC^0 , achieving three different tradeoffs in the overall dependence on M, d and $1/\varepsilon$. These were the PRG of Trevisan and Xue [65], which has seed length $\log^{d+O(1)}(Mn/\varepsilon)$; Harsha and Srinivasan’s improvement of Braverman’s generator [33], which has seed length $\log^{3d+O(1)}(Mn) \log(1/\varepsilon)$; and the [21] PRG, which has seed length $O(\log(n/\varepsilon)(\log(\log(n)/\varepsilon)) \cdot \log^{2d-2} M)$, i.e. essentially $\log^{2d-1}(Mn) \log^2(1/\varepsilon)$.

Theorem 1 unifies and improves these three incomparable seed lengths. Our PRG achieves an essentially optimal hardness to randomness conversion for AC^0 : our seed length of $\log^{d+O(1)}(Mn) \log(1/\varepsilon)$ comes very close to $\log^{d-1}(Mn) \log(1/\varepsilon)$, which is best possible without improving longstanding AC^0 circuit lower bounds that date back to the 1980s.

Table 1 provides a comparison of the seed length of our PRG (and the techniques that underlie our construction) and those of previous work.

Our approach. Our approach draws on and unifies ideas in the works of [6, 65, 33] discussed above, which we use in conjunction with our derandomization of the [35] multi-switching lemma to obtain our PRG.

At a high level, we adopt the overall conceptual strategy of Ajtai and Wigderson [6] and Trevisan and Xue [65], and obtain our PRG by derandomizing the proof of AC^0 lower bounds. The key technical ingredient in our PRG construction is our pseudorandom multi-switching lemma, a derandomization of the multi-switching lemmas which underlie the [39, 35] optimal correlation bounds for AC^0 against PARITY. Our pseudorandom multi-switching lemma improves both the pseudorandom switching lemma of [65] (a derandomization of Håstad’s

switching lemma [34] which underlies his exponential lower bounds against AC^0) and the pseudorandom switching lemma of [6] (a derandomization of Ajtai’s switching lemma [4] which underlies his superpolynomial lower bounds against AC^0).

Our derandomization of the [35] multi-switching lemma is largely influenced by Trevisan and Xue’s derandomization of the Håstad’s original switching lemma [34]. We describe our approach in detail in Section 4, but highlight here the simple but ingenious new idea underlying [65]’s argument. Very roughly speaking, they derandomize the [34] switching lemma by “fooling its proof”: showing that Håstad’s proof of his switching lemma “cannot δ -distinguish” between truly random restrictions and pseudorandom restrictions drawn from $\text{polylog}(n)$ -wise independent distributions. Since Håstad’s switching lemma holds for truly random restrictions, it thus follows that it also holds for pseudorandom restrictions drawn from $\text{polylog}(n)$ -wise independent distributions (up to a δ additive loss in the failure probability).

To accomplish this, Trevisan and Xue exploit the fact that Håstad’s proof of the switching lemma is “computationally simple”: for a fixed k -CNF F , there is a small depth-3 circuit that takes as input an encoding of a restriction ρ , and outputs 1 iff ρ is a bad restriction for the desired conclusion of Håstad’s switching lemma, contributing to its failure probability (more precisely, the failure event is that the “canonical decision tree” for $F \upharpoonright \rho$ has large depth). In similar spirit, our derandomization of the [35] multi-switching lemma also exploits the “computational simplicity” of its proof. In our case, for a fixed family \mathcal{F} of k -CNF formulas we construct a small depth-4 circuit for recognizing bad restrictions (the one additional layer of depth reflects the fact that multi-switching lemmas are, roughly speaking, “one quantifier more complex” than switching lemmas). To obtain optimal parameters in our PRG constructions, we use the $d = 3$ case of Harsha and Srinivasan’s strengthening of Braverman’s generator [33] to fool this depth-4 circuit, and hence show that [35]’s proofs of the multi-switching lemmas “cannot distinguish” between truly random and pseudorandom restrictions. The fact that [33] achieves an optimal $\log(1/\varepsilon)$ seed length dependence plays a crucial role in enabling the optimal $\log(1/\varepsilon)$ seed length dependence of our PRG.

2.2 PRGs for sparse \mathbb{F}_2 polynomials

Our second main result deals with the class of sparse \mathbb{F}_2 polynomials. Like AC^0 circuits, sparse \mathbb{F}_2 polynomials and low-degree \mathbb{F}_2 polynomials have been extensively studied in unconditional derandomization [51, 7, 50, 15, 66, 46, 68, 16, 47, 48, 22].

Via the hardness-versus-randomness paradigm, the problem of derandomizing \mathbb{F}_2 polynomials is intimately related to that of proving correlation bounds for \mathbb{F}_2 polynomials. A prominent open problem in the latter context – arguably the current flagship challenge in this area – is that of obtaining superpolynomially small correlation bounds against \mathbb{F}_2 polynomials of degree $\log n$. Degree $\log n$ represents the fundamental limit of our current suite of powerful techniques for proving \mathbb{F}_2 correlation bounds [9, 17, 20, 69], and breaking this “degree $\log n$ barrier” would constitute a significant technical breakthrough³. See Open Question 1 of Viola’s excellent survey [67] for a detailed discussion of this important open problem and its relationship with other central challenges in complexity theory.

As a second application of our pseudorandom multi-switching lemma, we give an ε -PRG for S -sparse \mathbb{F}_2 polynomials with seed length $2^{O(\sqrt{\log S})} \log(1/\varepsilon)$, which is best possible without breaking the aforementioned “degree $\log n$ barrier” for \mathbb{F}_2 correlation bounds:

► **Theorem 2 (PRG for sparse \mathbb{F}_2 polynomials).** *For every $S = 2^{\omega(\log \log n)^2}$ and $\varepsilon > 0$ there is a PRG with seed length $2^{O(\sqrt{\log S})} \log(1/\varepsilon)$ that ε -fools the class of n -variable S -sparse \mathbb{F}_2 polynomials.*

Background and prior PRGs for \mathbb{F}_2 polynomials. The first unconditional PRGs for \mathbb{F}_2 polynomials were given in early influential work of Luby, Veličković, and Wigderson [50], who constructed a PRG that ε -fools size- S $\text{SYM} \circ \text{AND}$ circuits – including S -sparse \mathbb{F}_2 polynomials as an important special case – with seed length $2^{O(\sqrt{\log(S/\varepsilon)})}$. To obtain their PRG, Luby et al. employed the Nisan–Wigderson framework [53] together with multi-party number-on-the-forehead (NOF) communication complexity lower bounds from the seminal work of Babai, Nisan, and Szegedy [9]. Viola [66] subsequently extended this $2^{O(\sqrt{\log(S/\varepsilon)})}$ seed length to the broader class of $\text{SYM} \circ \text{AC}^0$ circuits with a more modular proof. In recent work [61], the authors have improved the seed length dependence on ε of [50, 66] to $2^{O(\sqrt{\log(S)})} + \text{polylog}(1/\varepsilon)$. We discuss the relation between our techniques and those of [61] in more detail below.

In a related line of work, PRGs for *low-degree* \mathbb{F}_2 polynomials have also been intensively studied. Starting with the fundamental results of Naor and Naor [51] on ε -biased distributions (which resolved the degree-1 case), this research continued through an exciting line of work on the degree $k \geq 2$ case [15, 16] and culminated in the breakthroughs of Lovett [46] and Viola [68] which are described in more detail below. It is interesting to note that prior to our work, the underlying techniques used for the sparse case (multi-party communication complexity) are completely different from the techniques used for the low-degree case (Fourier analysis).

Our PRG and approach. Theorem 2 gives an exponential and optimal improvement of the PRG of [50] in terms of its dependence on the error parameter ε . Our PRG achieves an optimal hardness to randomness conversion for \mathbb{F}_2 polynomials: since every $\log(n)$ -degree \mathbb{F}_2 polynomial has at most $n^{\log n}$ monomials, it can be shown (using the simple Proposition 3.1 of [68]) that a PRG with seed length $2^{o(\sqrt{\log S})} \log(1/\varepsilon)$ would break the degree $\log n$ barrier.

³ Breaking this “degree $\log n$ barrier” is also well-known (via a simple and beautiful observation of Håstad and Goldmann [38]) to be a prerequisite for breaking the notorious “ $\log n$ party barrier” in multi-party communication complexity [9], a longstanding open problem that has resisted attack for over two decades.

Our techniques for Theorem 2 are substantially different from the techniques of [61, 66]. As summarized in Table 2, the basic approach of [61], like [66] and [50], is via the Nisan–Wigderson paradigm using multi-party communication complexity bounds; the main point of departure between [61] and [66] is that [61] leverages Håstad’s multi-switching lemma from [35] in place of his earlier [34] switching lemma which was used in [66]. (We note that similar to the situation for AC^0 circuits, it is straightforward to verify that our optimal $\log(1/\varepsilon)$ dependence is not achievable via the Nisan–Wigderson framework without dramatic breakthroughs in correlation bounds for \mathbb{F}_2 polynomials, going well beyond breaking the degree $\log n$ barrier.) In contrast, we do not use the Nisan–Wigderson framework or multi-party communication complexity lower bounds; instead, as for AC^0 , our approach is based on the [6] framework and our *derandomization* of the [35] multi-switching lemma. Indeed, our approach to obtaining Theorem 2 bridges the two previously disparate lines of work on pseudorandomness for sparse and low degree polynomials: roughly speaking, it can be viewed as a reduction from PRGs for S -sparse polynomials to PRGs for degree- $\sqrt{\log S}$ polynomials. This allows us to leverage the result of Viola [68] (building on the work of Lovett [46]), which gives PRGs for n -variable degree- k \mathbb{F}_2 polynomials with seed length

$$O(k \log n + k2^k \log(1/\varepsilon)).$$

More precisely, at the heart of our reduction is a new pseudorandom switching lemma for sparse \mathbb{F}_2 polynomials, showing that such a polynomial is very likely to collapse to a *small-depth decision tree with low-degree \mathbb{F}_2 polynomials at its leaves* under a suitable pseudorandom restriction. This is essentially a special case of our pseudorandom multi-switching lemma. With this reduction in hand, we then exploit the strength and generality of Viola’s result – roughly speaking, that the sum of k independent copies of a sufficiently strong ε -biased distribution fools degree- k polynomials – to show that his PRG extends to fool not only low-degree polynomials, but also small-depth decision trees with low-degree polynomials at their leaves.

Table 2 provides a comparison of the seed length of our PRG (and the techniques that underlie our construction) and those of previous work.

■ **Table 2** PRGs for ε -fooling \mathbb{F}_2 polynomials.

2.3 Organization

Section 2.4 recalls some basic preliminaries from unconditional pseudorandomness. We describe and contrast the original Håstad switching lemma [34] versus the [35] multi-switching lemma in Section 3. Section 3.1 establishes some infrastructure towards derandomizing the [35] switching lemma, and the actual derandomization result (the pseudorandom multi-switching lemma, Theorem 14) is stated in Section 4 and proved in Appendix A. In the full version we describe a general framework for constructing pseudorandom generators that is implicit in the work of Ajtai and Wigderson [6], and explain how our derandomized multi-switching lemma from Section 4 can be used (along with other ingredients) within this framework to establish the PRGs for AC^0 and for sparse \mathbb{F}_2 polynomials that are our main PRG results.

2.4 Preliminaries

For $r < n$, we say that a distribution \mathcal{D} over $\{0, 1\}^n$ can be *sampled efficiently with r random bits* if (i) \mathcal{D} is the uniform distribution over a multiset $z^{(1)}, \dots, z^{(s)}$ of strings from $\{0, 1\}^n$ where $s \in [\frac{1}{\text{poly}(n)} \cdot 2^r, 2^r]$ and (ii) there is a deterministic algorithm $\text{Gen}_{\mathcal{D}}$ which, given as input a uniform random element of $[s]$, runs in time $\text{poly}(n, s)$ and outputs a string drawn from \mathcal{D} .

For $\delta > 0$ and a class \mathcal{C} of functions from $\{0, 1\}^n$ to $\{0, 1\}$, we say that a distribution \mathcal{D} over $\{0, 1\}^n$ δ -fools \mathcal{C} with seed length r if (a) \mathcal{D} can be sampled efficiently with r random bits via algorithm $\text{Gen}_{\mathcal{D}}$, and (b) for every function $f \in \mathcal{C}$, we have

$$\left| \mathbf{E}_{\mathbf{s} \leftarrow \{0,1\}^r} [f(\text{Gen}_{\mathcal{D}}(\mathbf{s}))] - \mathbf{E}_{\mathbf{x} \leftarrow \{0,1\}^n} [f(\mathbf{x})] \right| \leq \delta.$$

Equivalently, we say that $\text{Gen}_{\mathcal{D}}$ is a δ -PRG for \mathcal{C} with seed length r .

Two kinds of distributions which are extremely useful in derandomization are δ -biased and k -wise independent distributions. We say that a distribution \mathcal{D} over $\{0, 1\}^n$ is δ -biased if it δ -fools the class of all 2^n parity functions $\{\text{PARITY}_S\}_{S \subseteq [n]}$, where $\text{PARITY}_S : \{0, 1\}^n \rightarrow \{0, 1\}$ is defined by $\text{PARITY}_S(x) = \sum_{i \in S} x_i \pmod 2$. We say that a distribution \mathcal{D} over $\{0, 1\}^n$ is k -wise independent with parameter p if for every $1 \leq i_1 < \dots < i_k \leq n$ and every $(b_1, \dots, b_k) \in \{0, 1\}^k$, we have

$$\mathbf{Pr}_{\mathbf{x} \leftarrow \mathcal{D}} [x_{i_1} = b_1 \text{ and } \dots \text{ and } x_{i_k} = b_k] = p^{\sum_{j=1}^k b_j} \cdot (1-p)^{k - \sum_{j=1}^k b_j},$$

i.e. every subset of k coordinates is distributed identically to a product distribution with parameter p .

A restriction ρ of variables x_1, \dots, x_n is an element of $\{0, 1, *\}^n$. We write $\text{supp}(\rho)$ to denote the set of coordinates that are fixed to 0 or 1 by ρ . Given a function $f(x_1, \dots, x_n)$ and a restriction ρ , we write $f \upharpoonright \rho$ to denote the function obtained by fixing x_i to $\rho(i)$ if $\rho(i) \in \{0, 1\}$ and leaving x_i unset if $\rho(i) = *$. For two restrictions $\rho, \rho' \in \{0, 1, *\}^n$, their composition, denoted $\rho\rho' \in \{0, 1, *\}^n$, is the restriction defined by

$$(\rho\rho')_i = \begin{cases} \rho_i & \text{if } \rho_i \in \{0, 1\} \\ \rho'_i & \text{otherwise.} \end{cases}$$

Given a collection $\mathcal{F} = \{f_1, \dots, f_M\}$ of functions and a restriction ρ we write $\mathcal{F} \upharpoonright \rho$ to denote the family $\{f_1 \upharpoonright \rho, \dots, f_M \upharpoonright \rho\}$.

Given an AC^0 circuit, we define its size to include the input variables (along with the number of gates in the circuit). We adopt this convention for notational convenience, since we may then always assume that the size M of an n -variable circuit is always at least n . (We do *not* adopt this convention for \mathbb{F}_2 polynomials: as is standard, we define the sparsity of an \mathbb{F}_2 polynomial to be the number of monomials in its support.)

Finally, if g is a Boolean function and \mathcal{C} is a class of circuits, we say that g is *computed by a (t, \mathcal{C}) -decision tree* if g is computed by a decision tree of depth t (with single Boolean variables x_i at internal nodes as usual) in which each leaf is labeled by a function from \mathcal{C} .

3 Multi-switching lemmas

At the heart of almost all applications of Håstad's original switching lemma [34] is a powerful structural fact about AC^0 circuits: every AC^0 circuit “collapses” (i.e. simplifies dramatically) to a depth- t decision tree with high probability, at least $1 - \varepsilon$, under a random restriction that randomly fixes a $(1 - p)$ -fraction of coordinates. In the precise quantitative statement of this fact, both t and p depend on ε : as the desired failure probability ε tends to 0, the $*$ -probability p tends to 0 (more coordinates are fixed) and t tends to n (the resulting decision tree is of larger depth). It is easy to see that this dependence is inherent given the statement of the [34] switching lemma, and indeed this will be clear from the discussion later in this section.

The recent multi-switching lemma of Håstad [35] (see also [39]) achieves a remarkable strengthening of the above: essentially the same structural fact about AC^0 holds (in terms of the quantitative relation between the decision tree depth t and the failure probability ε) *with the $*$ -probability p being independent of ε* . This is the key qualitative difference underlying the optimal AC^0 correlation bounds for PARITY obtained in [39, 35]; likewise, in this work, this is the key qualitative difference underlying the optimal ε -dependence in the seed lengths of our PRGs for AC^0 circuits and sparse \mathbb{F}_2 polynomials.

Let \mathcal{R}_p denote the random restriction which independently sets each variable x_i to 0 with probability $(1 - p)/2$, to 1 with probability $(1 - p)/2$, and to $*$ with probability p . We first recall the original switching lemma from [34]:

► **Theorem 3** (Håstad's switching lemma). *Let F be a k -CNF. Then for all $t \geq 1$, we have that*

$$\Pr_{\rho \leftarrow \mathcal{R}_p} [F \upharpoonright \rho \text{ does not have a decision tree of depth } t] \leq (5pk)^t.$$

In the context of AC^0 circuits the switching lemma is used to achieve *depth reduction* under random restrictions: we apply Theorem 3 separately to each of the bottom-layer depth-2 subcircuits, choosing t appropriately so that all of them “switch” to depth- t decision trees with high probability. The following corollary is what is typically used:

► **Corollary 4** (AC^0 depth reduction via Theorem 3). *Let \mathcal{C} be a size- M depth- d AC^0 circuit with bottom fan-in k , and let $p = 1/(10k)$. Then for all $\varepsilon > 0$,*

$$\Pr_{\rho \leftarrow \mathcal{R}_p} [\mathcal{C} \upharpoonright \rho \text{ is not computed by a depth-}(d-1)\text{ circuit with bottom fan-in } \log(M/\varepsilon)] \leq \varepsilon.$$

Proof. This follows from applying Theorem 3 with $t = \log(M/\varepsilon)$ to each of the bottom-layer depth-2 subcircuits of \mathcal{C} (at most M of them), along with the basic fact that a depth- t decision tree can be expressed as both a t -DNF as well as a t -CNF. ◀

The same argument is then repeated again on the ($k = \log(M/\varepsilon)$)-DNFs at the bottom two layers of the new circuit (applying the dual form of the switching lemma for k -DNFs rather than k -CNFs) to further reduce the depth to $d - 2$. However, observe that in this second application of the switching lemma (and in later applications as well), in order to use Corollary 4, the parameter p of the random restriction must now depend on ε , since we must now take $p < 1/(5k) = 1/(5 \log(M/\varepsilon))$ in order to get a nontrivial bound in Theorem 3. This is why standard applications of the [34] switching lemma (involving $d - 1$ iterative applications of Corollary 4) show that every size- M depth- d AC^0 circuit collapses to depth- $(t = \log(M/\varepsilon))$ decision tree with high probability, at least $1 - \varepsilon$, under a random restriction with $*$ -probability $p = \Theta(1/\log^{d-1}(M/\varepsilon))$. Note that t and p both depend on ε .

As alluded to above, the recent multi-switching lemma of [35] shows, remarkably, that essentially the same simplification holds under a random restriction with $*$ -probability $p = \Theta(1/\log^{d-1}(M))$, independent of ε . Let us establish some terminology and notation to present these results.

► **Definition 5** (Common partial decision tree). *Let $\mathcal{F} = \{F_1, \dots, F_M\}$ be a collection of Boolean functions. We say that a decision tree T is a common ℓ -partial decision tree for \mathcal{F} if every $F_i \in \mathcal{F}$ can be expressed as T with depth- ℓ decision trees at its leaves. (Equivalently, for every $F_i \in \mathcal{F}$ and root-to-leaf path π in T , we have that $F_i \upharpoonright \pi$ is computed by a depth- ℓ decision tree.)*

The multi-switching lemma of [35] is as follows:

► **Theorem 6** (Multi-switching lemma, Lemma 3.8 of [35]). *Let $\mathcal{F} = \{F_1, \dots, F_M\}$ be a collection of k -CNFs and $\ell := \log(2M)$. Then for all $t \geq 1$,*

$$\Pr_{\rho \leftarrow \mathcal{R}_p} [\mathcal{F} \upharpoonright \rho \text{ does not have a common } \ell := \log(2M)\text{-partial DT of depth } t] \leq M(24pk)^t.$$

The following corollary should be contrasted with Corollary 4:

► **Corollary 7** (AC^0 depth reduction via Theorem 6; c.f. Corollary 4). *Let \mathcal{C} be a size- M depth- d AC^0 circuit with bottom fan-in k , and let $p = 1/(48k)$. Then for all $\varepsilon > 0$, the probability (over $\rho \leftarrow \mathcal{R}_p$) that $\mathcal{C} \upharpoonright \rho$ is not computed by a $(\log(M/\varepsilon), \text{AC}^0(\text{depth } d - 1, \text{bottom fan-in } \log(2M)))$ -decision tree is at most ε .*

Proof. This follows by applying Theorem 6 with \mathcal{F} being the bottom-layer depth-2 subcircuits of \mathcal{C} and $t = \log(M/\varepsilon)$, along with the fact that a depth- ℓ decision tree can be expressed as both a ℓ -DNF and an ℓ -CNF. ◀

We highlight a crucial qualitative aspect of Corollary 7: while the depth $t = \log(M/\varepsilon)$ of the decision tree whose existence it asserts does depend on ε , the depth- $(d - 1)$ AC^0 circuits at its leaves have bottom fan-in $k = \log(2M)$ which does *not* depend on ε . This means that in successive application of Corollary 7, the values of $p = 1/(48k) = \Theta(1/\log M)$ will remain independent of ε . This leads to much better quantitative bounds than can be obtained through repeated applications of Corollary 4: $d - 1$ iterative applications of Corollary 7 imply that every size- M depth- d AC^0 circuit collapses to a depth- $O(2^d \log(M/\varepsilon))$ decision tree with high probability, at least $1 - \varepsilon$, under a random restriction with $*$ -probability $p = \Theta(1/\log^{d-1} M)$. Note that the overall $*$ -probability p is independent of ε .

Multi-switching lemmas and sparse \mathbb{F}_2 polynomials. The qualitative advantage of multi-switching lemmas – in particular, the crucial role of a common partial decision tree – can also be seen within the context of \mathbb{F}_2 polynomials.

Let P be an S -sparse \mathbb{F}_2 polynomial. It is an easy observation that P becomes a low-degree polynomial with high probability when hit with a random restriction: for all $\varepsilon, p \in (0, 1)$ and $k \in \mathbb{N}$,

$$\Pr_{\rho \leftarrow \mathcal{R}_{\frac{p}{2}}} [P \upharpoonright \rho \text{ is not a degree-}k \text{ polynomial}] \leq \frac{\varepsilon}{2} + S \binom{w}{k} p^k \quad \text{where } w = \Theta(\log(S/\varepsilon)). \quad (1)$$

(The proof follows by considering each monomial of P individually and taking a union bound over all S of them. For a fixed monomial, the probability that more than $\Omega(\log(S/\varepsilon))$ variables survive a random restriction from $\mathcal{R}_{\frac{p}{2}}$ is at most $\varepsilon/(2S)$; next, the probability that at least k variables in a width- w monomial survive a random restriction from \mathcal{R}_p is at most $\binom{w}{k} p^k$.) The failure probability of (1) can be made at most ε by choosing p and k appropriately, but note that at least one of p (the $*$ -probability) or k (the degree of the resulting polynomial) must depend on ε .

Using a slight extension of the ideas in the multi-switching lemmas of [35], we can instead bound the probability that $P \upharpoonright \rho$ becomes a *depth- t decision tree with degree- k polynomials at its leaves*. While this provides weaker structural information than the simple observation above (cf. Corollary 4 vs. Corollary 7 in the context of AC^0), the crucial win will come from the fact that p and k can *both* be taken to be independent of the failure probability ε (and only t will depend on ε).

3.1 Canonical common ℓ -partial decision trees

An important concept in the proof of Theorem 6 is that of a *canonical common ℓ -partial decision tree* for an ordered collection \mathcal{F} of k -CNFs, which we define in this section.

Given a k -CNF formula F (which we view as an ordered sequence of width- k clauses $C_1 \wedge C_2 \wedge \dots$), we recall the notion of the *canonical decision tree* for F , denoted $\text{CDT}(F)$. This is a decision tree which computes F and is obtained as follows:

- If any clause C_i is identically-0, then the tree is the constant 0.
- If every clause C_i is identically-1, then the tree is the constant 1.
- Otherwise, let C_{i_1} be the first clause that is not identically-1, and let $\kappa \in [k]$ be the number of variables in C_{i_1} . The first κ levels of $\text{CDT}(F)$ exhaustively query these κ variables. At each of the 2^κ resulting leaves of the tree (each one corresponding to some restriction $\eta \in \{0, 1\}^\kappa$ fixing those κ variables), recursively put down the canonical decision tree $\text{CDT}(F \upharpoonright \eta)$.

We observe that the tree $\text{CDT}(F)$ is unique given a fixed ordering C_1, C_2, \dots of the clauses in F .

Håstad’s proof of his original switching lemma (Theorem 3) actually shows that if F is a k -CNF, then the canonical decision tree $\text{CDT}(F \upharpoonright \rho)$ is shallow w.h.p. over $\rho \leftarrow \mathcal{R}_p$. This is crucially important for the arguments of Trevisan and Xue [65], who give a *derandomized* version of Håstad’s original switching lemma: they construct a pseudorandom distribution over restrictions to take the place of \mathcal{R}_p , and show that with high probability a restriction drawn from this pseudorandom distribution causes a k -CNF to collapse to a small-depth decision tree. Their argument uses the structure of a canonical decision tree in an essential way.

Turning to Håstad’s multi-switching lemma [35], we observe that analogous to his original switching lemma, the proof of Theorem 6 given in [35] implicitly establishes a stronger statement: $\mathcal{F} \upharpoonright \rho$ has a small-depth *canonical common ℓ -partial decision tree* w.h.p. over $\rho \leftarrow \mathcal{R}_p$. In fact, we will use the fact that it actually establishes an even stronger statement: w.h.p. over $\rho \leftarrow \mathcal{R}_p$, *every* canonical common ℓ -partial decision tree for $\mathcal{F} \upharpoonright \rho$ is shallow – as we explain below, there is more than one canonical common ℓ -partial decision tree for a sequence \mathcal{F} of CNFs.

Let us explain what a canonical common ℓ -partial decision tree for a sequence of CNFs \mathcal{F} is. We will see that there is a set of canonical common ℓ -partial decision trees for a given \mathcal{F} rather than just one tree; note that this is the case even though we assume a fixed ordering F_1, F_2, \dots on the elements of \mathcal{F} as well as on the clauses within each CNF. (Observe the contrast with the case of a canonical decision tree for a single formula F , where we assume a fixed ordering on the clauses of F ; in that setting, as explained above there is a single canonical decision tree $\text{CDT}(F)$.)

We need a preliminary definition to handle a technical issue related to the final segment of paths through a canonical decision tree.

► **Definition 8** (Full paths in the CDT). *Let $F = C_1 \wedge C_2 \wedge \dots$ be a k -CNF and consider the canonical decision tree $\text{CDT}(F)$ for F . Every path η in $\text{CDT}(F)$ can be written as the disjoint union of segments $\eta = \eta^{(1)} \circ \eta^{(2)} \circ \dots \circ \eta^{(u)}$, where for all $j \in [u]$, the segment $\eta^{(j)}$ is an assignment to the surviving variables in the restricted clause $C_{i_j} \upharpoonright \eta^{(1)} \circ \dots \circ \eta^{(j-1)}$, and C_{i_j} is the first clause in $F \upharpoonright \eta^{(1)} \circ \dots \circ \eta^{(j-1)}$ that is not identically-1.*

Furthermore, note that for $j \in [u-1]$, the segment $\eta^{(j)}$ is in fact an assignment fixing all the surviving variables in $C_{i_j} \upharpoonright \eta^{(1)} \circ \dots \circ \eta^{(j-1)}$. We say that η is full if this is also the case for the final segment: η is full if $\eta^{(u)}$ is an assignment fixing all the surviving variables in $C_{i_u} \upharpoonright \eta^{(1)} \circ \dots \circ \eta^{(u-1)}$.

► **Observation 9.** *Let F be a k -CNF and suppose $\text{depth}(\text{CDT}(F)) > \ell$. Then there is a full path η of length $|\eta| \in \{\ell+1, \dots, \ell+k\}$ in $\text{CDT}(F)$.*

To help minimize confusion, we will reserve “ η ” for paths or segments of paths in CDTs, and “ π ” for paths (or segments of paths) in CCDTs.

We are now ready to define the set of canonical common ℓ -partial decision trees:

► **Definition 10** (Canonical common ℓ -partial DT). *Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered collection of k -CNFs. The set of all canonical common ℓ -partial decision trees for \mathcal{F} , which we denote $\text{CCDT}_\ell(\mathcal{F})$, is defined inductively as follows:*

0. *If $M = 0$ (i.e. \mathcal{F} is an empty collection of k -CNFs) then $\text{CCDT}_\ell(\mathcal{F})$ contains a single tree, the empty tree with no nodes. (Note that otherwise $M \geq 1$, so there is some first formula F_1 in \mathcal{F} .)*
1. *If $\text{CDT}(F_1) \leq \ell$, then $\text{CCDT}_\ell(\mathcal{F})$ is simply $\text{CCDT}_\ell(\mathcal{F}')$, where $\mathcal{F}' = (F_2, \dots, F_M)$. (Note that in this case, since inductively each tree in $\text{CCDT}_\ell(\mathcal{F}')$ is a common ℓ -partial DT for \mathcal{F}' , each such tree is also a common ℓ -partial DT for \mathcal{F} .)*
2. *Otherwise, since $\text{CDT}(F_1) > \ell$ there must be a witnessing full path η of length between $\ell+1$ and $\ell+k$ in $\text{CDT}(F_1)$, and there are at most $2^{\ell+k}$ such witnessing full paths. Let P be the set of all such witnessing full paths. For each path $\eta \in P$, let T_η be the tree of depth $|\eta|$ obtained by exhaustively querying all the variables in η in the first $|\eta|$ levels. Recurse at the end of each path in T_η : for each path π in T_η , attach a tree T' from $\text{CCDT}_\ell(\mathcal{F} \upharpoonright \pi)$ at the end of the path. So in this case $\text{CCDT}_\ell(\mathcal{F})$ is the set of all trees that can be obtained in this way (across all possible choices of $\eta \in P$ and all possible choices of a tree $T' \in \text{CCDT}_\ell(\mathcal{F} \upharpoonright \pi)$ for each path $\pi \in T_\eta$).*

We write $\text{depth}(\text{CCDT}_\ell(\mathcal{F}))$ to denote the maximum depth of any tree in the set $\text{CCDT}_\ell(\mathcal{F})$.

The following slight variant of Theorem 6 can be extracted, with some effort, from a slight modification of the proof given in [35], which we provide in the full version:

► **Theorem 11** (Slight variant of Håstad’s multi-switching lemma. Theorem 6). *Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered collection of k -CNFs. Then for all $\ell, t \geq 1$,*

$$\Pr_{\rho \leftarrow \mathcal{R}_p} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)) \geq t] \leq M^{\lceil t/\ell \rceil} (32pk)^t.$$

A comparison of Theorem 6 (Håstad’s multi-switching lemma) and Theorem 11 (our variant of it). We emphasize that the differences are technical in nature, and all the ideas in our proof of Theorem 11 are from [35]. First, we observe that ℓ is now a free parameter rather than being fixed to $\log(2M)$; this flexibility will be necessary in our PRG construction for sparse \mathbb{F}_2 polynomials (where we take $\ell = \Theta(\sqrt{\log M})$). Second, our notion of a canonical common partial decision tree differs slightly from the one that is implicit in [35]: in case 2 of Definition 10, we query a witnessing full path of length between $\ell + 1$ and $\ell + k$, whereas [35] queries any witnessing path of length greater than ℓ .

4 A pseudorandom multi-switching lemma

As suggested earlier, the crux of our PRG construction is a *derandomization* of the multi-switching lemma of Theorem 11: we devise a suitable *pseudorandom* distribution over random restrictions in place of \mathcal{R}_p (the truly random distribution over restrictions) and show that a random restriction ρ drawn from this pseudorandom distribution satisfies a similar guarantee to Theorem 11.

Our derandomization of Theorem 11 is largely influenced by Trevisan and Xue’s [65] ingenious derandomization of Håstad’s original switching lemma (Theorem 3). Roughly speaking, we will derandomize the multi-switching lemma of Theorem 11 by “fooling its proof”: we will show that the proof of Theorem 11 (given in the full version, which we again emphasize is only a slight technical modification of Håstad’s proof of his multi-switching lemma, Theorem 6) “cannot δ -distinguish” between truly random restrictions and pseudorandom restrictions drawn from polylog(n)-wise independent distributions. Since Theorem 11 holds for truly random restrictions, it thus follows that it also holds for pseudorandom restrictions drawn from polylog(n)-wise independent distributions (up to a δ additive loss in the failure probability).

To accomplish this, we exploit the “computational simplicity” of Theorem 11’s proof: for a fixed family \mathcal{F} of k -CNF formulas, we will show that there is a small AC^0 circuit that takes as input an encoding of a restriction ρ , and outputs 1 iff ρ is a bad restriction for the desired conclusion of Theorem 11, contributing to its failure probability (i.e. iff $\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)) > t$). As alluded to in Section 3.1, this relies on the fact that Theorem 11 does not simply bound the depth of the *optimal* common ℓ -partial decision tree for $\mathcal{F} \upharpoonright \rho$, but instead the depth of any *canonical* common ℓ -partial decision tree for $\mathcal{F} \upharpoonright \rho$. Indeed, this “constructive” aspect of the proof is crucial for our derandomization strategy: it is not at all clear that there is a small circuit for checking if the *optimal* common ℓ -partial decision tree for $\mathcal{F} \upharpoonright \rho$ has depth greater than t .

It will be convenient for us to represent restrictions $\rho \in \{0, 1, *\}^n$ as bitstrings $(\varrho, \mathbf{y}) \in \{0, 1\}^{n \times q} \times \{0, 1\}^n := \{0, 1\}^{Y_q}$, where $q \in \mathbb{N}$ is a parameter.

► **Definition 12** (Representing restrictions as bitstrings). *We associate with each string $(\varrho, \mathbf{y}) \in \{0, 1\}^{Y_q}$ the restriction $\rho(\varrho, \mathbf{y}) \in \{0, 1, *\}^n$ defined as follows:*

$$\rho(\varrho, \mathbf{y})_i = \begin{cases} * & \text{if } \varrho_{i,1} = \dots = \varrho_{i,q} = 1 \\ y_i & \text{otherwise.} \end{cases}$$

The following observation explains the role of q :

► **Observation 13.** *Let (ϱ, \mathbf{y}) be drawn from the uniform distribution over $\{0, 1\}^{Y_q}$. Then the random restriction $\rho(\varrho, \mathbf{y}) \in \{0, 1, *\}^n$ is distributed according to \mathcal{R}_p where $p = 2^{-q}$.*

Now we are ready to state our pseudorandom multi-switching lemma:

► **Theorem 14** (Derandomized version of Theorem 11). *Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered list of Q -clause k -CNFs. Let $\delta, p \in (0, 1)$ and define $q = \log(1/p)$. Let \mathcal{D} be any distribution over $\{0, 1\}^{Y_q}$ that $(\delta/(M^{\lceil t/\ell \rceil} n^{O(t)}))$ -fools the class of depth-3 circuits of size $M(n^{O(\ell)} + Q2^{O(kq)})$. Then for all $\ell \geq k$ and all $t \in \mathbb{N}$,*

$$\Pr_{(\eta, z) \leftarrow \mathcal{D}} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\eta, z))) \geq t] \leq 16^{t+\ell} M^{\lceil t/\ell \rceil} (32pk)^t + \delta.$$

In the full version of the paper we prove this lemma and show how it, along with other ingredients, yields our circuit complexity derandomization results.

A Proof of Theorem 14

A.1 Bad restrictions and the structure of witnessing paths

Fix $\mathcal{F} = (F_1, \dots, F_M)$. We say that a restriction $\rho \in \{0, 1, *\}^n$ is *bad* if

$$\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)) \geq t.$$

Fix ρ to be a bad restriction. Recalling our definition of the set of canonical common partial decision trees (Definition 10), there exists a tree $T \in \text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)$ and a path Π of length exactly t through T . Furthermore, we have that

45:20 Improved PRGs from Pseudorandom Multi-Switching Lemmas

1. There exist indices $1 \leq i_1 \leq i_2 \leq \dots \leq i_u \leq M$ where $u \leq \lceil t/\ell \rceil$, and
2. $\Pi = \pi^{(1)} \circ \dots \circ \pi^{(u)}$, where for all $j \in [u]$, we have that $\text{supp}(\pi^{(j)}) = \text{supp}(\eta^{(j)})$ where $\eta^{(j)}$ is a path through the canonical decision tree

$$\text{CDT}(F_{i_j} \upharpoonright \rho \circ \pi^{(1)} \circ \dots \circ \pi^{(j-1)}).$$

Furthermore, for every $j \in [u-1]$ we have that $\eta^{(j)}$ is a full path of length between $\ell+1$ and $\ell+k$ through the CDT, and $\eta^{(u)}$ is a path of length exactly $t - \sum_{j=1}^{u-1} |\text{supp}(\eta^{(j)})|$.

(Note that $\eta^{(u)}$ is not necessarily a full path.)

(Note that by (2), these subpaths $\pi^{(j)}$ of Π are supported on mutually disjoint sets of coordinates.) With this structure of Π in mind, we make the following definition:

► **Definition 15** (\mathcal{F} -traversal). *Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered list of CNFs. An ℓ -segmented \mathcal{F} -traversal of length t is a tuple $P = (\mathcal{J}, \{S_1, \dots, S_u\}, \Pi, \mathbf{H})$ comprising:*

1. An ordered list of indices $\mathcal{J} = (i_1, \dots, i_u)$ where $1 \leq i_1 \leq \dots \leq i_u \leq M$ and $u \leq \lceil t/\ell \rceil$,
2. For each index $i_j \in \mathcal{J}$, a subset $S_j \subseteq [n]$ such that
 - a. These sets are mutually disjoint: $S_j \cap S_{j'} = \emptyset$ for all $j \neq j'$.
 - b. For $1 \leq j \leq u-1$, each S_j has size between $\ell+1$ and $\ell+k$, and S_u has size exactly $t - \sum_{j=1}^{u-1} |\text{supp}(\eta^{(j)})|$.

(Consequently $|S_1 \cup \dots \cup S_u| = t$.)

3. An assignment $\Pi = \pi^{(1)} \circ \dots \circ \pi^{(u)}$ to the variables in $S_1 \cup \dots \cup S_u$, where

$$\pi^{(j)} : \{0, 1\}^{S_j} \rightarrow \{0, 1\} \quad \text{for } 1 \leq j \leq u.$$

4. An assignment $\mathbf{H} = \eta^{(1)} \circ \dots \circ \eta^{(u)}$ to the variables in $S_1 \cup \dots \cup S_u$, where again

$$\eta^{(j)} : \{0, 1\}^{S_j} \rightarrow \{0, 1\} \quad \text{for } 1 \leq j \leq u.$$

By our discussion above, for any restriction $\rho \in \{0, 1, *\}^n$ and any tree $T \in \text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)$, every path Π of length t through $\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)$ uniquely induces an ℓ -segmented \mathcal{F} -traversal P of length t . We say that P occurs in $\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)$ if it is induced by some path Π of length t through T for some $T \in \text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho)$.

Definition 15 immediately yields the following:

► **Proposition 16** (Number of \mathcal{F} -traversals). *Fix an ordered list $\mathcal{F} = (F_1, \dots, F_M)$ of k -CNFs, and let $\mathcal{P}_{\mathcal{F}, \ell, t}$ denote the collection of all ℓ -segmented \mathcal{F} -traversals of length t . Then*

$$|\mathcal{P}_{\mathcal{F}, \ell, t}| \leq M^{\lceil t/\ell \rceil} n^{O(t)}.$$

A.2 A small AC⁰ circuit for recognizing bad restrictions

We begin by showing that for every \mathcal{F} -traversal $P = (\mathcal{J}, \{S_1, \dots, S_u\}, \Pi, \mathbf{H})$, there is a small circuit \mathcal{C}_P over $\{0, 1\}^{Y_q}$ that outputs 1 on input $(\varrho, y) \in \{0, 1\}^{Y_q}$ iff P occurs in $\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\varrho, y))$. Since

$$\begin{aligned} \rho(\varrho, y) \text{ is bad} &\iff \text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\varrho, y))) \geq t \\ &\iff \exists \ell\text{-segmented } \mathcal{F}\text{-traversal } P \text{ of length } t \text{ occurring in } \text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\varrho, y)), \end{aligned}$$

by considering

$$\mathcal{C}_{\mathcal{F}, \ell, t}(\varrho, y) := \bigvee_{P \in \mathcal{P}_{\mathcal{F}, \ell, t}} \mathcal{C}_P(\varrho, y) \tag{2}$$

we have that

$$\rho(\varrho, y) \text{ is bad} \iff \mathcal{C}_{\mathcal{F}, \ell, t}(\varrho, y) = 1.$$

▷ **Claim 17 (Circuit for a single \mathcal{F} -traversal).** Let $P = (J, \{S_1, \dots, S_u\}, \Pi, H)$ be an ℓ -segmented \mathcal{F} -traversal of length t . There is a depth-3 AND-OR-AND circuit $\mathcal{C}_P : \{0, 1\}^{Y_q} \rightarrow \{0, 1\}$ of size $M(n^{O(\ell)} + Q2^{O(kq)})$ such that

$$\forall (\varrho, y) \in \{0, 1\}^{Y_q}: \mathcal{C}_P(\varrho, y) = 1 \iff P \text{ occurs in } \text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\varrho, y))$$

Proof. Our circuit \mathcal{C}_P will be the AND of M many depth-3 subcircuits of size $n^{O(\ell)}$, one for each k -CNF $F \in \mathcal{F}$. As we will explain later, each of these subcircuits is one of two types. We first describe these two types of “candidate subcircuits”, and then explain precisely which M subcircuits of each type are AND-ed together to give \mathcal{C}_P . (Both these types of circuits are implicit in the work of [65].)

1. **First type: Circuits checking that a particular restriction η is a path in a particular CDT.** We claim that for any Q -clause k -CNF $F' = C_1 \wedge \dots \wedge C_Q$ and restriction η , there is a $Q2^{O(kq)}$ -clause $O(kq)$ -CNF G over $\{0, 1\}^{Y_q}$ that outputs 1 on input (ϱ, y) iff η is a path in $\text{CDT}(F' \upharpoonright \rho(\varrho, y))$.

For each $i \in [Q]$, we write Fixed_i to denote the set

$$\{j \in [n]: j \in \eta^{-1}(\{0, 1\}) \text{ and } x_j \text{ occurs in } C_i\}$$

of all variables that are fixed by η and occur in C_i . We write $\sigma^{(i)} \in \{0, 1\}^{\text{Fixed}_i}$ to denote η restricted to the coordinates in Fixed_i . It is straightforward to verify that η is a path in $\text{CDT}(F' \upharpoonright \rho(\varrho, y))$ iff for all $i \in [Q]$ such that $\text{Fixed}_1 \cup \dots \cup \text{Fixed}_{i-1} \subsetneq \text{supp}(\eta)$,

- a. If $\text{Fixed}_i \setminus (\text{Fixed}_1 \cup \dots \cup \text{Fixed}_{i-1}) = \emptyset$ then the clause C_i is satisfied by $\rho(\varrho, y) \circ \sigma^{(1)} \circ \dots \circ \sigma^{(i-1)}$. (Hence this clause does not contribute to $\text{CDT}(F' \upharpoonright \rho(\varrho, y))$; it is “skipped” in the canonical decision tree construction process.)
- b. Otherwise, writing $\text{Fixed}'_i := \text{Fixed}_i \setminus (\text{Fixed}_1 \cup \dots \cup \text{Fixed}_{i-1})$,
 - i. $\rho(\varrho, y)_j = *$ for all $j \in \text{Fixed}'_i$, and
 - ii. $\rho(\varrho, y) \circ \sigma_1 \circ \dots \circ \sigma_{i-1}$ falsifies all the remaining literals in C_i and are not in Fixed'_i .
 In other words, the clause

$$C_i \upharpoonright \rho(\varrho, y) \circ \sigma^{(1)} \circ \dots \circ \sigma^{(i-1)}$$

is not satisfied and its surviving variables are precisely those in Fixed'_i . (Hence the variables in Fixed'_i are exactly those queried by the canonical decision tree construction process when it reaches C_i .)

Since both conditions (a) and (b) depend only on the coordinates of $\rho(\varrho, y)$ that occur in C_i (at most k such coordinates since C_i has width at most k), and hence at most $k(q+1)$ coordinates of $(\varrho, y) \in \{0, 1\}^{Y_q}$, it is clear that both conditions can be checked by a $2^{O(kq)}$ -clause $O(kq)$ -CNF over $\{0, 1\}^{Y_q}$. The overall CNF G is simply the AND of all Q many of these CNFs, one for each clause C_i of F' , and hence G is itself a $Q2^{O(kq)}$ -clause $O(kq)$ -width CNF.

2. **Second type: Circuits checking that a particular CDT has depth at most ℓ .** Next, we claim that for every Q -clause k -CNF F' , there is a depth-3 AND-OR-AND circuit with fan-in sequence $((2n)^{\ell+1}, Q2^{O(kq)}, O(kq))$ that outputs 1 on input (ϱ, y) iff $\text{depth}(\text{CDT}(F' \upharpoonright \rho(\varrho, y))) \leq \ell$.

We establish this by showing that there is a depth-3 OR-AND-OR circuit Σ with the claimed fan-in sequence that outputs 1 on input (ϱ, y) if $\text{depth}(\text{CDT}(F' \upharpoonright \rho(\varrho, y))) > \ell$; given such a circuit Σ , the desired AND-OR-AND circuit is obtained by negating Σ and using de Morgan’s law. Certainly $\text{depth}(\text{CDT}(F' \upharpoonright \rho(\varrho, y))) > \ell$ iff there is a path η of

45:22 Improved PRGs from Pseudorandom Multi-Switching Lemmas

length $\ell + 1$ in $\text{CDT}(F' \upharpoonright \rho(\varrho, y))$. There are at most $(2n)^{\ell+1}$ many possible paths of length $\ell + 1$ (every path is simply an ordered list of literals), and as argued in (1) above, for every path η there is a $Q2^{O(kq)}$ -clause, $O(kq)$ -CNF over $\{0, 1\}^{Y_q}$ that checks if η is a path in $\text{CDT}(F' \upharpoonright \rho(\varrho, y))$. The overall circuit Σ is simply the OR of at most $(2n)^{\ell+1}$ such circuits, one for each path η .

With these two types of circuits in hand the overall circuit \mathcal{C}_P is now easy to describe. \mathcal{C}_P is the AND of M many depth-3 subcircuits, one for each k -CNF $F \in \mathcal{F}$:

- For each of the u indices $i_j \in \mathcal{J}$, a circuit of the first type that checks that $\eta^{(j)}$ is a path in $\text{CDT}(F_{i_j} \upharpoonright \rho(\varrho, y) \circ \pi^{(1)} \circ \dots \circ \pi^{(j-1)})$ (recall from Definition 15 that $\eta^{(j)}$ is \mathbb{H} restricted to the variables in S_j);
- For all $M - u$ other indices $i \in [M] \setminus \mathcal{J}$, a circuit of the second type that checks that $\text{depth}(\text{CDT}(F_i \upharpoonright \rho(\varrho, y) \circ \pi^{(1)} \circ \dots \circ \pi^{(i^-)})) \leq \ell$, where $i^- = \max\{j \in [u] : i_j < i\}$.

The bound on the size of this overall circuit follows from a union bound over the sizes of the subcircuits given in (1) and (2) above. \triangleleft

A.3 Putting the pieces together: Proof of Theorem 14

Recalling the definition (2) of $\mathcal{C}_{\mathcal{F}, \ell, t}$,

$$\mathcal{C}_{\mathcal{F}, \ell, t}(\varrho, y) := \bigvee_{P \in \mathcal{P}_{\mathcal{F}, \ell, t}} \mathcal{C}_P(\varrho, y),$$

Proposition 16 giving a bound on its top fan-in, and Claim 17 giving a bound on the size of its subcircuits, we have shown the following:

▷ **Claim 18** (Circuit for recognizing bad restrictions). Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered list of Q -clause k -CNFs, and let $\ell, t \geq 1$. There is a depth-4 circuit $\mathcal{C}_{\mathcal{F}, \ell, t}$ over $\{0, 1\}^{Y_q}$ such that

$$\mathcal{C}_{\mathcal{F}, \ell, t}(\varrho, y) = 1 \iff \text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\varrho, y))) \geq t.$$

This circuit $\mathcal{C}_{\mathcal{F}, \ell, t}$ is the OR of $M^u n^{O(t)}$ many depth-3 circuits of size $M(n^{O(\ell)} + Q2^{O(kq)})$.

The following observation will be useful for us:

► **Observation 19.** Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered collection of k -CNFs. For $\ell \geq k$, the total number of paths Π such that Π is a path of length exactly t in some tree $T \in \text{CCDT}_\ell(\mathcal{F})$ is at most $(2^{\ell+k} \cdot 2^{\ell+k})^{\lceil t/\ell \rceil} \leq 16^{t+\ell}$. Consequently, if $(\varrho, y) \in \{0, 1\}^{Y_q}$ is such that $\mathcal{C}_{\mathcal{F}, \ell, t}(\varrho, y) = 1$, then $\mathcal{C}_P(\varrho, y) = 1$ for (at least one) and at most $16^{t+\ell}$ many ℓ -segmented \mathcal{F} -traversals P of length t .

Proof. This follows by inspection of the recursive construction of the set $\text{CCDT}_\ell(\mathcal{F})$ of canonical common ℓ -partial decision trees for \mathcal{F} . Each time case (2) of the definition is reached, the set P of witnessing full paths has size at most $2^{\ell+k}$, and for each path in P there are at most $2^{\ell+k}$ possible assignments to the variables on the path. Finally, there are at most $\lceil t/\ell \rceil$ levels of recursive calls. \blacktriangleleft

With Claim 18 and Observation 19 in hand, we are now ready to prove our main result of this section (Theorem 14), a derandomized version of the multi-switching lemma (Theorem 11). We restate Theorem 14 here for the reader's convenience:

► **Theorem 14.** Let $\mathcal{F} = (F_1, \dots, F_M)$ be an ordered list of Q -clause k -CNFs. Let $\delta, p \in (0, 1)$ and define $q = \log(1/p)$. Let \mathcal{D} be any distribution over $\{0, 1\}^{Y_q}$ that $(\delta/(M^{\lceil t/\ell \rceil} n^{O(t)}))$ -fools the class of depth-3 circuits of size $M(n^{O(\ell)} + Q2^{O(kq)})$. Then for all $\ell \geq k$ and all $t \in \mathbb{N}$,

$$\Pr_{(\boldsymbol{\eta}, \mathbf{z}) \leftarrow \mathcal{D}} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\boldsymbol{\eta}, \mathbf{z}))) \geq t] \leq 16^{t+\ell} M^{\lceil t/\ell \rceil} (32pk)^t + \delta.$$

Proof.

$$\begin{aligned} & \Pr_{(\boldsymbol{\eta}, \mathbf{z}) \leftarrow \mathcal{D}} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\boldsymbol{\eta}, \mathbf{z}))) \geq t] \\ &= \mathbf{E}_{(\boldsymbol{\eta}, \mathbf{z}) \leftarrow \mathcal{D}} [\mathcal{C}_{\mathcal{F}, \ell, t}(\boldsymbol{\eta}, \mathbf{z})] && \text{(Claim 18)} \\ &\leq \sum_{P \in \mathcal{P}_{\mathcal{F}, \ell, t}} \mathbf{E}_{(\boldsymbol{\eta}, \mathbf{z}) \leftarrow \mathcal{D}} [\mathcal{C}_P(\boldsymbol{\eta}, \mathbf{z})] && \text{(union bound)} \\ &\leq \sum_{P \in \mathcal{P}_{\mathcal{F}, \ell, t}} \left(\mathbf{E}_{(\boldsymbol{q}, \mathbf{y}) \leftarrow \mathcal{U}} [\mathcal{C}_P(\boldsymbol{q}, \mathbf{y})] + \frac{\delta}{M^{\lceil t/\ell \rceil} n^{O(t)}} \right) && (\mathcal{D} \text{ } (\delta/(M^{\lceil t/\ell \rceil} n^{O(t)}))\text{-fools } \mathcal{C}_P) \\ &\leq \delta + \mathbf{E}_{(\boldsymbol{q}, \mathbf{y}) \leftarrow \mathcal{U}} \left[\sum_{P \in \mathcal{P}_{\mathcal{F}, \ell, t}} \mathcal{C}_P(\boldsymbol{q}, \mathbf{y}) \right] && \text{(Proposition 16)} \\ &\leq \delta + 16^{t+\ell} \mathbf{E}_{(\boldsymbol{q}, \mathbf{y}) \leftarrow \mathcal{U}} [\mathcal{C}_{\mathcal{F}, \ell, t}(\boldsymbol{q}, \mathbf{y})] && \text{(Observation 19)} \\ &= \delta + 16^{t+\ell} \Pr_{(\boldsymbol{q}, \mathbf{y}) \leftarrow \mathcal{U}} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \rho(\boldsymbol{q}, \mathbf{y}))) \geq t] && \text{(Claim 18)} \\ &= \delta + 16^{t+\ell} \Pr_{\boldsymbol{\rho} \leftarrow \mathcal{R}_p} [\text{depth}(\text{CCDT}_\ell(\mathcal{F} \upharpoonright \boldsymbol{\rho})) \geq t] && \text{(Observation 13)} \\ &\leq \delta + 16^{t+\ell} M^{\lceil t/\ell \rceil} (32pk)^t. && \text{(Theorem 11)} \end{aligned}$$

Unconstraining Graph-Constrained Group Testing

Abstract

In network tomography, one goal is to identify a small set of failed links in a network using as little information as possible. One way of setting up this problem is called *graph-constrained group testing*. Graph-constrained group testing is a variant of the classical combinatorial group testing problem, where the tests that one is allowed are additionally constrained by a graph. In this case, the graph is given by the underlying network topology.

The main contribution of this work is to show that for most graphs, the constraints imposed by the graph are no constraint at all. That is, the number of tests required to identify the failed links in graph-constrained group testing is near-optimal even for the corresponding group testing problem *with no graph constraints*. Our approach is based on a simple randomized construction of tests. To analyze our construction, we prove new results about the size of giant components in randomly sparsified graphs.

Finally, we provide empirical results which suggest that our connected-subgraph tests perform better not just in theory but also in practice, and in particular perform better on a real-world network topology.

1 Introduction

Suppose you run a network with n switches and m links between the switches. Occasionally links will fail, and it is your goal to find and fix them. One common approach is to have each switch send a test packet on its neighboring links and report the results to a central monitoring system. However, in large networks these monitoring systems – and the volume of data that they produce – can become hard to manage. In light of this, the problem (sometimes called *network tomography* [5]) is: how little information does this central system need to find failing links quickly?

In the version of this problem that we focus on, suppose that some set of at most d links fail. Instead of observing these failures directly, we may send test packets along any connected walks in the network, and we observe whether or not each packet reaches its destination.¹ The goal is to identify any set of up to d failed links while sending as few packets as possible.

¹ We explain a bit more about how this, or tests equivalent to this, might be implemented in Section 2.3.1.

We focus on the *non-adaptive* setting, where the packet walks must be fixed ahead of time. Non-adaptive tests are faster since they allow packets to be sent in parallel, and are easier to implement since these walks can be hard-coded once into the switches.

As observed by [6, 18], this problem is a variant of a well-studied problem called *combinatorial group testing*. Combinatorial group testing, originally motivated by the problem of cheaply testing for disease [10], has been studied since the 1940’s and has applications from computational biology to wireless networks. We refer the reader to [11] for a survey. In the combinatorial group testing problem there are m items, at most d of which are “defective.” A single test reveals whether or not there are any defectives in a subset T of items. The goal is to identify the defective items, by observing the output of a few tests.

The connection to network tomography is as follows: each link is defective if it fails, and each test T corresponds to a set of links. In the network tomography setting, there is one additional requirement: a test $T \subseteq [m]$ must correspond to a walk that a packet could take through the network. Because of this connection, [6] called this problem “graph-constrained group testing.”

Our Question. A natural question is whether graph-constrained group testing is more difficult than classical group testing. That is, whether the additional constraints of graph-constrained group testing lead to significantly more tests. For the unconstrained group testing problem, the state-of-the-art construction uses $O(d^2 \log(m/d))$ tests [25], which nearly matches the lower bound of $\Omega(d^2 \log_d m)$ tests [13, 27]. Thus, our question is as follows:

► **Question 1.** *For what graphs G can we solve the graph-constrained group testing problem using $O(d^2 \log(m/d))$ tests?*

Previous work [18] has shown that certain graphs, such as a line, require $\Omega(m)$ tests, far more than the $O(d^2 \log(m/d))$ we would need for the unconstrained problem. However, it is also known that for sufficiently “well-connected” graphs (for example, those with large minimum cuts, many disjoint spanning trees, or constant mixing time), a sublinear number of tests suffice [6, 18]. These works have proposed using large subtrees [18] or random walks [6] as the tests. However, both of these approaches stop short (by polylogarithmic factors or more) of obtaining an $O(d^2 \log(m/d))$ bound for most graphs.

Our contributions. We improve upon the results of [6, 18] to show that $O(d^2 \log(m/d))$ tests are sufficient for a wide collection of graphs, including many of the graphs already considered in prior work. Our construction – which is randomized – is quite simple: we sparsify the graph by choosing edges at random, and use the resulting large connected subgraphs. This is similar in flavor to earlier work – for example, [6] considered random walks – but our tests lead to stronger theorems, and also appear to perform better in practice. Moreover, our approach is quite general and works for other variants of the group-testing problem. To illustrate this, we show that it also gives near-optimal results in a model of random link failures. Concretely, our contributions are as follows:

■ **$O(d^2 \log(m/d))$ tests suffice for (β, α) -edge expanders.** Our main result, Theorem 8, applies to graphs which are (β, α) -edge expanders, meaning that every set $S \subseteq V$ of size at most βn has at least $\alpha|S|$ edges coming out of it. We show that $O(d^2 \log(m/d))$ tests suffice when β is constant and $\alpha \gtrsim d$. Moreover, if β is sub-constant, then the number of tests required degrades gracefully with β .

(β, α) -edge expansion is a general notion, and our results imply improved graph-constrained group-testing schemes for several natural classes of graphs like Erdős-Rényi graphs and constant-degree expanders. Moreover, our results are even optimal when applied to certain “counter-example” graphs like the barbell graph which foil earlier work.

■ **Table 1** Summary of general results using connected-subgraph tests to identify any d defective edges for “well-connected” graphs with n vertices and m edges, for various notions of “well-connected.” See discussion in Section 3 for slightly more general statements of results in previous work.

Source	Graph	Max. defective edges	Number of Tests
[18]	G has min-cut K	$d \leq \lceil \frac{K-1}{2} \rceil - 1$	$O(d^3 \log(m))$
[6]	G is D -regular, with mixing time τ	$d \leq d_0$ for some $d_0 = \Omega(D/\tau^2)$	$O(\tau^2 d^2 \log(m/d))$
Proposition 2	G has min-cut K	$d \leq \frac{K}{5 \log n}$	$O(d^2 \log(m/d))$
Theorem 8	G is a (β, α) -edge expander	$d \leq 1.99\alpha$	$O\left(\frac{d^2 \log(m/d)}{\beta}\right)$

Our general theorem (Theorem 8) is compared to existing general theorems in Table 1. The results for a few specific families of graphs are shown in Table 2. These results are presented in more detail in Section 4.

- **New results about large connected components of random graphs.** While our construction is quite simple, the analysis requires some delicacy. In order to show that our tests work, we prove new results about giant components in randomly sparsified graphs.

More precisely, our main technical theorem (Theorem 10) establishes the following. Suppose that $G = (V, E)$ is a (β, α) -edge expander, and let $G(p) = G(V, E')$ be the graph where $E' \subseteq E$ is a random subset where each edge is kept independently with probability p . We show that if $p \geq (1 + \varepsilon)/\alpha$, then for any edge $e \in E$, with probability $\Omega(p\varepsilon)$ then not only does e survive, but also e 's connected component in $G(p)$ has size at least βn . This is of a similar flavor to previous work on giant components of randomly sparsified graphs, but with two important differences: first, our result works even if β is small (so the components are “big” but not “giant”) and second, we require that any edge e be contained in a large component with decent probability after sparsification. Theorem 10 is stated and proved in Section 5.

- **A general algorithm for graph-constrained group testing problems.** Our approach is to simulate a uniformly random (unconstrained) approach in the constrained setting. Because a uniformly random approach is near-optimal for many variants on the group testing problem, our results extend to variants of the graph-constrained group testing setting. We illustrate this in the full version of this paper, where we show that our algorithm also achieves near-optimal results in the stochastic model (where the link failures are random) [28].
- **Empirical results.** Finally, we present empirical results which suggest that our approach significantly out-performs the random-walk method of [6] and in many cases, nearly matches the performance of unconstrained random tests. On complete graphs and hypercubes it uses less than half the tests of the random-walk method. On a family of graphs often used in datacenter networks (the “fat-tree” topology), our approach is able to find defectives using a nontrivial number of tests while the random-walk method is not.

■ **Table 2** Summary of work on the number of connected-subgraph tests required to identify any $d \leq d_0$ failures, for specific families of graphs. All graphs have n vertices and m edges. Results which meet the near-optimal $O(d^2 \log(m/d))$ tests or which have only the asymptotically optimal restriction $d \leq d_0$ for some $d_0 = \Omega(\text{degree})$ are highlighted in grey.

Graph	Source	Number of tests	Limit d_0 so that recovery of $d \leq d_0$ failures is possible
Complete Graphs	[6]	$O(d^2 \log(m/d))$	$d_0 = \Omega(n)$
	This work	$O(d^2 \log(m/d))$	$d_0 = \Omega(n)$
D -Regular Expanders ($O(1)$ spectral gap)	[18]	$O(d^3 \log m)$	$d_0 = \Omega(D)$
	[6]	$O(d^2 \log^3(m))$	$d_0 = \Omega(D/\log^2(n))$
	This work	$O(d^2 \log(m/d))$	$d_0 = \Omega(D)$
Erdős-Rényi Graphs $G(n, D/n)$	[6]	$O(d^2 \log^3(m))$	$d_0 = \Omega(D/\log^2(n))$
	This work	$O(d^2 \log(m/d))$	$d_0 = \Omega(D)$
Barbells	[18]	$O(d^3 \log m)$	$d_0 = 1$
	[6]	m (see discussion)	$d_0 = n$
	This work	$O(d^2 \log(m/d))$	$d_0 = \Omega(n)$
Fat-Trees	[18]	$O(d^3 \log m)$	$d_0 = 1$
	This work	$O(d^2 \log(m/d))$	$d_0 = \Omega(D/\log D)$

1.1 Overview of approach

Our approach is quite simple: we just choose random edges and take the large connected components. Intuitively, the reason that this works is because:

1. If we just chose random edges, we would be back in the traditional group testing setting, where random tests are nearly optimal by Proposition 6.
2. We will show that if G is a (β, α) -edge expander, then the graph $G(p)$ formed by choosing random edges has mostly large components, of size at least βn . Intuitively this means that throwing away the few disconnected parts should not matter much.

There are several challenges in making the above intuition rigorous. First, once we throw away the edges that are not in a large connected component, the edges that remain, conditional on remaining, are no longer independent. Thus, the intuition from point 1 above does not quite hold. However, this ends up being reasonably straightforward to deal with.

The second and more interesting challenge is that, while there is a great deal of work on when random sparsifications of graphs have giant components, we need a different result that to the best of our knowledge does not appear in the literature. The first difference between our setting and existing work is that we work with (β, α) -edge expanders; this means that we need to show that there are “decently big” connected components rather than “giant” components if β is small. The second difference is that we must show that each edge e is still contained in a test with high probability. That is, when we pass from G to $G(p) = (V, E')$,

the probability that $e \in E'$ is p ; for the analysis in the random case to still work, we need the probability that e is in a large connected component of E' to also be proportional to p .

To address this second challenge, we reduce the question to one about random walks. Taking inspiration from [22] who study random sparsifications of the complete graph, we introduce a process to generate the connected component of a particular edge v , and argue that this process generates a large connected component if and only if an appropriately chosen random walk diverges with decent probability; then we prove it does converge.

The details of the approach are given in Section 5. However, as a warm-up to show why the intuition presented above is believable, we first prove an easy statement of the same flavor where neither of these challenges arise. Proposition 2 below shows that if we replace (β, α) -expansion with the property of having a large min-cut, $O(d^2 \log(m/d))$ tests suffice.

► **Proposition 2 (Informal).** *There is a constant $C > 0$ so that the following holds. Suppose that $G = (V, E)$ is a graph with $|V| = n$, $|E| = m$. Let $d \geq 1$ be an integer. Suppose that the minimum cut K of G satisfies $K \geq 5(d+1) \log(n)$. Let \mathcal{T} be a set of tests $T \subseteq E$ generated according to the following process:*

- Initialize $\mathcal{T} = \emptyset$.
- For $t = 1, 2, \dots, Cd^2 \log(m/d)$:
 - Let $T \subseteq E$ be a random set where each edge is included with probability $1/(d+1)$.
 - Add T to \mathcal{T} .

Then \mathcal{T} can identify d failed edges, and with high probability each test is connected.

Proof sketch. As we will see in Proposition 6, \mathcal{T} is able to identify d failed edges, and so it suffices to show that a random set T is connected with high probability. Fortunately, this is true:

► **Theorem 3 ([21]).** *Let K be the minimum cut of G . If $p > \min\left(\frac{5 \log n}{K}, 1\right)$, $G(p)$ is connected with probability at least $1 - \frac{1}{n}$.*

By Theorem 3 and a union bound, the probability any test is disconnected is at most $|\mathcal{T}|/n = O\left(\frac{d^2 \log(m/d)}{n}\right)$. ◀

Proposition 2 is already enough to establish order-optimal results for some of the examples shown in Table 2 (for example the complete graph and the fat tree), but for the others we will need Theorem 8 about (α, β) -expanders.

Organization. In Section 2, we formally set up the problem. In Section 3, we survey related work, and we state our theoretical results in Section 4. The proofs of these results follow in Section 5. Finally, we present our empirical results in Section 6.

2 Setup and Preliminaries

We begin with some basic notation and definitions.

2.1 Graph-theoretic preliminaries

Throughout, we will be working with undirected, unweighted graphs $G = (V, E)$ with $|V| = n$, $|E| = m$. For a set of vertices $A \subseteq V$, the *boundary* of A is $\partial A = \{\{u, v\} \in E : u \in A, v \notin A\}$. For a set of edges $B \subseteq E$, we use the notation $N(B)$ to denote the set of vertices v that are endpoints of an edge in B : $N(B) = \{v \in V : \exists u, \{u, v\} \in B\}$.

The minimum cut K of a graph G is defined by $K = \min_{A \subseteq V} |\partial A|$. Our main theorem is about *edge expanders*. We give a slightly more general definition than the usual notion (which would have $\beta = 1/2$ below), so that we can state a more general theorem.

► **Definition 4.** A graph $G = (V, E)$ is a (β, α) -edge expander if for all sets $A \subseteq V$ with $|A| \leq \beta|V|$, $|\partial A| \geq \alpha|A|$.

We will consider random sparsifications of graphs. For a graph $G = (V, E)$ and $p \in (0, 1)$, $G(p) = (V, E')$ denotes the random graph where $E' \subseteq E$ is generated by including each edge of E in E' independently with probability p . We use $G(n, p) = K_n(p)$ to denote the Erdős-Rényi graph where each edge is included independently with probability p . (Here, K_n denotes the complete graph on n vertices).

2.2 Group testing preliminaries

The combinatorial group testing problem is set up as follows (using slightly non-standard notation in order to be consistent with the graph-constrained set-up below). Let E be a set of size m , and suppose that $B \subseteq E$ is a set of at most d special or “defective” items in E . A test $T \subseteq E$ is a collection of items, and we say that the *outcome* of the test T is TRUE if $T \cap B \neq \emptyset$ and FALSE otherwise. We say that a collection of tests $\mathcal{T} \subseteq 2^E$ (here, 2^E denotes the power set of E , consisting of all subsets of E) *can identify up to d defective items in E* if for any $B \subseteq E$ with $|B| \leq d$, B is uniquely determined from the outcomes of the tests $T \in \mathcal{T}$. The goal is to design a collection of tests $\mathcal{T} \subseteq 2^E$ which can identify up to d defective items, so that $|\mathcal{T}|$ is as small as possible. A useful notion in the group testing literature is *disjunctness*, which is a sufficient condition for recovery.

► **Definition 5.** Let E be a set and $\mathcal{T} \subseteq 2^E$. We say that \mathcal{T} is d -disjunct if for all $e \in E$, for all $B \subseteq E$ where $|B| \leq d$ and $e \notin B$, there exists a test $T \in \mathcal{T}$ so that $e \in T$ and $B \cap T = \emptyset$.

If \mathcal{T} is d -disjunct, then \mathcal{T} can identify up to d defective items in E . More precisely, it is not hard to see that the following algorithm will do the job: for each item $e \in E$, declare $e \in B$ if and only if all the tests $T \in \mathcal{T}$ with $e \in T$ had outcome TRUE.

Choosing tests completely at random is a good way to obtain d -disjunct sets.

► **Proposition 6** (See e.g. [11] Theorem 8.1.3). Let $d \geq 1$. Let E be a set. Consider a random test $T \subseteq E$ such that each $e \in E$ is included in T independently with probability $p = \frac{1}{d+1}$. Let $\mathcal{T} = \{T_1, \dots, T_\tau\}$, where each $T_i \in \mathcal{T}$ is chosen independently from the above distribution. Then there is a value $\tau = O(d^2 \log(m/d))$ so that \mathcal{T} is d -disjunct with probability at least $1 - 1/m$.

This is nearly optimal, up to a factor of $O(1/\log d)$:

► **Theorem 7** ([13]). Let E be a set of size m and $\mathcal{T} \subseteq 2^E$. If \mathcal{T} is d -disjunct, then $|\mathcal{T}| = \Omega(d^2 \log_d m)$

2.3 Graph-constrained group testing

Given a graph $G = (V, E)$, the graph-constrained group testing problem on G is the same as the standard group testing problem on a set of items E , with the additional constraint that each test $T \subseteq E$ be a connected subgraph of G . That is, in the network tomography application, a packet must be able to traverse a test T . We say that a *connected-subgraph test* is a set of edges $T \subseteq E$ so that the graph $(N(T), T)$ is connected.

We note that the definition of disjunctness directly applies to the graph-constrained setting, and our goal in this work will be to design d -disjunct collections \mathcal{T} of connected-subgraph tests, such that \mathcal{T} is as small as possible.

2.3.1 Why connected-subgraph tests?

Our work, like existing work on graph-constrained group testing [6, 18, 20], uses connected-subgraph tests. Connected-subgraph tests can be implemented in an actual network in a number of ways:

- The test can be converted into a path on the graph by solving an instance of the Chinese Postman Problem [14]. A packet can then be sent along this path, for instance by using source routing or by adding a rule at each switch on the path matching the packet's source IP, destination IP, and time-to-live.
- We can compute a spanning tree of subgraph. Each switch in the subgraph checks the health of its links, and forwards a bit to its parent in the tree: 1 if its adjacent links are healthy, and 0 otherwise. If the link from a switch to its parent in the tree is down, then it cannot send anything. If the root node receives all 1's, it knows that all the links in the subgraph are healthy; otherwise at least one of the links is broken.

One could also imagine restricting the tests to be, for example, simple paths or trees. Some restrictions on tests do have some advantages in implementation (in particular, tests which are *shortest* paths may be easier to implement than general connected-subgraph tests: for example many networks support equal-cost multipath routing (ECMP) which splits traffic across all the shortest paths between a pair of hosts). However, connected subgraph tests are strictly more powerful than either simple paths or trees for the constrained group-testing problem. We provide some examples which demonstrate this in the full version of this paper [28].

3 Related Work

Boolean network tomography. Most of the work on *boolean network tomography* (that is, the problem of identifying failures in a graph using end-to-end traffic) has a much harsher set-up than the one we consider here, in that both the graph and the tests are taken to be worst-case, or at least very constrained. For example, all the tests may be required to be simple paths starting from a particular vertex. The reason for the harsh set-up is that historically, networks have been quite inflexible, which severely limits both the graph topologies and the sorts of tests that are used. Since identifying failures uniquely is often impossible in these settings, this work has focused on doing as well as possible given the circumstances, for example by finding *any* set of failures that will explain the test outcomes [3, 8] or by finding the most likely set of failures given some underlying distribution [12, 24]. When the input graph and set of allowed tests is worst-case, these problems are hard, and the usual approach is to reduce to some NP-hard problem and use a heuristic or approximation algorithm.

Graph-constrained group testing. More recently, the field of networking has shifted towards flexible datacenter networks, where the tomography problem is still interesting [26, 30]. Modern datacenter networks, however, fundamentally change the constraints of the tomography problem. Datacenters are good expanders [9, 29], so the worst-case assumptions about the graphs can be relaxed. Modern networks are programmable [4]: instead of the network defining what can and cannot be done, operators program networks to do what they want. Thus, the set of allowed tests \mathcal{T} need not be worst-case. This leads to graph-constrained group testing, where we can design the tests, and make assumptions about the connectivity of the underlying network.

We are not the first to investigate group testing with graph constraints (although to the best of our knowledge our work is the first to consider graph-constrained group testing with random failures). Du and Hwang discuss two different group-testing problems on graphs in Chapter 12 of [11], although neither are exactly the same as the setup we consider here. The connection between boolean network tomography and group testing was first observed by [18]. They give results for specific families of graphs including line graphs, grids, and binary trees. Their most general result is that if a graph has d edge-disjoint spanning trees T_1, \dots, T_d with δ being the maximum diameter of the trees, then $O(d^3 \log m + d \min(\delta + \log^2 n, \delta \log n))$ tests are sufficient to identify at most d failures. (As a corollary, this implies that any graph with minimum cut K can identify $d \leq \lceil \frac{K-1}{2} \rceil - 1$ failed edges, which is what is stated in Table 1). Finally, [20] considers the adaptive version of graph-constrained group testing. They present an adaptive algorithm which, on any graph, uses a number of tests that is within a constant factor of the optimal number.

The work closest to our is that of Cheraghchi et al. [6], who give a randomized construction of connected-subgraph tests via random walks. They show that $O(d^2 \log(m/d))$ tests suffice for *very* well-connected graphs (those with constant mixing time), and $O(d^2 \log^3(m))$ tests suffice for certain expanders and Erdős-Rényi graphs. Their most general result is that for graphs with mixing time τ and where there exists some $c > 0$ such that the degree D_v of each vertex $v \in V$ lies in between $6c^2 d \tau^2 \leq D_v \leq 6c^3 d \tau^2$, at most $O(c^4 \tau^2 d^2 \log(m/d))$ tests are sufficient. We summarize the general results for related work in non-adaptive graph-constrained group testing in Table 1.

Giant components in random graphs. Finally, we mention some related work on the size of giant components of randomly sparsified graphs, since our main technical theorem (Theorem 10) is related to this. This question is well-studied, but we need a slightly different result. One difference is that we work with (β, α) -edge expansion, and in particular our “giant” components need not be so giant if β is small. A second difference is that we require that every edge be contained in a large connected component with constant probability; to the best of our knowledge, existing work does not explicitly give such a guarantee.

The study of giant components in $G(n, p)$ (aka, a randomly sparsified complete graph) was initiated by Erdős and Rényi in [15]. This was extended to sparsifications of the hypercube [1] and sufficiently good expander graphs [16] and [7]. Our approach to Theorem 10 is based on that of Krivelevich and Sudakov [22] who give a simpler argument for existing results on giant components.

Most of these results show that as long as $p \leq \frac{1+\epsilon}{D}$, where D is the degree of the graph G , then $G(p)$ contains a giant component. We show a similar result: if $p \leq \frac{1+\epsilon}{\alpha}$, where G is a (β, α) -edge expander, then there exists a connected component of size at least βn . (And moreover, any edge is contained in such a component with decent probability).

4 Results

4.1 Main result

Our group testing scheme is quite simple: the idea is just to choose random edges of the graph, and keep any large-enough connected components. Recall the notation that for a graph $G = (E, V)$, $G(p) = (V, E')$ is the graph where each edge in E is included in E' independently with probability p . Then the randomized algorithm for constructing the tests is given in Algorithm 1.

■ **Algorithm 1** Make-Tests.

input : Graph $G = (V, E)$; number of failed edges d ; parameters $\frac{2}{d} \leq \delta \leq 1/3$,
 $\beta \in (0, \frac{1}{2}]$, and $\tau \in \mathbb{N}$

output : A collection of tests $\mathcal{T} \subseteq 2^E$

- 1 $\mathcal{T} \leftarrow \emptyset$;
- 2 $p \leftarrow \frac{1}{\delta d}$;
- 3 **for** $t = 1, \dots, \tau$ **do**
- 4 Draw $G' \sim G(p)$ independently from all the other rounds;
- 5 Find the connected components A_1, A_2, \dots, A_r of $G(p)$;
- 6 **for** each A_i so that $|A_i| \geq \beta n$ **do**
- 7 Add the test A_i to \mathcal{T} ;
- 8 **end**
- 9 **end**
- 10 **return** \mathcal{T}

Our main theorem implies that any (β, α) -edge expander with large enough α admits a group testing scheme with $O(d^2 \log(m/d)/\beta)$ tests.

► **Theorem 8.** *There are constants $c, C > 0$ so that the following holds. Suppose that $G = (V, E)$ is a graph with $|V| = n, |E| = m$. Let $d \geq 1$ be an integer, and $\frac{2}{d} \leq \delta \leq \frac{1}{3}$. Suppose that G is a (β, α) -edge-expander with $\beta \in (0, 1/2]$ and such that $\alpha \geq 1$ satisfies*

$$\alpha \geq d \left(\frac{1}{2} + \delta \right). \tag{1}$$

Let \mathcal{T} be the set of tests returned by Algorithm 1 run with parameters δ, β , and

$$\tau = Cd^2 \log(m/d) e^{(1+\delta)/\delta}.$$

Then with probability at least $1 - m^{-cd}$, \mathcal{T} is d -disjunct. Further,

$$|\mathcal{T}| \leq \frac{Cd^2 \log(m/d) e^{(1+\delta)/\delta}}{\beta}.$$

If β, δ are constant, then the number of tests required is $O(d^2 \log(m/d))$, which is nearly optimal even for the unconstrained group testing problem (that is, it nearly matches Theorem 7). Moreover, the requirement on the expansion factor α is nearly tight. That is, in (1), we may take $\alpha = d(\frac{1}{2} + \delta)d$ for any constant $\delta > 0$, while still maintaining the near-optimal $O(d^2 \log(m/d))$ test complexity. On the other hand, such a statement could not hold for α much smaller than $d/2$. More precisely, we show below in Proposition 9 that the degree D of the graph G must be at least $d/2$ to obtain any nontrivial bound on $|\mathcal{T}|$. Since for any $\gamma > 0$, there exist D -regular (β, α) -edge expanders with $\alpha = (1 - \gamma)D$ for small $\beta \sim \gamma$, this implies that the cut-off for α of $d/2$ in Theorem 8 cannot be improved.

► **Proposition 9.** *Let $G = (V, E)$ be a D -regular graph with $|E| = m$. If $\mathcal{T} \subseteq 2^E$ is a collection of d -disjunct connected-subgraph tests, for $d \geq 2D - 2$, then $|\mathcal{T}| \geq m$.*

Proof. Suppose that $\mathcal{T} \subseteq 2^E$ with $|\mathcal{T}| < m$. Then there is some edge $e = \{u, v\}$ so $\{e\} \notin \mathcal{T}$. Let $B = \partial(\{u, v\})$ be the set of edges adjacent to e , so $|B| = 2D - 2 \leq d$. Then the only connected-subgraph test $T \subseteq E$ so that $e \in T$ but $T \cap B = \emptyset$ is $\{e\}$, which by assumption is not in \mathcal{T} . Thus, \mathcal{T} is not d -disjunct. (See Figure 1). ◀

■ **Figure 1** Proof of Proposition 9. Suppose that the number of edges that may fail is $d \geq 2D - 2$ where D is the degree of the graph. If the set of tests \mathcal{T} does not contain the singleton $\{e\}$ for an edge $e = \{u, v\}$, then the set B of dashed edges – all of the neighbors of e – provides an counter-example to d -disjunctness.

We instantiate Theorem 8 for several different families of graphs in Appendix A; the results are summarized in Table 2. We note that our results also extend to a model with random link failures; we defer this discussion to the full version of this paper [28].

5 Proofs

In this section, we prove Theorem 8. Our proof is based on the following theorem, which implies that any edge e is reasonably likely to be contained in a large connected component of $G(p)$.

► **Theorem 10.** *Let $\beta \in (0, 1/2)$ and $\alpha \geq 1$, and let $G = (V, E)$ be a graph with $|V| = n$, $|E| = m$ so that, for any set $A \subset V$ of size $2 \leq |A| \leq \beta n$, we have $|\partial A| \geq \alpha|A|$. For an edge $e \in E$, let C_e denote the connected component of $G(p)$ containing e , or \emptyset if there is no such connected component (that is, if $e \notin G(p)$ was deleted), and let $|C_e|$ denote the number of vertices in C_e .*

Choose any $\varepsilon \in (0, 1/3)$, and suppose that $p \geq \frac{1+\varepsilon}{\alpha}$. Then for all edges $e \in E$,

$$\mathbb{P}(|C_e| \geq \beta n) \geq \frac{p\varepsilon}{8}. \quad (2)$$

Before we prove Theorem 10, we discuss how it can be used to prove Theorem 8.

Let $G = (V, E)$, and let $G(p) = (V, E')$ be the random sparsification. Fix $B \subseteq E$ with $|B| = d$ and $e \in E$. The following lemma shows that with high probability, at least one of the tests in \mathcal{T} will separate e from B . Then one can union bound over all choices for e and B to conclude that \mathcal{T} is d -disjunct. We defer the details to the full version of this paper [28].

► **Lemma 11.** *Consider one draw of $G(p)$ in Make-Tests, and let T_1, T_2, \dots be the connected components of $G(p)$ which have size at least βn . Fix $B \subseteq E$ with $|B| = d$ and $e \in E$. Then*

$$\mathbb{P}(\exists i \text{ s.t. } e \in T_i \text{ and } B \cap T_i = \emptyset) \geq \frac{\delta p}{8} \cdot (1-p)^d.$$

Proof. We have

$$\begin{aligned} \mathbb{P}(\exists i \text{ s.t. } e \in T_i \text{ and } B \cap T_i = \emptyset) &= \mathbb{P}(|C_e| \geq \beta n \text{ and } B \cap C_e = \emptyset) \\ &\leq \mathbb{P}(|C_e| \geq \beta n \text{ and } B \cap E' = \emptyset) \\ &= \mathbb{P}(|C_e| \geq \beta n \mid B \cap E' = \emptyset) \cdot \mathbb{P}(B \cap E' = \emptyset). \end{aligned}$$

We have $\mathbb{P}(B \cap E' = \emptyset) = (1-p)^d$, since this is just the probability that all the edges in B survive in $G(p)$.

For our fixed e, B , let $\bar{G} = (V, E \setminus B)$ be the graph with all the edges in B removed. Consider the distribution of $G(p)$ conditioned on the event that $B \cap E' = \emptyset$. This is the same as the distribution of $\bar{G}(p)$. To see this, notice that for $A \subseteq E \setminus B$, the random sets of $A \cap E'$ and $B \cap E'$ are independent. Let \bar{C}_e be the connected component containing e in $\bar{G}(p)$. Then

$$\mathbb{P}(|C_e| \geq \beta n \mid B \cap E' = \emptyset) = \mathbb{P}(|\bar{C}_e| \geq \beta n).$$

Notice that since G is a (β, α) -edge expander with $\alpha \geq d(\frac{1}{2} + \delta)$, then for any set $A \subset V$ of size $2 \leq |A| \leq \beta n$, we have $|\partial A| \geq \alpha|A| - d \geq (\alpha - \frac{d}{2})|A|$. Thus, we may apply Theorem 10 to \bar{G} . Choose $p = \frac{1+\delta}{d\delta}$, and apply Theorem 10. Our assumption (1) that $\alpha \geq d(\frac{1}{2} + \delta)$ and the choice of p implies that $p \geq \frac{1+\delta}{\alpha-d/2}$, we conclude that $\mathbb{P}(|\bar{C}_e| \geq \beta n) \geq \frac{\delta p}{8}$. Putting things together proves the lemma. ◀

Proof of Theorem 10. As in the theorem statement, suppose $p \geq (1 + \varepsilon)/\alpha$ for some $\varepsilon \in (0, 1/3)$, and let $G = (V, E)$ be a (β, α) -edge expander. Write $G(p) = (V, E')$, so that $E' \subseteq E$. Choose $p \geq (1 + \varepsilon)/\alpha$.

Consider the probability (u, v) is in a large component,

$$\mathbb{P}(C_{(u,v)} \geq \beta n) = \mathbb{P}((u, v) \in E') \cdot \mathbb{P}(|C_{(u,v)}| \geq \beta n \mid (u, v) \in E').$$

Condition on the event that $(u, v) \in E'$, and imagine building $C_{(u,v)}$ by starting with $\{(u, v)\}$ and building the set outwards, one at a time. More precisely, consider the following randomized process:

- $S_0 \leftarrow \{(u, v)\}, B_0 \leftarrow \emptyset$
- For $t = 0, 1, 2, \dots$:
 1. Let $N(S_t)$ be the set of vertices in V adjacent to S_t .
 2. Let $U_t = \partial(N(S_t)) \setminus B_t$ be the set of unvisited edges that lie on the boundary of $N(S_t)$.
 3. If $|U_t| = 0$, **break**.
 4. $S_{t+1} \leftarrow S_t, B_{t+1} \leftarrow B_t$.
 5. Choose an edge $e \in U_t$ arbitrarily.
 6. With probability p , declare that e has survived and add it to S_{t+1} .
 7. Otherwise (with probability $1 - p$) add e to B_{t+1} .

This process is illustrated in Figure 2.

■ **Figure 2** First few steps of the process to build $C_{(u,v)}$ in the proof of Theorem 10. The edge from U_t which we chose ended up being in E' in steps $t = 1$ and $t = 3$, but not $t = 2$.

46:12 Unconstraining Graph-Constrained Group Testing

It is not hard to see that this process terminates at the first time t_{\max} so that $|U_{t_{\max}}| = 0$, and when it does, $N(S_{t_{\max}})$ is distributed identically to the set of vertices in $C_{(u,v)}$. Thus, to bound $|C_{(u,v)}|$ with high probability, we can bound the set $|N(S_t)|$ with high probability. Notice that S_t is a tree; thus, $|S_t| = |N(S_t)| - 1$, and so it suffices to show that $|S_{t_{\max}}| > \beta n - 1$ with high probability. To that end, we will show that, as long as $|S_t| \leq \beta n - 1$, the probability that $|U_t| = 0$ is very small.

At each step t , we either add an edge to B_t or to S_t , so $|S_t| + |B_t| = t$. Let X_t be the random variable which is 1 if we added an edge to S_t in step t ; thus $X_t \sim \text{Ber}(p)$ and $|S_t| = 1 + \sum_{i=1}^t X_i$.

Suppose that S_t is nonempty and $|S_t| \leq \beta n - 1$, so $2 \leq |N(S_t)| \leq \beta n$. By our expansion assumption, we have $|\partial N(S_t)| \geq \alpha |S_t|$, and so

$$\begin{aligned} |U_t| &= |\partial(N(S_t)) \setminus B_t| \geq \alpha |S_t| - |B_t| = \alpha |S_t| - (t - |S_t|) = (1 + \alpha) |S_t| - t \\ &= (1 + \alpha) \left(1 + \sum_{i=1}^t X_i \right) - t \geq \sum_{i=1}^t ((1 + \alpha) X_i - 1) + \alpha. \end{aligned}$$

Thus,

$$\begin{aligned} \mathbb{P}(\exists t > 0 \text{ s.t. } |S_t| \leq \beta n - 1 \text{ and } |U_t| = 0) &= \mathbb{P}(\exists t > 0 \text{ s.t. } |S_t| \leq \beta n - 1 \text{ and } |U_t| \leq 0) \\ &\leq \mathbb{P}\left(\exists t > 0 \text{ s.t. } \sum_{i=1}^t ((1 + \alpha) X_i - 1) \leq -\alpha\right). \end{aligned}$$

Let $Y_i = (\alpha + 1)X_i - 1$, so that $Y_i = \alpha$ with probability p , and $Y_i = -1$ with probability $1 - p$. Let $Z_t = \sum_{i=1}^t Y_i$ be a random walk. The above shows that

$$\mathbb{P}(\exists t > 0, |S_t| \leq \beta n - 1 \text{ and } |U_t| = 0) \leq \mathbb{P}(\exists t > 0, Z_t \leq -\alpha). \quad (3)$$

Let $\tau_k(Y_i)$ denote the smallest t so that $|\sum_{i=1}^t Y_i| \geq |k|$ and $\text{sign}(\sum_{i=1}^t Y_i) = \text{sign}(k)$. We claim that $\mathbb{P}(\exists t > 0, Z_t \leq -\alpha) \leq 1 - \inf_{M > 0} \mathbb{P}(\tau_M(Y_i) \leq \tau_{-\alpha}(Y_i))$. Indeed, suppose that there is some $t > 0$ so that $Z_t \leq -\alpha$. Then there is some sufficiently large $M > \alpha t$ so that Z_t could not have reached M in t steps, and so the random walk does not arrive at M before arriving at $-\alpha$. Thus

$$\begin{aligned} \mathbb{P}(\exists t > 0, Z_t \leq -\alpha) &\leq \mathbb{P}(\exists M, \tau_M(Y_i) > \tau_{-\alpha}(Y_i)) \\ &= \sup_M \mathbb{P}(\tau_M(Y_i) > \tau_{-\alpha}(Y_i)) = 1 - \inf_{M > 0} \mathbb{P}(\tau_M(Y_i) \leq \tau_{-\alpha}(Y_i)). \end{aligned}$$

Thus our goal is to show that $\mathbb{P}(\tau_M(Y_i) \leq \tau_{-\alpha}(Y_i))$ is bounded away from zero for all M ; then there will be some constant probability that the edge-exploration process will make progress as long as $|S_t| \leq \beta n - 1$.

▷ **Claim 12.** Using the notation above, for all $M > 0$,

$$\mathbb{P}(\tau_M(Y_i) \leq \tau_{-\alpha}(Y_i)) \geq \frac{\varepsilon}{8}.$$

The proof of the claim can be found in the full version of this paper [28]. The main idea is as follows: suppose for simplicity that $\alpha \in \mathbb{Z}$. Then we replace the walk defined with the Y_i 's by one whose steps W_i are ± 1 , where the probability of 1 is chosen so that the probability that W_i reaches α before -1 is at most p . Analyzing this walk is then an instance of the Asymmetric Gambler's Ruin problem (see, for example, [17]).

■ **Figure 3** A small example of the fat tree topology with $n = 36, m = 48$. In our experiments, we consider larger versions ($n = 80, m = 256$ and $n = 45, m = 108$).

Using the claim and the discussion following (3), we have that

$$\mathbb{P}(\exists t > 0 \text{ s.t. } |S_t| \leq \beta n - 1, |U_t| = 0) \leq 1 - \varepsilon/8.$$

Finally,

$$\begin{aligned} \mathbb{P}(|C_{(u,v)}| \geq \beta n) &= \mathbb{P}(|C_{(u,v)}| \geq \beta n \mid (u,v) \in E') \cdot \mathbb{P}((u,v) \in E') \\ &= p \cdot (1 - \mathbb{P}(\exists t \text{ s.t. } |S_t| \leq \beta n - 1, |U_t| = 0)) \geq \frac{p\varepsilon}{8}. \end{aligned}$$

This completes the proof. ◀

6 Empirical Results

In this section, we numerically compare Algorithm 1 to existing work. We compare to the random walk based approach of [6] and to the randomized group testing *without* graph constraints of Proposition 6. We find that the random subgraph tests perform nearly as well as the unconstrained versions in most settings, and often perform significantly better than the random walk approach.

Below, we test the following randomized constructions of tests:

- Our approach, Algorithm 1 (called “Subgraph” in the figures). We use $p = 1/(d + 1)$ and include only the largest connected component of $G(p)$.
- The random walk approach of [6] (called “Random walks” in the figures). We empirically estimate the mixing time τ by picking a node at random and finding the first time that the total variation distance to the equilibrium distribution is less than $1/(2cn)^2$, as per the definition in [6], where c is defined so that the graph $G = (V, E)$ has $D \leq \deg(v) \leq cD$ for each $v \in V$. We fix a constant $\ell > 0$ and run each random walk for $\lceil \frac{\ell n D}{c^3 d \tau} \rceil$ steps. We tried a few of values of ℓ and present the best results for each graph: for the complete graph we chose $\ell = 1$ and for all other graphs we chose $\ell = 4$.
- Unconstrained random approach (called “Random” in the figures). We include each edge in a test with probability $p = 1/(d + 1)$, and ignore the graph constraints.

We consider four types of graphs. The first three – random regular graphs, complete graphs, and hypercubes – are idealized graphs that may or may not capture real networks. For our last graph, we choose the “Fat-Tree” graph [23], originally designed for use in supercomputers and which is now widely used in datacenter networks [2]. As the name suggests, this is a “fattened” tree, where the fatness (number of links) near the top of the tree is greater than the fatness near the leaves. (See Figure 3).

We perform two types of experiments:

1. In the first type of experiment, we compare the probability of obtaining a d -disjunct matrix from any of these three randomized approaches. Unfortunately, it is computationally intense to determine whether or not a given collection \mathcal{T} of tests is d -disjunct, and so we are only able to do this for small d ($d = 1$ and $d = 2$).
2. In the second type of experiment, we are trying to understand the performance of our method for larger d . Since determining d -disjunctness is computationally infeasible for large d , instead we choose d random defectives and estimate the probability of success under each of the three methods. We note that, as shown in the full version of this paper [28], our algorithm is order-optimal for random defectives.

6.1 Number of tests required for d -disjunctness

First, we estimate the number of tests required for d -disjunctness for Algorithm 1 and compare it to [6] and randomized group testing without graph constraints. We find that for many graphs, our approach requires roughly the same number of tests as group testing without constraints.

Figure 4 (resp. Figure 5) shows the probability that a randomly generated test matrix is 1-disjunct (resp. 2-disjunct) for various graphs, algorithms, and numbers of tests. Each point is the empirical mean of 200 independent trials, and we plot error bars of width $1/\sqrt{200} \approx 0.07$. (Notice that by Hoeffding’s inequality, the probability that the true average lies outside the error bars is at most $1/e^2$).

Algorithm 1 performs similarly to the nearly optimal randomized group testing procedure of Proposition 6. Notably, for the Fat-Tree graph, Algorithm 1 significantly outperforms the approach of [6].

6.2 Number of tests required for d random failures

As mentioned above, determining d -disjunctness is computationally infeasible for larger d , and so to assess larger d we consider performance on random failures, which we address in the full version [28].

For our experiments with random failures, we focus on the fat-tree topology. The main reasons for this are (a) that the “Fat-Tree with random failures” set-up is perhaps the most relevant for real-life applications, and (b) the other topologies yield graphs that look similar, but the differences between the three approaches are less pronounced.

We find that Algorithm 1 significantly out-performs the random walk approach of [6], but performs less well as d grows. In this graph once d becomes much larger than 5, even the random group testing construction without graph constraints requires at least m tests.

Figure 6 shows the probability that a set of tests correctly identifies d random failures, where the probability is taken over both the tests and the failures. Each point is the empirical mean of 200 independent trials, and we plot error bars of width $1/\sqrt{200} \approx 0.07$. As above, by a Hoeffding bound the probability that the true mean lies outside the error bars is at most e^{-2} .

7 Conclusion

We have given a simple randomized construction which shows that for many graphs, graph-constrained group testing is possible with a near-optimal number of tests. Our results – which are proved by analyzing a particular random walk – improve over previous work, and also apply to a wider range of graphs. However, many open questions remain, and we conclude with a few of these here.

1. Both our approach and the approach of [6] give randomized constructions. Derandomizing these constructions remains a fascinating open question. Such a derandomization would be especially useful if it allowed a node to extremely efficiently determine which of its neighbors a test packet should be sent to next, using only minimal information stored in the packet.
2. While (β, α) -expansion is reasonably general, it is not completely general. For example, hypercubes are not very good (β, α) -expanders, but the result of [18] implies that (since they have many disjoint spanning trees) hypercubes are reasonably good for the graph-constrained group-testing problem: $O(d^3 \log m)$ tests suffice to identify d defectives for $d \lesssim \log(n)$. It seems possible that one could modify our analysis using the approach of [1] – which shows that random sparsifications of hypercubes have large connected components with high probability – to obtain a good result for hypercubes as well. Thus, it is an open question to see how well our approach works for hypercubes, but more generally if there is some quantity (more general than (β, α) -edge expansion) which precisely captures when our approach works and when it does not.
3. In the full version [28], we show that simple paths are not as powerful as connected-subgraph tests for graph-constrained group testing. However, in practice it is often the case that simple paths (and especially shortest paths) are easier to implement. It would be interesting to characterize the limitations of graph-constrained group testing when the tests are restricted to (shortest) simple paths.

■ **Figure 4** Probability that a randomly generated test matrix with a certain number of tests is 1-disjunct for various graphs. Each point is the mean of 200 trials, with error bars of $1/\sqrt{200}$. “Subgraph” is our approach, “Random Walk” the approach of [6], “Random” the nearly-optimal randomized construction for unconstrained group testing.

46:16 Unconstraining Graph-Constrained Group Testing

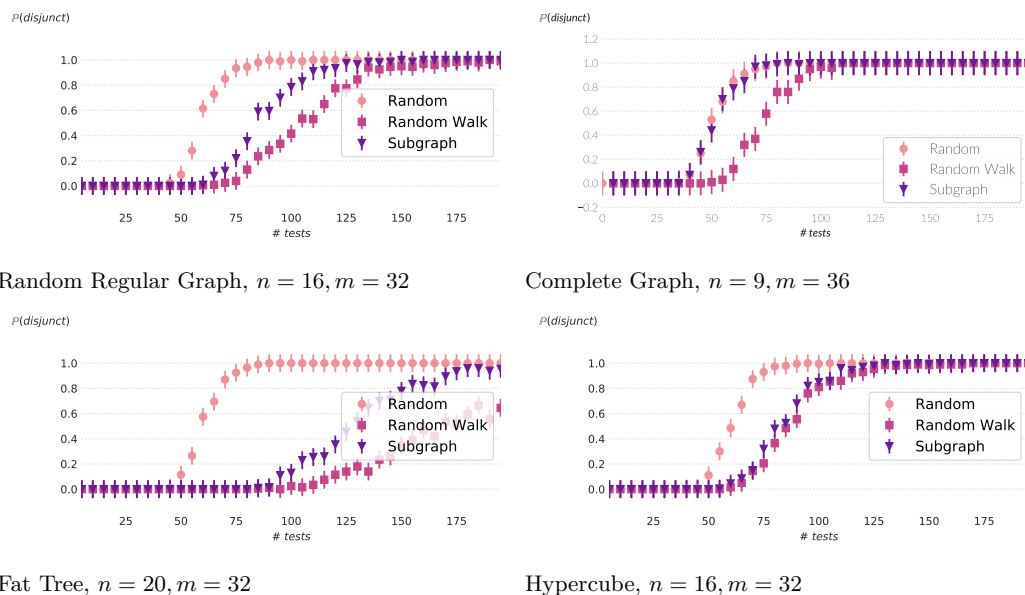

Figure 5 Probability that a randomly generated test matrix with a certain number of tests is 2-disjunct for various graphs. Each point is the mean of 200 trials, and with error bars of $1/\sqrt{200}$. “Subgraph” is our approach, “Random Walk” the approach of [6], “Random” the nearly-optimal randomized construction for unconstrained group-testing.

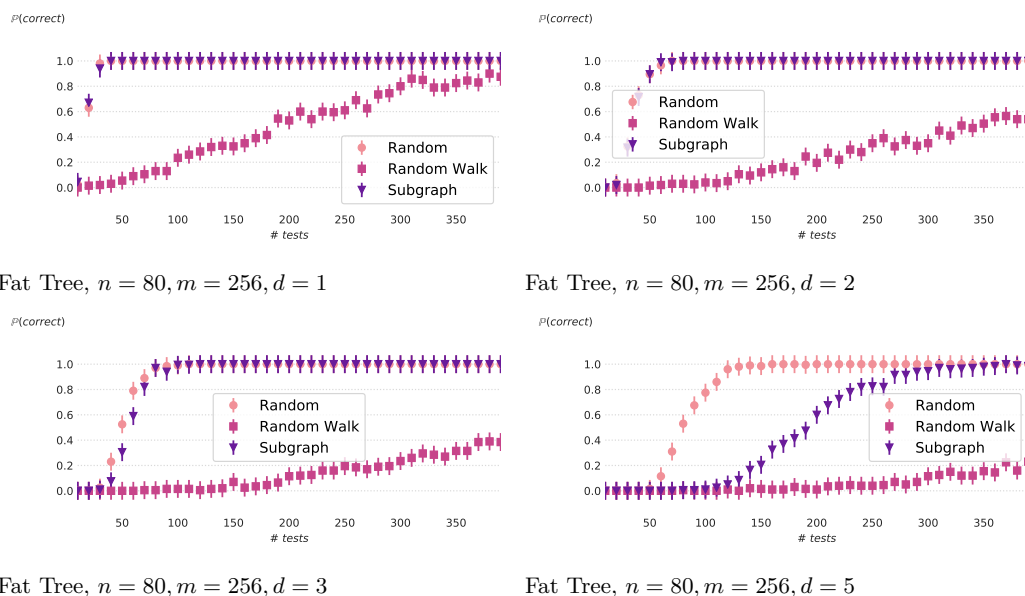

Figure 6 The probability that tests generated from various schemes with a certain number of tests correctly identifies d random failed edges. “Subgraph” is our approach, “Random Walk” the approach of [6], “Random” the nearly-optimal randomized construction for unconstrained group testing.

A Instantiations of Theorem 8

In this appendix, we instantiate Theorem 8 for several families of graphs and compare them to existing results. We remark that some of these families (D -regular expanders, or $G(n, p)$) are natural candidates, while others (like a barbell graph) are concocted to show the difference between our theorem and that of previous work. A summary is shown in Table 2, and we go into the details below.

A.1 Complete Graphs

The mixing time for a complete graph is constant, so [6] gives an optimal construction requiring $O(d^2 \log(m/d))$ tests. Theorem 8 gives the same result.

A.2 D -Regular Expander Graphs with Constant Spectral Gap

D -regular expander graphs are D -regular graphs which are very “well-connected.” One way of measuring this is the *spectral gap*, that is the difference between the largest eigenvalue D of the adjacency matrix A_G and the second-largest eigenvalue, λ . (We refer the reader to the excellent survey [19] for more background on expander graphs.) We consider families of D -regular graphs G whose second largest eigenvalue λ is bounded away from D by a constant: $\lambda \leq D(1 - c)$ for some constant $c \in (0, 1)$ independent of n .

For larger $D = \Omega(\log^2 n)$, [6] show that $O(d^2 \log^3(m))$ tests are sufficient, which is optimal up to logarithmic factors. For smaller D , in particular when D is a constant, the best previously known result guarantees $O(d^3 \log(m/d))$ tests [18].

As we will see below, Theorem 8 guarantees $O(d^2 \log(m/d))$ tests are sufficient for all D . In order to apply Theorem 8, we relate the second largest eigenvalue to edge-expansion as follows:

► **Theorem 13** (See [19] Theorem 4.11). *Let $G = (V, E)$ be a finite, connected, D -regular graph and let λ be its second eigenvalue. Then G is $(1/2, \alpha)$ -edge expander with*

$$\frac{D - \lambda}{2} \leq \alpha \leq \sqrt{2D(D - \lambda)}.$$

By plugging in Theorem 13 to Theorem 8 (with constant and sufficiently small $\delta > 0$) we obtain the following corollary:

► **Corollary 14.** *Let G be a D -regular expander with second largest eigenvalue $\lambda \leq D(1 - c)$ for some constant $c > 0$. Then for any $d < cD/2$, there is a collection \mathcal{T} of connected subgraph tests so that \mathcal{T} is d -disjunct and $|\mathcal{T}| = O(d^2 \log(m/d))$.*

Notice that by Proposition 9, the restriction that $d \leq d_0$ for some $d_0 = O(D)$ is necessary.

A.3 Erdős-Rényi Graphs

Like the D -regular expanders above, an Erdős-Rényi random graph $G(n, p)$ on n nodes with parameter $0 \leq p \leq 1$ is well-connected, and has good spectral properties with high probability. However, these graphs are not D -regular so we consider them separately.

For larger $p = \Omega(\log^2 n/n)$, [6] show that $O(d^2 \log^3(m))$ tests are sufficient to guarantee d -disjunctness. Theorem 8 can improve this to $O(d^2 \log(m/d))$, with only the restriction $p \geq p_0$ for some $p_0 = \Omega(1/n)$.

In order to apply Theorem 8, we use the following lemma from [6], which implies that $G(n, D/n)$ for $D = \Omega(d \log n)$ has $(1/2, \alpha)$ edge expansion for $\alpha \geq (2 + \epsilon)d$. Theorem 8 immediately implies that $O(d^2 \log(m/d))$ tests are sufficient.

► **Lemma 15** ([6] Lemma 32). *For every $\phi < 1/2$ there is an $\alpha > 0$ such that a random graph $G = G(n, p)$ with $p \geq \alpha \ln n/n$ has edge expansion $\alpha \geq \phi D$ with probability $1 - o(1)$.*

A.4 Barbells

One of the advantages of our result over previous work is that the notion of (β, α) -edge expansion captures a more general notion of “well-connected” than is captured by minimum cuts or mixing times. As an extreme example of this, consider a barbell graph G , which we define as two copies of the complete graph $K_{n/2}$ on $n/2$ vertices, connected by one edge e (Figure 7).

■ **Figure 7** A barbell graph.

This graph is great for graph-constrained group testing: we test the connecting edge e on its own, then use $O(d^2 \log(m/d))$ tests to identify up to d failures in each of the two copies of $K_{n/2}$. Thus, $O(d^2 \log(m/d))$ tests are sufficient. However, this is a worst-case

graph for existing work. It has a minimum cut of one edge, so [18] only allows $d = 1$. The mixing time of this graph is quite large: the probability of reaching the center edge is $O(1/n)$, so certainly $\tau = \Omega(n)$. The degree condition of [6] is not satisfied as $D \leq n/2$ which is not $O(1/n^2)$. However, even if we could ignore this condition, [6] would use at least $\tilde{O}(n^2 d^2 \log(m/d))$ tests (or, therefore $O(m)$ tests since this is the naive solution).

On the other hand, our results using (β, α) -expansion match the intuition that this example should be easy. Setting $\beta = \frac{1}{4}$ and $\alpha \geq \frac{n}{2} - \frac{n}{4} = \frac{n}{4}$, Theorem 8 gives an $O(d^2 \log(m/d))$ bound.

This example is meant to highlight the difference between our work and existing work. While the barbell graph is unlikely to be used in practice, it illustrates the intuition that (β, α) -connectivity does better capture somewhat “clustery” graphs – that is, graphs with higher connectivity in some areas than in others – than either minimum cuts or mixing time. This notion may be useful for real-life networks; for example, networks may have higher connectivity within a rack than between racks.

A.5 Fat-Trees

The “Fat-Tree” graph [23] was originally designed for use in supercomputers, and is now widely used in datacenter networks [2]. As the name suggests, this is a “fattened” tree, where the fatness (number of links) near the top of the tree is greater than the fatness near the leaves.

We illustrate the fat-tree topology in Figure 3. For some parameter $D > 0$, each node in the fat-tree has degree D or $D/2$. The Fat-Tree consists of a “core” of $(\frac{D}{2})^2$ nodes and a set of D pods. Each pod consists of a complete bipartite graph where each layer has $D/2$ nodes. Each node in the core has one edge to one node in the top layer of each pod.

The minimum cut of the fat tree is $D/2$ and it has $n = 5D^2/4$ nodes. If $D/2 \geq 5(d+1) \log(5D^2/4)$, or equivalently $d \leq \frac{D}{20 \log(5D/4)} - 1 = O(D/\log D)$, Proposition 2 gives an upper bound of $O(d^2 \log(m/d))$ on the number of tests required.

On the other hand, the guarantee of [18] gives a graph-constrained group testing scheme for the fat-tree topology with $O(d^3 \log(m/d))$ tests. It is not clear what the mixing time of the fat-tree is, so we do not compare to the bound from [6] which is in terms of the mixing time. (However, as shown in Section 6, it seems that our approach requires fewer tests than that of [6] on this graph).

Near-Neighbor Preserving Dimension Reduction for Doubling Subsets of ℓ_1

Abstract

Randomized dimensionality reduction has been recognized as one of the fundamental techniques in handling high-dimensional data. Starting with the celebrated Johnson-Lindenstrauss Lemma, such reductions have been studied in depth for the Euclidean (ℓ_2) metric, but much less for the Manhattan (ℓ_1) metric. Our primary motivation is the approximate nearest neighbor problem in ℓ_1 . We exploit its reduction to the decision-with-witness version, called approximate *near* neighbor, which incurs a roughly logarithmic overhead. In 2007, Indyk and Naor, in the context of approximate nearest neighbors, introduced the notion of nearest neighbor-preserving embeddings. These are randomized embeddings between two metric spaces with guaranteed bounded distortion only for the distances between a query point and a point set. Such embeddings are known to exist for both ℓ_2 and ℓ_1 metrics, as well as for doubling subsets of ℓ_2 . The case that remained open were doubling subsets of ℓ_1 . In this paper, we propose a dimension reduction by means of a *near* neighbor-preserving embedding for doubling subsets of ℓ_1 . Our approach is to represent the pointset with a carefully chosen covering set, then randomly project the latter. We study two types of covering sets: c -approximate r -nets and randomly shifted grids, and we discuss the tradeoff between them in terms of preprocessing time and target dimension. We employ Cauchy variables: certain concentration bounds derived should be of independent interest.

1 Introduction

Proximity search is a fundamental computational problem with several applications in Computer Science and beyond. Proximity problems in metric spaces of low dimension have been typically handled by methods which discretize the space and therefore are affected by the curse of dimensionality, making them unfit for high-dimensional spaces. In the past two decades, the increasing need for analyzing high-dimensional data led researchers to devise randomized and approximation algorithms with polynomial dependence on the dimension.

A fundamental proximity problem is Approximate Nearest Neighbor search. By known reductions [11], one can (up to polylogarithmic factors) focus on the decision version with witness, namely the (c, R) -Approximate Near Neighbor problem:

► **Definition 1** (Approximate Near Neighbor). *Let (X, d_X) be a metric space. Given $P \subseteq X$ and reals $R > 0$, $c \geq 1$, build a data structure \mathcal{S} that, given a query point $q \in X$, performs as follows:*

- *If the nearest neighbor of q lies within distance at most R , then \mathcal{S} is allowed to report any point $p^* \in P$ such that $d_X(q, p^*) \leq cR$.*
- *If all points lie at distance more than cR from q , then \mathcal{S} should return \perp .*

In general, \mathcal{S} returns either a point at distance $\leq cR$ or \perp , even when none of the above two cases occurs.

From now on, we assume $R = 1$ because we can re-scale the data set, and we refer to this problem as c -ANN, or simply ANN. We focus on subsets of ℓ_1^d : the input dataset consists of n vectors in \mathbb{R}^d and the distance function is the standard ℓ_1 norm $\|\cdot\|_1$. Note that all logarithms are base 2.

Previous work. Some highlights in the study of data structures for high-dimensional normed spaces are the various variants, proofs, and applications of the Johnson Lindenstrauss Lemma (e.g. [1, 2, 3]), sketches based on p -stable distributions [14], and Locality Sensitive Hashing (e.g. [15, 4, 5]). In the core of most high-dimensional solutions lies the fact that for certain metric spaces e.g. $\ell_p, p \in [1, 2]$, the distance can be efficiently sketched. Spaces which are considered to be harder in this context, such as ℓ_∞ , can also be treated [13], and are very interesting since they can be used as host spaces for various norms [6].

Significant amount of work has been undertaken for pointsets of low doubling dimension, since it is today one of the primary paradigms for capturing input structure (formal definitions in the next section). For any finite metric space X of doubling dimension $\dim(X)$, there exists a data structure [12, 9] with expected preprocessing time $O(2^{\dim(X)} n \log n)$, space usage $O(2^{\dim(X)} n)$ (or even $O(n)$) and query time $O(2^{\dim(X)} \log n + \varepsilon^{-O(\dim(X))})$.

In [16], they introduced the notion of nearest-neighbor preserving embeddings, and it was proven that in this context one can achieve dimension reduction for doubling subsets of ℓ_2 , with the target dimension depending only on the dataset's doubling dimension. Even before, Indyk [14] had introduced a randomized embedding for dimension reduction in ℓ_1 , which is suitable for proximity search purposes, and it achieves target dimension polylogarithmic in the size of the pointset. Naturally, such approaches can be easily combined with any known data structure to be used in the projection space. Randomized embeddings have been recently used in the ANN context [8], for doubling subsets of ℓ_p , $2 < p < \infty$.

It is known that dimension reduction in ℓ_1 cannot be achieved in the same generality as in ℓ_2 , even assuming that the pointset is of low doubling dimension [18]: there are arbitrarily large n -point subsets $P \subseteq \ell_1$ which are doubling with constant 6, such that every embedding

with distortion D of P into ℓ_1^k requires dimension $n^{\Omega(1/D^2)}$. Aiming for more restrictive guarantees, e.g. preserving distances within some pre-defined range, is a relevant workaround. Then, dimension reduction techniques for doubling subsets of ℓ_p , $p \in [1, 2]$, exist [7], but they rely on partition algorithms which require the whole pointset to be known in advance. Hence, applicability of such techniques is quite limited and, specifically, it is not clear whether they can be used in an online setting where query points are not known beforehand.

Contribution. In this paper, we establish two non-linear *near* neighbor-preserving embeddings for doubling subsets of ℓ_1^d . We use a definition which is essentially a modified version of the nearest neighbor preserving embedding of [16]: the guarantees which are required are weaker since we consider the decision version of the problem, therefore the embedding depends on some range parameter $R > 0$.

► **Definition 2** (Near-neighbor preserving embedding). *Let (Y, d_Y) , (Z, d_Z) be metric spaces and $X \subseteq Y$. A distribution over mappings $f : Y \rightarrow Z$ is a near-neighbor preserving embedding with range $R > 0$, distortion $D \geq 1$ and probability of correctness $\mathcal{P} \in [0, 1]$ if for every $\alpha \geq D$ and any $q \in Y$, if $x \in X$ is such that $d_Y(x, q) \leq R$, then with probability at least \mathcal{P} ,*

- $d_Z(f(x), f(q)) \leq D \cdot R$,
- $\forall p \in X : d_Y(p, q) > D \cdot \alpha \cdot R \implies d_Z(f(p), f(q)) > \alpha \cdot R$.

Considering a pointset $P \subset \ell_1^d$ of cardinality n , our results concern ℓ_1^k as the target space, where k depends on the doubling dimension of P . We assume that $R = 1$, since we can rescale the dataset. More specifically:

1. In Theorem 10, we prove that for every $\varepsilon \in (0, 1/2)$ and $c \geq 1$, there is a randomized mapping $h : \ell_1^d \rightarrow \ell_1^k$ that can be computed in time $\tilde{O}(dn^{1+1/\Omega(c)})$ and is *near* neighbor-preserving for P with distortion $1+6\varepsilon$ and probability of correctness $\Omega(\varepsilon)$, where

$$k = (\log \lambda_P \cdot \log(c/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon),$$

for a function $\zeta(\varepsilon) > 0$ depending only on ε . Although the mapping h depends on the pointset, the parameter c is user-defined and therefore provides a trade-off between preprocessing time and target dimension.

2. In Theorem 13, we show that for every $\varepsilon \in (0, 1/2)$, there is a randomized mapping $h' : \ell_1^d \rightarrow \ell_1^k$ that can be computed in time $O(dkn)$ and is *near* neighbor-preserving for P with distortion $1+6\varepsilon$ and probability of correctness $\Omega(\varepsilon)$, where

$$k = (\log \lambda_P \cdot \log(d/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon),$$

for a function $\zeta(\varepsilon) > 0$ depending only on ε . In this case, the function h' is oblivious to P and well-defined over the whole space, but the target dimension depends on d .

On the low-preprocessing-time extreme, one can embed the dataset in near-linear time, but the target dimension is polynomial in $\log n$. This is to be juxtaposed to the analogous result by Indyk [14], which provides with target dimension polynomial in $\log n$, without any assumption on the doubling dimension of the dataset. On the other hand, one can obtain a preprocessing time of $dn^{1+\delta}$ for any constant $\delta > 0$, and target dimension which depends solely on the doubling dimension.

Techniques. Both embeddings consist of two basic components. First, we represent the pointset P with an ε -covering set, and then we apply a random linear projection à la Indyk [14] to that set, using Cauchy variables.

The role of the covering set is to exploit the doubling dimension of P . In the analogous result for ℓ_2 [16], no representative sets were used; the mapping was just a random linear projection of P . In the case of ℓ_1 however, a similar analysis of a linear projection with Cauchy variables without these representative sets seems to be impossible, since the Cauchy distribution is heavy tailed.

In Theorem 10, we consider c -approximate r -nets as a covering set. Inspired by the algorithm of [10] for ℓ_2 , we design an algorithm that computes a c -approximate r -net in ℓ_1 in subquadratic –but superlinear– time. On the other hand, Theorem 13 relies on randomly shifted grids, which can be computed in linear time, but are inferior to nets in terms of capturing the doubling dimension of the pointset.

To bound the distortion incurred by the randomized projection, we exploit the 1-stability property of the Cauchy distribution. To this end, we prove a concentration bound for sums of independent Cauchy variables that should be of interest beyond the scope of this paper. To overcome the technical difficulties associated with the heavy tails of the Cauchy distribution, we study sums of *square roots* of Cauchy variables, where in [14], Indyk considers sums of *truncated* Cauchy variables instead. Although our concentration bound is rather weak, it is sufficient for our purposes and its analysis is much simpler compared to Indyk’s.

Algorithmic implications. Our results show that efficient dimension reduction for doubling subsets of ℓ_1 is possible, in the context of ANN. In particular, these results imply efficient sketches, meaning that one can solve ANN with minimal storage per point. Dimension reduction also serves as a problem reduction from a high-dimensional hard instance to a low-dimensional easy instance. Since the algorithms presented in this paper are quite simple, they should also be of practical interest: they easily extend the scope of any implementation which has been optimized to solve the problem in low dimension, so that it may handle high-dimensional data.

Our embedding can be combined with the bucketing method of [11] for the $(1+\varepsilon)$ -ANN problem in ℓ_1^d . For instance, setting $c = \log n$ in Theorem 10, yields preprocessing time $dn^{1+o(1)}$, space $n^{1+o(1)}$ and query time $O(d) \cdot (\log \lambda_P \cdot \log \log n)^{O(1/\varepsilon)}$ assuming that the doubling dimension is a fixed constant. This improves upon existing results: the query time of [17] depends on the aspect ratio of the dataset, while the data structures of [12, 9] support queries with time complexity which depends exponentially on the doubling dimension. However, it is worth noting that one could potentially improve the results of [17, 12, 9] in the special case of ℓ_1 , by employing ANN data structures with fast query time, in order to accelerate the traversal of the net-tree. Hence, while our result gives a simple framework for exploiting the intrinsic dimension of doubling subsets of ℓ_1 , it is unlikely that it shall improve upon simple variants of previous results in terms of complexity bounds.

Organization. The next section introduces basic concepts and some relevant existing results. Section 3 establishes a concentration bound on sums of independent Cauchy variables. Section 4, achieves dimensionality reduction by means of representing the pointset by a carefully chosen net, while Section 5 employs randomly shifted grids for the same task. We conclude with discussion of results and potential improvements.

2 Preliminaries

In this section, we define basic notions about doubling metrics and present useful previous results.

► **Definition 3.** Consider any metric space (X, d_X) and let $B(p, r) = \{x \in X \mid d_X(x, p) \leq r\}$. The doubling constant of X , denoted λ_X , is the smallest integer λ_X such that for any $p \in X$ and $r > 0$, the ball $B(p, r)$ can be covered by λ_X balls of radius $r/2$ centered at points in X .

The doubling dimension of (X, d_X) is defined as $\log \lambda_X$. Nets play an important role in the study of embeddings, as well as in designing efficient data structures for doubling metrics.

► **Definition 4.** For $c \geq 1$, $r > 0$ and metric space (V, d_V) , a c -approximate r -net of V is a subset $\mathcal{N} \subseteq V$ such that no two points of \mathcal{N} are within distance r of each other, and every point of V lies within distance at most $c \cdot r$ from some point of \mathcal{N} .

► **Theorem 5.** Let $P \subset \ell_1^d$ such that $|P| = n$. Then, for any $c > 0$, $r > 0$, one can compute a c -approximate r -net of P in time $\tilde{O}(dn^{1+1/c'})$, where $c' = \Omega(c)$. The result is correct with high probability. The algorithm also returns the assignment of each point of P to the point of the net which covers it.

Proof. We employ some basic ideas from [11]. An analogous result for ℓ_2 is stated in [10]. First, we assume $r = 1$, since we are able to re-scale the point set. Now, we consider a randomly shifted grid with side-length 2. The probability that two points $p, q \in P$ fall into the same grid cell, is at least $1 - \|p - q\|_1/2$. For each non-empty grid cell we snap points to a grid: each coordinate is rounded to the nearest multiple of $\delta = 1/10dc$. Then, coordinates are multiplied by $1/\delta$ and each point $x = (x_1, \dots, x_d) \in [2\delta]^d$ is mapped to $\{0, 1\}^{2d/\delta}$ by a function G as follows: $G(x) = (g(x_1), \dots, g(x_d))$, where $g(z)$ is a binary string of z ones followed by $2/\delta - z$ zeros. For any two points p, q in the same grid cell, let $f(p), f(q)$ be the two binary strings obtained by the above mapping. Notice that,

$$\|f(p) - f(q)\|_1 \in (2/\delta) \cdot \|p - q\|_1 \pm 1.$$

Hence,

$$\|p - q\|_1 \leq 1 \implies \|f(p) - f(q)\|_1 \leq (2/\delta) + 1,$$

$$\|p - q\|_1 \geq c \implies \|f(p) - f(q)\|_1 \geq (2/\delta) \cdot c - 1.$$

Now, we employ the LSH family of [11], for the Hamming space. After standard concatenation, we can assume that the family is $(\rho, c'\rho, n^{-1/c'}, n^{-1})$ -sensitive, where $\rho = (2/\delta) + 1$ and $c' = \Omega(c)$. Let $\alpha = n^{-1/c'}$ and $\beta = n^{-1}$.

Notice that for the above two-level hashing table we obtain the following guarantees. Any two points $p, q \in P$, such that $\|p - q\|_1 \leq 1$, fall into the same bucket with probability $\geq \alpha/2$. Any two points $p, q \in P$, such that $\|p - q\|_1 \geq c$, fall into the same bucket with probability $\leq \beta$.

Finally, we independently build $k = \Theta(n^{1/c'} \log n)$ hashtables as above, where the random hash function is defined as a concatenation of the function which maps points to their grid cell id and one LSH function. We pick an arbitrary ordering $p_1, \dots, p_n \in P$. We follow a greedy strategy in order to compute the approximate net. We start with point p_1 , and we add it to the net. We mark all (unmarked) points which fall at the same bucket with p_1 , in one of the k hashtables, and are at distance $\leq cr$. Then, we proceed with point p_2 . If p_2 is unmarked, then we repeat the above. Otherwise, we proceed with p_3 . The above iteration stops when all points have been marked. Throughout the procedure, we are able to store one pointer for each point, indicating the center which covered it.

Correctness. The probability that a good pair p, q does not fall into the same bucket for any of the k hashtables is $\leq (1 - \alpha/2)^k \leq n^{-10}$. Hence, with high probability, the packing property holds, and the covering property holds because the above algorithm stops when all points are marked.

Running time. The time to build the k hashtables is $k \cdot n = \tilde{O}(n^{1+1/c'})$. Then, at most n queries are performed: for each query, we investigate k buckets and the expected number of false positives is $\leq k \cdot n^2 \cdot \beta = \tilde{O}(n^{1+1/c'})$. Hence, if we stop after having seen a sufficient amount of false positives, we obtain time complexity $\tilde{O}(n^{1+1/c'})$ and the covering property holds with constant probability. We can repeat the above procedure $O(\log n)$ times to obtain high probability of success. \blacktriangleleft

The main result in the context of randomized embeddings for dimension reduction in ℓ_1^d is the following theorem, which exploits the 1-stability property of Cauchy random variables and provides with an asymmetric guarantee: The probability of non-contraction is high, but the probability of non-expansion is constant. Nevertheless, this asymmetric property is sufficient for proximity search.

► **Theorem 6** (Thm 5, [14]). *For any $\varepsilon \leq 1/2$, $\delta > 0$, $\varepsilon > \gamma > 0$ there is a probability space over linear mappings $f : \ell_1^d \rightarrow \ell_1^k$, where $k = (\ln(1/\delta))^{1/(\varepsilon-\gamma)}/\zeta(\gamma)$, for a function $\zeta(\gamma) > 0$ depending only on γ , such that for any pair of points $p, q \in \ell_1^d$:*

$$\begin{aligned} \Pr \left[\|f(p) - f(q)\|_1 \leq (1 - \varepsilon) \|p - q\|_1 \right] &\leq \delta, \\ \Pr \left[\|f(p) - f(q)\|_1 \geq (1 + \varepsilon) \|p - q\|_1 \right] &\leq \frac{1 + \gamma}{1 + \varepsilon}. \end{aligned}$$

Note that the embedding is defined as $f(u) = Au/T$, where A is a $k \times d$ matrix with each element being an i.i.d. Cauchy random variable. In addition, T is a scaling factor defined as the expectation of a sum of truncated Cauchy variables, such that $T = \Theta(k \log(k/\varepsilon))$ (see Lemma 5 in [14]).

One key observation here is that given a pointset P in a space of bounded aspect ratio Φ , one can directly employ Theorem 6. The number of points can be upper bounded by a function of λ_P and Φ , and hence the new dimension, k , depends only on these parameters. This paper proves better bounds than the ones of Theorem 6 for doubling subsets of ℓ_1^d , without any assumption on the aspect ratio.

3 Concentration bounds for Cauchy variables

In this section, we prove some basic properties of the Cauchy distribution, which serves as our main embedding tool.

Let $C_{\mathcal{D}}$ denote the Cauchy distribution with density $c(x) = (1/\pi)/(1+x^2)$. One key property of the Cauchy distribution is the so-called 1-stability property: Let $v = (v_1, \dots, v_k) \in \mathbb{R}^k$ and X_1, \dots, X_k be i.i.d. random variables following $C_{\mathcal{D}}$, then $\sum_{j=1}^k X_j v_j$ is distributed as $X \cdot \|v\|_1$, where $X \sim C_{\mathcal{D}}$.

The Cauchy distribution has undefined mean. However, for $0 < q < 1$, the mean of the q -th power of a Cauchy random variable can be defined. More specifically, for some $X \sim C_{\mathcal{D}}$ we have

$$\mathbb{E} \left[|X|^{1/2} \right] = \frac{2}{\pi} \int_0^{\infty} \frac{\sqrt{x}}{1+x^2} dx = \frac{2}{\pi} \frac{\pi}{\sqrt{2}} = \sqrt{2}.$$

The following lemma provides a bound for the moment-generating function of $|X|^{1/2}$.

► **Lemma 7.** *Let $X \sim C_D$. Then for any $\beta > 1$:*

$$\mathbb{E} \left[\exp(-\beta |X|^{1/2}) \right] \leq \frac{2}{\beta}.$$

Proof. For any constant β ,

$$\int_0^1 e^{-\beta x^{1/2}} dx = \frac{2}{\beta^2} \left(1 - \frac{\beta + 1}{e^\beta} \right).$$

Then, for any $\beta > 1$,

$$\begin{aligned} \mathbb{E} \left[\exp(-\beta |X|^{1/2}) \right] &= \int_{-\infty}^{\infty} e^{-\beta |x|^{1/2}} \cdot c(x) dx = \frac{2}{\pi} \int_0^{\infty} e^{-\beta x^{1/2}} \cdot \frac{1}{1+x^2} dx \\ &= \frac{2}{\pi} \int_0^1 e^{-\beta x^{1/2}} \cdot \frac{1}{1+x^2} dx + \frac{2}{\pi} \int_1^{\infty} e^{-\beta x^{1/2}} \cdot \frac{1}{1+x^2} dx \\ &\leq \frac{2}{\pi} \int_0^1 e^{-\beta x^{1/2}} dx + \frac{2}{\pi} \int_1^{\infty} e^{-\beta} \cdot \frac{1}{1+x^2} dx \\ &= \frac{2}{\pi} \cdot \frac{2}{\beta^2} \left(1 - \frac{\beta + 1}{e^\beta} \right) + \frac{1}{2e^\beta} \\ &\leq \frac{4}{\pi\beta^2} + \frac{1}{2e^\beta} \\ &\leq \frac{2}{\beta}. \end{aligned}$$

Let $S := \sum_{j=1}^k |X_j|$ where each X_j is an i.i.d. Cauchy variable. To prove concentration bounds for S , we study the sum $\tilde{S} := \sum_{j=1}^k |X_j|^{1/2}$. By Hölder's Inequality, for any $x \in \mathbb{R}^d$ and $p > q > 0$,

$$\|x\|_p \leq \|x\|_q \leq d^{1/q-1/p} \|x\|_p.$$

Consequently, for $x = (X_1, \dots, X_k) \in \mathbb{R}^k$, $p = 1$ and $q = 1/2$ we have that $S \leq \tilde{S}^2 \leq k \cdot S$, hence for any $t > 0$,

$$\Pr[S \leq t] \leq \Pr[\tilde{S} \leq \sqrt{tk}]. \tag{1}$$

We use the bound on the moment-generating function, to prove a Chernoff-type concentration bound for \tilde{S} , which by Eq. (1) translates into a concentration bound for S .

► **Lemma 8.** *For every $D > 1$,*

$$\Pr \left[\tilde{S} \leq \frac{\mathbb{E}[\tilde{S}]}{D} \right] \leq \left(\frac{10}{D} \right)^k.$$

Proof. Since X_j 's are independent, $\mathbb{E}[\tilde{S}] = \sqrt{2}k$. Then, by Lemma 7 and Markov's inequality, for any $\beta > 1$, it follows that

$$\begin{aligned} \Pr \left[\tilde{S} \leq \frac{\mathbb{E}[\tilde{S}]}{D} \right] &= \Pr \left[\exp(-\beta \tilde{S}) \geq \exp \left(-\beta \cdot \frac{\mathbb{E}[\tilde{S}]}{D} \right) \right] \\ &\leq \frac{\mathbb{E}[\exp(-\beta \tilde{S})]}{\exp(-\beta \mathbb{E}[\tilde{S}]/D)} \\ &= \frac{\mathbb{E}[\exp(-\beta |X_j|^{1/2})]^k}{\exp(-\beta \sqrt{2}k/D)} \\ &\leq \left(\frac{2}{\beta} \right)^k \cdot e^{\sqrt{2}\beta k/D}. \end{aligned}$$

Setting $\beta = D$ completes the proof.

4 Net-based dimension reduction

In this section we describe the dimension reduction mapping for ℓ_1 via r -nets. Let $P \subset \ell_1^d$ be a set of n points with doubling constant λ_P . For some point $x \in \mathbb{R}^d$ and $r > 0$, we denote by $B_1(x, r)$ the ℓ_1 -ball of radius r around x . The embedding is non-linear and is carried out in two steps.

First, we compute a c -approximate (ε/c) -net \mathcal{N} of P with the algorithm of Theorem 5. Moreover, the algorithm assigns each point of P to the point of \mathcal{N} which covered it. Let $g : P \rightarrow \mathcal{N}$ be this assignment. In the second step, for every $s \in \mathcal{N}$ and any query point $q \in \ell_1^d$, we apply the linear map of Theorem 6. That is, $f(s) = As/T$, where A is a $k \times d$ matrix with each element being an i.i.d. Cauchy random variable. Recall that value $T = \Theta(k \log(k/\varepsilon))$. By the 1-stability property of the Cauchy distribution, $f(s)$ is distributed as $\|s\|_1 \cdot (Y_1, \dots, Y_k)$, where each Y_j is i.i.d. and $Y_j \sim C_{\mathcal{D}}$. Hence, $\|f(s)\|_1 = \|s\|_1 \cdot S$ where $S := \sum_j |Y_j|$.

We define the embedding to be $h = f \circ g$. We apply h to every point in P , and f to any query point q . It is clear from the properties of the net that g incurs an additive error of $\pm\varepsilon$ on the distance between q and any point in P , so it is sufficient to consider the distortion of f .

Our analysis consists of studying separately the following disjoint subsets of \mathcal{N} : Points that lie at distance at most D_0 from the query and points that lie at distance at least D_0 , for some $D_0 > 1$ chosen appropriately. For the former set, we directly apply Theorem 6, as it has bounded diameter.

The next lemma guarantees the low distortion for points of the latter set, namely those that are sufficiently far from the query. We consider the sum of the square roots of each $|Y_j|$, i.e., $\tilde{S} = \sum_j |Y_j|^{1/2}$, in order to employ the tools of Section 3.

► **Lemma 9.** *Fix a query point $q \in \ell_1^d$. For any $\varepsilon \leq 1/2$, $c \geq 1$, $\delta \in (0, 1)$, there exists $D_0 = O(\log(k/\varepsilon))$ such that for $k = \Theta(\log^2 \lambda_P \cdot \log(c/\varepsilon) + \log(1/\delta))$, with probability at least $1 - \delta$,*

$$\forall s \in \mathcal{N} : \|s - q\|_1 \geq D_0 \implies \|f(s) - f(q)\|_1 \geq 4.$$

Proof. Assume wlog that the query point is the origin $(0, \dots, 0)$. For some $D_0 > 1$, we define the following subsets of \mathcal{N} :

$$N_i := \{s \in \mathcal{N} \mid D_i \leq \|s\|_1 < D_{i+1}\}, \quad D_i = 2^{2i} D_0, \quad i = 0, 1, 2, \dots$$

By the definition of doubling constant and the fact that two points of \mathcal{N} lie at distance at least ε ,

$$|N_i| \leq \lambda_P^{\lceil \log(4cD_{i+1}/\varepsilon) \rceil} \leq \lambda_P^{4 \log(cD_{i+1}/\varepsilon)}.$$

Therefore, by the union bound, and Eq. (1):

$$\begin{aligned} \Pr \left[\exists i \exists s \in N_i : \|f(s)\|_1 \leq \frac{4\|s\|_1}{D_i} \right] &= \Pr \left[\exists i \exists s \in N_i : S \leq \frac{4T}{D_i} \right] \\ &\leq \sum_{i=0}^{\infty} |N_i| \Pr \left[\tilde{S} \leq \frac{\sqrt{4kT}}{\sqrt{D_i}} \right] \\ &= \sum_{i=0}^{\infty} |N_i| \Pr \left[\tilde{S} \leq \mathbb{E}[\tilde{S}] \cdot \sqrt{\frac{2T}{k2^{2i}D_0}} \right]. \end{aligned}$$

By Lemma 8, for $D_0 = \lceil 800T/k \rceil = \Theta(\log(k/\varepsilon))$ and $k > 4 \cdot \log \lambda_P \cdot \log(cD_0/\varepsilon) + 2 \log(2\lambda_P/\delta)$:

$$\begin{aligned}
\sum_{i=0}^{\infty} |N_i| \Pr \left[\tilde{S} \leq \frac{\mathbb{E}[\tilde{S}]}{10 \cdot 2^{i+1}} \right] &\leq \sum_{i=0}^{\infty} \lambda_P^{4 \log(cD_{i+1}/\varepsilon)} \left(\frac{1}{2^{i+1}} \right)^k \\
&= \sum_{i=0}^{\infty} \frac{2^{\log(\lambda_P)(4 \log(cD_0/\varepsilon) + 2i + 2)}}{2^{k(i+1)}} \\
&\leq \sum_{i=0}^{\infty} \frac{2^{\log(\lambda_P) \cdot 4 \log(cD_0/\varepsilon)} \cdot 2^{2 \log(\lambda_P)(i+1)}}{2^{(4 \log \lambda_P \cdot \log(cD_0/\varepsilon))(i+1)} \cdot 2^{2 \log(2\lambda_P/\delta)(i+1)}} \\
&\leq \sum_{i=0}^{\infty} 2^{-2 \log(2/\delta)(i+1)} \\
&= \sum_{i=0}^{\infty} \left(\frac{\delta^2}{4} \right)^i - 1 \\
&= \frac{\delta^2}{4 - \delta^2} \\
&\leq \delta.
\end{aligned}$$

Finally, for some large enough constant C , we demand that

$$k > C (\log \lambda_P \cdot \log(c \log k/\varepsilon) + \log(1/\delta)) > 4 \cdot \log \lambda_P \cdot \log(cD_0/\varepsilon) + 2 \log(2\lambda_P/\delta)$$

which is satisfied for $k = \Theta(\log^2 \lambda_P \cdot \log(c/\varepsilon) + \log(1/\delta))$. \blacktriangleleft

► Theorem 10. *Let $P \subset \ell_1^d$ such that $|P| = n$. For any $\varepsilon \in (0, 1/2)$ and $c \geq 1$, there is a non-linear randomized embedding $h = f \circ g : \ell_1^d \rightarrow \ell_1^k$, where $k = (\log \lambda_P \cdot \log(c/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon)$, for a function $\zeta(\varepsilon) > 0$ depending only on ε , such that, for any $q \in \ell_1^d$, if there exists $p^* \in P$ such that $\|p^* - q\|_1 \leq 1$, then, with probability $\Omega(\varepsilon)$:*

$$\begin{aligned}
\|h(p^*) - f(q)\|_1 &\leq 1 + 3\varepsilon, \\
\forall p \in P : \|p - q\|_1 > 1 + 9\varepsilon &\implies \|h(p) - f(q)\|_1 > 1 + 3\varepsilon.
\end{aligned}$$

Set P can be embedded in time $\tilde{O}(dn^{1+1/\Omega(\varepsilon)})$, and any query $q \in \ell_1^d$ can be embedded in time $O(dk)$.

Proof. Let f, g be the mappings defined in the beginning of the section and $D_0 = \Theta(\log(k/\varepsilon))$. Assume wlog for simplicity that $q = 0^d$. Then, by Lemma 9 for $k = \Theta(\log^2 \lambda_P \cdot \log(c/\varepsilon))$, with probability at least $1 - \varepsilon/5$, we have:

$$\forall p \in P : \|p - q\|_1 \geq D_0 + \varepsilon \implies \|h(p) - f(q)\|_1 \geq 4.$$

By Theorem 6, for $\gamma = \varepsilon/10$ and $\delta = \varepsilon/(5\lambda_P^{8 \log(cD_0/\varepsilon)})$, with probability at least $1 - \varepsilon/5$, we get:

$$\forall p \in P : \|p - q\|_1 \in (1 + 9\varepsilon, D_0 + \varepsilon) \implies \|h(p) - f(q)\|_1 > (1 + 8\varepsilon)(1 - \varepsilon) \geq 1 + 3\varepsilon.$$

Moreover,

$$\Pr \left[\|h(p^*) - f(q)\|_1 \leq 1 + 3\varepsilon \right] \geq 1 - \frac{1 + \varepsilon/10}{1 + \varepsilon} \geq 1 - (1 - \varepsilon/2).$$

47:10 Near-Neighbor Preserving Dimension Reduction for Doubling Subsets of ℓ_1

Then, the target dimension needs to satisfy the following inequality:

$$k \geq \frac{(\ln(5\lambda_P^{8\log(cD_0/\varepsilon)}/\varepsilon))^{2/\varepsilon}}{\zeta(\varepsilon)} = \frac{(\Theta(\log \log k \cdot \log \lambda_P + \log \lambda_P \cdot \ln(c/\varepsilon)))^{2/\varepsilon}}{\zeta(\varepsilon)}.$$

Hence, for $k = (\log \lambda_P \cdot \log(c/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon)$, we achieve a total probability of success in $\Omega(\varepsilon)$, which completes the proof. \blacktriangleleft

5 Dimension reduction based on randomly shifted grids

In this section, we explore some properties of randomly shifted grids, and we present a simplified embedding which consists of a first step of snapping points to a grid, and a second step of randomly projecting grid points.

Let $w > 0$ and t be chosen uniformly at random from the interval $[0, w]$. The function

$$h_{w,t}(x) = \left\lfloor \frac{x-t}{w} \right\rfloor$$

induces a random partition of the real line into segments of length w . Hence, the function

$$g_w(x) = (h_{w,t_1}(x_1), \dots, h_{w,t_d}(x_d)),$$

for t_1, \dots, t_d independent uniform random variables in the interval $[0, w]$, induces a randomly shifted grid in \mathbb{R}^d . For a set $X \subseteq \mathbb{R}^d$, we denote by $g_w(X)$, the image of X on the randomly shifted grid points defined by g_w . For some $x \in \mathbb{R}^d$ and $r > 0$, the number of grid cells of $g_w(\ell_1^d)$ that $B_1(x, r)$ intersects per axis is independent, and in expectation is $1+2r/w$. Then, the expected total number of grid cells that $B_1(x, r)$ intersects is at most $(1+2r/w)^d$.

Now let $P \subset \ell_1^d$ be a set of n points with doubling constant λ_P and $q \in \ell_1^d$ a query point. For $w = \varepsilon/d$, the ℓ_1 -diameter of each cell is ε and therefore $g_w(P)$ is an ε -covering set of P .

► **Lemma 11.** *Let $\mathcal{R} > 1$ and $P' := B_1(q, \mathcal{R}) \cap P$. Then, for $w = \varepsilon/d$*

$$\mathbb{E}[|g_w(P')|] \leq 8\lambda_P^{2\log(d\mathcal{R}/\varepsilon)}.$$

Proof. By the doubling constant definition, there exists a set of balls of radius ε/d^2 centered at points in P' , of cardinality at most $\lambda_P^{2\log(d\mathcal{R}/\varepsilon)}$ which covers P' . For each ball of radius ε/d^2 , the expected number of intersecting grid cells is $(1+2/d)^d \leq e^2$. The lemma follows by linearity of expectation. \blacktriangleleft

The next lemma shows that, with constant probability, the growth on the number of representatives, as we move away from q , is bounded.

► **Lemma 12.** *Let $\{D_i\}_{i \in \mathbb{N}}$ be a sequence of radii such that, for any i , $D_{i+1} = 4D_i$. Let A_i be the points of $g_w(P)$ within distance $D_{i+1} = 2^{2(i+1)}D_0$ from q . Then, with probability at least $1/3$,*

$$\forall i \in \{-1, 0, \dots\} : |A_i| \leq 4^{i+3} \lambda_P^{2\log(dD_{i+1}/\varepsilon)}.$$

Proof. By Lemma 11, $\mathbb{E}[|A_i|] \leq 8\lambda_P^{2\log(dD_{i+1}/\varepsilon)}$ for every $i \in \{-1, 0, \dots\}$. Then, a union bound followed by Markov's inequality yields

$$\Pr[\exists i \in \{0, 1, \dots\} : |A_i| \geq 4^{i+1} \mathbb{E}[|A_i|]] \leq 1/3.$$

In addition,

$$\Pr[|A_{-1}| \geq 4\mathbb{E}[|A_{-1}|]] \leq 1/4. \quad \blacktriangleleft$$

► **Theorem 13.** *Let $P \subset \ell_1^d$ such that $|P| = n$. For any $\varepsilon \in (0, 1/2)$, there is a non-linear randomized embedding $h' : \ell_1^d \rightarrow \ell_1^k$, where $k = (\log \lambda_P \cdot \log(d/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon)$, for a function $\zeta(\varepsilon) > 0$ depending only on ε , such that for any $q \in \ell_1^d$, if there exists $p^* \in P$ such that $\|p^* - q\|_1 \leq 1$, then with probability $\Omega(\varepsilon)$,*

$$\begin{aligned} \|h'(p^*) - f(q)\|_1 &\leq 1 + 3\varepsilon, \\ \forall p \in P : \|p - q\|_1 > 1 + 9\varepsilon &\implies \|h'(p) - f(q)\|_1 > 1 + 3\varepsilon. \end{aligned}$$

Any point can be embedded in time $O(dk)$.

Proof. We follow the same reasoning as in the proof of Theorem 10. The embedding is $h' = f \circ g_{\varepsilon/d}$, where f is the randomized linear map defined in Section 4. As before, we apply h' to every point in P , and only f to queries. The randomly shifted grid incurs an additive error of ε in the distances between q and P .

Assume wlog that $q = 0^d$ and let A_i be the points of $g_{\varepsilon/d}(P)$ within distance $D_{i+1} = 2^{2(i+1)}D_0$ from q . Hence, by Lemma 12,

$$\begin{aligned} \Pr \left[\exists i \exists s \in A_i : \|f(s)\|_1 \leq \frac{4\|s\|_1}{D_i} \right] &\leq \sum_{i=0}^{\infty} |A_i| \Pr \left[S \leq \frac{4T}{D_i} \right] \\ &\leq \sum_{i=0}^{\infty} 4^{i+3} \lambda_P^{2 \log(dD_{i+1}/\varepsilon)} \Pr \left[\tilde{S} \leq \frac{\sqrt{4kT}}{\sqrt{D_i}} \right]. \end{aligned}$$

As in Lemma 9, for $D_0 = \lceil 800T/k \rceil = \Theta(\log(k/\varepsilon))$, $k \geq 20 \log \lambda_P \cdot \log(dD_0/\varepsilon)$ and $\delta = \varepsilon/5$,

$$\sum_{i=0}^{\infty} 4^{i+3} \lambda_P^{2 \log(dD_{i+1}/\varepsilon)} \Pr \left[\tilde{S} \leq \frac{\sqrt{4kT}}{\sqrt{D_i}} \right] \leq \sum_{i=0}^{\infty} \frac{2^{2i+6+2 \log \lambda_P [\log(dD_0/\varepsilon)+2(i+1)]}}{2^{k(i+1)}} \leq \varepsilon/5.$$

Hence, for $k = \Omega((\log^2 \lambda_P \cdot \log(d/\varepsilon)))$, with probability at least $1 - \varepsilon/5$, we have:

$$\forall p \in P : \|p - q\|_1 \geq D_0 + \varepsilon \implies \|h'(p) - f(q)\|_1 \geq 4.$$

Now, we are able to use Theorem 6 for points which are at distance at most $D_0 + \varepsilon$ from q , and the near neighbor. By Lemma 12, with constant probability, the number of grid points at distance $\leq D_0 + \varepsilon$, is at most $32 \cdot \lambda_P^{4 \log(dD_0/\varepsilon)}$. Hence, by Theorem 6, for $\gamma = \varepsilon/10$ and $\delta = \varepsilon/(160 \lambda_P^{4 \log(dD_0/\varepsilon)})$, with probability at least $1 - \varepsilon/5$, it holds:

$$\forall p \in P : \|p - q\|_1 \in (1 + 9\varepsilon, D_0 + \varepsilon) \implies \|h'(p) - f(q)\|_1 > 1 + 3\varepsilon.$$

Moreover, with probability at least $\varepsilon/2$, we obtain:

$$\|h'(p^*) - f(q)\|_1 \leq 1 + 3\varepsilon.$$

As in Theorem 10, the target dimension needs to satisfy the following:

$$k \geq \frac{(\ln(160 \lambda_P^{4 \log(dD_0/\varepsilon)} / \varepsilon))^{2/\varepsilon}}{\zeta(\varepsilon)}.$$

Hence, for $k = (\log \lambda_P \cdot \log(d/\varepsilon))^{\Theta(1/\varepsilon)} / \zeta(\varepsilon)$ we achieve total probability of success $\Omega(\varepsilon)$. ◀

6 Conclusion

We have filled in a gap in the spectrum of randomized embeddings with bounded distortion only for distances between the query and a pointset: such embeddings existed for ℓ_2 and ℓ_1 and for doubling subsets of ℓ_2 . Here we settle the case of doubling subsets of ℓ_1 with a *near* neighbor-preserving embedding. In the meantime, we obtain concentration bounds on sums of independent Cauchy variables. Our algorithms are quite simple, therefore they should also be of practical interest.

We rely on approximate r -nets or randomly shifted grids. For the former, Theorem 10 provides with a trade-off between the preprocessing time required and the target dimension. On the other hand, Theorem 13 has the advantage of fast preprocessing: any point is embedded in $O(dk)$ time, and the embedding is oblivious to the pointset. In regards to the near-linear preprocessing time, the two results are comparable, since the dimension in Theorem 13 can be substituted by the target dimension of Theorem 6.

Notice that any potential improvements to Theorem 6 should lead to improvements to Theorems 10 and 13. The target dimension in these theorems follows from a direct application of Theorem 6 to the representative data points which lie inside a bounding ball centered at the query.

Abstract

Strong spatial mixing (SSM) is a form of correlation decay that has played an essential role in the design of approximate counting algorithms for spin systems. A notable example is the algorithm of Weitz (2006) for the hard-core model on weighted independent sets. We study SSM for the q -colorings problem on the infinite $(d+1)$ -regular tree. Weak spatial mixing (WSM) captures whether the influence of the leaves on the root vanishes as the height of the tree grows. Jonasson (2002) established WSM when $q > d + 1$. In contrast, in SSM, we first fix a coloring on a subset of internal vertices, and we again ask if the influence of the leaves on the root is vanishing. It was known that SSM holds on the $(d + 1)$ -regular tree when $q > \alpha d$ where $\alpha \approx 1.763\dots$ is a constant that has arisen in a variety of results concerning random colorings. Here we improve on this bound by showing SSM for $q > 1.59d$. Our proof establishes an L^2 contraction for the BP operator. For the contraction we bound the norm of the BP Jacobian by exploiting combinatorial properties of the coloring of the tree.

1 Introduction

Consider random q -colorings of the complete tree T_h of height h with branching factor d . Does the influence of the leaves on the root decay to zero in the limit as the height grows? If so, this corresponds to weak spatial mixing, which we will define more precisely momentarily.

Now suppose we fix the coloring τ for a subset of internal vertices. Is it still the case that the influence of the leaves on the root decay to zero as the height grows? One might intuitively expect that these internal “agreements” defined by τ only help in the sense that the influence of the leaves decrease, however this problem is much more challenging; it corresponds to strong spatial mixing, which is the focus of this paper.

For statistical physics models, the key algorithmic problems are the counting problem of estimating the partition function and the problem of sampling from the Gibbs distribution, which corresponds to the equilibrium state of the system. Strong spatial mixing (SSM) is a key property of the system for the design of efficient counting/sampling algorithms.

SSM has a variety of algorithmic implications. A direct consequence of SSM on amenable graphs, such as the integer lattice \mathbb{Z}^d , is fast mixing of the Glauber dynamics, which is the simple Markov chain that updates the spin at a randomly chosen vertex in each step, see, e.g. [21, 22, 6, 9, 14, 4, 3]. SSM also plays a critical role in the efficiency of correlation-decay techniques of Weitz [26] which yields an FPTAS for the partition function of the hard-core model in the tree uniqueness region; this approach has been extended to 2-spin antiferromagnetic models [18] and other interesting examples, e.g., [19]; note, the approach of Barvinok [1] utilizing a zero-free region of the partition function in the complex plane has recently been extended to the same range of parameters for the hard-core model [23, 25].

The fundamental question in statistical physics is the uniqueness/non-uniqueness phase transition which corresponds to whether long-range correlations persist or die off, in the limit as the volume of the system tends to infinity. In the uniqueness region the correlations die off, which corresponds to *weak spatial mixing* (WSM). While WSM (or equivalently uniqueness) is a notoriously challenging problem on the 2-dimensional integer lattice \mathbb{Z}^2 (e.g., see the recent breakthrough work of Boffara and Duminil-Copin [2] for the ferromagnetic Potts model), the corresponding WSM problem on the infinite $(d+1)$ -regular tree \mathbb{T}_d , known as the Bethe lattice, is typically simpler since it can be analyzed using recursions due to the absence of cycles (e.g., see Kelly [17] for the hard-core model). However, for the colorings problem, which is the focus of this paper, even WSM is far from trivial on the regular tree [16]. In fact, for the closely related antiferromagnetic Potts model the precise range of parameters for WSM is only known for fixed values of q, d [11].

The focus of this paper is on these correlation decay properties on the infinite $(d+1)$ -regular tree \mathbb{T}_d for the *colorings* problem. We give an informal definition of WSM and SSM, and refer the interested reader to Section 2 for formal definitions.

Let T_h denote the complete tree of height h where all internal vertices have degree $d+1$. For integer $q \geq 3$, let μ_h denote the uniform distribution over proper (vertex) q -colorings of T_h . Consider a pair of sequences of colorings (η_h) and (η'_h) for the leaves of T_h . Let p_h and p'_h denote the marginal probability that the root receives a specific color c under μ_h conditional on the leaves having the fixed coloring η_h and η'_h , respectively. Roughly, if $\lim_{h \rightarrow \infty} |p_h - p'_h| = 0$ for all sequences $(\eta_h), (\eta'_h)$ and colors c , then we say WSM holds (see also Section 2). Jonasson [16] proved that WSM holds when $q \geq d+2$. When $q \leq d+1$, the pair of boundary conditions can actually “freeze” the color at the root; moreover, Brightwell and Winkler [5] showed that there are multiple semi-translation invariant Gibbs measures on \mathbb{T}_d when $q \leq d$.

Now consider an arbitrary coloring τ for a subset $S \subset \mathbb{T}_d$. Let r_h and r'_h denote the marginal probability that the root receives color c under μ_h conditional on $\eta_h \cup \tau$ and $\eta'_h \cup \tau$, respectively. If these limits are the same then we say **SSM** holds. The challenge of establishing **SSM** is illustrated by the fact that if **WSM** holds then we know that $\lim_{h \rightarrow \infty} p_h = 1/q$ but that is not necessarily the case in the **SSM** setting.

Ge and Štefankovič [13] proved that **SSM** holds on \mathbb{T}_d when $q > \alpha d$ where $\alpha \approx 1.763\dots$ is the root of $\frac{1}{\alpha} \exp(1/\alpha) = 1$. Gamarnik, Katz, and Misra [12] extended this result to arbitrary triangle-free graphs of maximum degree d , under the same condition on q . Recent work of Liu, Sinclair, and Srivastava [20] builds upon [12] together with the approximate counting approach of [1, 23] to obtain an **FPTAS** for counting colorings of triangle-free graphs when $q > \alpha d$. Prior to these works, Goldberg, Martin, and Paterson [14] established the above form of **SSM** on triangle-free amenable¹ graphs, also when $q > \alpha d$. In addition to the above results, the threshold $\alpha \approx 1.76\dots$ has arisen in numerous rapid mixing results, e.g., [7, 15, 8].

Our main result presents the first substantial improvement on the 1.76... threshold of [13], we establish **SSM** on the tree when $q > 1.59d$. We state a somewhat informal version of our main theorem here, the formal version will be given once we define more precisely **SSM**, cf. Theorem 3 below.

► **Theorem 1** (Informal version of Theorem 3). *There exists an absolute constant $\beta > 0$ such that, for all positive integers q, d satisfying $q \geq 1.59d + \beta$, the q -coloring model exhibits strong spatial mixing on the regular tree \mathbb{T}_d .*

We remark that the constant 1.59 in Theorem 1 can be replaced with any $\alpha' > 1$ satisfying

$$\frac{1}{\alpha'} \exp\left(\frac{1}{\alpha'}\right) \exp\left(-\frac{1}{\alpha' - 1 + \exp\left(\frac{1}{\alpha' - 1}\right)}\right) < 1,$$

the smallest such value up to four decimal digits is 1.5897.

We give an overview of our proof approach in Section 3 after formally defining **SSM** in Section 2 and stating the formal version of Theorem 1. We then present detailed proofs of the three main lemmas in Section 3.

2 Definitions

Let $q \geq 3$ be an integer and $G = (V, E)$ be a graph. A proper q -coloring of G is an assignment $\sigma : V \rightarrow [q]$ such that for every $(u, v) \in E$ it holds that $\sigma(u) \neq \sigma(v)$. We use Ω_G to denote the set of all proper q -colorings of G and μ_G to denote the uniform probability distribution on Ω_G (provided that Ω_G is non-empty).

For $\sigma \in \Omega_G$ and a set $\Lambda \subset V$, we use σ_Λ to denote the restriction of σ to Λ . When Λ consists of a single vertex v , we will often use the shorthand σ_v to denote the color of v under σ . We say that an assignment $\eta : \Lambda \rightarrow [q]$ is *extendible* if there exists a coloring $\sigma \in \Omega_G$ such that $\sigma_\Lambda = \eta$.

We can now formally define **SSM**.

► **Definition 2.** *Let $\zeta : \mathbb{Z}_{\geq 0} \rightarrow [0, 1]$ be a real-valued function on the positive integers.*

*The q -coloring model exhibits strong spatial mixing, denoted **SSM**, on a finite graph $G = (V, E)$ with decay rate $\zeta(\cdot)$ iff for every $v \in V$, for every $\Lambda \subset V$, for any two extendible*

¹ Roughly, a graph is amenable if for every subset S of vertices, the neighborhood satisfies $|N(S)| \leq \text{poly}(|S|)$.

48:4 Improved Strong Spatial Mixing for Colorings on Trees

assignments $\eta, \eta' : \Lambda \rightarrow [q]$ and any color $c \in [q]$ it holds that

$$\left| \mu_G(\sigma_v = c \mid \sigma_\Lambda = \eta) - \mu_G(\sigma_v = c \mid \sigma_\Lambda = \eta') \right| \leq \zeta(\text{dist}(v, \Delta)), \quad (1)$$

where $\Delta \subseteq \Lambda$ denotes the set of vertices where η and η' disagree.

In the case where G is infinite, we say that the q -coloring model exhibits strong spatial mixing on G with decay rate $\zeta(\cdot)$ if it exhibits strong spatial mixing on every finite subgraph of G with decay rate $\zeta(\cdot)$.

The definition of weak spatial mixing has one modification: in the RHS of (1) we replace $\text{dist}(v, \Delta)$ by the weaker condition $\text{dist}(v, \Lambda)$. WSM says that the influence of a pair of boundary conditions decays at rate $\zeta(\cdot)$ in the distance to the boundary Λ . In SSM the pair of boundaries η, η' might only differ on a subset $\Delta \subset \Lambda$; do these fixed “agreements” on $\Lambda \setminus \Delta$ influence the marginal at v ? If SSM holds then the difference in the marginal at v decays at rate $\zeta(\cdot)$ in the distance to the “disagreements” in η, η' .

With these definitions in place, we are now ready to give the formal version of Theorem 1.

► **Theorem 3.** *There exists an absolute constant $\beta > 0$ such that, for all positive integers q, d satisfying $q \geq 1.59d + \beta$, the q -coloring model exhibits strong spatial mixing on the regular tree \mathbb{T}_d with exponentially decaying rate.*

That is, there exist constants $\alpha, C > 0$ and a function ζ satisfying $\zeta(\ell) \leq C \exp(-\alpha\ell)$ for all integers $\ell \geq 0$ such that for all finite subtrees T of \mathbb{T}_d the q -coloring model exhibits strong spatial mixing on T with decay rate ζ .

3 Proof Approach

For a set $\Lambda \subset V$ and an extendible assignment $\eta : \Lambda \rightarrow [q]$, we use $\pi_{G,v,\eta}$ to denote the q -dimensional probability vector whose entries give the marginal distribution of colors at v under the boundary condition η , i.e., for a color $c \in [q]$, the c -th entry of $\pi_{G,v,\eta}$ is given by $\mu_G(\sigma_v = c \mid \sigma_\Lambda = \eta)$.

The key ingredient to prove Theorem 3 is the following.

► **Theorem 4.** *There exist absolute constants $\beta > 0$ and $U \in (0, 1)$ such that the following holds for all positive integers q, d satisfying $q \geq 1.59d + \beta$.*

Let $T = \mathbb{T}_{d,h,\rho}$ be the d -ary tree with height h rooted at ρ , Λ be a subset of the vertices of T , and $\eta, \eta' : \Lambda \rightarrow [q]$ be two extendible assignments of T with $\text{dist}(\rho, \Delta) \geq 3$ where $\Delta \subseteq \Lambda$ is the set of vertices where η and η' disagree. Let v_1, \dots, v_d be the children of ρ and for $i \in [d]$ let $T_i = (V_i, E_i)$ be the subtree of T rooted at v_i which consists of all descendants of v_i in T . Then

$$\|\pi - \pi'\|_2^2 \leq U \max_{i \in [d]} \|\pi_i - \pi_{i'}\|_2^2,$$

where $\pi = \pi_{T,\rho,\eta}$, $\pi' = \pi_{T,\rho,\eta'}$ and for $i \in [d]$ we denote $\pi_i = \pi_{T_i,v_i,\eta(\Lambda \cap V_i)}$, $\pi_{i'} = \pi_{T_i,v_i,\eta'(\Lambda \cap V_i)}$.

Intuitively, Theorem 4 says that disagreements between η and η' have smaller impact on the marginals as we move upwards on the tree. More precisely, the marginals of the root under η and under η' are closer in L^2 distance than the distance between the marginals of any child (under the induced distributions on the subtrees hanging from them).

Using Theorem 4, the proof of Theorem 3 of strong spatial mixing follows from rather standard considerations, the proof can be found in Section 7. In the following section, we focus on the more interesting proof of Theorem 4 and explain the new aspects of our analysis.

3.1 The three main lemmas

In this section, we lay down the main technical steps in proving Theorem 4. In particular, we will assume throughout that, for appropriate integers q, d, h , $T = \hat{\mathbb{T}}_{d,h,\rho}$ is the d -ary tree with height h rooted at ρ , Λ is a subset of the vertices of T , and $\eta, \eta' : \Lambda \rightarrow [q]$ are two extendible assignments of T with $\text{dist}(\rho, \Delta) \geq 3$ where $\Delta \subseteq \Lambda$ is the set of vertices where η and η' disagree. We also let v_1, \dots, v_d be the children of ρ and for $i \in [d]$ let $T_i = (V_i, E_i)$ be the subtree of T rooted at v_i which consists of all descendants of v_i in T .

To prove Theorem 4, we will use tree recursions to express the marginal at the root in terms of the marginals at the children (as in previous works on WSM/SSM, see, e.g., [5, 13, 11]). This recursion is the well-known *Belief Propagation* (BP) equation [24]; our proof of Theorem 4 will be based on bounding appropriately the gradient of the BP equations. The new ingredient in our analysis is that we incorporate the combinatorial structure of agreements close to the root into a refined L^2 analysis of the gradient.

Prior to delving into the analysis, we first describe the BP equation for the colorings model. Following the notation of Theorem 4, let $\boldsymbol{\pi} = \boldsymbol{\pi}_{T,\rho,\eta}$, $\boldsymbol{\pi}' = \boldsymbol{\pi}_{T,\rho,\eta'}$ be the marginal distributions at the root of the tree T under the boundary conditions η and η' , respectively. Similarly, for $i \in [d]$, let $\boldsymbol{\pi}_i, \boldsymbol{\pi}'_i$ be the marginals at the root v_i of the subtree T_i under $\eta(\Lambda \cap V_i)$ and $\eta'(\Lambda \cap V_i)$, respectively.

We can now relate the distribution $\boldsymbol{\pi}$ with the distributions $\{\boldsymbol{\pi}_i\}_{i \in [d]}$ (and similarly, $\boldsymbol{\pi}'$ with the distributions $\{\boldsymbol{\pi}'_i\}_{i \in [d]}$) as follows. For q -dimensional probability vectors $\mathbf{x}_1, \dots, \mathbf{x}_d$ and a color $c \in [q]$, let f_c be the function

$$f_c(\mathbf{x}_1, \dots, \mathbf{x}_d) = \frac{\prod_{i \in [d]} (1 - x_{i,c})}{\sum_{j \in [q]} \prod_{i \in [d]} (1 - x_{i,j})}, \tag{2}$$

where, for $i \in [d]$ and $j \in [q]$, $x_{i,j}$ denotes the j -th entry of the vector \mathbf{x}_i . Then, with π_c and π'_c denoting the c -th entries of $\boldsymbol{\pi}$ and $\boldsymbol{\pi}'$, we have that

$$\begin{aligned} \pi_c &= \mu_T(\sigma_\rho = c \mid \sigma_\Lambda = \eta) = f_c(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d), \\ \pi'_c &= \mu_T(\sigma_\rho = c \mid \sigma_\Lambda = \eta') = f_c(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d). \end{aligned} \tag{3}$$

The functions $\{f_c\}_{c \in [q]}$ correspond to the BP equations for the coloring model.

We are now ready to describe in more detail our SSM analysis. Specifically, to get a bound on the norm $\|\boldsymbol{\pi} - \boldsymbol{\pi}'\|_2$, we will study the gradient of f_c as we change the arguments $(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d)$ to $(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d)$ along the line connecting them. Our gradient analysis will take account of the following combinatorial notions.

► **Definition 5.** A vertex v of T is called frozen under η if $v \in \Lambda$ and non-frozen otherwise. For a non-frozen vertex v of T , a color k is blocked for v (under η) if there is a neighbor $u \in \Lambda$ of v such that $\eta(u) = k$; the color is called available for v otherwise.

► **Observation 6.** In the setting of Theorem 4, we have that the disagreements between η and η' occur at distance at least 3 from the root. It follows that the set of the root's children that are frozen as well as the set of blocked colors for each of the non-frozen children are identical under both η and η' .

We will utilize that the gradient components that correspond to either frozen children or blocked colors can be disregarded since, by Observation 6, the corresponding arguments in (3) are fixed to the same value. Namely, we will track, for each color c , the fraction of non-frozen children which have color c available. This will allow us in the upcoming Lemma 10 to aggregate accurately the gradient components corresponding to color c . The following definitions setup some relevant notation.

► **Definition 7.** Let D be the indices of the children of the root which are non-frozen under η and η' . For a color $c \in [q]$, let $\gamma_c \in [0, 1]$ be the fraction of indices $i \in D$ such that color c is available for v_i under η and η' (cf. Observation 6). Let $\boldsymbol{\gamma}$ and $\sqrt{\boldsymbol{\gamma}}$ be the q -dimensional vector with entries $\{\gamma_c\}_{c \in [q]}$ and $\{\sqrt{\gamma_c}\}_{c \in [q]}$, respectively.

Intuitively, if γ_c is close to 0, color c is blocked at a lot of the children and hence the distance $\|\boldsymbol{\pi} - \boldsymbol{\pi}'\|_2$ at the root should not depend a lot on the color c (since most components of the gradient corresponding to color c are zero).

The following couple of definitions will be relevant for capturing more precisely the gradient of the functions $\{f_c\}_{c \in [q]}$. To begin with, the gradient will actually turn out to be related to the value of f_c as we move along the line $(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d)$ to $(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d)$. More precisely, we have the following definition.

► **Definition 8.** For $t \in [0, 1]$, let $\hat{\boldsymbol{\pi}}(t) = \{\hat{\pi}_c(t)\}_{c \in [q]}$ be the q -dimensional probability vector whose c -th entry is given by $f_c(t\boldsymbol{\pi}_1 + (1-t)\boldsymbol{\pi}'_1, \dots, t\boldsymbol{\pi}_d + (1-t)\boldsymbol{\pi}'_d)$.

Note that $\hat{\boldsymbol{\pi}}(1) = \boldsymbol{\pi}$ and $\hat{\boldsymbol{\pi}}(0) = \boldsymbol{\pi}'$; in this sense, we can think of the vector $\hat{\boldsymbol{\pi}}(t)$ as having the marginals at the root as we interpolate between $(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d)$ to $(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d)$.

The next definition will be relevant for bounding the L^2 norm of the gradient along the line connecting to $(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d)$ to $(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d)$. The bound will be in terms of the “marginals” at the root, as captured by the vector $\hat{\boldsymbol{\pi}}(t)$ (cf. Definition 8), and the availability of the q colors at the children, as captured by the vector $\boldsymbol{\gamma}$ (cf. Definition 7). In particular, we will be interested in the L^2 norm of the following matrix, which is an idealized version to the Jacobian of the BP equation (see (13) for the precise formula).²

► **Definition 9.** Let $\hat{\boldsymbol{\pi}}, \hat{\boldsymbol{\gamma}}$ be q -dimensional vectors with non-negative entries. The matrix $\mathbf{M}_{\hat{\boldsymbol{\pi}}, \hat{\boldsymbol{\gamma}}}$ corresponding to the vectors $\hat{\boldsymbol{\pi}}, \hat{\boldsymbol{\gamma}}$ is given by $(\text{diag}(\hat{\boldsymbol{\pi}}) - \hat{\boldsymbol{\pi}}\hat{\boldsymbol{\pi}}^\top)\text{diag}(\hat{\boldsymbol{\gamma}})$.³

Our first main lemma shows how to bound the distance between the marginals at the root under η and η' , i.e., $\|\boldsymbol{\pi} - \boldsymbol{\pi}'\|_2^2$, in terms of the aggregate distance at the children. The new ingredient in our bound is to account more carefully for the availability of the colors at the children (i.e., the vector $\boldsymbol{\gamma}$).

► **Lemma 10.** Let q, d be positive integers so that $q \geq d + 2$. Then

$$\|\boldsymbol{\pi} - \boldsymbol{\pi}'\|_2^2 \leq |D|K^2 \sum_{i \in [d]} \|\boldsymbol{\pi}_i - \boldsymbol{\pi}'_i\|_2^2 \quad \text{where } K := \frac{1}{1 - \frac{1}{q-d}} \max_{t \in (0,1)} \|\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}}\|_2,$$

where $D, \boldsymbol{\gamma}, \sqrt{\boldsymbol{\gamma}}$ are as in Definition 7, $\hat{\boldsymbol{\pi}}(t)$ is as in Definition 8, and $\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}}$ is as in Definition 9.

Given Lemma 10, we are left with obtaining a good upper bound on the norm $\|\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}}\|_2$ that takes advantage of the presence of the vector $\boldsymbol{\gamma}$. It is not hard to see that the L^2 norm of the matrix $(\text{diag}(\hat{\boldsymbol{\pi}}) - \hat{\boldsymbol{\pi}}\hat{\boldsymbol{\pi}}^\top)$ is bounded by $\max_{j \in [q]} \hat{\pi}_j$. The following result can be seen as a generalisation of this fact, which is however significantly more involved to prove. The proof is given in Section 4.

² For a square matrix \mathbf{M} , we use $\|\mathbf{M}\|_2$ to denote its L^2 norm, i.e., $\|\mathbf{M}\|_2 = \max_{\|\mathbf{x}\|_2=1} \|\mathbf{M}\mathbf{x}\|_2$. A fact that will be useful later is that $\|\mathbf{M}\|_2 = \max_{\|\mathbf{x}\|_2=1} \|\mathbf{x}^\top \mathbf{M}\|_2$, even for non-symmetric matrices \mathbf{M} .

³ For a vector \mathbf{x} , $\text{diag}(\mathbf{x})$ denotes the diagonal matrix with the entries of \mathbf{x} on the diagonal.

► **Lemma 11.** *Let q be a positive integer, $\hat{\pi}$ be a q -dimensional probability vector and $\hat{\gamma}$ be a q -dimensional vector with non-negative entries which are all bounded by 1. Then, the L^2 norm of the matrix $\mathbf{M}_{\hat{\pi}, \hat{\gamma}} = (\text{diag}(\hat{\pi}) - \hat{\pi}\hat{\pi}^\top)\text{diag}(\hat{\gamma})$ satisfies*

$$\|\mathbf{M}_{\hat{\pi}, \hat{\gamma}}\|_2 \leq \frac{1}{2} \max_{j \in [q]} \hat{\pi}_j (1 + (\hat{\gamma}_j)^2),$$

where $\{\hat{\pi}_j\}_{j \in [q]}, \{\hat{\gamma}_j\}_{j \in [q]}$ are the entries of $\hat{\pi}, \hat{\gamma}$, respectively.

The final component of our proof is to utilize the bound in Lemma 11 to derive an upper bound on the norm of the matrix $\mathbf{M}_{\hat{\pi}(t), \sqrt{\gamma}}$ appearing in Lemma 10. To prove Theorem 4, we roughly need to show that the norm is bounded by $1/|D|$. We show that this is indeed the case in Section 6.

► **Lemma 12.** *There exist absolute constants $\beta > 0$ and $K' \in (0, 1)$ such that the following holds for all positive integers q, d satisfying $q \geq 1.59d + \beta$.*

Let $\gamma, \hat{\pi}(t)$ be the q -dimensional vectors of Definitions 7 and 8, respectively. Then, for all $t \in [0, 1]$ and all colors $k \in [q]$, it holds that

$$\frac{1}{2} \hat{\pi}_k(t) (1 + \gamma_k) < K' / |D|,$$

where D is the set of non-frozen children of ρ under η and η' .

Assuming Lemmas 10, 11 and 12 for now, we next conclude the proof of Theorem 4.

Proof of Theorem 4. Let $U' := (1 + K')/2$ where $K' \in (0, 1)$ is the constant in Lemma 12. Let $\beta > 0$ be a sufficiently large constant so that, for all $q \geq 1.59d + \beta$, the conclusion of Lemma 12 applies and $\frac{1}{1 - \frac{1}{q-d}} K' < U'$. We will show that

$$\|\pi - \pi'\|_2^2 \leq U \max_{i \in [d]} \|\pi_i - \pi_{i'}\|_2^2, \text{ with } U := (U')^2. \quad (4)$$

Indeed, by Lemmas 10, 11 and 12, we have that

$$\|\pi - \pi'\|_2^2 \leq \frac{U}{|D|} \sum_{i \in [d]} \|\pi_i - \pi_{i'}\|_2^2.$$

Note that an index $i \notin D$ corresponds to a frozen child v_i and therefore $\pi_i = \pi_{i'}$ for all $i \notin D$ and hence

$$\frac{1}{|D|} \sum_{i \in [d]} \|\pi_i - \pi_{i'}\|_2^2 \leq \max_{i \in [d]} \|\pi_i - \pi_{i'}\|_2^2,$$

proving (4). This completes the proof of Theorem 4. ◀

4 Bound on the matrix norm: proof of Lemma 11

In this section, we prove Lemma 11.

Proof of Lemma 11. For this proof, it will be convenient to simplify notation and use π instead of $\hat{\pi}$ and γ instead of $\hat{\gamma}$, so that $\mathbf{M}_{\hat{\pi}, \hat{\gamma}}$ becomes $(\text{diag}(\pi) - \pi\pi^\top)\text{diag}(\gamma)$. Let $C := \frac{1}{2} \max_{j \in [q]} \pi_j (1 + \gamma_j^2)$. We will establish that $\|\mathbf{M}_{\pi, \gamma}\|_2 \leq C$ by showing that for an arbitrary q -dimensional vector \mathbf{x} it holds that

$$\|\mathbf{x}^\top \mathbf{M}_{\pi, \gamma}\|_2^2 \leq C^2 \|\mathbf{x}\|_2^2. \quad (5)$$

48:8 Improved Strong Spatial Mixing for Colorings on Trees

We will focus on proving (5) in the case where the entries of the vector γ are all nonnegative and strictly less than one; the case where some of the entries of γ are equal to 1 follows from the continuity of (5) with respect to γ .

So, assume that $\gamma_j \in [0, 1)$ for all $j \in [q]$. Observe that

$$\|\mathbf{x}^\top \mathbf{M}_{\pi, \gamma}\|_2^2 = \sum_{j \in [q]} \pi_j^2 \gamma_j^2 (x_j - w)^2 \text{ where } w := \sum_{j \in [q]} \pi_j x_j.$$

Let $y_j = x_j - w$ for $j \in [q]$. Since π is a probability vector, we have

$$\sum_{j \in [q]} \pi_j y_j = 0.$$

Moreover, we can rewrite (5) as

$$\sum_{j \in [q]} \frac{\pi_j^2 \gamma_j^2}{C^2} y_j^2 \leq \sum_{j \in [q]} (y_j + w)^2. \quad (6)$$

Note that the function $f(z) = \sum_{j \in [q]} (y_j + z)^2$ achieves its minimum for $z^* = -\frac{1}{q} \sum_{j \in [q]} y_j$ and $f(z^*) = \sum_{j \in [q]} y_j^2 - \frac{1}{q} (\sum_{j \in [q]} y_j)^2$. Hence, to prove (6) (and therefore (5)), it suffices to show that

$$\left(\sum_{j \in [q]} y_j \right)^2 \leq q \sum_{j \in [q]} \frac{y_j^2}{A_j}, \text{ where } A_j := \frac{C^2}{C^2 - \pi_j^2 \gamma_j^2} \quad (7)$$

Note that the A_j 's are well-defined and greater than 1 for all $j \in [q]$ by our assumption that $\gamma_j \in [0, 1)$, cf. the argument below (5). Using that $\sum_{j \in [q]} \pi_j y_j = 0$, we therefore obtain that (7) is equivalent to

$$\left(\sum_{j \in [q]} y_j (1 + t\pi_j) \right)^2 \leq q \sum_{j \in [q]} \frac{y_j^2}{A_j}, \text{ where } A_j := \frac{C^2}{C^2 - \pi_j^2 \gamma_j^2}, \quad (8)$$

for any real number t – we will specify t soon (cf. the upcoming (10)). In particular, by the Cauchy-Schwarz inequality, we have

$$\left(\sum_{j \in [q]} y_j (1 + t\pi_j) \right)^2 \leq \sum_{j \in [q]} \frac{y_j^2}{A_j} \sum_{j \in [q]} A_j (1 + t\pi_j)^2,$$

so (8) and hence (7) will follow if we find t such that

$$\sum_{j \in [q]} A_j (1 + t\pi_j)^2 \leq q. \quad (9)$$

We will choose t to minimise the l.h.s. in (9), i.e., set

$$t := -\frac{\sum_{j \in [q]} A_j \pi_j}{\sum_{j \in [q]} A_j \pi_j^2}, \text{ so that } \sum_{j \in [q]} A_j (1 + t\pi_j)^2 = \sum_{j \in [q]} A_j - \frac{(\sum_{j \in [q]} A_j \pi_j)^2}{\sum_{j \in [q]} A_j \pi_j^2}. \quad (10)$$

Therefore, for this choice of t , (9) becomes

$$\sum_{j \in [q]} (A_j - 1) \sum_{j \in [q]} A_j \pi_j^2 \leq \left(\sum_{j \in [q]} A_j \pi_j \right)^2. \quad (11)$$

Using that $A_j = \frac{C^2}{C^2 - \pi_j^2 \gamma_j^2}$, (11) is equivalent to (note the division by C^2 of both sides)

$$\sum_{j \in [q]} \frac{\pi_j^2 \gamma_j^2}{C^2 - \pi_j^2 \gamma_j^2} \sum_{j \in [q]} \frac{\pi_j^2}{C^2 - \pi_j^2 \gamma_j^2} \leq \left(\sum_{j \in [q]} \frac{C \pi_j}{C^2 - \pi_j^2 \gamma_j^2} \right)^2. \quad (12)$$

We next establish (12). We can upper bound the l.h.s. of (12) using the inequality $ab \leq \left(\frac{a+b}{2}\right)^2$, which gives that

$$\sum_{j \in [q]} \frac{\pi_j^2 \gamma_j^2}{C^2 - \pi_j^2 \gamma_j^2} \sum_{j \in [q]} \frac{\pi_j^2}{C^2 - \pi_j^2 \gamma_j^2} \leq \left(\sum_{j \in [q]} \frac{\pi_j^2 (1 + \gamma_j^2)}{2(C^2 - \pi_j^2 \gamma_j^2)} \right)^2.$$

So, to prove (12), it suffices to show that for each $i \in [q]$, it holds that

$$\frac{\pi_j^2 (1 + \gamma_j^2)}{2(C^2 - \pi_j^2 \gamma_j^2)} \leq \frac{C \pi_j}{C^2 - \pi_j^2 \gamma_j^2}$$

which is indeed true, since $C \geq \frac{1}{2} \pi_j (1 + \gamma_j^2)$ for all $i \in [q]$ by the definition of C .

This proves (12), which in turn establishes (8) for the choice of t in (10). This yields (7) and hence (5) as well, finishing the proof of Lemma 11. \blacktriangleleft

5 Gradient analysis with blocked colors: proof of Lemma 10

In this section, we prove Lemma 10.

Proof of Lemma 10. For $i \in [d]$ and $j \in [q]$, let $F_{c,j}^{(i)}(\mathbf{x})$ be the partial derivative $\frac{\partial f_c}{\partial x_{i,j}}$ viewed as a function of the “concatenated” vector $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_d)$. Note that, whenever $x_{i,j} \neq 1$, we have that

$$\begin{aligned} F_{c,j}^{(i)}(\mathbf{x}) &= -\frac{f_c(\mathbf{x}_1, \dots, \mathbf{x}_d) - (f_c(\mathbf{x}_1, \dots, \mathbf{x}_d))^2}{1 - x_{i,j}} \text{ if } j = c, \\ F_{c,j}^{(i)}(\mathbf{x}) &= \frac{f_c(\mathbf{x}_1, \dots, \mathbf{x}_d) f_j(\mathbf{x}_1, \dots, \mathbf{x}_d)}{1 - x_{i,j}} \text{ if } j \neq c. \end{aligned} \quad (13)$$

As mentioned earlier, we will interpolate between $\boldsymbol{\pi}$ and $\boldsymbol{\pi}'$ by interpolating along the straight-line segment connecting $(\boldsymbol{\pi}_1, \dots, \boldsymbol{\pi}_d)$ and $(\boldsymbol{\pi}'_1, \dots, \boldsymbol{\pi}'_d)$. In particular, for $t \in [0, 1]$, let $\hat{\pi}_c(t)$ denote the c -th entry of the vector $\hat{\boldsymbol{\pi}}(t)$ defined in the statement of the lemma. Then, we have that

$$\hat{\pi}_c(t) = f_c(\mathbf{z}(t)), \text{ where } \mathbf{z}(t) \text{ is the vector } (t\boldsymbol{\pi}_1 + (1-t)\boldsymbol{\pi}'_1, \dots, t\boldsymbol{\pi}_d + (1-t)\boldsymbol{\pi}'_d). \quad (14)$$

We will use $z_{i,j}(t)$ to denote the j -th entry of the i -th vector in $\mathbf{z}(t)$, i.e., $z_{i,j}(t) = t\pi_{i,j} + (1-t)\pi'_{i,j}$.

Let D be the set of indices i such that v_i is not frozen under η and η' (cf. Observation 6). Observe that, for all $i \notin D$ and $c, j \in [q]$, we have that $z_{i,j}(t) = \pi_{i,j} = \pi'_{i,j}$ for $t \in [0, 1]$. Moreover, for $i \in D$ and $j \in [q]$ we have that $\pi_{i,j}, \pi'_{i,j} \leq 1/(q-d)$ (since the child v_i has at least $q-d$ available colors in the subtree T_i) and hence

$$0 \leq z_{i,j}(t) \leq 1/(q-d). \quad (15)$$

Since $z_{i,j}(t) \neq 1$ for $i \in D$ and $j \in [q]$, it follows that

$$\frac{d\hat{\pi}_c}{dt} = \sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}).$$

48:10 Improved Strong Spatial Mixing for Colorings on Trees

Using (3), we therefore have that

$$\begin{aligned} (\pi_c - \pi'_c)^2 &= (\hat{\pi}_c(1) - \hat{\pi}_c(0))^2 = \left(\int_0^1 \frac{d\hat{\pi}_c}{dt} dt \right)^2 = \left(\int_0^1 \sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}) dt \right)^2 \\ &\leq \int_0^1 \left(\sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}) \right)^2 dt, \end{aligned}$$

where the last inequality follows by applying the Cauchy-Schwarz inequality for integrals. By summing over all colors $c \in [q]$, we obtain

$$\|\boldsymbol{\pi} - \boldsymbol{\pi}'\|_2^2 \leq \int_0^1 \sum_{c=1}^q \left(\sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}) \right)^2 dt. \quad (16)$$

To simplify the r.h.s. of (16), we first note that, by (13) and (14), we have

$$F_{c,j}^{(i)}(\mathbf{z}(t)) = \frac{A_{c,j}(t)}{1 - z_{i,j}(t)} \text{ where } A_{c,j} := \begin{cases} (\hat{\pi}_c(t))^2 - \hat{\pi}_c(t), & \text{if } j = c, \\ \hat{\pi}_c(t)\hat{\pi}_j(t), & \text{if } j \neq c \end{cases} \quad (17)$$

Moreover, for $j \in [q]$, set

$$u_j(t) = \frac{1}{|D|\gamma_j} \sum_{i \in D} \frac{\pi_{i,j} - \pi'_{i,j}}{1 - z_{i,j}(t)} \text{ if } \gamma_j > 0, \text{ else set } u_j(t) = 0. \quad (18)$$

Note that if color j is blocked for the child v_i we have that $\pi_{i,j} - \pi'_{i,j} = 0$, so using the power mean inequality we have that

$$\gamma_j (u_j(t))^2 \leq \frac{1}{|D|} \sum_{i \in D} \left(\frac{\pi_{i,j} - \pi'_{i,j}}{1 - z_{i,j}(t)} \right)^2. \quad (19)$$

Then, for $c \in [q]$, we have that

$$\sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}) = \sum_{j=1}^q A_{c,j}(t) \sum_{i \in D} \frac{\pi_{i,j} - \pi'_{i,j}}{1 - z_{i,j}(t)} = |D| \sum_{j=1}^q A_{c,j}(t) \gamma_j u_j(t), \quad (20)$$

where the last equality follows from (18) and observing that if $\gamma_j = 0$ then $\pi_{i,j} - \pi'_{i,j} = 0$ for all $i \in D$. Note that the (c, q) -entry of $\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}}$ is exactly $-A_{c,j}(t)\sqrt{\gamma_j}$ (cf. (17) and Definition 9) and hence, using (20), we can write the integrand in the r.h.s. of (16) as

$$\sum_{c=1}^q \left(\sum_{i \in D} \sum_{j=1}^q F_{c,j}^{(i)}(\mathbf{z}(t)) (\pi_{i,j} - \pi'_{i,j}) \right)^2 = |D|^2 \|\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}} \mathbf{u}(t)\|_2^2, \quad (21)$$

where, for $t \in [0, 1]$, $\mathbf{u}(t)$ is the q -dimensional vector with entries $\{\sqrt{\gamma_j} u_j(t)\}_{j \in [q]}$. Let

$$W := \max_{t \in [0,1]} \|\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}}\|_2, \text{ so that } K = \frac{W}{1 - \frac{1}{q-d}}.$$

Then, for $t \in [0, 1]$, we have that

$$\begin{aligned} \|\mathbf{M}_{\hat{\boldsymbol{\pi}}(t), \sqrt{\boldsymbol{\gamma}}} \mathbf{u}(t)\|_2^2 &\leq W^2 \|\mathbf{u}(t)\|_2^2 = W^2 \sum_{j \in [q]} \gamma_j (u_j(t))^2 \leq \frac{W^2}{|D|} \sum_{j \in [q]} \sum_{i \in D} \left\| \frac{\pi_{i,j} - \pi'_{i,j}}{1 - z_{i,j}(t)} \right\|_2^2 \\ &\leq \frac{K^2}{|D|} \sum_{j \in [q]} \sum_{i \in D} \|\pi_{i,j} - \pi'_{i,j}\|_2^2 = \frac{K^2}{|D|} \sum_{i \in [d]} \|\boldsymbol{\pi}_i - \boldsymbol{\pi}'_i\|_2^2, \end{aligned} \quad (22)$$

where the first inequality is by definition of the norm, the second inequality follows from (19), the third inequality follows from $0 \leq z_{i,j}(t) \leq 1/(q-d)$, and the last equality follows from the fact that for $i \notin D$ we have that $\pi_i = \pi'_i$. Combining (16), (21) and (22), we obtain that

$$\|\pi - \pi'\|_2^2 \leq |D|K^2 \sum_{i \in [d]} \|\pi_i - \pi'_i\|_2^2.$$

This finishes the proof of Lemma 10. \blacktriangleleft

6 Bounds on the marginals: proof of Lemma 12

In this section, we prove Lemma 12. We begin with the following lemma.

► **Lemma 13.** *Let q, d, h be positive integers so that $q \geq d+1$ and $h \geq 1$. Let $T = \mathbb{T}_{d,h,\rho}$ be the d -ary tree with height h rooted at ρ , Λ be a subset of the vertices of T such that $\rho \notin \Lambda$, and $\eta : \Lambda \rightarrow [q]$ be an extendible assignment of T . Then, for all colors $k \in [q]$ that are available for ρ under η , it holds that*

$$\mu_T(\sigma_\rho = k \mid \sigma_\Lambda = \eta) \geq \frac{(1 - \frac{1}{q-d})^d}{d + (q-d)(1 - \frac{1}{q-d})^d}.$$

Proof. Let $Q \subseteq [q]$ be the set of all colors that are available for ρ under η and let $k \in Q$. Let v_1, \dots, v_d be the children of ρ in T and let $D = \{i \in [d] \mid v_i \notin \Lambda\}$ be the indices of the children of ρ that do not belong to Λ .

For $i \in [d]$, let $T_i = (V_i, E_i)$ be the subtree of T rooted at v_i which consists of all descendants of v_i in T (together with v_i itself). Further, for a color $j \in [q]$, let

$$x_{i,j} = \mu_{T_i}(\sigma_{v_i} = j \mid \sigma_{\Lambda \cap V_i} = \eta_{\Lambda \cap V_i}),$$

i.e., $x_{i,j}$ is the marginal probability that v_i takes the color j at v_i in μ_{T_i} with boundary condition $\eta_{\Lambda \cap V_i}$. Note that

$$0 \leq x_{i,j} \leq \frac{1}{q-d} \text{ for all } i \in D \text{ and } j \in [q], \quad \sum_{j \in [q]} x_{i,j} = 1 \text{ for all } i \in [d]. \quad (23)$$

Using the tree recursion (2) and ignoring summands that are 0 or factors that are equal to 1, the marginal $\mu_T(\sigma_\rho = k \mid \sigma_\Lambda = \eta)$ is expressed in terms of $x_{i,j}$ as follows:

$$\mu_T(\sigma_\rho = k \mid \sigma_\Lambda = \eta) = \frac{\prod_{i \in D} (1 - x_{i,k})}{\sum_{j \in Q} \prod_{i \in D} (1 - x_{i,j})}. \quad (24)$$

We prove the lemma by deriving an appropriate lower bound on the quantity at the r.h.s. of (24) subject to the constraint in (23). For the numerator in (24), we have that

$$\prod_{i \in D} (1 - x_{i,k}) \geq \left(1 - \frac{1}{q-d}\right)^{|D|}. \quad (25)$$

For the denominator we are going to show the following:

$$\sum_{j \in Q} \prod_{i \in D} (1 - x_{i,j}) \leq d + (q-d) \left(1 - \frac{1}{q-d}\right)^{|D|}. \quad (26)$$

48:12 Improved Strong Spatial Mixing for Colorings on Trees

Before showing that (26) is indeed true, note that the lemma follows by plugging (25), (26) into (24), yielding

$$\mu_T(\sigma_\rho = k \mid \sigma_\Lambda = \eta) \geq \frac{\left(1 - \frac{1}{q-d}\right)^{|D|}}{d + (q-d) \left(1 - \frac{1}{q-d}\right)^{|D|}} \geq \frac{\left(1 - \frac{1}{q-d}\right)^d}{d + (q-d) \left(1 - \frac{1}{q-d}\right)^d},$$

where the last inequality follows by noting that the ratio in the middle is decreasing in $|D|$ and $|D| \leq d$.

We now proceed with the proof of (26). First, we have the simple bound

$$\sum_{j \in Q} \prod_{i \in D} (1 - x_{i,j}) \leq \sum_{j \in [q]} \prod_{i \in D} (1 - x_{i,j}). \quad (27)$$

For $j \in [q]$, let $x_j = \frac{1}{|D|} \sum_{i \in D} x_{i,j}$ and note that (x_1, \dots, x_q) is a probability vector whose entries are in $[0, 1/(q-d)]$. By the AM-GM inequality, we can bound the r.h.s. of (27) by

$$\sum_{j \in [q]} \prod_{i \in D} (1 - x_{i,j}) \leq \sum_{j \in [q]} (1 - x_j)^{|D|}. \quad (28)$$

It remains to observe that the function $f(\mathbf{z}) = \sum_{j \in [q]} (1 - z_j)^{|D|}$ is convex over the space of probability vectors $\mathbf{z} = (z_1, \dots, z_q)$ whose entries are in $[0, 1/(q-d)]$, and hence f attains its maximum at the extreme points of the space, which are given by (the permutations of) the probability vector whose first d entries are equal to zero and the rest are equal to $1/(q-d)$. It follows that

$$\sum_{j \in [q]} (1 - x_j)^{|D|} \leq d + (q-d) \left(1 - \frac{1}{q-d}\right)^{|D|}. \quad (29)$$

Combining (27), (28) and (29) yields (26), thus concluding the proof of Lemma 13. \blacktriangleleft

We are now ready to prove Lemma 12.

Proof of Lemma 12. For convenience, let $r = 1.59$, so that $q/d \geq r$. We will use that r satisfies

$$C := \frac{1}{r} \exp\left(\frac{1}{r}\right) \exp\left(-\frac{1}{r-1 + \exp\left(\frac{1}{r-1}\right)}\right) < 1. \quad (30)$$

We will show the result with the constant $K' = (1 + C)/2$. For the rest of this proof, we will focus on the case $q \in [1.59d + \beta, 2.01d]$, for some large constant $\beta > 0$ (when $q > 2.01d$ the desired bound follows rather crudely, see Footnote 4 below for details).

Recall that v_1, \dots, v_d are the children of ρ in T and D is the set of (indices of the) non-frozen children of the root ρ . Let $Q \subseteq [q]$ be the set of all colors that are available for ρ under η ; since at most $d - |D|$ colors can be blocked for ρ , we have that

$$|Q| \geq q - (d - |D|). \quad (31)$$

For $i \in [d]$, let $T_i = (V_i, E_i)$ be the subtree of T rooted at v_i which consists of all descendants of v_i in T (together with v_i itself). Further, for a color $j \in [q]$, recall that

$$\begin{aligned} \pi_{i,j} &= \mu_{T_i}(\sigma_{v_i} = j \mid \sigma_{\Lambda \cap V_i} = \eta_{\Lambda \cap V_i}), \\ \pi'_{i,j} &= \mu_{T_i}(\sigma_{v_i} = j \mid \sigma_{\Lambda \cap V_i} = \eta'_{\Lambda \cap V_i}), \end{aligned} \quad (32)$$

i.e., $\pi_{i,j}$ is the marginal probability that v_i takes the color j at v_i in μ_{T_i} with boundary condition $\eta_{\Lambda \cap V_i}$. For a non-frozen child v_i (i.e., $i \in D$), note that, if color j is available for v_i (in T_i), then we have from Lemma 13 the bounds

$$L \leq \pi_{i,j}, \pi_{i,j}, \text{ where } L = \frac{\left(1 - \frac{1}{q-d}\right)^d}{d + (q-d)\left(1 - \frac{1}{q-d}\right)^d}. \quad (33)$$

Another useful bound to observe for later is that

$$dL < 1/3 \text{ for all } d \geq 2.$$

Consider arbitrary $k \in Q$. For $t \in [0, 1]$, let $\mathbf{z}(t)$ be the vector $(t\pi_1 + (1-t)\pi'_1, \dots, t\pi_d + (1-t)\pi'_d)$. Using the tree recursion (2) and ignoring summands that are 0 or factors that are equal to 1, we obtain

$$\hat{\pi}_k(t) = \frac{\prod_{i \in D} (1 - z_{i,k}(t))}{\sum_{j \in Q} \prod_{i \in D} (1 - z_{i,j}(t))}. \quad (34)$$

Recall, our goal is to show that $\frac{1}{2}\hat{\pi}_k(t)(1 + \gamma_k) < K'/|D|$ for all $t \in [0, 1]$, where $\gamma_k \in [0, 1]$ is the fraction of non-frozen children that have color k available. ⁴Note that, if color j is available for the child v_i , (33) gives that

$$L \leq z_{i,j}(t) \text{ for } t \in [0, 1],$$

so, using the fact that the color k is available for $|D|\gamma_k$ non-frozen children, we obtain that the numerator of (34) is bounded by

$$\prod_{i \in D} (1 - z_{i,k}(t)) \leq (1 - L)^{|D|\gamma_k} \leq \exp(-L|D|\gamma_k), \quad (35)$$

whereas the denominator, using the AM-GM inequality analogously to [7, Lemma 2.1], by

$$\sum_{j \in Q} \prod_{i \in D} (1 - z_{i,j}(t)) \geq q \exp(-|D|/q) - (d - |D|). \quad (36)$$

From (34), (35), and (36), it follows that $\hat{\pi}_k(t) \leq \frac{\exp(-L|D|\gamma_k)}{q \exp(-|D|/q) - (d - |D|)}$. Therefore, the lemma will follow by showing that

$$\frac{|D| \exp(-|D|L\gamma_k)}{q \exp(-|D|/q) - (d - |D|)} (1 + \gamma_k) < 2K'. \quad (37)$$

Note that the function $h(x) = (1 + x) \exp(-dLx)$ is increasing when $x \in [0, 1]$, since

$$h'(x) = \exp(-dLx)(1 - dL(1 + x)) \geq \exp(-dLx)(1 - 2dL) > 0.$$

Therefore, to prove (37), it suffices to show that

$$\frac{|D| \exp(-|D|L)}{q \exp(-|D|/q) - (d - |D|)} < K', \text{ or equivalently that } f(|D|) > 0 \quad (38)$$

⁴ For $q > 2.01d$, we have from (34) and (31) that $\hat{\pi}_k(t) \leq \frac{1}{|Q|-|D|} \leq \frac{1}{q-d} < \frac{1}{1.01d} \leq K'/|D|$, yielding the desired inequality.

48:14 Improved Strong Spatial Mixing for Colorings on Trees

where $f(x) := K'(q \exp(-x/q) - d + x) - x \exp(-Lx)$ for $x \in [0, d]$. We claim that $f(x)$ is decreasing in x . We have

$$f'(x) = K' - K' \exp(-x/q) - \exp(-Lx)(1 - Lx)$$

which is maximised for $x = d$. In particular,

$$\begin{aligned} f'(x) &\leq f'(d) = K' - K' \exp(-d/q) - \exp(-dL)(1 - dL) \\ &\leq K' - K' \exp(-1/r) - \exp(-1/3)(1 - 1/3) \leq 0, \end{aligned}$$

where the second to last inequality follows from the fact that $dL < 1/3$ and the last inequality using that $K' < 1$. For $|D| = d$, (38) becomes

$$\frac{d \exp(-dL)}{q \exp(-d/q)} < K'. \quad (39)$$

Now, we have that

$$dL \geq \frac{1}{r - 1 + \exp\left(\frac{d}{(r-1)d-1}\right)}.$$

Therefore, by choosing β large enough, we can ensure that

$$\frac{d \exp(-dL)}{q \exp(-d/q)} < \frac{1 + C}{2} = K',$$

where C is the constant in (30). This proves (39) and therefore concludes the proof of Lemma 12. \blacktriangleleft

7 Proof of Theorem 3

Finally, utilizing Theorem 4, we give the proof of Theorem 3.

Proof of Theorem 3. From Theorem 4, we know that there exist constants $\beta > 0$ and $U \in (0, 1)$ such that for all $q \geq 1.59d + \beta$ the conclusion of Theorem 4 applies. Note that Theorem 4 applies to the d -ary tree rather than the $(d+1)$ -regular tree but these trees differ only at the degree of the root. To account for it, we will assume that $q \geq 1.59(d+1) + \beta$, i.e., prove Theorem 3 with constant $\beta' = \beta + 1.59$. Consider the function ζ given by $\zeta(\ell) = 2U^{\ell-2}$ for $\ell \geq 0$ and note that ζ is exponentially decaying. We will show that the q -coloring model has strong spatial mixing on the $(d+1)$ -regular tree with decay rate ζ .

We first show by induction on h that, for the tree $T = \hat{\mathbb{T}}_{d+1, h, \rho}$ (that is, the $(d+1)$ -ary tree with height h rooted at ρ), for any subset Λ of vertices of T and arbitrary extendible assignments $\eta, \eta' : \Lambda \rightarrow [q]$ of T , it holds that

$$\|\pi_{T, \rho, \eta} - \pi_{T, \rho, \eta'}\|_2^2 \leq \zeta(\text{dist}(\rho, \Delta)), \quad (40)$$

where $\Delta \subseteq \Lambda$ is the set of vertices where η and η' disagree. The base cases $h = 0, 1, 2$ are trivial so assume $h \geq 3$ in what follows. Let $\ell = \text{dist}(\rho, \Delta)$. Once again, (40) is trivial when $\ell \leq 2$, so assume $\ell \geq 3$ in what follows. Let v_1, \dots, v_{d+1} be the children of ρ and, for $i \in [d+1]$, let $T_i = (V_i, E_i)$ be the subtree of T rooted at v_i which consists of all descendants of v_i in T . Further, let $\pi_i = \pi_{T_i, v_i, \eta(\Lambda \cap V_i)}$, $\pi'_i = \pi_{T_i, v_i, \eta'(\Lambda \cap V_i)}$. Then, by Theorem 4 and since $q \geq 1.59(d+1) + \beta$, we have that

$$\|\pi_{T, \rho, \eta} - \pi_{T, \rho, \eta'}\|_2^2 \leq U \max_{i \in [d+1]} \|\pi_i - \pi'_i\|_2^2. \quad (41)$$

For $i \in [d+1]$, since T_i is isomorphic to $\hat{\mathbb{T}}_{d+1, h-1, \rho}$ we have by the induction hypothesis that

$$\|\pi_i - \pi_{i'}\|_2^2 \leq \zeta(\ell - 1).$$

Combining this with (41) and the fact that $\zeta(\ell) = U\zeta(\ell - 1)$ yields (40), completing the induction and therefore that strong spatial mixing holds on T with decay rate ζ .

Now, let $T = (V, E)$ be a finite subtree of the $(d+1)$ -regular tree, v be an arbitrary vertex of T , Λ be a subset of vertices of T and $\eta, \eta' : \Lambda \rightarrow [q]$ be arbitrary extendible assignments of T . Then, we can view T as a subgraph of $T_v = \hat{\mathbb{T}}_{d+1, h, v}$ for some appropriate height h . It also holds that (see, for example, [10, Lemma 25])

$$\|\pi_{T, v, \eta} - \pi_{T, v, \eta'}\|_2 = \|\pi_{T_v, v, \eta} - \pi_{T_v, v, \eta'}\|_2.$$

Therefore, from (40) (applied to the tree T_v) we obtain that

$$\|\pi_{T, v, \eta} - \pi_{T, v, \eta'}\|_2^2 \leq \zeta(\text{dist}(v, \Delta)),$$

where $\Delta \subseteq \Lambda$ is the set of vertices where η and η' disagree.

This completes the proof of Theorem 3. ◀

Abstract

Consider a kidney-exchange application where we want to find a max-matching in a random graph. To find whether an edge e exists, we need to perform an expensive test, in which case the edge e appears independently with a *known* probability p_e . Given a budget on the total cost of the tests, our goal is to find a testing strategy that maximizes the expected maximum matching size.

The above application is an example of the stochastic probing problem. In general the optimal stochastic probing strategy is difficult to find because it is *adaptive* – decides on the next edge to probe based on the outcomes of the probed edges. An alternate approach is to show the *adaptivity gap* is small, i.e., the best *non-adaptive* strategy always has a value close to the best adaptive strategy. This allows us to focus on designing non-adaptive strategies that are much simpler. Previous works, however, have focused on Bernoulli random variables that can only capture whether an edge appears or not. In this work we introduce a multi-value stochastic probing problem, which can also model situations where the weight of an edge has a probability distribution over multiple values.

Our main technical contribution is to obtain (near) optimal bounds for the (worst-case) adaptivity gaps for multi-value stochastic probing over prefix-closed constraints. For a monotone submodular function, we show the adaptivity gap is at most 2 and provide a matching lower bound. For a weighted rank function of a k -extendible system (a generalization of intersection of k matroids), we show the adaptivity gap is between $O(k \log k)$ and k . None of these results were known even in the Bernoulli case where both our upper and lower bounds also apply, thereby resolving an open question of Gupta et al. [23].

1 Introduction

Consider a kidney-exchange application where we want to find a maximum matching in a random graph. To find whether an edge e exists, we need to perform an expensive test, in which case the edge e appears independently with a known probability p_e . Given a budget on the total cost of the tests, our goal is to design a testing strategy that maximizes the expected size of the found matching.

The above application can be modeled as a constrained *stochastic probing* problem [5, 21, 3, 22, 23]. In this setting, we are given a universe V of *elements* (e.g., the set of all possible edges), each with an *activation* probability p_v for $v \in V$ (e.g., the probability an edge exists). We define a random set $A \subseteq V$ of *active* elements that contains every v independently with probability p_v . A *probe* at v reveals whether $v \in A$ or $v \notin A$, and we are only allowed to probe certain *feasible subsets* $S \in \mathcal{F} \subseteq 2^V$ (e.g., subsets of edges whose tests fit in our budget). Our goal is to design a *probing strategy* to find a feasible set $S \in \mathcal{F}$ of elements to maximize $\mathbb{E}_A[f(A \cap S)]$, where f is some combinatorial function $f : 2^V \rightarrow \mathbb{R}_{\geq 0}$ (e.g., the cardinality of the maximum matching). Notice our probing strategy could be *adaptive*, i.e., we could decide which element to probe next based on the outcomes of already probed elements.

Besides matching [13, 7], stochastic probing has applications for stochastic variants of several other combinatorial problems. E.g., it can be used for Bayesian mechanism design problems [21], robot path-planning problems [22, 23], and stochastic set cover problems that arise in database applications [27, 16]. As observed in these prior works, the optimal strategy for stochastic probing can be represented as a binary *decision tree* where each node represents an element of V : You first probe the root node element, and then depending on whether it is active or inactive, you either move to the right or the left subtree. In general, such an optimal decision tree can be exponentially sized and is hard to describe. We do not even understand how to capture it for very simple functions and constraints (e.g., the max function with cardinality constraints [24]).

An alternate approach is to focus on *non-adaptive* strategies. Such a strategy commits to probing a feasible set $S \in \mathcal{F}$ in the beginning, irrespective of which of these elements turn out active. A non-adaptive strategy has several benefits: (a) it is easy to represent since we can just store the set S , (b) it is easy to find for many classes of functions and constraints (e.g., submodular functions over intersection of matroids [12]), and (c) it is parallelizable because we do not need feedback. The concern is that the expected value of the optimal non-adaptive strategy might be much smaller than that of the optimal adaptive strategy. This raises the (worst-case instance) *adaptivity gap* question: What is the maximum ratio between the expected values of the optimal adaptive and the optimal non-adaptive strategies for stochastic probing? If this ratio is small then we can focus on non-adaptive strategies and reap its benefits with only a small loss in value (see Figure 1).

Since for general combinatorial functions or constraints the adaptivity gaps can be made arbitrarily large, we need to consider special classes of functions and constraints. In a surprising result, Gupta et al. prove that for any *monotone submodular* function and any *prefix-closed constraints*², the adaptivity gap is at most 3 [23]. The best known lower bound in this setting, however, is only $\frac{e}{e-1} \approx 1.58$ due to Asadpour et al. [5]. This leaves open the following question:

For stochastic probing, what is the (worst-case) adaptivity gap for monotone submodular functions over prefix-closed constraints?

² Prefix-closed constraints stipulate that any prefix of a feasible probing sequence is also feasible. This class contains any downward-closed/packing constraint.

■ **Figure 1** An α -approximation to the best non-adaptive solution implies an $(\alpha \cdot \text{GAP})$ -approximation to the best adaptive algorithm, where GAP is the adaptivity gap.

We show that both the previously known upper bound of 3 and the lower bound of $\frac{e}{e-1}$ are not tight. Instead, the adaptivity gap is exactly 2.

One might notice that submodular functions do not capture the max-matching function used to model kidney-exchanges. This motivates us to consider more general combinatorial functions; in particular, we study the weighted rank function of a k -extendible system (defined in §2). This class generalizes intersection of k -matroids [29], e.g., a 2-extendible system captures matching in general graphs (unlike intersections of two matroids). Our goal is to bound the adaptivity gap for such functions over arbitrary prefix-closed constraints.

A major drawback of the stochastic probing model is that it only considers Bernoulli random variables. One would ideally allow for more modeling power by permitting the outcome of a probe to be a non-binary value. For example, in the kidney-exchange application, one might desire to summarize an edge probe by the risk involved in performing the match: a value of 0 describes an impossible match, a value of 1 indicates a safe match, and the possibilities in between are represented by intermediate values. Notice that the optimal adaptive strategy is still a decision tree; however, it may no longer be binary.

The main contributions of this paper are (1) a model that extends the binary stochastic probing to the multi-value setting, (2) the exact calculation of the adaptivity gap for stochastic probing of monotone submodular functions (in both the binary and multi-value setting), and (3) a nearly-tight adaptivity gap for stochastic probing of weighted rank functions over k -extendible systems.

1.1 Overview of Results

Our conceptual contribution is to present a generalization of the stochastic probing model to *stochastic multi-value probing* (SMP) described in §2. Roughly, the idea is that each element has t potential types, and a probe reveals which one of its types it takes. This trivially captures stochastic probing for $t = 2$, where the two types are active and inactive. In general these different types can be used to model different weights of an element, or to even encode different kinds of complementary relationships in the element values.

Although the SMP model is more general than the stochastic probing model, our main technical result in §3 is that for monotone submodular functions the adaptivity gap is bounded by 2. We also give a matching lower bound which proves this cannot be further reduced. This is despite the fact that the optimal decision tree for SMP may no longer be binary.

► **Theorem 1.** *The adaptivity gap for SMP where the constraints are prefix-closed and the function is monotone non-negative submodular is exactly 2.*

Since SMP is strictly more general than stochastic probing, Theorem 1 also improves the previously known upper bound of 3 for monotone submodular stochastic probing. In fact, our lower bound SMP instance in Theorem 1 is Bernoulli. Thus it resolves an open question of [23] of finding the optimal adaptivity gaps for submodular stochastic probing.

Our main technical result in §4 is that the adaptivity gap for weighted rank function of a k -extendible system is $\tilde{\Theta}(k)$.

► **Theorem 2.** *The adaptivity gap for SMP where the constraints are prefix-closed and the function is a weighted rank function of a k -extendible system is between k and $O(k \log k)$. Moreover, for unweighted rank functions, the adaptivity gap is between k and $2k$.*

Since the weighted rank of function of intersection of k -matroids is a k -extendible system, Theorem 2 implies as a corollary that the adaptivity gaps for this class is at most $\tilde{\Theta}(k)$. This improves the previously best known upper bound for intersection of k matroids of $O(k^4 \cdot \log n)$ due to Gupta et al. [22]³. We also give an $\Omega(\sqrt{k})$ -lower bound in this setting.

1.2 Techniques and Challenges

In this section we outline our main techniques and challenges for SMP adaptivity gaps.

Submodular Functions. To prove a small adaptivity gap, we need to show existence of a “good” non-adaptive solution. A priori it is not clear how to construct such a solution, e.g., LP based approaches do not extend beyond matroid constraints because of large integrality gaps. Since we only need to show *existence*, we can assume the optimal (exponential sized) decision tree is known. A crucial idea of [22] is to perform a random walk on this optimal decision tree (with probabilities given by the tree) and probing elements on the sampled root-leaf path. In other words, consider a non-adaptive strategy that randomly chooses a root-leaf path in the decision tree with the same probability as the optimal adaptive strategy. While this idea is natural in hindsight, its analysis for the non-adaptive strategy has been challenging.

In [22], the authors use Freedman’s inequality – linear functions are “well-concentrated” for a martingale – to argue that *simple* submodular functions are well-concentrated. This step requires massive union bounds over a polynomial number of linear functions, which loses logarithmic factors. To overcome this super-constant loss, in [23] the authors use an inductive approach and induct over subtrees where in each step a *stem* – the all-no path – is observed. A “stem lemma” allows them to argue that for every stem the expected value of the non-adaptive algorithm is within a factor 2 to the expected adaptive strategy. Finally, they “stitch” back the stem for induction by using submodularity, overall losing a factor of 3.

In this work, to prove the improved adaptivity gap of 2 in Theorem 1, our insight is to modify the above induction to observe a *single node* at each step (instead of a *stem* as in [23]). While we still induct over subtrees, this allows us to avoid any additional loss due to the stitching step. This induction turns out to be nontrivial because the adaptive and non-adaptive strategies can observe different types of the root element. In other words, although the non-adaptive random walk strategy follows the distribution of root-leaf paths of the adaptive strategy, it has to independently re-sample (re-probe) all the nodes on the chosen path. This hinders a direct application of induction as the marginal values in the subtrees change between the two strategies. We remedy this issue using two main ideas. First,

³ We remark that although not explicitly stated in Gupta et al. [23], their techniques can be used to remove the dependency on n , but it still only gives $\Omega(k^2)$ adaptivity gaps.

we compare the non-adaptive strategy to a “super-strategy” that can choose from both the elements chosen by the adaptive and the non-adaptive strategies. (This is also the intuition for the gap of 2 since the “super-strategy” has two chances to sample an element.) Second, the non-adaptive strategy forfeits any potential future value that the adaptive strategy gained at the root but the non-adaptive missed due to re-sampling. (This can be done by contracting the element sampled by the adaptive strategy without receiving its value.) Notice that both these steps are pessimistic and hence give a valid upper bound on the adaptivity gap. Together these ideas suffice to match the marginal values in the subtrees and apply induction without the stitching step, yielding an adaptivity gap of 2. Our lower bounds in §3.2 show examples where the super-strategy does not have any advantage over the adaptive strategy. Thus the adaptivity gap of 2 is optimal.

Rank Functions. A technical challenge in extending the above *inductive* approach to k -extendible system rank functions is that their marginal values do not belong to the same class. Namely, after contracting an element, the marginal value of a submodular function is submodular but the marginal value of a k -extendible system rank function may not even be subadditive. To overcome this, we first focus on *unweighted* rank functions. Instead of directly comparing the non-adaptive strategy to the adaptive strategy, our insight is to compare it to a *greedy procedure*. We show that this greedy procedure is a k -approximation to the adaptive strategy. Moreover, we show it has a notion of a marginal value. This allows us to compare the non-adaptive strategy to the greedy procedure in a similar way as for submodular functions, by losing another factor of 2. Our lower bound in §4.3 shows that the factor k loss in comparing to a greedy procedure is unavoidable, thereby making our analysis tight up to constants.

Finally, the challenge in proving Theorem 2 for *weighted* k -extendible system rank functions is that the greedy procedure only guarantees a k -approximation if we go in the order of decreasing weights. Instead, our adaptivity gap proofs only work when we are greedy in the root-to-leaf path order. One way around this is to partition the elements into $O(\log n)$ exponentially weighted *classes* (e.g., $1, 2, 2^2, \dots$) and apply the unweighted argument to the most valuable class. Unfortunately, this loses an $\Omega(\log n)$ factor. To obtain bounds independent of the universe size n , our insight is that picking an element in a class “removes” at most k elements from a lower weight class. We can therefore improve the $\log n$ factor loss to a $\log k$ by increasing the gap between successive classes to $\Omega(k)$. To achieve this we further combine $O(\log k)$ consecutive classes into a “super-class” (bucket). It is an interesting open question to find if this $\log k$ loss is essential in going from unweighted to weighted k -extendible system rank functions.

1.3 Further Related Work

The adaptivity gap of stochastic packing problems has seen much interest; see, e.g., for knapsack [14, 10, 28], packing integer programs [15, 13, 7], budgeted multi-armed bandits [17, 19, 26, 28], and orienteering [18, 20, 8]. All except the orienteering results rely on having relaxations that capture the constraints of the problem via linear constraints. For stochastic monotone submodular functions where the probing constraints are given by matroids, Asadpour et al. [4] bounded the adaptivity gap by $\frac{e}{e-1}$; Hellerstein et al. [25] bound it by $\frac{1}{\tau}$, where τ is the smallest probability of some set being materialized. Other relevant papers are [27, 16].

The work of Chen et al. [13] (see also [1, 7, 9, 2]) sought to maximize the size of a matching subject to b -matching constraints; this was motivated by applications to online dating and kidney exchange. See also [30, 6] for pointers to other work on kidney exchange

problems. The work of [21] abstracted out the general problem of maximizing a function (in their case, the rank function of the intersection of matroids or knapsacks) subject to probing constraints (again, intersection of matroids and knapsacks). This was improved and generalized by Adamczyk et al. [3] to submodular objectives. All these results use LPs or geometric relaxations, and do not extend to arbitrary packing constraints due to large integrality gaps of the relaxations.

2 Stochastic Multi-Value Probing Model

In this section we formally define our *stochastic multi-value probing* (SMP) model using the idea of combinatorial valuation over independent elements. We also discuss some preliminaries.

2.1 Combinatorial Valuation over Independent Elements

The multi-value paradigm is based on the notion of *type*, which represents different “values” an element can take. This leads to combinatorial valuations over independent elements where each element *independently* takes its type. Similar notions have been defined before; e.g., see [31] and references therein.

► **Definition 3** (Combinatorial valuation $\text{val}_{\mathbf{X}}$ over independent elements). *Consider a finite universe V of elements and size $n = |V|$. Each element $e \in V$ obtains exactly one type from a finite set T_e according to a given probability distribution \mathcal{D}_e over T_e . These types are assigned independently across different elements, i.e., the random vector of types $\mathbf{X} \in (T_e)_{e \in V}$ is drawn from the product distribution $\prod_{e \in V} \mathcal{D}_e$. Given a combinatorial function $f : 2^T \rightarrow \mathbb{R}_{\geq 0}$ for $T \stackrel{\text{def}}{=} \bigcup_{e \in V} T_e$, the valuation of a set $S \subseteq V$ is*

$$\text{val}_{\mathbf{X}}(S) \stackrel{\text{def}}{=} f(\{\mathbf{X}_e \mid e \in S\}) = f(\mathbf{X}_S),$$

where we define $\mathbf{X}_S \stackrel{\text{def}}{=} \{\mathbf{X}_e \mid e \in S\}$ to simplify notation.

For example, in the Bernoulli case studied in the stochastic probing literature, each element has two types: active and inactive, the distributions \mathcal{D}_e are Bernoulli, and the valuation function $\text{val}_{\mathbf{X}}(S) = f(\{e \in S \mid e \text{ is active}\})$. Another example is the multi-value max-weight matching problem described in the introduction. Here different types of an element (edge) correspond to its different weights and $\text{val}_{\mathbf{X}}(S)$ is the max-weight matching in the induced subgraph on S .

In this work we always assume the combinatorial function $f : 2^T \rightarrow \mathbb{R}_{\geq 0}$ satisfies $f(\emptyset) = 0$ and is *monotone*, i.e., $f(A) \leq f(B)$ for all $A \subseteq B$. We also assume it belongs to one of the following classes.

- *subadditive* if $f(A \cup B) \leq f(A) + f(B)$ for all $A, B \subseteq T$.
- *submodular* if $f(A \cup B) + f(A \cap B) \leq f(A) + f(B)$ for all $A, B \subseteq T$. For $S \subseteq T$, the contraction

$$f_S(A) \stackrel{\text{def}}{=} f(S \cup A) - f(S) \tag{1}$$

of a monotone submodular function is also monotone submodular.

- *weighted rank function* of a family $\mathcal{F} \subseteq 2^T$ if $f(A) = \max_{B \in \mathcal{F}} w(A \cap B)$ where $w : 2^T \rightarrow \mathbb{R}_{\geq 0}$ is a linear function with non-negative weights. When w is the all ones vector (i.e., $w(A) = |A|$), we call it the *unweighted rank function* of \mathcal{F} .

In particular, we work with rank functions of two special families $\mathcal{F} \subseteq 2^V$. Subsets in the family are called *independent* subsets. A family $\mathcal{F} \ni \emptyset$ forms a

- *matroid* if for every $A, B \in \mathcal{F}$ with $|A| > |B|$ there exists $x \in A \setminus B$ such that $B \cup \{x\} \in \mathcal{F}$.
- *k-extendible system* if for every $A \subseteq B \in \mathcal{F}$ and $e \in T$ where $A \cup \{e\} \in \mathcal{F}$, we have that there is a set $Z \subseteq B \setminus A$ such that $|Z| \leq k$ and $B \setminus Z \cup \{e\} \in \mathcal{F}$.

This latter family is important because it generalizes the family of intersection of k matroids, e.g., a 2-extendible systems captures general graph matchings (see [11] for further discussion).

2.2 Adaptive Strategies and SMP

Roughly, the goal of an SMP problem is to maximize a combinatorial function over independent elements under some “feasibility constraints”. We define a *probe* of an element $e \in V$ to be an operation that reveals its random type $X_e \in T_e$. A *probing sequence* is an ordered sequence of probes on some elements.

The SMP problem only allows a family of probing sequences \mathcal{C} , which are called *feasible*. We assume minimal properties from this family. Specifically, it is *prefix-closed*, i.e., for every sequence in \mathcal{C} , each of its prefix is also in \mathcal{C} . This prefix-closed family is powerful because it generalizes any *downward-closed* family \mathcal{F} (i.e., for all $A \in \mathcal{F}$ and $B \subseteq A$ we have $B \in \mathcal{F}$) and can also capture precedence constraints.

We now define an *adaptive strategy* which constitutes a feasible solution for SMP. The nodes in this tree correspond to probes of elements

► **Definition 4** (Adaptive strategy \mathcal{T}). *It is a rooted decision tree where each non-leaf node is labeled with an element $e \in V$ and has $|T_e|$ arcs to child nodes. Each arc is uniquely labeled with a type $t \in T_e$. Whenever we encounter a node labeled e , the adaptive strategy probes e and proceeds to the subtree corresponding to the arc labeled $X_e \sim \mathcal{D}_e$. The strategy terminates on reaching a leaf and receives a value of $\text{val}_{\mathbf{X}}(S(\mathbf{X}))$, where $S(\mathbf{X}) \subseteq V$ is the set of probed elements by strategy \mathcal{T} for type vector \mathbf{X} . The objective is the expected valuation, which we denote by*

$$\text{adap}(\mathcal{T}, f) \stackrel{\text{def}}{=} \mathbb{E}_{\mathbf{X}}[\text{val}_{\mathbf{X}}(S(\mathbf{X}))]. \quad (2)$$

Notice, since f is monotone, a strategy never gains value by removing a probed element. We say a strategy \mathcal{T} is *feasible* for \mathcal{C} if every root-leaf path belongs to \mathcal{C} . We now formally define an SMP problem.

► **Definition 5** (SMP problem $(\mathcal{C}, \text{val}_{\mathbf{X}})$). *Given a prefix-closed family of probing constraints \mathcal{C} and a combinatorial valuation $\text{val}_{\mathbf{X}}$ over independent elements, an SMP problem is to find a feasible adaptive strategy \mathcal{T} to maximize the expected valuation $\text{adap}(\mathcal{T}, f)$.*

2.3 Non-Adaptive Strategies and Adaptivity Gaps

A strategy to solve an SMP problem can benefit from adjusting its probing sequence based on the outcomes of the already probed elements. For instance, in the kidney-exchange example if one finds an edge incident to a vertex u , one may choose not to probe any other edges incident to u . On the other hand, a strategy that always decides the next probe independent of the outcomes of the probed elements is called *non-adaptive*. Our goal is to study the largest ratio between adaptive and non-adaptive strategies.

► **Definition 6** (Adaptivity gap for \mathcal{P}). Let \mathcal{P} be a class of SMP problems (e.g., monotone submodular functions over prefix-closed constraints). Define the adaptivity gap as the largest (worst-case instance) ratio of the optimal adaptive and optimal non-adaptive strategies for a problem $(\mathcal{C}, \text{val}_{\mathbf{X}}) \in \mathcal{P}$, i.e.,

$$\sup_{(\mathcal{C}, \text{val}_{\mathbf{X}}) \in \mathcal{P}} \frac{\sup_{\mathcal{T} \text{ is feasible in } \mathcal{P}} \text{adap}(\mathcal{T}, f)}{\sup_{S \in \mathcal{C}} \mathbb{E}_{\mathbf{X}}[\text{val}_{\mathbf{X}}(S)]}.$$

Notice that in the denominator S does not depend on \mathbf{X} .

The adaptivity gap for a general combinatorial function f is unbounded [22]. In this work we focus on monotone submodular functions and (weighted) rank functions of a k -extendible system. We bound adaptivity gaps by analyzing the following natural random walk non-adaptive strategy.

► **Definition 7** (Random walk non-adaptive strategy). For any given adaptive strategy \mathcal{T} , there is a corresponding non-adaptive strategy that (virtually) draws a sample $\mathbf{X} \sim \prod_{e \in V} \mathcal{D}_e$ from the product distribution and traverses \mathcal{T} along the root-leaf path for \mathbf{X} (i.e., when at a node labeled e , traverse the unique arc labeled X_e). Let $S(\mathbf{X})$ be the random set of elements probed by such a root-leaf path. The true (non-virtual) types of elements correspond to the vector of outcomes $\mathbf{X}' \sim \prod_{e \in V} \mathcal{D}_e$. Here \mathbf{X} and \mathbf{X}' are i.i.d. r.v.s. The random walk non-adaptive strategy probes S according to the above distribution and receives the valuation

$$\text{alg}(\mathcal{T}, f) \stackrel{\text{def}}{=} \mathbb{E}_{\mathbf{X}, \mathbf{X}'}[\text{val}_{\mathbf{X}'}(S(\mathbf{X}))]. \quad (3)$$

3 Adaptivity Gaps for a Monotone Submodular Function

In this section we prove our first main result, the optimal adaptivity gap for submodular functions. In §3.1 we prove the upper bound and in §3.2 we prove the lower bound of Theorem 1.

► **Theorem 1.** *The adaptivity gap for SMP where the constraints are prefix-closed and the function is monotone non-negative submodular is exactly 2.*

3.1 Upper Bound of 2

Our non-adaptive strategy samples a random root-leaf path using the optimal adaptive strategy tree \mathcal{T} (Definition 7). In other words, it performs a “dry-run” of a random walk along the tree without probing anything. In the end it queries all the elements on this random root-leaf path. We argue that its expected value is at least half of the adaptive strategy. We encourage the reader to follow the proof idea outlined in §1.2 since algebra can conceal the main ideas.

Proof of the upper bound in Theorem 1. We induct over the depth of the tree \mathcal{T} , i.e., for any monotone submodular function f and tree \mathcal{T} of depth at most d , we have

$$\text{alg}(\mathcal{T}, f) \geq \frac{1}{2} \text{adap}(\mathcal{T}, f).$$

The base case for $d = 1$ is trivially true because the tree is a single node. For induction, let e be the root node of the optimal decision tree \mathcal{T} . Denote by $I \stackrel{\text{def}}{=} X_e$ the (random) type of element e when probed by the adaptive strategy (and also the virtual type of the

non-adaptive strategy), while $R \stackrel{\text{def}}{=} X'_e$ be the (random) true type when probed by the non-adaptive strategy. Also, let \mathcal{T}_I denote the subtree the adaptive strategy goes to when the root element is in type I and let f_I be the contraction from Eq. (1). This implies

$$\text{adap}(\mathcal{T}, f) = \mathbb{E}_I[f(I) + \text{adap}(\mathcal{T}_I, f_I)] \quad \text{and} \quad \text{alg}(\mathcal{T}, f) = \mathbb{E}_{I,R}[f(R) + \text{alg}(\mathcal{T}_I, f_R)]. \quad (4)$$

Now using submodularity and monotonicity of f on every root-leaf path of the adaptive strategy,

$$\begin{aligned} \text{adap}(\mathcal{T}, f) &\leq \mathbb{E}_{I,R}[f(I \cup R) + \text{adap}(\mathcal{T}_I, f_{I \cup R})] \\ &\leq \mathbb{E}_{I,R}[f(I) + f(R) + \text{adap}(\mathcal{T}_I, f_{I \cup R})], \end{aligned}$$

where the last inequality uses that every monotone submodular function is subadditive. Notice that I and R are i.i.d. variables. This along with linearity of expectation implies

$$\text{adap}(\mathcal{T}, f) \leq \mathbb{E}_{I,R}[2 \cdot f(R) + \text{adap}(\mathcal{T}_I, f_{I \cup R})]. \quad (5)$$

Next, we lower bound the expected value of the non-adaptive strategy from Eq. (4). We use monotonicity of f to get

$$\text{alg}(\mathcal{T}, f) = \mathbb{E}_{I,R}[f(R) + \text{alg}(\mathcal{T}_I, f_R)] \geq \mathbb{E}_{I,R}[f(R) + \text{alg}(\mathcal{T}_I, f_{I \cup R})]. \quad (6)$$

Since $f_{I \cup R}$ is also a monotone submodular function over independent elements and \mathcal{T}_I is an adaptive strategy tree of depth at most $d - 1$, by induction hypothesis

$$\text{alg}(\mathcal{T}_I, f_{I \cup R}) \geq \frac{1}{2} \text{adap}(\mathcal{T}_I, f_{I \cup R}).$$

Combining this with Eq. (5) and Eq. (6), we get

$$\text{alg}(\mathcal{T}, f) \geq \frac{1}{2} \text{adap}(\mathcal{T}, f),$$

which finishes the proof of the upper bound by induction. \blacktriangleleft

3.2 Lower Bound of 2

In this section we show a monotone non-negative submodular function and a prefix-closed set of constraints where the adaptivity gap for stochastic probing is arbitrarily close to 2. Combined with §3.1, this proves Theorem 1 that the optimal adaptivity gap is exactly 2.

The proof below uses a stochastic probing instance on an infinite universe. Since submodular functions are defined only on finite sets, the proof below is informal. We do this to explain our main ideas and defer the formal proof to Appendix A.

Informal proof of the lower bound in Theorem 1. Our example is on a universe $V := \{e_{(k,l)} \mid k, l \in \mathbb{Z}_{\geq 0}\}$ where every element is independently active with probability ϵ for some $0 < \epsilon < 1$.

Example. We define our submodular objective f to be the weighted rank function of a partition matroid that selects at most one element from each part. The elements are partitioned according to their first label – for every $k \in \mathbb{Z}_{\geq 0}$ the set $\{e_{(k,l)} \mid l \in \mathbb{Z}_{\geq 0}\}$ is a

49:10 (Near) Optimal Adaptivity Gaps for Stochastic Multi-Value Probing

part of the partition matroid with weight $(1 - \epsilon)^k$. In other words, for any set $S \subseteq V$ let $K(S) := \{k \mid e_{(k,l)} \in S\}$ be the (unique) set of first labels, then

$$f(S) \stackrel{\text{def}}{=} \sum_{k \in K(S)} (1 - \epsilon)^k.$$

Note that this series always converges so f is well defined.

To define our prefix-closed constraints, we consider an infinite directed acyclic graph where every element is identified with a single node in the graph. Every node/element $e_{(k,l)}$ has exactly two outgoing edges: towards $e_{(k,l+1)}$ and towards $e_{(k+l+1,0)}$. We denote $\{e_{(k,0)}, e_{(k,1)}, \dots\}$ as the elements on *column* k . The probing constraint is that a sequence of elements can be probed if and only if it corresponds to a directed path starting at $e_{(0,0)}$. See Figure 2 for an illustration.

■ **Figure 2** Adaptivity gap lower bound example for monotone submodular functions.

Analysis. We first give an adaptive strategy with value $2 - \epsilon$ (in Eq. (7)) and later argue that every non-adaptive strategy has value at most 1 (in Eq. (8)); thereby, proving this theorem. Although, the probing constraint allows for infinite strategies, and in a different setting it would not be clear how to define their expected values, since f is monotone we include every active element in the solution. So the expected value of an infinite strategy can be defined as the limit of strategies that only probe a finite number of elements. The finite lower bound example in Appendix A is constructed by reducing V so that the resulting strategies are close to this limit.

Our adaptive strategy **adap** starts with probing element $e_{(0,0)}$. It is defined recursively: after probing $e_{(k,l)}$, the next element to probe is either $e_{(k+l+1,0)}$ if $e_{(k,l)}$ is found active, or $e_{(k,l+1)}$ otherwise. In other words, it probes elements on a column until it finds one active, and then probes another column.

Let $\text{adap}(k)$ denote the expected additional value our above adaptive strategy if the next probed element is $e_{(k,0)}$ and let $\text{adap} \stackrel{\text{def}}{=} \text{adap}(0)$ denote the expected value of the entire strategy. Note that $\text{adap}(k)$ does not depend on the set of elements found active before probing $e_{(k,0)}$ (i.e., the elements $e_{(k',l')}$ where $k' < k$). Furthermore, the subgraph reachable from $e_{(k,0)}$ is similar to the entire graph on V in the sense that one can relabel the elements in the subgraph to match the entire graph exactly, the only difference being that the value of any subset is multiplied by a factor of $(1 - \epsilon)^k$. Therefore, we have

$$\text{adap}(k) = (1 - \epsilon)^k \cdot \text{adap}(0).$$

Now, summing over the number of inactive elements on column 0, we get

$$\begin{aligned} \text{adap}(0) &= \sum_{k=0}^{\infty} (1 - \epsilon)^k \cdot \epsilon \cdot \left(1 + \text{adap}(k + 1)\right) \\ &= \sum_{k=0}^{\infty} (1 - \epsilon)^k \cdot \epsilon \left(1 + (1 - \epsilon)^{k+1} \cdot \text{adap}(0)\right), \end{aligned}$$

which uses $\text{adap}(k) = (1 - \epsilon)^k \cdot \text{adap}(0)$. Solving this equation yields the result:

$$\text{adap} = \text{adap}(0) = 2 - \epsilon. \tag{7}$$

Similarly, let $\text{alg}(k)$ denote the expected additional value of the optimal non-adaptive strategy if the next probed element is $e_{(k,0)}$, and let $\text{alg} = \text{alg}(0)$ denote the expected value of the optimal non-adaptive strategy. By the same argument as $\text{adap}(k)$, we have

$$\text{alg}(k) = (1 - \epsilon)^k \cdot \text{alg}(0).$$

Let k denote the number of elements the optimal non-adaptive strategy probes on column 0. We get

$$\text{alg}(0) = \sup_{k \geq 1} \left\{1 - (1 - \epsilon)^k + \text{alg}(k)\right\} = \sup_{k \geq 1} \left\{1 - (1 - \epsilon)^k + (1 - \epsilon)^k \cdot \text{alg}(0)\right\},$$

which uses $\text{alg}(k) = (1 - \epsilon)^k \cdot \text{alg}(0)$. This implies

$$\text{alg} = \text{alg}(0) = 1. \tag{8}$$

Combining Eq. (7) and Eq. (8), we get an adaptivity gap arbitrarily close to 2 for $\epsilon \rightarrow 0$. ◀

4 Adaptivity Gaps for a Weighted Rank Function of a k -Extendible System

For a downward-closed family \mathcal{F} , recollect that we define its rank function $f_{\mathcal{F}} : 2^V \rightarrow \mathbb{R}_{\geq 0}$ to be the largest cardinality subset in \mathcal{F} , i.e., $f_{\mathcal{F}}(S) \stackrel{\text{def}}{=} \max_{T \subseteq S \ \& \ T \in \mathcal{F}} |T| = \max_{T \in \mathcal{F}} |S \cap T|$. In this section we prove our results on the adaptivity gaps of a weighted rank function of a k -extendible system.

► **Theorem 2.** *The adaptivity gap for SMP where the constraints are prefix-closed and the function is a weighted rank function of a k -extendible system is between k and $O(k \log k)$. Moreover, for unweighted rank functions, the adaptivity gap is between k and $2k$.*

In §4.1 we prove the upper bound for unweighted k -extendible systems, and in §4.2 we give a reduction from weighted to unweighted k -extendible systems that loses a factor $O(\log k)$ in the adaptivity gap. Our lower bound is presented in §4.3.

To simplify our proofs, we define an element $e \in T$ as a *loop* in $\mathcal{F} \subseteq 2^T$ if $\{e\} \notin \mathcal{F}$. Furthermore, given a non-loop element $e \in T$, we define the *contraction* \mathcal{F}/e as $\{F \setminus \{e\} \mid F \in \mathcal{F}, e \in F\}$, i.e., the family of subsets that contain e but with e removed. We also need the following property of k -extendible systems, which intuitively means a set $E \in \mathcal{F}$ hurts at most $k \cdot |E|$ from another set $B \in \mathcal{F}$. We include the proof for completeness in Appendix B.

Let $\mathcal{F} \subseteq 2^T$ be a k -extendible system. For every $A \subseteq B \in \mathcal{F}$ and $E \subseteq T$ where $A \cup E \in \mathcal{F}$, there exists a set $Z \subseteq B \setminus A$ such that $|Z| \leq k \cdot |E|$ and $B \setminus Z \cup E \in \mathcal{F}$.

4.1 Upper Bound of $2k$ for an Unweighted k -Extendible System

Let \mathcal{T} denote the optimal adaptive strategy for maximizing the rank function f of a given k -extendible system \mathcal{F} . We prove the following unweighted upper bound of Theorem 2.

► **Theorem 8.** *The adaptivity gap for SMP where the constraints are prefix-closed and the function is an unweighted rank function of a k -extendible system is at most $2k$.*

We use the random walk strategy to convert the adaptive strategy \mathcal{T} into a non-adaptive strategy. To analyze our algorithm, we define a natural *greedy procedure* to select a subset of $A \subseteq T$ that is also in $\mathcal{F} \subseteq 2^T$. First, consider elements of A in an arbitrary order (which can even be determined on the fly). If the currently considered element is a non-loop, it gets contracted in \mathcal{F} ; otherwise it gets ignored. Any such computed set is in \mathcal{F} and the final output, the number of contracted elements, is denoted by $\text{greedy}(A)$. We first show that for k -extendible systems such a greedy procedure produces a k -approximation to the largest subset in \mathcal{F} . A similar statement has been proven by Mestre [29].

► **Lemma 9.** *Let f be a rank function of a k -extendible system $\mathcal{F} \subseteq 2^T$. Fix any subset $A \subseteq T$ and consider the output of the greedy procedure $\text{greedy}(A)$ with an arbitrary ordering of A . We have that $f(A) \leq k \cdot \text{greedy}(A)$. Even more, for any $A \subseteq B \subseteq T$ we have that $f(A) \leq k \cdot \text{greedy}(B)$.*

Proof. Let $G \subseteq B$ be the set picked by $\text{greedy}(B)$. Notice that G is a maximal set in \mathcal{F} (need not be maximum). On the other hand, let $\text{OPT} \subseteq A$ be the set picked by $f(A)$, i.e., the maximum set in \mathcal{F} on A . Our goal is to prove $|\text{OPT}| \leq k \cdot |G|$.

Let $C \stackrel{\text{def}}{=} \text{OPT} \cap G$, note that $G = C \cup (G \setminus C) \in \mathcal{F}$ and $C \subseteq \text{OPT}$, hence by Section 4 there is a $Z \subseteq \text{OPT} \setminus C$ with $|Z| \leq k \cdot |G \setminus C| = k \cdot |G| - k \cdot |C|$ such that $\text{OPT} \setminus Z \cup (G \setminus C) = (\text{OPT} \setminus C) \setminus Z \cup G \in \mathcal{F}$. However, since G is a maximal set and $(\text{OPT} \setminus C) \cap G = \emptyset$ we know that $\text{OPT} \setminus C \setminus Z = \emptyset$ and hence $|\text{OPT}| \leq |Z| + |C| \leq k \cdot |G| - k \cdot |C| + |C| = k \cdot |G| - (k-1)|C| \leq k \cdot |G|$. ◀

Given the above properties of a k -extendible system, we can now prove Theorem 8.

Proof of Theorem 8. Let \mathbf{X} and \mathbf{X}' denote the element types for the adaptive and the non-adaptive algorithms, respectively. The adaptive strategy on the optimal decision tree \mathcal{T} gets value $f(\mathbf{X}_S)$, where $S \subseteq V$ is the set of probed elements by strategy \mathcal{T} for type vector \mathbf{X} . We compare this value to a greedy strategy $\text{greedy}(\mathbf{X}_S \cup \mathbf{X}'_S)$ in which

1. we consider the elements of S in root-to-leaf order in which they appear on the tree and
2. for any $e \in S$ we first consider \mathbf{X}'_e (the true type) before \mathbf{X}_e (the virtual type) in the greedy order.

Note by Lemma 9 we have

$$\text{adap}(\mathcal{T}, f) = \mathbb{E}_{\mathbf{X}}[f(\mathbf{X}_S)] \leq k \cdot \mathbb{E}_{\mathbf{X}, \mathbf{X}'}[\text{greedy}(\mathbf{X}_S \cup \mathbf{X}'_S)].$$

By induction on the subtrees, below we prove

$$\mathbb{E}_{\mathbf{X}, \mathbf{X}'}[\text{greedy}(\mathbf{X}_S \cup \mathbf{X}'_S)] \leq 2 \cdot \text{alg}(\mathcal{T}, f). \quad (9)$$

This finishes the proof of Theorem 8 because the optimal non-adaptive algorithm has value at least

$$\text{alg}(\mathcal{T}, f) \geq \frac{1}{2} \cdot \mathbb{E}_{\mathbf{X}, \mathbf{X}'}[\text{greedy}(\mathbf{X}_S \cup \mathbf{X}'_S)] \geq \frac{1}{2k} \cdot \text{adap}(\mathcal{T}, f).$$

To prove the missing Eq. (9), we induct on the height of the tree and \mathcal{F} being any downward-closed family. For consistency, we define the notation of $\text{greedy}(\mathcal{T}, f)$ to denote the value of the above greedy strategy when run on \mathcal{T} with a rank function f . Thus, $\text{greedy}(\mathcal{T}, f) = \mathbb{E}_{\mathbf{X}, \mathbf{X}'}[\text{greedy}(\mathbf{X}_S \cup \mathbf{X}'_S)]$. Suppose $e \in V$ is the label of the root of \mathcal{T} . Denote by $I \stackrel{\text{def}}{=} X_e$ the (random) type of element e when probed by the adaptive strategy (which is also the virtual type of the non-adaptive strategy), and denote $R \stackrel{\text{def}}{=} X'_e$ the (random) true type when probed by the non-adaptive strategy. Also, let \mathcal{T}_I denote the subtree the adaptive strategy goes to when the root e is in state I . We have

$$\text{greedy}(\mathcal{T}, f) \leq \mathbb{E}_{I,R}[f(I \cup R) + \text{greedy}(\mathcal{T}_I, (f/R)/I)],$$

where by $(f/R)/I$ we mean the rank function of \mathcal{F} after we first contract R if it is a non-loop, and then contract I if it is still a non-loop. Now subadditivity of f gives

$$\begin{aligned} \text{greedy}(\mathcal{T}, f) &\leq \mathbb{E}_{I,R}[f(I) + f(R) + \text{greedy}(\mathcal{T}_I, (f/R)/I)] \\ &= \mathbb{E}_{I,R}[2 \cdot f(R) + \text{greedy}(\mathcal{T}_I, (f/R)/I)], \end{aligned} \tag{10}$$

where the last equality uses linearity of expectation as I and R are identically distributed.

Next, we lower bound the value of our non-adaptive algorithm. Although it takes a random root-leaf path and decides the set of elements to retain in the end, we lower bound its value by an online algorithm that greedily selects R (unless it is a loop), however, always also contracts I if it is a non-loop. This gives,

$$\text{alg}(\mathcal{T}, f) \geq \mathbb{E}_{I,R}[f(R) + \text{alg}(\mathcal{T}_I, (f/R)/I)]. \tag{11}$$

Since $(f/R)/I$ is also a rank function of a downward-closed system and \mathcal{T}_I is an adaptive strategy, by induction hypothesis we have

$$\text{alg}(\mathcal{T}_I, (f/R)/I) \geq \frac{1}{2} \text{greedy}(\mathcal{T}_I, (f/R)/I).$$

Combining this with Eq. (10) and Eq. (11), we get

$$\text{greedy}(\mathcal{T}, f) \leq 2 \cdot \text{alg}(\mathcal{T}, f),$$

which proves Eq. (9) by induction. ◀

4.2 Reducing Weighted to Unweighted k -Extendible System by Losing $O(\log k)$

We show how to extend the adaptivity gap result for an unweighted k -extendible system to a weighted k -extendible system by losing an $O(\log k)$ factor.

► **Theorem 10.** *For SMP over prefix-closed constraints, the adaptivity gap for a weighted rank function of a k -extendible system is at most $32k \log_2 k$.*

Proof. Given a weighted rank function f of a k -extendible system $\mathcal{F} \subseteq 2^T$ over a set of types T , we define f_j for $j \in \mathbb{Z}$ to be an unweighted rank function of the k -extendible system \mathcal{F} ; however, the new weights are changed such that only the types with original weights in

49:14 (Near) Optimal Adaptivity Gaps for Stochastic Multi-Value Probing

$(2^{j-1}, 2^j]$ participate with new weight of 1, while the other elements have a new weight of 0. Note that this partitions the set of types T into pairwise disjoint *classes*. Notice, we have

$$\text{adap}(\mathcal{T}, f) \leq \sum_j 2^j \cdot \text{adap}(\mathcal{T}, f_j), \quad (12)$$

where $\text{adap}(\mathcal{T}, f_j)$ denotes the expected value of an adaptive strategy given by the common decision tree \mathcal{T} with respect to the rank function f_j .

Now, since $\text{adap}(\mathcal{T}, f_j)$ is an unweighted k -extendible system problem, we know that a random root-leaf path returns a solution with expected value

$$\text{alg}(\mathcal{T}, f_j) \geq \frac{1}{2k} \cdot \text{adap}(\mathcal{T}, f_j). \quad (13)$$

In the following lemma, we show that these non-adaptive solutions for f_j can be combined to obtain a feasible and “high-value” non-adaptive solution for f .

► **Lemma 11.** *The random-walk non-adaptive algorithm alg has expected value*

$$\text{alg}(\mathcal{T}, f) \geq \frac{1}{16 \cdot \log k} \sum_j 2^j \cdot \text{alg}(\mathcal{T}, f_j).$$

Before proving Lemma 11, we finish the proof of Theorem 10 by combining it with Eq. (13) and Eq. (12):

$$\begin{aligned} \text{alg}(\mathcal{T}, f) &\geq \frac{1}{16 \cdot \log k} \sum_j 2^j \cdot \text{alg}(\mathcal{T}, f_j) \geq \frac{1}{32k \log k} \sum_j 2^j \cdot \text{adap}(\mathcal{T}, f_j) \\ &\geq \frac{1}{32k \log k} \cdot \text{adap}(\mathcal{T}, f). \quad \blacktriangleleft \end{aligned}$$

Informally, in the proof of Lemma 11 we combine the unweighted solutions of $\text{alg}(\mathcal{T}, f_i)$ by running a “greedy-optimal” algorithm from the higher weight to the smaller weight classes and fixing the types chosen in earlier classes. Unfortunately, in general such an approach loses an extra factor k in the approximation. To fix this, our second idea is to increase the weight gap between successive classes. We achieve this by combining $O(\log k)$ consecutive classes into a *bucket*, where in each bucket we focus on the class with the largest non-adaptive value. Because of boundary issues, we only take either odd or even buckets.

Proof of Lemma 11. Let $a \leq b \in \mathbb{Z}$ denote the indices of the smallest and the highest weight classes. We define buckets consisting of $2 \log k$ consecutive classes, where bucket B_i consists of classes $\{b - 2i \log k, b - 2i \log k - 1, \dots, b - 2(i - 1) \log k\}$. For each B_i , let

$$j(i) \stackrel{\text{def}}{=} \operatorname{argmax}_{j \in B_i} \{2^j \cdot \text{alg}(\mathcal{T}, f_j)\}.$$

Since each bucket has size $2 \log k$, this implies

$$\sum_i 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}) \geq \frac{1}{2 \cdot \log k} \sum_j 2^j \cdot \text{alg}(\mathcal{T}, f_j).$$

Without loss of generality we can assume the odd indices satisfy

$$\sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}) \geq \frac{1}{2} \sum_i 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}).$$

Otherwise, use the same argument for even indices. Combining the last two equations, we get

$$\sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}) \geq \frac{1}{4 \cdot \log k} \sum_j 2^j \cdot \text{alg}(\mathcal{T}, f_j). \quad (14)$$

We now claim that a *greedy-optimal* algorithm has a large value: It goes over classes $j(i)$ in decreasing order of (odd) buckets, but it always selects the maximum independent set (instead of selecting a maximal greedy set) in the current class $j(i)$ given its choices in the previous. This algorithm is, therefore, a combination of greedy and optimal algorithms. The proof of the following is deferred to Appendix C.

▷ **Claim 12.** Consider an algorithm that goes over the odd numbered buckets in decreasing order of weights and selects the *maximum* set from class $j(i)$ in bucket i such that the resulting set is still feasible in \mathcal{F} . (After a set in a class is selected, it gets fixed for all smaller choices.) The finally chosen set has value at least $\frac{1}{4} \sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)})$.

Using Claim 12, we have

$$\text{alg}(\mathcal{T}, f) \geq \frac{1}{4} \sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}),$$

which combined when with Eq. (14) proves Lemma 11. ◀

4.3 Lower Bounds

We present two very similar lower bound examples: one where the adaptivity gap is $k - o(1)$ for a rank function of an unweighted k -extendible system and another where the adaptivity gap is $\Omega(\sqrt{k})$ for a rank function of an intersection of k matroids. A related example was also shown in [23].

Example. For generality we work in the Bernoulli setting where each element in V is either active or inactive. Consider a perfect w -ary tree of depth k whose edges correspond to the ground set V . Each edge is active with probability $p > 0$. For any leaf ℓ , let P_ℓ denote the unique path from the root to ℓ . The objective value on any set is the maximum number of edges in the set on the *same* root-leaf path, i.e., for any $S \subseteq V$,

$$f(S) \stackrel{\text{def}}{=} \max_{\text{leaf } \ell} |P_\ell \cap S|.$$

The feasibility constraints are such that a set of edges can be probed if and only if there exists some root-leaf path P_ℓ such that every probed edge has at least one endpoint on P_ℓ . Note that this implies that a maximum of $w \cdot k$ edges can be probed.

Analysis. Let the adaptive strategy be the following: probe all w edges incident to the root. If any of them is active, start probing the edges directly below the active edge, otherwise below the first edge. Continue recursively until a leaf is reached. On every level, the adaptive strategy has $1 - (1 - p)^w$ probability of finding an active edge. Therefore, the expected value of the adaptive strategy is $k \cdot (1 - (1 - p)^w)$.

For any non-adaptive strategy, the feasibility constraints imply there exists a root-leaf path P_ℓ such that all probed edges have an endpoint on it. Suppose all $w \cdot k$ edges incident to P_ℓ are probed. The non-adaptive strategy can get value at most 1 from the edges not on P_ℓ and in expectation at most $k \cdot p$ from the edges on P_ℓ . So, the non-adaptive strategy has an expected value of at most $1 + k \cdot p$.

Lower Bound of k for an unweighted k -extendible system

Consider the example described above and set $w \stackrel{\text{def}}{=} k^4$ and $p \stackrel{\text{def}}{=} \frac{1}{k^3}$. The function f is trivially a rank function of a k -extendible system because the rank of the system is k , i.e., $f(V) = k$. The adaptive strategy has an expected value

$$k \cdot \left(1 - \left(1 - \frac{1}{k^3}\right)^{k^4}\right) \geq k \cdot \left(1 - \frac{1}{e^k}\right) = k - o(1),$$

whereas any non-adaptive strategy has an expected value at most $1 + \frac{1}{k^2}$. This gives an adaptivity gap of $k - o(1)$.

Lower Bound of $\Omega(\sqrt{k})$ for an unweighted intersection of k matroids

In this section we show how to model the above example as an intersection of $t = k^2$ matroids, yielding an adaptivity gap of $\Omega(\sqrt{t})$ for an intersection of t matroids. Consider the example described above and set $w \stackrel{\text{def}}{=} k$ and $p \stackrel{\text{def}}{=} \frac{1}{k}$. The adaptive strategy has an expected value of

$$k \cdot \left(1 - \left(1 - \frac{1}{k}\right)^k\right) \geq k \cdot \left(1 - \frac{1}{e}\right) = \Omega(k)$$

and the non-adaptive strategy gets at most 2 in expectation; so the adaptivity gap is $\Omega(k)$.

All that remains to show is that f can be represented as an intersection of k^2 simple partition matroids. We use the term simple partition matroid for a matroid that partitions the V into multiple parts and a set is independent if it contains at most one element in every part.

Suppose that k is prime and label each node v with a list L_v as follows: the root's label is an empty list $()$. Let $L(i)$ denote the i^{th} element of the list L and $L + x$ a list equal to L with x appended to it. All the other nodes are labeled recursively: let v be a node with children $\{v_0, v_1, \dots, v_{k-1}\}$. Define $L_{v_i} \stackrel{\text{def}}{=} L_v + i$. Hence, u is an ancestor of v if and only if L_u is a prefix of L_v , and otherwise $L_u(i) \neq L_v(i)$ for some i .

Let e_v denote the edge/element between v and its parent. We define k^2 partition matroids $M_{i,j}$ for $i \in \{1, 2, \dots, k\}$ and $j \in \{0, 1, \dots, k-1\}$. Each $M_{i,j}$ consists of k *big* partitions indexed from 0 to $k-1$, and all other partitions contain only a single element. Let

$$I_v(i, j) \stackrel{\text{def}}{=} L_v(i)j + d_v \pmod{k}.$$

For a node v on depth $d_v \geq i$, element e_v is in the $I_v(i, j)^{\text{th}}$ *big* partition of $M_{i,j}$. For a node v on depth $d_v < i$, e_v is the only element in its partition in $M_{i,j}$.

We claim that f is the rank function of $\mathcal{F} \stackrel{\text{def}}{=} \bigcap_{i=1}^k \bigcap_{j=0}^{k-1} M_{i,j}$, which is an intersection of k^2 matroids. Since \mathcal{F} is an intersection of simple partition matroids, $S \in \mathcal{F}$ if and only if $\{a, b\} \in \mathcal{F}$ for every $a, b \in S$. Now consider two nodes u, v such that $\{e_u, e_v\} \notin \mathcal{F}$. This means $I_u(i, j) = I_v(i, j)$ for some $i \leq d_u, d_v$ and $j \in \{0, 1, \dots, k-1\}$, which is equivalent to

$$L_u(i) \cdot j + d_u \equiv L_v(i) \cdot j + d_v \pmod{k}.$$

Since k is prime, this holds for some i, j if and only if $d_u = d_v$ (for $j = 0, i = 1$) or $L_u(i) \neq L_v(i)$ for any i . That is, $\{e_u, e_v\} \notin \mathcal{F}$ if and only if u and v are not ancestors of one another, which completes the proof.

A Adaptivity Gap Lower Bound of 2 for Submodular Functions

Proof. As mentioned, the finite lower bound example is constructed by reducing the infinite example given in Section 3.2. However, this reduction loses the nice similarity properties of the graph so much more calculation is required in order to bound the strategies.

Let $0 < \epsilon < 1/2$ and D be the smallest integer such that $(1 - \epsilon)^D < \epsilon^2$. The ground set is the result of removing elements $e_{(k,l)}$ where $k + l > D$, that is $V \stackrel{\text{def}}{=} \{e_{(k,l)} : k, l \in \mathbb{Z}_{\geq 0}, k + l \leq D\}$ where each node is active with probability ϵ . The probing constraint

and the objective function f are naturally reduced to this set: a sequence of elements can be probed if they correspond to a (finite) path starting at $e_{(0,0)}$ in the given graph, and $f(S) \stackrel{\text{def}}{=} \sum_{k \in K(S)} (1 - \epsilon)^k$ where $K(S)$ is the set of (unique) first labels which now finite. Similarly as before, we will denote $\{e_{(k,0)}, e_{(k,1)}, \dots, e_{(k,D-k)}\}$ as the vertices on the *column* k .

We first show that any non-adaptive strategy has expectation at most 1. Let $\text{alg}(k)$ denote the additional expected value of the optimal non-adaptive strategy if the next probed element is $e_{(k,0)}$. We will inductively prove $\text{alg}(k) < (1 - \epsilon)^k$, which is sufficient for our claim. For the base case $k = D$, the inequality clearly holds since $\text{alg}(D) = \epsilon(1 - \epsilon)^D < (1 - \epsilon)^D$. For $0 \leq k < D$ let i be the second label of the last vertex probed on the column k .

$$\begin{aligned} \text{alg}(k) &= \max_{i=0}^{D-k} \left[(1 - \epsilon)^k \Pr[k \in K(\text{active})] + \text{alg}(k + i + 1) \right] \\ &= \max_{i=0}^{D-k} \left[(1 - \epsilon)^k (1 - (1 - \epsilon)^{i+1}) + \text{alg}(k + i + 1) \right] \\ &< \max_{i=0}^{D-k} \left[(1 - \epsilon)^k (1 - (1 - \epsilon)^{i+1}) + (1 - \epsilon)^{k+i+1} \right] = (1 - \epsilon)^k. \end{aligned}$$

This completes the induction and proves that non-adaptive strategies get at most 1.

Finally, we show that there exists an adaptive strategy with expected value at least $2 - O(\epsilon)$ for sufficiently small $\epsilon > 0$. This finalizes the proof since it implies a gap of 2 by taking $\epsilon \rightarrow 0$. The strategy is naturally reduced: first probe $e_{(0,0)}$ and after probing some $e_{(k,l)}$ terminate if $k + l = D$, otherwise probe $e_{(k+l+1,0)}$ if $e_{(k,l)}$ is active and $e_{(k,l+1)}$ if not. Let $\text{adap}(k)$ denote the expected value this strategy gets when the next probed element is $e_{(k,0)}$, for $0 \leq k \leq D$. For convenience, define $\text{adap}(D + i) \stackrel{\text{def}}{=} 0$ for all $i \geq 1$.

We prove by induction that $\text{adap}(k) > \frac{4-6\epsilon}{2-\epsilon}(1 - \epsilon)^k - 8\epsilon$, which is sufficient to finalize the proof since then $\text{adap}(0) > 2 - O(\epsilon)$. For k large enough that $\frac{4-6\epsilon}{2-\epsilon}(1 - \epsilon)^k < 8\epsilon$, the inequality clearly holds and presents our base case. Otherwise, $(1 - \epsilon)^k \geq 8\frac{2-\epsilon}{4-6\epsilon}\epsilon > 4\epsilon$. Let i be the second label of the last vertex probed on the column k and let A denote the set of active elements.

$$\begin{aligned} \text{adap}(k) &= \sum_{i=0}^{D-k} \Pr \left[v_{(k,i)} \in A, v_{(k,0)} \notin A, \dots, v_{(k,i-1)} \notin A \right] \left[(1 - \epsilon)^k + \text{adap}(k + i + 1) \right] \\ &= \sum_{i=0}^{D-k} (1 - \epsilon)^i \epsilon \left[(1 - \epsilon)^k + \text{adap}(k + i + 1) \right] \\ &= \epsilon \cdot \sum_{i=0}^{D-k} (1 - \epsilon)^{k+i} + \epsilon \cdot \sum_{i=0}^{D-k} (1 - \epsilon)^i \text{adap}(k + i + 1) \\ &= \epsilon \cdot \frac{1}{\epsilon} (1 - \epsilon)^k \left(1 - (1 - \epsilon)^{D-k+1} \right) + \epsilon \cdot \sum_{i=0}^{D-k} (1 - \epsilon)^i \cdot \text{adap}(k + i + 1). \end{aligned}$$

Using the induction hypothesis, we get

$$\begin{aligned} \text{adap}(k) &> (1 - \epsilon)^k - (1 - \epsilon)^{D+1} + \epsilon \sum_{i=0}^{D-k} (1 - \epsilon)^i \left(\frac{4-6\epsilon}{2-\epsilon} (1 - \epsilon)^{k+i+1} - 8\epsilon \right) \\ &= (1 - \epsilon)^k - (1 - \epsilon)^{D+1} + \epsilon \sum_{i=0}^{D-k} \frac{4-6\epsilon}{2-\epsilon} (1 - \epsilon)^{k+2i+1} - 8\epsilon^2 \sum_{i=0}^{D-k} (1 - \epsilon)^i \\ &= (1 - \epsilon)^k - (1 - \epsilon)^{D+1} + (1 - \epsilon)^{k+1} \frac{4-6\epsilon}{(2-\epsilon)^2} \left(1 - (1 - \epsilon)^{2(D-k+1)} \right) \\ &\quad - 8\epsilon \left(1 - (1 - \epsilon)^{D-k+1} \right). \end{aligned}$$

49:20 (Near) Optimal Adaptivity Gaps for Stochastic Multi-Value Probing

After dropping some positive summands and using $(1 - \epsilon)^D < \epsilon$ and $(1 - \epsilon)^k > \epsilon$, we get

$$\text{adap}(k) > (1 - \epsilon)^k - \epsilon^2 + (1 - \epsilon)^{k+1} \frac{4 - 6\epsilon}{(2 - \epsilon)^2} (1 - \epsilon^2) - 8\epsilon.$$

It is sufficient to prove

$$(1 - \epsilon)^k - \epsilon^2 - 8\epsilon + (1 - \epsilon)^{k+1} \frac{4 - 6\epsilon}{(2 - \epsilon)^2} (1 - \epsilon^2) > \frac{4 - 6\epsilon}{2 - \epsilon} (1 - \epsilon)^k - 8\epsilon.$$

Multiplying by $\frac{(2 - \epsilon)^2}{(1 - \epsilon)^k} > 0$, we get an equivalent statement to prove:

$$(2 - \epsilon)^2 - \epsilon^2 \cdot \frac{(2 - \epsilon)^2}{(1 - \epsilon)^k} + (1 - \epsilon)(4 - 6\epsilon)(1 - \epsilon^2) > (4 - 6\epsilon)(2 - \epsilon).$$

Finally, using $\epsilon^2 \frac{(2 - \epsilon)^2}{(1 - \epsilon)^k} < \epsilon^2 (2 - \epsilon)^2 \frac{1}{4\epsilon} = \epsilon + O(\epsilon^2)$ and expanding out, we note that the left-hand side is $8 - 15\epsilon + O(\epsilon^2)$, while the right-hand side is $8 - 16\epsilon + O(\epsilon^2)$. Therefore, the inequality holds for sufficiently small $\epsilon > 0$. This concludes the proof. \blacktriangleleft

B Proof of the k -Extendible Property for Set Extension

Let $\mathcal{F} \subseteq 2^T$ be a k -extendible system. For every $A \subseteq B \in \mathcal{F}$ and $E \subseteq T$ where $A \cup E \in \mathcal{F}$, there exists a set $Z \subseteq B \setminus A$ such that $|Z| \leq k \cdot |E|$ and $B \setminus Z \cup E \in \mathcal{F}$.

Proof. Enumerate the elements $E = \{e_1, \dots, e_r\}$ where $r \stackrel{\text{def}}{=} |E|$ and denote by $E_i \stackrel{\text{def}}{=} \{e_1, \dots, e_i\}$ for $0 \leq i \leq r$. Initialize $Z_0 \stackrel{\text{def}}{=} \emptyset$ and consider the following procedure to construct Z_1, Z_2, \dots, Z_r that satisfies the invariants $A \subseteq B \setminus Z_i$, $B \setminus Z_i \cup E_i \in \mathcal{F}$ and $|Z_i| \leq k \cdot i$.

In the i^{th} step we have that $A \cup E_{i-1} \cup \{e_i\} \in \mathcal{F}$ by downward-closeness and $A \cup E_{i-1} \subseteq B \setminus Z_{i-1} \cup E_{i-1}$ by the induction hypothesis. Hence by k -extendibility we can find $Z' \subseteq B \setminus (Z_{i-1} \cup A \cup E_{i-1})$ with $|Z'| \leq k$ and where $(B \setminus Z_{i-1} \cup E_{i-1}) \setminus Z' \cup \{e_i\} = B \setminus (Z_{i-1} \cup Z') \cup E_i \in \mathcal{F}$. Set $Z_i \stackrel{\text{def}}{=} Z_{i-1} \cup Z'$ and note that $|Z_i| \leq |Z_{i-1}| + |Z'| \leq (i - 1) \cdot k + k = i \cdot k$. Furthermore, already deduced that $B \setminus Z_i \cup E_i \in \mathcal{F}$ and finally $A \subseteq B \setminus Z_i = B \setminus Z_{i-1} \setminus Z'$ since $Z' \cap A = \emptyset$. We satisfied all stipulations of the induction, hence we report Z_r as the solution. \blacktriangleleft

C Proof of Claim 12

\triangleright **Claim 12.** Consider an algorithm that goes over the odd numbered buckets in decreasing order of weights and selects the *maximum* set from class $j(i)$ in bucket i such that the resulting set is still feasible in \mathcal{F} . (After a set in a class is selected, it gets fixed for all smaller choices.) The finally chosen set has value at least $\frac{1}{4} \sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)})$.

Proof. The intuition is that for a k -extendible system by Section 4 any selected member can “hurt” at most k members from lower buckets. Since we only consider odd numbered buckets, two types in different buckets differ in their weights by at least a factor of $2^{2 \log k} = k^2$. Thus, losing k types of lower weight should not significantly impact the value.

Let ℓ be the random variable denoting the leaf reached by the random walk on the decision tree \mathcal{T} , and let R be the random set of elements seen by the random-walk non-adaptive strategy on this path. Furthermore, let A_i denote the set of elements picked by the non-adaptive strategy with respect to $f_{j(i)}$, let $A'_i \subseteq A_i$ be the set of elements picked by our greedy-optimal non-adaptive strategy from bucket i , and let $A'_{<i}$ denote $\bigcup_{i' < i : i' \text{ is odd}} A_{i'}$.

In other words, $A'_{<i}$ is the greedy-optimal solution up to bucket number i and A'_i is the maximum subset of A_i such that $A'_i \cup A'_{<i} \in \mathcal{F}$. Note that A_i , A'_i and $A'_{<i}$ are random variables depending on ℓ and R .

Using Section 4 on the k -extendible system \mathcal{F} with the preconditions $\emptyset \cup A'_{<i} \in \mathcal{F}$ and $\emptyset \subseteq A_i$, there exists a set Z with $|Z| \leq k \cdot |A'_{<i}|$ such that $A_i \setminus Z \in \mathcal{F}$. Hence, we have

$$|A'_i| \geq |A_i \setminus Z| \geq |A_i| - k \cdot |A'_{<i}|.$$

Multiplying by $2^{j(i)}$ and summing over all odd i gives

$$\begin{aligned} \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A'_i| &\geq \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i| - k \cdot \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A'_{<i}| \\ &= \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i| - k \cdot \sum_{i \text{ is odd}} |A'_i| \sum_{i' > i : i' \text{ is odd}} 2^{j(i')}. \end{aligned} \quad (15)$$

Now, since every bucket i contains $2 \log k$ classes, where two successive class weights differ by a factor of 2, we know

$$2^{j(i+2)} \leq \frac{2^{j(i)}}{k^2}.$$

Combining this with Eq. (15) gives

$$\begin{aligned} \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A'_i| &\geq \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i| - k \cdot \sum_{i \text{ is odd}} |A'_i| \sum_{i' > i : i' \text{ is odd}} \frac{2^{j(i'+2)}}{k^2} \\ &\geq \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i| - \sum_{i \text{ is odd}} |A'_i| \cdot 2^{j(i)}, \end{aligned}$$

where the last inequality uses

$$\sum_{i' > i : i' \text{ is odd}} 2^{j(i'+2)} = \sum_{i' \geq i : i' \text{ is odd}} 2^{j(i')} \leq 2 \cdot 2^{j(i)} \leq k \cdot 2^{j(i)}.$$

After rearranging,

$$\sum_{i \text{ is odd}} 2^{j(i)} \cdot |A'_i| \geq \frac{1}{2} \cdot \sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i|.$$

Notice that by definition of a class, each type in class $j(i)$ has weight at least $2^{j(i)-1}$. Using this fact and taking expectation over ℓ and R , we get

$$\begin{aligned} \text{alg}(\mathcal{T}, f) &\geq \mathbb{E}_{\ell, R} \left[\sum_{i \text{ is odd}} 2^{j(i)-1} \cdot |A'_i| \right] \\ &\geq \frac{1}{4} \mathbb{E}_{\ell, R} \left[\sum_{i \text{ is odd}} 2^{j(i)} \cdot |A_i| \right] = \frac{1}{4} \sum_{i \text{ is odd}} 2^{j(i)} \cdot \text{alg}(\mathcal{T}, f_{j(i)}), \end{aligned}$$

which finishes the proof of Claim 12. \triangleleft

Testing Odd Direct Sums Using High Dimensional Expanders

Roy Gotlib

kaufmant@mit.edu

Abstract

In this work, using methods from high dimensional expansion, we show that the property of k -direct-sum is testable for odd values of k . Previous work of [9] could inherently deal only with the case that k is even, using a reduction to linearity testing. Interestingly, our work is the first to combine the topological notion of high dimensional expansion (called co-systolic expansion) with the combinatorial/spectral notion of high dimensional expansion (called colorful expansion) to obtain the result.

The classical k -direct-sum problem applies to the complete complex; Namely it considers a function defined over all k -subsets of some n sized universe. Our result here applies to any collection of k -subsets of an n -universe, assuming this collection of subsets forms a high dimensional expander.

1 Introduction

Given a collection X of k -subsets of $[n]$, a function $F : X \rightarrow \{0, 1\}$ is a k -direct-sum if there exists a function $f : [n] \rightarrow \{0, 1\}$ such that for every A in X : $F(A) = \sum_{a \in A} f(a)$ (where the sum is performed modulo 2). A (Q, E) -tester for k -direct-sums is an algorithm that queries F on Q inputs from X , accepts k -direct-sums and rejects with probability of at least ξ , every function whose distance from the k -direct-sums is at least $E\xi$ (see Definition 16 for distance and [8] for a survey on property testing). In this work we present a new novel method for testing k -direct-sums using high dimensional expanders. Our method is the first to deal with k -direct-sums for odd constant values of k .

The question of testing whether a function is a k -direct-sum, as well as the entire area of testability, has strong relations to PCP constructions. For example, one can consider the gap amplification proof of the PCP theorem [5]. This proof uses two steps: First powering the graph which results in every node having an “opinion” about its neighbors’ color (which increases the alphabet size) and then reducing the alphabet. A better understanding of the direct sum problem could potentially help in replacing the direct product done in the graph powering phase, and might even allow omitting the alphabet reduction stage which would yield a simpler proof to the PCP theorem and, possibly, better parameters.

Previous Work

There were several works on k -direct-sums, but none of them could deal with the odd constant case due to inherent limitations of their methods: The first work to link direct-sums and high dimensional expanders was done by Kaufman and Lubotzky [9], who showed a test for the 2-direct-sum problem on any simplicial complex that is a high dimensional expander. Their proof is tailored to the case where $k = 2$. Following the work of Kaufman and Lubotzky was a work by David, Dinur, Goldenberg, Kindler, and Shinkar [4] that proposed a tester for k -direct-sums on the for the case where the input set is $\binom{[n]}{k}$. Their tester is based on linearity testing: It picks $x, y \in X$ such that $x\Delta y \in X$, and tests whether $f(x) + f(y) = f(x\Delta y)$ (for more papers on linearity testing see [1, 2, 3]). But in order to get $x, y, x\Delta y \in X$, **k must be even**. In a recent work by Dinur and Kaufman [6], it is shown that the result of David et al. [4] can be applied to testing functions whose inputs are taken from a subset of $\binom{[n]}{k}$ that forms a high dimensional expander. However the limitation above still stands.

In this paper we introduce a new method for testing k -direct-sums that can tackle the odd case for the first time. Specifically we show:

► **Theorem 1** (Main Theorem Informal, for formal see Theorem 34). *If X is a collection of subsets that forms a high dimensional expander then there is an $(O(k^2), O(k^2))$ -tester for the k -direct-sums where k is an odd constant.*

Interestingly we combine two notions of high dimensional expanders, a topological notion and a combinatorial notion, to obtain this result. This is the first time that both notions were used together.

In order to describe our strategy we will first have to introduce a generalization of graphs to higher dimensions (called simplicial complexes) as well as both notions of high dimensional expanders:

Simplicial Complexes

A simplicial complex can be thought of as a hypergraph with a closure property, meaning that if F is a hyperedge in the hypergraph then so is every subset of F . We also define the dimension of a hyperedge F to be $|F| - 1$, and denote the set of i -dimensional edges of a complex X as $X(i)$. For example: In a graph, the vertices are considered the 0-dimensional hyperedges, and the edges are considered the 1-dimensional hyperedges. Now that we have defined the dimension of a hyperedge, we can define the dimension of the complex as the dimension of the maximal hyperedge. For example: A 2-dimensional simplicial complex is a simplicial complex that contains 2-dimensional hyperedges, often called the “triangles” (note that these hyperedges contain 3 vertices). Throughout this paper, we will use a standard weighted counting norm denoted as $\|\cdot\|$ (which will be defined in 8). In this work we will be interested in simplicial complexes whose maximal hyperedges are all of the same dimension (which are called “pure simplicial complexes”).

As previously discussed, we will use two generalizations of expansion that apply to simplicial complexes: The first will be co-systolic expanders and the second will be colorful expanders. In order to discuss these notions of expansion, it will be useful to reexamine the Cheeger constant in the 1-dimensional case (aka graphs):

$$\min_{S \neq \emptyset, V} \left\{ \frac{\|E(S, \bar{S})\|}{\min\{\|S\|, \|\bar{S}\|\}} \right\}$$

In any higher dimensional analogue, we would still like the essence of this constant to hold, every set of hyperedges of some dimension i (in graphs - vertices) has a number of out-going hyperedges of dimension $i + 1$ (in graphs - edges) relative to its size. Because we are dealing with multi-dimensional objects we would also like this bound to apply in every dimension. The only question remaining is how to generalize the notion of an out-going edge to higher dimensions.

Co-systolic Expanders

The first notion of expansion we will introduce is the co-systolic expansion, which is the more topological of the two. In this form of expansion, a hyperedge of dimension $i + 1$, is said to be going out of a set E of hyperedges of dimension i , if it has an odd number of i -dimensional sub-edges in the set E^1 . We denote the set of hyperedges that are going out of a set E , according to this notion, as δE . Note that the Cheeger constant is normalized over the distance of E from a set that has no neighbors (in the 1-dimensional case the only sets with no neighbors are the empty set and the entire graph). Therefore we normalize our new high-dimensional analogue accordingly and receive the following definition:

$$\epsilon^i(X) = \min_{\substack{S \in \{0,1\}^{X(i)} \\ \delta S \neq \emptyset}} \left\{ \frac{\|\delta S\|}{\text{dist}(S, \{Z \mid \delta Z = \emptyset\})} \right\}$$

A simplicial complex is a co-systolic expander if there exists some ϵ such that in every dimension i : $\epsilon^i(X) \geq \epsilon$. Note that there is another property that a simplicial complex must fulfill in order to be a co-systolic expander. However, it is not required in the proof of this paper and can be found in definition 20.

Colorful Expanders

The other notion of expansion we will introduce is the colorful expansion, which is the more combinatorial of the two. In this form of expansion, a hyperedge of dimension $i + 1$, is said to be going out of a set E of hyperedges of dimension i , if it has at least one i -dimensional sub-edge in E and at least one i -dimensional sub-edge outside of E . We denote the set of hyperedges that are going out of a set E , according to this notion, as $c(E)$. Using this definition of out-going edges, we get the following generalization of the Cheeger constant (for the i -th dimension):

$$\sigma^i(X) = \min_{S \neq \emptyset, X(i)} \left\{ \frac{\|c(S)\|}{\min \{\|S\|, \|X(i) \setminus S\|\}} \right\}$$

A simplicial complex is a σ -colorful-expander if in every dimension i : $\sigma^i(X) \geq \sigma$.

1.1 Proof Layout

We will start by defining the property of being a k -direct-sum again, this time using the language of simplicial complexes: Given a simplicial complex X , a function $F : X(k - 1) \rightarrow \{0, 1\}$ is called a k -direct-sum if there exists a function $f : X(0) \rightarrow \{0, 1\}$ such that for every A in $X(k - 1)$: $F(A) = \sum_{a \in A} f(a)$. Note that we define a k -direct-sum to be a function from

¹ In the 1-dimensional case we say that an edge crosses a cut if it has exactly one vertex in the cut. Note that if there is an odd number of vertices in an edge the odd number must be one since edges are of cardinality 2.

50:4 Testing Odd Direct Sums Using High Dimensional Expanders

the $(k - 1)$ -dimensional hyperedges of the complex, and not the k -dimensional hyperedges of the complex, because we want the k to represent the size of the set and not the dimension of the face.

We will show that the following algorithm tests whether a given function is a k -direct-sum for odd constant values of k :

■ **Algorithm 1** $T_{\text{assembled-}k\text{-direct-sum}}$.

-
- 1 **pick** one of the following options uniformly:
 - 2 Test whether δF is a $(k + 1)$ -direct-sum using a known test for even sized sets^a.
 - 3 **pick** $m \in X(k + 1)$ randomly:
 - 4 | Check whether $F|_m$ is a k -direct-sum.
-

^a Note that $k + 1$ is even and, whenever the known test asks to query $\delta F(a)$, the algorithm queries every set in $\binom{a}{k}$ and returns the sum of the results.

In order to analyze this test, it would first be useful to deconstruct F into three functions $F = D + Z + G$ where D is a k -direct-sum, $\delta Z = 0$, and the remainder G .

Bounding the Norm of G Using Co-Systolic expansion

First we will show that the rejection probability of step (2) bounds $\|G\|$ from above. In order to do so we must first consider the following two properties of δ :

- δ is linear.
- If D is a k -direct-sum (and k is odd) then δD is a $(k + 1)$ -direct-sum (See Lemma 28). Combining these properties with the fact that the complex is a co-systolic expander, yields an upper bound for G . Specifically: Because $\delta F = \delta D + \delta G$, the test performed in step (2) gives an upper bound to $\|\delta G\|$ (since δD is a direct sum) and co-systolic expansion implies that $\|G\| \leq \epsilon \|\delta G\|$.

Bounding the Norm of Z Using Colorful Expansion

Secondly, we will show how to bound $\|Z\|$ from above. Alas, step (3) does not bound $\|Z\|$ from above unconditionally, but if we assume that $G = 0$, we can bound $\|Z\|$ from above using the rejection probability of step (3). We do that in two steps: The first is noting that $\|Z\|$ is bounded from above by all the $(k + 1)$ -faces that Z “touches”, namely $\{m \in X(k + 1) | Z|_m \neq 0\}$ due to a property of the norm (Lemma 10). We then show the following property: Step (3) rejects every $(k + 1)$ -dimensional face m on which $Z|_m \notin \{0, \mathbb{1}\}$. In expander graphs, given a set of vertices S , the set of edges that are going out of S bounds from above the edges that connect two vertices within S . Similarly in higher dimensional colorful expanders, the set of edges that stay within a set S is bounded from above by the set of edges that are going out of S . We think of an edge m on which $Z|_m = \mathbb{1}$ as an edge that connects vertices within S , and an edge m on which $Z|_m \notin \{0, \mathbb{1}\}$ as an edge that is going out of S . Thus by colorful expansion we can bound $\|\{m \in X(k + 1) | Z|_m = \mathbb{1}\}\|$ using $\|\{m \in X(k + 1) | Z|_m \notin \{0, \mathbb{1}\}\}\|$. We conclude that $\|Z\|$ can be bounded from above as follows:

$$\begin{aligned} \|Z\| &\leq \|\{m \in X(k + 1) | Z|_m \neq 0\}\| = \\ &\quad \|\{m \in X(k + 1) | Z|_m \notin \{0, \mathbb{1}\}\}\| + \|\{m \in X(k + 1) | Z|_m = \mathbb{1}\}\| \leq \\ &\quad \|\{m \in X(k + 1) | Z|_m \notin \{0, \mathbb{1}\}\}\| + c \|\{m \in X(k + 1) | Z|_m \notin \{0, \mathbb{1}\}\}\| = \\ &\quad (1 + c) \|\{m \in X(k + 1) | Z|_m \notin \{0, \mathbb{1}\}\}\| \end{aligned}$$

which is bounded from above by the probability that step (3) rejects.

We end the proof by showing a way to combine both bounds. Note this is not trivial since the bound on $\|Z\|$ is dependent on the fact that $G = 0$. However, we can mitigate for this dependency, since G can be bounded independently of Z .

2 Preliminaries

► **Notation 2.** Given a set S and an integer k denote by $\binom{S}{k} = \{s \subseteq S \mid |s| = k\}$.

2.1 Simplicial Complexes

We are now going to provide formal definitions of simplicial complexes and a norm on them:

► **Definition 3 (Simplicial complex).** A simplicial complex is a pair $X = (V, E)$ such that: $E \subseteq P(V)$, and if $F \in E$ then every $F' \subseteq F$ is in E as well. Elements in the set E are called the faces of X .

► **Definition 4 (Dimension of a face).** Let m be a face in X . Define the dimension of m to be:

$$\dim(m) := |m| - 1$$

Also, define the set $X(i)$ to be the set of all faces of dimension i (note that $X(-1) = \{\emptyset\}$).

► **Notation 5.** Let X be a d -dimensional simplicial complex, given $-1 \leq i < j \leq d$, a function $F : X(i) \rightarrow \{0, 1\}$, and $m \in X(j)$. Denote by $F|_m$ the function $F|_m : \binom{X(j)}{i+1} \rightarrow \{0, 1\}$ such that $\forall q \in X(i) : F|_m(q) = F(q)$.

► **Definition 6 (Dimension of a simplicial complex).** Let $X = (V, F)$ be a simplicial complex. Define the dimension of X to be:

$$\dim(X) := \max_{f \in F} \dim(f)$$

► **Definition 7 (Pure simplicial complex).** A d -dimensional simplicial complex X is called pure if all of its maximal faces are of dimension d .

► **Definition 8 (Norm over the faces).** Let X be a pure simplicial complex of dimension d . Define the weight of the face a to be:

$$w(a) = \frac{|\{F \in X(d) \mid a \subseteq F\}|}{\binom{d+1}{|a|} \cdot |X(d)|}$$

and the norm $\|\cdot\| = \|\cdot\|^k : P(X(i)) \rightarrow [0, 1]$ to be: $\|A\| := \sum_{a \in A} w(a)$.

We will show in Appendix A that w defines a distribution on every dimension where the probability of a face to be chosen is equal to its norm. For the rest of the paper, when an algorithm chooses a face (unless a distribution is explicitly specified), it chooses a face with the distribution implied by w .

► **Definition 9 (Container).** Let X be a d -dimensional simplicial complex, let $-1 \leq i \leq r \leq d$ and let $A \subseteq X(i)$. Define $\Gamma^r(A) := \{a \in X(r) \mid \exists b \in A : b \subseteq a\}$.

► **Lemma 10.** Let X be a d -dimensional simplicial complex, and let $-1 \leq i \leq j \leq d$. Then for any $A \subseteq X(i)$:

$$\|A\| \leq \|\Gamma^j(A)\| \leq \binom{j+1}{i+1} \|A\|$$

► **Lemma 11.** *Let $A \subseteq X(i): \forall j : \left\| \left\{ A' \in X(i+j) \mid \binom{A'}{i} \subseteq A \right\} \right\| \leq \|A\|$*

The proofs of Lemma 10 and Lemma 11 can be found in Appendix B.

► **Notation 12.** *Given a complex X , and a test T whose random choice is some $m \in X$, denote the result of the test T when testing the function F and the random face chosen is m from the complex X by $T_X^F(m)$.*

2.2 Co-systolic Expansion

We will now present the first notion of expansion used in this paper, namely - co-systolic expanders. Co-systolic expansion was introduced by Evra and Kaufman in [7] and is the more topological notion of expansion we will use in this paper. In order to define this notion of expansion we must first define some spaces and operators over simplicial complexes:

► **Definition 13 (Co-chains).** *Let X be a simplicial complex, define the i -co-chains of X to be $C^i(X) = \{0, 1\}^{X(i)}$.*

Note that the norm defined in Definition 8 implies a norm on the co-chains by setting the norm of a co-chain to be the norm of set of faces on which it returns 1. Formally:

► **Definition 14 (Extension of the norm to co-chains).** *For every $C \in C^i(X)$ define:*

$$\|C\| := \|\{a \in X(i) \mid C(a) = 1\}\|$$

Now that we have defined the co-chains and a norm on them, we can also define the distance between co-chains as well as the distance of a co-chain from the k -direct-sums.

► **Definition 15 (Distance between co-chains).** *Given $C_1, C_2 \in C^k(X)$, the distance between C_1 and C_2 is:*

$$dist(C_1, C_2) = \|C_1 + C_2\|$$

► **Definition 16.** *We define the distance of a co-chain $C \in C^k(X)$ to the k -direct-sum to be:*

$$\min_{D \in \{k\text{-direct-sum}\}} \{dist(C, D)\}$$

► **Definition 17 (Co-boundary operator).** *Let $\delta_i : C^i(X) \rightarrow C^{i+1}(X)$ be the following function:*

$$\delta_i(F)(m) = \sum_{q \in \binom{m}{i-1}} F(q)$$

Note that $F : X(i) \rightarrow \{0, 1\}$ and $m \in X(i+1)$.

Lastly we will define two more spaces over the faces of the simplicial complex:

► **Definition 18 (Co-cycles and co-boundaries).** *Let X be a simplicial complex, define the following spaces:*

- *The i -co-cycles: $Z^i(X) = Ker(\delta_i) = \{Z \in C^i(X) \mid \delta_i Z = 0\}$.*
- *The i -co-boundaries: $B^i(X) = Im(\delta_{i-1}) = \{B \in C^i(X) \mid \exists B' \in C^{i-1}(X) : B = \delta_{i-1} B'\}$.*

► **Fact 19.** *For every dimension i : $B^i(X) \subseteq Z^i(X) \subseteq C^i(X)$.*

A complex X is an (ϵ, μ) -co-systolic expander if any i -co-chain that is far from being a co-cycle “touches” an odd number of times many $(i+1)$ -co-chains. In addition to that, any co-cycle that is not a co-boundary must be large. Formally:

► **Definition 20** (Co-systolic expander). *Let X be a d -dimensional simplicial complex and let $\epsilon, \mu > 0$. X is an (ϵ, μ) -co-systolic-expander if for every $i = 0, 1, \dots, d - 1$:*

$$\text{exp}^i(X) = \min \left\{ \frac{\|\delta_i(f)\|}{\min_{z \in Z^i(X)} \{\|f + z\|\}} \mid f \in C^i(X) \setminus Z^i(X) \right\} \geq \epsilon$$

and

$$\text{syst}^i(X) = \min \{ \|z\| \mid z \in Z^i(X) \setminus B^i(X) \} \geq \mu$$

Note that $\min_{z \in Z^i(X)} \{\|f + z\|\}$ is the distance of f from being a co-cycle.

This notion of expansion implies that the simplicial complex has the topological overlapping property (which is explained in detail in [7]). In this paper, we will use this definition of expansion in order to estimate the non-co-cyclic part of the difference between the function given to us and its closest k -direct-sum. We will do that by first applying the co-boundary operator to the function given to us, and then test whether the result is a $(k + 1)$ -direct-sum (we will see why this suffices in section 3).

2.3 Colorful Expansion

The other form of high dimensional expansion we use is a combinatorial one. It was first introduced by Kaufman and Mass in [10]. This notion of expansion considers every face on which the i -co-chain is equal to 1 as if it is colored in one color, and every face on which the i -co-chain is equal to 0 as if it is colored in a different color. Then we look at all the $(i + 1)$ -faces that are not monochromatic. More formally:

► **Definition 21** (Colorful Operator). *Let $c_i : C^i(X) \rightarrow C^{i+1}(X)$ be the following function:*

$$c_i(F)(m) = \begin{cases} 1 & \exists a, b \in \binom{m}{k-1} : F(a) = 1 \text{ and } F(b) = 0 \\ 0 & \text{otherwise} \end{cases}$$

Note that $F : X(i) \rightarrow \{0, 1\}$ and $m \in X(i + 1)$.

A simplicial complex is a colorful expander if every sufficiently small i -co-chain implies a lot of non-monochromatic $(i + 1)$ -faces. Formally:

► **Definition 22** (Colorful Expander). *Let X be a d -dimensional simplicial complex. We say that X is a σ -colorful-expander if for any $W \in C^i(X)$ ($0 \leq i < d$) such that $\|W\| \leq 0.5$:*

$$\frac{\|c_i(W)\|}{\|W\|} \geq \sigma$$

This notion of expansion deals with random walks - consider the random walk that moves between two i -faces through a common $(i + 1)$ -face that contains them both. In [10] it was shown that such random walks converge rapidly to the stationary distribution. In this paper we will use this notion of expansion in order to estimate the co-cyclic part of the difference between the function given to us and its closest k -direct-sum (which would be impossible to do using the other notion of expansion).

3 Properties of Direct Sums

We will now present what the k -direct-sums are and show some useful properties of k -direct-sums.

► **Definition 23** (*k -direct-sum*). A co-chain $D : X(k-1) \rightarrow \{0, 1\}$ is called a k -direct-sum if there is some function $d : X(0) \rightarrow \{0, 1\}$ such that $D(a) = \sum_{v \in a} d(v)$ (The sum is performed modulo 2).

► **Definition 24** (*Origin function*). Let $D : X(k) \rightarrow \{0, 1\}$ be a k -direct-sum. An origin function of D is any function $d : X(0) \rightarrow \{0, 1\}$ such that $D(a) = \sum_{v \in a} d(v)$.

In the rest of this chapter we will explore properties of the k -direct-sums. We will start by finding a set of functions that spans the k -direct-sums. Then we will use these functions in order to show how direct-sums behave when applying the co-boundary operator to them. We will start by showing that the set of k -direct-sums is linear:

► **Lemma 25** (*Direct sums are closed under addition*). Let F and G be two k -direct-sums whose origin functions are f and g respectively then $F + G$ is a k -direct-sum and its origin function is $f + g$.

Proof. We know that $F(a) = \sum_{b \in a} f(b)$ and $G(a) = \sum_{b \in a} g(b)$. It is easy to see that $F + G = \sum_{b \in a} f(b) + \sum_{b \in a} g(b) = \sum_{b \in a} (f(b) + g(b)) = \sum_{b \in a} (f + g)(b)$. Therefore $F + G$ is a k -direct-sum and $f + g$ is its origin function. ◀

We will now wish to find a set of functions that spans the k -direct-sum so:

► **Definition 26** (*Spanning set of the k -direct-sums*). Let $u \in X(0)$. Define $H_u^k : X(k-1) \rightarrow \{0, 1\}$ to be:

$$H_u^k(a) = \begin{cases} 1 & \text{if } u \in a \\ 0 & \text{otherwise} \end{cases}$$

One can easily check that $\forall k : H_u^k$ is a k -direct-sum whose origin function is:

$$h_u^k(v) = \begin{cases} 1 & \text{if } v = u \\ 0 & \text{otherwise} \end{cases}$$

We can now prove that $\{H_u^k\}$ spans the set of k -direct-sums:

► **Lemma 27.** The set of k -direct-sums is spanned by $\{H_u^k | u \in X(0)\}$

Proof. Let F be a k -direct-sum. By definition there exists $f : X(0) \rightarrow \{0, 1\}$ such that $F(a) = \sum_{b \in a} f(b)$. Consider the support of f : $\text{sup}(f) = \{u \in X(0) | f(u) = 1\}$, and define $G = \sum_{u \in \text{sup}(f)} H_u^k$. It is easy to see that $F(a) = \sum_{b \in a} f(b) = \sum_{b \in a} H_u^k(b)$ and therefore $F \in \text{span} \{H_u^k | u \in X(0)\}$.

Let $F \in \text{span} \{H_u^k | u \in X(0)\}$ therefore there exists some set $I \subseteq X(0)$ such that $F = \sum_{u \in I} H_u^k$. We know that $\{H_u^k\}_{u,k}$ are k -direct-sums, therefore F is a sum of k -direct-sums and, due to Lemma 25, F is a k -direct-sum as well. ◀

We will now show a connection between the k -direct-sums in the odd dimensions and the k -direct-sums in the even dimensions:

► **Lemma 28.** For odd values of k : $\delta_k H_u^k = H_u^{k+1}$

Proof.

$$\delta_k H_u^k(a) = \sum_{\substack{b \subset a \\ |b|=|a|-1}} H_u^k(B) = |\{b | b \subset a, |b| = |a| - 1, u \in b\}| = \begin{cases} \binom{k}{k-1} & \text{if } v_i \in a \\ 0 & \text{otherwise} \end{cases} =$$

$$\begin{cases} k & \text{if } u \in a \\ 0 & \text{otherwise} \end{cases} = \begin{cases} 1 & \text{if } u \in A \\ 0 & \text{otherwise} \end{cases} = H_u^{k+1} \quad \blacktriangleleft$$

► **Lemma 29.** For odd values of k , if F is k -direct-sum then δF is a $(k + 1)$ -direct-sum.

Proof. F is a k -direct-sum therefore there exists some $I \subseteq X(0)$ such that $F = \sum_{u \in I} H_u^k$. And thus $\delta F = \delta(\sum_{u \in I} H_u^k) = \sum_{u \in I} \delta H_u^k = \sum_{u \in I} H_u^{k+1} \in \text{span} \{H_u^{k+1} | u \in X(0)\}$ and δF is a $(k + 1)$ -direct-sum. ◀

► **Lemma 30.** For even values of k , if F is a k -direct-sum then $F \in B^{k+1}(X) \subseteq Z^{k-1}(X)$.

Proof. F is a k -direct-sum therefore there exists $I \subseteq X(0)$ such that $F = \sum_{u \in I} H_u^k = \sum_{u \in I} \delta H_u^{k-1}$. Finally we get that $F \in B^{k-1}(X) \subseteq Z^{k-1}(X)$. ◀

Note that the previous two Lemmas imply that Lemma 29 is true for any value of k .

4 Definition of Components Appearing in the Tester

In this section, we will provide some definitions that will help us build the test for the k -direct-sum problem.

We would first like to define a relaxed version of the k -direct-sum, namely the k -co-cycle-indifferent-direct-sum:

► **Definition 31** (Co-cycle indifferent direct sum). Define the property of being a k -co-cycle-indifferent-direct-sum to be:

$$CI = \{F = D + Z \mid D \text{ is a } k\text{-direct-sum and } Z \in Z^{k-1}(X)\}$$

In section 6 will show that this property is testable for odd values of k .

We would also want to define a separator which helps in separating k -direct-sums from non k -direct-sums. Unlike tests, in which the rejection probability is linear in the distance from the property, separators reject with (at least) constant probability when their input is not in the property.

► **Definition 32** (Direct sum separator). Let X be a simplicial complex. An algorithm T is called an (n, k, Q, η) -direct-sum-separator if, for the complete complex on $n - 1$ nodes (denoted by X_{n-1}), when given $f \in C^{k+1}(X_{n-1})$, the following applies:

- If f is a k -direct-sum then $\Pr[T^f = 1] = 1$.
- If f is not a k -direct-sum then $\Pr[T^f = 0] \geq \eta$.
- T queries f on at most Q faces in $X_{n-1}(k - 1)$.

In appendix C we will show an explicit separator whose error probability is 0 and queries the entire complex. We will also show how to construct a separator from a test. It is important to note that one can reduce the query complexity of the test presented in this paper by providing a different separator with lower query complexity (using, for example, Lemma 54).

5 Presenting A Test for Being a k -direct-sum

In this section, we will prove the main theorem. But first recall the definition of a (Q, E) -test for being a k -direct-sum:

► **Definition 33** ((Q, E) -test for being a k -direct-sum). *A (Q, E) -test for being a k -direct-sum is an algorithm that:*

- Queries F on Q inputs from X .
- Accepts k -direct-sums.
- Rejects with probability of at least ξ every function whose distance from the k -direct-sums is at least $E\xi$.

► **Theorem 34** (Main Theorem). *Let X be a d -dimensional pure simplicial complex, and $0 < k \leq d - 2$ be an odd constant. Also assume there exists a (Q, E) -test for being a $(k + 1)$ -direct-sum on X and let $F : X(k - 1) \rightarrow \{0, 1\}$ be a function. Then, if X is an (ϵ, μ) -co-systolic expander and a σ -colorful-expander, there exists a test T such that:*

- T queries F a maximum of $\max\left\{(k + 1) \cdot Q, \binom{k+2}{k}\right\}$ times.
- F is a k -direct-sum $\Leftrightarrow \Pr[T \text{ accepts } F] = 1$.
- If $\Pr[T \text{ rejects } F] \leq \xi$ then there exists a k -direct-sum F' such that

$$\text{dist}(F, F') \leq \left(\left(1 + \frac{1}{\sigma}\right) \left(\binom{k+2}{k} \frac{E}{\epsilon} + 1 \right) + \frac{E}{\epsilon} \right) \xi.$$

As a corollary we show that the k -direct-sum problem on the complete complex is testable with $O(k^2)$ -queries for odd k .

► **Corollary 35** (k -direct-sum is testable on the complete complex for odd k 's). *On the complete complex there exists a $(O(k^2), E)$ -test for being a k -direct-sum where E is constant and k is odd.*

The proof of this corollary will be presented in Appendix C. We also show that:

► **Corollary 36.** *For any dimension d , there exists a family of **bounded** degree simplicial complexes X such that the property of k -direct-sum is testable on X .*

Proof. We will show that Ramanujan complexes satisfy the conditions of Theorem 34:

- In [7] it was shown that for any dimension d there exists q_0 , such that for any prime power $q > q_0$, there are $\mu = \mu(d)$ and $\epsilon = \epsilon(d, q)$ such that if X is the d -dimensional complex induced by a q -thick Ramanujan complex then X is an (ϵ, μ) -co-systolic expander.
- In addition to that in [10] it was proven that for any dimension d , there exists a constant $q'_0 = q'_0(d)$ such that, if X is a d -dimensional q' -thick Ramanujan complex for $q' > q'_0$, then there are $\sigma = \sigma(d, q')$ such that X is a σ -colorful expander.

We end this proof by noting that it was shown in [11] that there is an explicit construction of Ramanujan complexes (and therefore there is an explicit construction for complexes that are both co-systolic expanders and colorful expanders). ◀

We will prove the main theorem using a (Q_{CI}, ζ) -test for the k -co-cycle-indifferent-direct-sum problem called T_{CI} and a $(k + 2, k, Q_{sep}, \eta)$ -direct-sum-separator T_{sep} . Specifically, we will prove that the following is a tester for the k -direct-sum problem:

■ **Algorithm 2** $T_{direct-sum}$.

-
- 1 **pick** one of the following options uniformly:
 - 2 | Run T_{CI} and return its result.
 - 3 | **pick** $m \in X(k + 1)$ randomly:
 - 4 | | Run T_{sep} on m with $F|_m$ and return its result.
-

Formally we will prove that:

► **Theorem 37** (*k*-direct-sums are testable). *On any complex that is a σ -colorful-expander and for any constant odd value of k , given:*

- T_{sep} - A $(k + 2, k, Q_{sep}, \eta)$ -direct-sum-separator for the complete complex.
- T_{CI} - A (Q_{CI}, ζ) -test for the k -co-cycle-indifferent-direct-sum.

We can construct $T_{direct-sum}$ as shown above such that $T_{direct-sum}$ is a:

$$\left(\max \{Q_{CI}, Q_{sep}\}, \left(1 + \frac{1}{\sigma}\right) \left(\frac{1}{\eta} + \binom{k+2}{k} \zeta\right) + \zeta \right) \text{-test}$$

for the k -direct-sum problem.

In order to understand why the test works, consider a deconstruction of F into three parts: $F = D + Z + G$. In this deconstruction we assume that:

- G is minimal with regards to the k -co-cycle-indifferent-direct-sum.
- Z is the minimal co-cycle with regards to the k -direct-sum problem.
- D is a k -direct-sum.

In sub-section 5.1 we will show that the rejection probability of step (2) bounds from above $\|G\|$. In sub-section 5.2 we will show that, when ignoring G , step (3)'s rejection probability bounds $\|Z\|$ from above. Finally in sub-section 5.3 we will show how the combination of both steps provides a test for being a k -direct-sum. Note that unlike step (2) (in which there is no assumption on Z), the analysis of step (3) assumes that $G = 0$.

5.1 Step (2) of the test estimates the Norm of G

► **Lemma 38.** *Let T_{CI} be a (Q_{CI}, ζ) -test for the k -co-cycle-indifferent-direct-sum then:*

$$\|G\| \leq \zeta \cdot \Pr[\text{step (2) rejects}]$$

Proof. $\|G\| = \text{dist}(F, CI) \leq \zeta \cdot \Pr[T_{CI} = 0] = \zeta \cdot \Pr[\text{step (2) rejects}]$ The second inequality holds due to the definition of T_{CI} . ◀

5.2 Step (3) of the Test Estimates Norm of Z Assuming That There is No Remainder

In step (3) we pick a $(k + 1)$ -dimensional face randomly and then check whether the function is a k -direct sum on that specific face. In this section, we will show that the failure probability of doing so bounds $\|Z\|$ from above. We will do that by first observing that given m , a $(k + 1)$ -dimensional face, either $F|_m$ is not a k -direct-sum or $Z|_m \in \{0, 1\}$:

► **Lemma 39.** *Let $F = D + Z$ such that D is a k -direct-sum and $Z \in Z^{k-1}(X)$ then for every odd value k and $m \in X(k + 1)$: If $F|_m$ is a k -direct-sum on m then: $Z|_m \in \{0, 1\}$.*

Proof. $F|_m$ is a k -direct-sum and, because $G = 0$, so is $Z|_m$ as $Z|_m = F|_m + D|_m$. Assuming that $Z|_m \notin \{0, 1\}$, let $z : m \rightarrow \{0, 1\}$ be an origin function of Z and let $A_i = \{v \in m | z(v) = i\}$. Pick the largest possible set (of up to $k + 1$ elements) of odd size out of A_1 (the set is not empty because otherwise $Z|_m = 0$) and name it A . Add to that set $k + 1 - |A|$ items from A_0 (which cannot be empty since $Z|_m \neq 1$) to form a $(k + 1)$ -face which we will denote as t . It is easy to see that $\delta Z|_m(t) = \sum_{v \in t} z(v) = \sum_{v \in A} z(v) = 1$ (the last equality holds because $|A|$ is odd) which contradicts the fact that $Z \in Z^{k-1}(X)$ ◀

50:12 Testing Odd Direct Sums Using High Dimensional Expanders

We now observe that the set of $(k+1)$ -dimensional faces on which $Z|_m \neq 0$ can be split into two sets:

- The set of all $m \in X(k+1)$ on which $F|_m$ is not a k -direct-sum.
- The set of all $m \in X(k+1)$ such that $Z|_m = \mathbb{1}$ (which we will denote as S).

It is easy to see that the rejection probability of step (3) bounds the first set (since step (3) fails on every face in the set). We will spend the majority of this sub-section proving that $\|S\|$ can also be bounded from above using the rejection probability of step (3). We will end this sub-section by combining the aforementioned bounds.

Before discussing how to bound $\|S\|$ from above, it will be useful to present Lemma 39 again, this time with the new terminology described above:

► **Corollary 40.** *Let $m \in X(k+1)$ then:*

$$F|_m \text{ is not a } k\text{-direct-sum} \Leftrightarrow m \in \Gamma^{k+1}(Z) \setminus S$$

Proof. $m \in \Gamma^{k+1}(Z)$ iff $Z|_m \neq 0$ (due to the definition of Γ) and $m \notin S$ iff $Z|_m \neq \mathbb{1}$ (due to the definition of S) therefore:

$$F|_m \text{ is not a } k\text{-direct-sum} \Leftrightarrow Z \notin \{0, \mathbb{1}\} \Leftrightarrow m \in \Gamma^{k+1}(Z) \setminus S \quad \blacktriangleleft$$

In order to bound $\|S\|$ we will look at a different function whose norm bounds $\|S\|$ from above, specifically:

► **Definition 41.** *Define $E : X(k) \rightarrow \{0, 1\}$ to be the following function:*

$$E(a) = \begin{cases} 1 & \text{if } Z|_a = \mathbb{1} \\ 0 & \text{otherwise} \end{cases}$$

This function helps in bounding $\|S\|$ from above because every face in S is comprised solely of k -dimensional faces on which E returns 1. Combining this fact with Lemma 11 yields that $\|S\| \leq \|E\|$.

All we have to do now is to bound $\|E\|$. This will be done by first showing that step (3) of the test rejects every non-monochromatic $(k+1)$ -face (where E is considered the coloring). We will then show that $\|E\| < 0.5$ which will allow to use the colorful expansion in order to bound $\|E\|$.

► **Lemma 42 (Step (3) Fails on the Non-Monochromatic Faces).** *Let $m \in Z(k+1)$. If $c(E)(m) = 1$ then $F|_m$ is not a k -direct-sum.*

Proof. $c(E)(m) = 1 \Rightarrow \exists a, b \in \binom{m}{k+1} : E(a) = 1$ and $E(b) = 0$. Using the definition of E we get that:

- $E(b) = 0 \Rightarrow \exists c \in \binom{b}{k} : Z(c) = 0$
- $E(a) = 1 \Rightarrow \forall t \in \binom{a}{k} : Z(t) = 1$

Therefore $Z|_m \notin \{0, \mathbb{1}\}$ and $F|_m$ is not a k -direct-sum (Lemma 39). ◀

► **Lemma 43.** *For every function of the form $F = D + Z + G$ it holds that $\|Z\| \leq 0.5$ (Note that this lemma is true even if $G \neq 0$).*

Proof. It is easy to see that the function $f(v) = 1$ is the origin function of $\mathbb{1}$ and therefore $\mathbb{1}$ is a k -direct-sum. Now, assuming that $\|Z\| > 0.5$ we conclude that $\|\mathbb{1} + Z\| \leq 0.5$ and $(\mathbb{1} + D) + (\mathbb{1} + Z) = D + Z$. Also $(\mathbb{1} + D)$ is a k -direct-sum. We conclude that $\|\mathbb{1} + Z\| < \|Z\|$ and $F + G + (\mathbb{1} + Z) = \mathbb{1} + D$ which is a k -direct-sum. This contradicts the fact that Z is minimal. ◀

► **Corollary 44.** $\|E\| \leq 0.5$.

Proof. By the definition of E if $E(a) = 1$ then $\forall a' \in \binom{a}{k} : Z(a') = 1$. Using Lemma 11 yields that $\|E\| \leq \|Z\|$ which finishes the proof. ◀

We are now finally ready to bound E using the colorful expansion of X :

► **Lemma 45 (Estimating E).** *On every σ -colorful expander X :*

$$\|E\| \leq \frac{1}{\sigma} \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\|$$

Proof. X is a colorful expander and $\|E\| \leq 0.5$ therefore $\sigma \leq \frac{\|c(E)\|}{\|E\|}$ which in turn means that:

$$\sigma \|E\| \leq \|c(E)\| \leq \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\|$$

(the second inequality is due to Lemma 42) and therefore:

$$\|E\| \leq \frac{1}{\sigma} \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\| \quad \blacktriangleleft$$

► **Lemma 46 (Estimating Z).** *Let X be a σ -colorful-expander, and let F be a function of the form $F = D + Z$ such that D is a k -direct-sum and Z is a co-cycle then:*

$$\|Z\| \leq \frac{1}{\eta} \left(1 + \frac{1}{\sigma}\right) \Pr[\text{step (3) rejects}]$$

Proof.

$$\begin{aligned} \|Z\| &\leq \|\Gamma^{k+1}(Z)\| \leq \|(\Gamma^{k+1}(Z) \setminus S) \cup S\| = \|\Gamma^{k+1}(Z) \setminus S\| + \|S\| \leq \\ &\|\Gamma^{k+1}(Z) \setminus S\| + \|E\| \leq \|\Gamma^{k+1}(Z) \setminus S\| + \frac{1}{\sigma} \|\Gamma^{k+1}(Z) \setminus S\| = \\ &\left(1 + \frac{1}{\sigma}\right) \|\Gamma^{k+1}(Z) \setminus S\| = \\ &\left(1 + \frac{1}{\sigma}\right) \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\| \end{aligned}$$

Note that the inequality found at the end of the first row is due to Lemma 11, the inequality in the second row is due to Lemma 45 and the last equality is due to Corollary 40.

Note that:

$$\begin{aligned} \Pr[\text{step (3) rejects}] &= \\ \Pr[F|_m \text{ is not a } k\text{-direct-sum}] \cdot \Pr[T_{sep} \text{ rejects} \mid F|_m \text{ is not a } k\text{-direct-sum}] &= \\ \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\| \cdot \eta \end{aligned}$$

All the probabilities are over a choice of $m \in X(k+1)$.

We conclude by noting that this yields that:

$$\|Z\| \leq \frac{1}{\eta} \left(1 + \frac{1}{\sigma}\right) \Pr[\text{step (3) rejects}] \quad \blacktriangleleft$$

5.3 Combining the Estimations

Now that we know how to estimate both $\|G\|$ and $\|Z\|$ (with the assumption that $G = 0$), it is finally time to combine both estimations in order to estimate $\|Z + G\|$. Note that our estimation of $\|Z\|$ is dependent on our estimation of $\|G\|$. We will deal with this dependency by bounding the interference of G using our estimation of it. We will then estimate $\|Z\|$ as if wherever G would have interfered, step (3) rejected.

► **Lemma 47.** *Let $F = D + Z + G$ such that D is a k -direct-sum, Z is a $(k-1)$ -co-cycle and G is the remainder. Then if $\Pr [T_{direct-sum}^F \text{ rejects}] \leq \xi$ then $\|Z\| \leq (1 + \frac{1}{\sigma}) \left(\frac{1}{\eta} + \binom{k+2}{k} \zeta \right) \xi$.*

Proof. First note that because $\Pr [T_{direct-sum}^F \text{ rejects}] \leq \xi$ we know that $\Pr [\text{step (2) rejects } F] \leq \xi$ and $\Pr [\text{step (3) rejects } F] \leq \xi$. Also, consider what happens when we run the test on $F' = D + Z$. Note that on F' the bound found in Lemma 46 holds. Also note the the co-cyclic part of F and F' is Z . Therefore if we could bound the rejection probability of step (3) on F' using the rejection probability of steps (2) and (3) on F we would have a bound for $\|Z\|$. We will start by bounding the set of $(k+1)$ -faces on which F' is not a k -direct-sum:

$$\begin{aligned} & \{m \in X(k+1) \mid F'|_m \text{ is not a } k\text{-direct-sum}\} \subseteq \\ & \{m \in X(k+1) \mid (F' + G)|_m \text{ is not a } k\text{-direct-sum and } G|_m = 0\} \cup \\ & \{m \in X(k+1) \mid G|_m \neq 0\} = \\ & \{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\} \cup \{m \in X(k+1) \mid G|_m \neq 0\} = \\ & \{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\} \cup \Gamma^{k+1}(G) \end{aligned}$$

Knowing this, we get that:

$$\begin{aligned} & \Pr [\text{step (3) rejects } m \text{ when testing } F'] = \\ & \eta \|\{m \in X(k+1) \mid F'|_m \text{ is not a } k\text{-direct-sum}\}\| \leq \\ & \eta \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\| + \eta \|\Gamma^{k+1}(G)\| \end{aligned}$$

Using Lemma 38, we know that $\|G\| \leq \zeta \cdot \Pr [\text{step (2) rejects}]$ and therefore, using Lemma 10 we get that $\|\Gamma^{k+1}(G)\| \leq \binom{k+2}{k} \|G\| \leq \binom{k+2}{k} \zeta \cdot \Pr [\text{step (2) rejects}]$. Therefore:

$$\begin{aligned} & \Pr [\text{step (3) rejects } m \text{ when testing } F'] \leq \\ & \eta \|\{m \in X(k+1) \mid F|_m \text{ is not a } k\text{-direct-sum}\}\| + \eta \|\Gamma^{k+1}(G)\| \leq \\ & \Pr [\text{step (3) rejects } m \text{ when testing } F] + \binom{k+2}{k} \eta \zeta \cdot \Pr [\text{step (2) rejects}] \leq \\ & \left(1 + \binom{k+2}{k} \eta \zeta \right) \xi \end{aligned}$$

We will now use the bound obtained in Lemma 46 on F' which would yield:

$$\eta \frac{1}{1 + \frac{1}{\sigma}} \|Z\| \leq \left(1 + \binom{k+2}{k} \eta \zeta \right) \xi \Rightarrow \|Z\| \leq \left(1 + \frac{1}{\sigma} \right) \left(\frac{1}{\eta} + \binom{k+2}{k} \zeta \right) \xi \quad \blacktriangleleft$$

We are now finally ready to prove Theorem 37:

Proof of Theorem 37. First, consider the number of queries performed by $T_{direct-sum}$. If step (2) is chosen then $T_{direct-sum}$ performs Q_{CI} queries and if step (3) is chosen then $T_{direct-sum}$ performs Q_{sep} queries. Therefore $T_{direct-sum}$ performs, at most, $\max \{Q_{CI}, Q_{sep}\}$ queries.

Suppose that $\Pr [T_{direct-sum}^F \text{ rejects}] \leq \xi$ then, using Lemma 38 and Lemma 47 we get that:

$$\begin{aligned} \|Z + G\| &\leq \|Z\| + \|G\| \leq \left(1 + \frac{1}{\sigma}\right) \left(\frac{1}{\eta} + \binom{k+2}{k} \zeta\right) \xi + \zeta \xi = \\ &\left(\left(1 + \frac{1}{\sigma}\right) \left(\frac{1}{\eta} + \binom{k+2}{k} \zeta\right) + \zeta\right) \xi \end{aligned}$$

Now all that is left to prove is that a k -direct-sum will always pass the test. If step (2) is chosen then, because a k -direct-sum is also a k -co-cycle-indifferent-direct-sum, the test will always accept. Otherwise, if step (3) is chosen then, because the function is a k -direct-sum, it will be a k -direct-sum on any sub-complex of dimension $k + 1$ and therefore step (3) will always accept as well. ◀

We can now prove the main theorem using Theorem 37:

Proof of Theorem 34. Combining Lemma 49 and Lemma 53 we get that there exists a $\left(\max\left\{(k+1) \cdot Q, \binom{k+2}{k}\right\}, \left(1 + \frac{1}{\sigma}\right) \left(\binom{k+2}{k} \frac{E}{\epsilon} + 1\right) + \frac{E}{\epsilon}\right)$ -test for k -direct-sum for odd values of k . ◀

6 Providing a Test for Being a k -co-cycle-indifferent-direct-sum

In this section we will show how to obtain a test for being a k -co-cycle-indifferent-direct-sum using a test for being a $(k + 1)$ -direct-sum. We will do that by considering the expansion of k -direct sums under co-systolic expansion.

► **Lemma 48.** For any function $F = D + Z + G$ (G is minimal) on an ϵ -co-systolic expander: $\|G\| \leq \frac{1}{\epsilon} \text{dist}(\delta F, k\text{-direct-sum})$

Proof. First note that $\delta F = \delta D + \delta Z + \delta G = \delta D + \delta G$. In addition, because the complex is an ϵ -co-systolic expander and G is minimal: $\|G\| \leq \frac{1}{\epsilon} \|\delta G\|$. Also $\|\delta G\| = \text{dist}(\delta F, k\text{-direct-sum})$ and therefore $\|G\| \leq \frac{1}{\epsilon} \text{dist}(\delta F, k\text{-direct-sum})$. ◀

We are now ready to provide the actual test:

► **Lemma 49.** Let X be an (ϵ, μ) -co-systolic-expander. If there is a (Q, ξ) -test for being a $(k + 1)$ -direct-sum (denoted by T) on X , then there is also a $((k + 1) \cdot Q, \frac{\xi}{\epsilon})$ -test for being a k -co-cycle-indifferent-direct-sum on X .

Proof. Consider the following test:

Algorithm 3 T_{CI} .

-
- 1 Return the result of T on δF (whenever T queries δF , calculate it and send the result).
-

It is easy to see that:

$$\begin{aligned} \text{dist}(F, k\text{-co-cycle-indifferent-direct-sum}) &= \|G\| \leq \\ \frac{1}{\epsilon} \text{dist}(\delta F, k\text{-direct-sum}) &\leq \frac{\xi}{\epsilon} \Pr [T_{CI} = 0] \end{aligned}$$

Also, F is a k -co-cycle-indifferent-direct-sum $\Leftrightarrow G = 0 \Leftrightarrow \Pr [T_{CI} \text{ accepts } F] = 1$

For any query T makes, T_{CI} makes $\binom{k+1}{k} = (k + 1)$ queries and therefore T_{CI} performs at most $(k + 1) \cdot Q$ queries. ◀

A Sampling According to the Norm

In this section we will show how to pick a face with probability that equals to its norm. Consider the following sampling algorithm:

■ **Algorithm 4** *Sample*(l, r).

```

1 pick uniformly (using the random bits from  $r$ )  $m \in X(d)$ .
2 while  $|m| > l + 1$  do
3   | pick uniformly (using the random bits from  $r$ )  $v \in m$ .
4   |  $m \leftarrow m \setminus \{v\}$ .
5 end
6 return  $m$ .
```

Note that steps 3 and 4 are equivalent to choosing a sub-face of m of dimension $\dim(m) - 1$. We are going to require a way to denote a specific value of m during the run of the sampling algorithm:

► **Definition 50.** Given a single run of *Sample*(l, r), define for every $l + 1 < i < d + 1$: M_i^r to be the value of m when $|m| = i$ and the random bits chosen by the algorithm are r .

It is easy to see that these sets satisfy the following properties:

- $\forall r \forall i : M_i^r \subset M_{i+1}^r$.
- $\forall i \forall a \in X(i - 1) : \Pr[M_i^r = a] = \Pr[\text{Sample}(i - 1, r) = a]$.

► **Lemma 51.** *Let X be a simplicial complex of dimension d and let $-1 \leq l \leq d$ then:*

$$\forall a \in X(l) : \Pr[\text{Sample}(l, r) = a] = w(a)$$

And also:

$$\forall A \in P(X(i)) : \|A\| = \Pr[\text{Sample}(i, r) \in A]$$

Where *Sample* is the algorithm 4.

Proof. We will prove this lemma using induction:

Base case: $l = d$: Notice that $\forall a \in X(d) : w(a) = \frac{1}{\binom{d+1}{d+1} |X(d)|}$.

The lemma holds because *Sample*($d + 1, r$) simply chooses a face of dimension d uniformly.

Assuming that $\forall a \in X(l + 1) : \Pr[\text{Sample}(l + 1, r) = a] = w(a)$ we will now prove that $\forall a \in X(l) : \Pr[\text{Sample}(l, r) = a] = w(a)$ (where M_i^r are the values defined in definition 50):

$$\begin{aligned} \forall a \in X(l) : \Pr[\text{Sample}(l, r) = a] &= \\ &= \sum_{b \in \{b \in X(l+1) | a \subseteq b\}} \Pr[\text{Sample}(l, r) = a | M_{l+1}^r = b] \cdot \Pr[M_{l+1}^r = b] = \\ &= \sum_{b \in \{b \in X(l+1) | a \subseteq b\}} \frac{1}{l+2} w(b) = \sum_{b \in \{b \in X(l+1) | a \subseteq b\}} \frac{1}{l+2} \frac{|\{q \in X(d) | b \subseteq q\}|}{\binom{d+1}{|b|} \cdot |X(d)|} = \\ &= \sum_{b \in \{b \in X(l+1) | a \subseteq b\}} \frac{1}{d-l} \frac{|\{q \in X(d) | b \subseteq q\}|}{\binom{d+1}{|b|-1} \cdot |X(d)|} = \\ &= \frac{1}{(d-l) \binom{d+1}{|a|} \cdot |X(d)|} \sum_{b \in \{b \in X(l+1) | a \subseteq b\}} |\{q \in X(d) | b \subseteq q\}| \\ &= \frac{|\{q \in X(d) | a \subseteq q\}|}{\binom{d+1}{|a|} \cdot |X(d)|} = w(a) \end{aligned}$$

The fourth equation holds because:

$$\begin{aligned} (l+2) \binom{d+1}{l+2} &= (l+2) \frac{(d+1)!}{(l+2)!(d-l-1)!} = \frac{(d+1)!}{(l+1)!(d-l-1)!} \\ &= (d-l) \frac{(d+1)!}{(l+1)!(d-l)!} = (d-l) \binom{d+1}{l+1} \end{aligned}$$

The sixth equation holds because every maximal face that contains a is counted $\binom{d+1-(l+1)}{1} = d-l$ times. Finally we can see that:

$$\begin{aligned} \Pr[\text{Sample}(i, r) \in A] &= \Pr \left[\bigvee_{a \in A} \text{Sample}(i, r) = a \right] = \sum_{a \in A} \Pr[\text{Sample}(i, r) = a] = \\ &= \sum_{a \in A} w(\{a\}) = \|A\| \end{aligned} \quad \blacktriangleleft$$

B Proofs of Bounds on the Norm

Proof of Lemma 10. First consider how a single face behaves under Γ^j :

$$\begin{aligned}
\forall a \in X(i) : \|\Gamma^j(\{a\})\| &= \sum_{\substack{b \in X(j) \\ a \subseteq b}} w(b) = \sum_{\substack{b \in X(j) \\ a \subseteq b}} \frac{|\{q \in X(d) | b \subseteq q\}|}{\binom{d+1}{|b|} \cdot |X(d)|} \\
&= \sum_{\substack{b \in X(j) \\ a \subseteq b}} \sum_{\substack{q \in X(d) \\ b \subseteq q}} \frac{1}{\binom{d+1}{|j+1|} \cdot |X(d)|} = \sum_{\substack{q \in X(d) \\ a \subseteq q}} \sum_{\substack{b \in X(j) \\ a \subseteq b \subseteq q}} \frac{1}{\binom{d+1}{|j+1|} \cdot |X(d)|} \\
&= \sum_{\substack{q \in X(d) \\ a \subseteq q}} \frac{\binom{d-i}{|j-i|}}{\binom{d+1}{|j+1|} \cdot |X(d)|} = \frac{\binom{d-i}{|j-i|} \cdot |\{q \in X(d) | a \subseteq q\}|}{\binom{d+1}{|j+1|} \cdot |X(d)|} = \frac{\binom{d-i}{|j-i|} \cdot \binom{d+1}{|i+1|}}{\binom{d+1}{|j+1|}} w(\{a\}) \\
&= \binom{j+1}{i+1} w(\{a\})
\end{aligned}$$

Note that the last equation holds because:

$$\frac{\binom{d-i}{|j-i|} \cdot \binom{d+1}{|i+1|}}{\binom{d+1}{|j+1|}} = \frac{\binom{d+1}{|d-j|} \binom{d-i}{|i+1|} \binom{d-i}{|d-i|}}{\binom{d+1}{|d-j|} \binom{d+1}{|j+1|}} = \frac{(j+1)!}{(j-i)!(i+1)!} = \binom{j+1}{i+1}$$

Now one can easily check that:

$$\begin{aligned}
\forall A \subseteq X(i) : \|\Gamma^j(A)\| &= \left\| \bigcup_{a \in A} \Gamma^j(\{a\}) \right\| \leq \sum_{a \in A} \|\Gamma^j(\{a\})\| = \sum_{a \in A} \binom{j+1}{i+1} w(\{a\}) \\
&= \binom{j+1}{i+1} \sum_{a \in A} w(\{a\}) = \binom{j+1}{i+1} \|A\|
\end{aligned}$$

The other direction can be achieved by looking at the algorithm presented in Lemma 51: Consider the set of values M_i^r defined in definition 50. Note that for every co-chain A : If $M_{i+1}^r \in A$ then $M_{j+1}^r \in \Gamma^j(A)$ (because $M_{i+1}^r \subseteq M_{j+1}^r$). Now we can see that:

$$\begin{aligned}
\forall A \subseteq X(i) : \|A\| &= \Pr[\text{Sample}(i, r) \in A] = \Pr[M_{i+1}^r \in A] \leq \Pr[M_{j+1}^r \in \Gamma^j(A)] \\
&= \Pr[\text{Sample}(j, r) \in \Gamma^j(A)] = \|\Gamma^j(A)\| \quad \blacktriangleleft
\end{aligned}$$

Proof of Lemma 11. First denote $U = \left\{ A' \in X(i+j) \mid \binom{A'}{i} \subseteq A \right\}$ and let M_i^r be the values defined in definition 50. Due to Lemma 51 we know that:

$$\begin{aligned}
\|A\| &= \Pr[\text{Sample}(i, r) \in A] = \Pr[M_{i+1}^r \in A] = \\
&\Pr[M_{i+1}^r \in A | M_{i+j}^r \in U] \cdot \Pr[M_{i+j}^r \in U] + \\
&\Pr[M_{i+1}^r \in A | M_{i+j}^r \notin U] \cdot \Pr[M_{i+j}^r \notin U] \geq \\
&\Pr[M_{i+1}^r \in A | M_{i+j}^r \in U] \cdot \Pr[M_{i+j}^r \in U] = \\
&\Pr[M_{i+j}^r \in U] = \Pr[\text{Sample}(i+j, r) \in U] = \|U\| \quad \blacktriangleleft
\end{aligned}$$

C Direct Sum Separators

In this section we will provide two direct sum separators: One using reconstructing the origin-function of F , and the other using a test for being a k -direct-sum. The first method provided here yields a separator that separates a k -direct-sum from other functions with probability 1. The other method, allows reducing the query complexity while increasing the error margin.

C.1 Direct Sum Separator Using Reconstruction

In this section we will provide a simple direct sum separator that, given F , attempts to reconstruct the origin function of F and accepts whenever it succeeds.

► **Lemma 52.** *Let X_{k+2} be a complete simplicial complex on $k+2$ nodes and $F : X_{k+2}(k-1) \rightarrow \{0, 1\}$. Define f to be a function that, given $v \in X_{k+2}(0)$, picks a $q \in X_{k+2}(k-1)$ such that $v \notin q$ and returns $\sum_{w \in \binom{q}{k-1}} F(w \cup \{v\})$. We will show that: F is a k -direct-sum $\Leftrightarrow f$ is an origin function of F .*

Proof. \Rightarrow F is a k -direct-sum therefore there exists an origin function to F denoted by f' .

$$\begin{aligned} \forall q : f(v) &= \sum_{w \in \binom{q}{k-1}} F(w \cup \{v\}) = \sum_{w \in \binom{q}{k-1}} \left(f'(v) + \sum_{v' \in w} f'(v') \right) = \\ &= \binom{k}{k-1} f'(v) + \sum_{v' \in q} \binom{k-1}{k-2} f'(v') = k \cdot f'(v) + \sum_{v' \in q} (k-1) \cdot f'(v') = f'(v) \end{aligned}$$

And therefore f is an origin function of F .

\Leftarrow F has an origin function and therefore it is a k -direct-sum. ◀

This lemma allows us to create the following $(k+2, k, \binom{k+2}{k}, 1)$ -separator:

► **Lemma 53** (Direct Sum Separator for Odd Values of k). *The following is a $(k+2, k, \binom{k+2}{k}, 1)$ -direct-sum-separator (given a function $F \in C^k(X)$ on a simplicial complex X):*

■ **Algorithm 5** T_{sep} .

```

1 foreach node  $v \in X(0)$  do
2   | Calculate  $f(v)$ .
3 end
4 foreach face  $q \in X(k)$  do
5   | Check whether  $F(q) = \sum_{e \in q} f(e)$ , if it is not return 0.
6 end
7 Return 1

```

Proof. The algorithm returns 1 $\Leftrightarrow F$ is a k -direct-sum on X due to Lemma 52.

It is easy to see that the separator queries the entire function (Therefore it uses $\binom{k+2}{k}$ queries). ◀

C.2 Obtaining a Direct Sum Separator From Test

In this section we will show how to construct a separator out of a test for the k -direct-sums over a $k+1$ dimensional complex. This will help reduce query complexity.

► **Lemma 54** (Separator from Test). *If there is a (Q, E) -test (denoted by T) for being a k -direct-sum on a $k+1$ dimensional complex then there is a $(k+2, k, Q, \rho)$ -direct-sum-separator such that $\rho = \min_{F \in C^{k-1}(X) \setminus \{k\text{-direct-sums}\}} \{Pr[T_X^G = 0]\}$ where X is the complete $(k+1)$ -dimensional complex.*

Proof. Consider the following tester:

50:20 Testing Odd Direct Sums Using High Dimensional Expanders

■ **Algorithm 6** T'_{sep} .

1 Run T on F and return its output.

It is easy to see that the algorithm queries F exactly Q times. All we have to prove is that if F is not a k -direct-sum then the algorithm returns false with probability of at least ρ . $F \in C^{k-1}(X) \setminus \{k\text{-direct-sums}\}$ and therefore:

$$Pr[T_X^G = 0] \geq \min_{G \in C^{k-1}(X) \setminus \{k\text{-direct-sums}\}} \{Pr[T_X^G = 0]\} = \rho$$

Note that $\rho > 0$ because if $\rho = 0$ then there would exist a function F' such that $F' \in C^{k-1}(X) \setminus \{k\text{-direct-sums}\}$ and $Pr[T_X^{F'} = 0] = 0$. Note that T is a test and therefore if $Pr[T_X^{F'} = 0] = 0$ then F' is a k -direct-sum which contradicts the assumption about F' . ◀

Lastly, we can prove corollary 35:

Proof of Corollary 35. Combining the second test provided in [4] and Lemma 54 we get a $(k + 2, k, O(k), \rho)$ -separator. From the first test provided in [4] and Lemma 49 we get a $(3k + 3, E')$ -test for being a k -co-cycle-indifferent-direct-sum. Combining both of these results with Theorem 37 yields the desired result. ◀

A Lower Bound for Sampling Disjoint Sets

Abstract

Suppose Alice and Bob each start with private randomness and no other input, and they wish to engage in a protocol in which Alice ends up with a set $x \subseteq [n]$ and Bob ends up with a set $y \subseteq [n]$, such that (x, y) is uniformly distributed over all pairs of disjoint sets. We prove that for some constant $\beta < 1$, this requires $\Omega(n)$ communication even to get within statistical distance $1 - \beta^n$ of the target distribution. Previously, Ambainis, Schulman, Ta-Shma, Vazirani, and Wigderson (FOCS 1998) proved that $\Omega(\sqrt{n})$ communication is required to get within some constant statistical distance $\varepsilon > 0$ of the uniform distribution over all pairs of disjoint sets of size \sqrt{n} .

1 Introduction

In most traditional computational problems, the goal is to take an input and produce the “correct” output, or produce one of a set of acceptable outputs. In a *sampling* problem, on the other hand, the goal is to generate a random sample from a specified probability distribution D , or at least from a distribution that is close to D . There has been a surge of interest in studying sampling problems from a complexity theory perspective [7, 36, 73, 1, 58, 32, 74, 13, 72, 47, 77, 15, 78, 75, 79, 76]. Unlike more traditional computational problems, sampling problems do not necessarily need to have any real input, besides the uniformly random bits fed into a sampling algorithm.

One commonly studied type of target distribution is “input–output pairs” of a function f , i.e., $(D, f(D))$ where D is perhaps the uniform distribution over inputs to f . Using an algorithm for computing f , one can sample $(D, f(D))$ by first sampling from D , then evaluating f on that input. However, for some functions f , generating an input jointly with the corresponding output may be computationally easier than evaluating f on an adversarially-chosen input. Thus in general, sampling lower bounds tend to be more challenging to prove than lower bounds for functions.

Many of the above-cited works focus on concrete computational models such as low-depth circuits. We consider the model of 2-party communication complexity, for which comparatively less is known about sampling. Which problem should we study? Well, the single most important function in communication complexity is Set-Disjointness, in which Alice gets a set

$x \subseteq [n]$, Bob gets a set $y \subseteq [n]$, and the goal is to determine whether $x \cap y = \emptyset$. Identifying the sets with their characteristic bit strings, this can be viewed as $\text{DISJ}: \{0, 1\}^n \times \{0, 1\}^n \rightarrow \{0, 1\}$ where $\text{DISJ}(x, y) = 1$ iff $x \wedge y = 0^n$. The applications of communication bounds for Set-Disjointness are far too numerous to list, but they span areas such as streaming, circuit complexity, proof complexity, data structures, property testing, combinatorial optimization, fine-grained complexity, cryptography, and game theory. Because of its central role, Set-Disjointness has become the de facto testbed for proving new types of communication bounds. This function has been studied in the contexts of randomized [9, 49, 62, 10, 17] and quantum [25, 43, 63, 2, 66, 70] protocols; multi-party number-in-hand [6, 10, 27, 41, 48, 18, 22] and number-on-forehead [40, 71, 12, 66, 28, 57, 11, 69, 68, 61, 60] models; Merlin–Arthur and related models [50, 3, 35, 39, 38, 4, 64, 29]; with a bounded number of rounds of interaction [52, 46, 80, 19, 23]; with bounds on the sizes of the sets [42, 56, 59, 31, 26, 65]; very precise relationships between communication and error probability [20, 21, 39, 33, 30]; when the goal is to find the intersection [24, 34, 79, 8]; in space-bounded, online, and streaming models [53, 16, 5]; and direct product theorems [54, 12, 14, 45, 51, 67, 69, 68]. We contribute one more result to this thorough assault on Set-Disjointness.

Here is the definition of our 2-party sampling model: Let D be a probability distribution over $\{0, 1\}^n \times \{0, 1\}^n$; we also think of D as a matrix with rows and columns both indexed by $\{0, 1\}^n$ where $D_{x,y}$ is the probability of outcome (x, y) . We define $\text{Samp}(D)$ as the minimum communication cost of any protocol where Alice and Bob each start with private randomness and no other input, and at the end Alice outputs some $x \in \{0, 1\}^n$ and Bob outputs some $y \in \{0, 1\}^n$ such that (x, y) is distributed according to D . Note that $\text{Samp}(D) = 0$ iff D is a product distribution (x and y are independent), and $\text{Samp}(D) \leq n$ for all D (since Alice can privately sample (x, y) and send y to Bob). Allowing public randomness would not make sense since Alice and Bob could read a properly-distributed (x, y) off of the randomness without communicating. We define $\text{Samp}_\varepsilon(D)$ as the minimum of $\text{Samp}(D')$ over all distributions D' with $\Delta(D, D') \leq \varepsilon$, where Δ denotes statistical (total variation) distance, defined as

$$\Delta(D, D') := \max_{\text{event } E} |\mathbb{P}_D[E] - \mathbb{P}_{D'}[E]| = \max_{\text{event } E} (\mathbb{P}_D[E] - \mathbb{P}_{D'}[E]) = \frac{1}{2} \sum_{\text{outcome } o} |\mathbb{P}_D[o] - \mathbb{P}_{D'}[o]|.$$

1.1 A story

Our story begins with [7], which proved that $\text{Samp}_\varepsilon((D, \text{DISJ}(D))) \geq \Omega(\sqrt{n})$ for some constant $\varepsilon > 0$, where D is uniform over the set of all pairs of sets of size \sqrt{n} (note that this D is a product distribution and is approximately balanced between 0-inputs and 1-inputs of DISJ); here it does not matter which party is responsible for outputting the bit $\text{DISJ}(D)$. The main tool in the proof was a lemma that was originally employed in [9] to prove an $\Omega(\sqrt{n})$ bound on the randomized communication complexity of *computing* DISJ . The latter bound was improved to $\Omega(n)$ via several different proofs [49, 62, 10], which leads to a natural question: Can we improve the sampling bound of [7] to $\Omega(n)$ by using the techniques of [49, 62, 10] instead of [9]?

For starters, the answer is “no” for the particular D considered in [7] – there is a trivial exact protocol with $O(\sqrt{n} \log n)$ communication since it only takes that many bits to specify a set of size \sqrt{n} . What about other interesting distributions D ? The following illuminates the situation.

▷ **Observation 1.** For any D and constants $\varepsilon > \delta > 0$, if $\text{Samp}_\varepsilon((D, \text{DISJ}(D))) \geq \omega(\sqrt{n})$ then $\text{Samp}_\delta(D) \geq \Omega(\text{Samp}_\varepsilon((D, \text{DISJ}(D))))$.

Proof. It suffices to show $\text{Samp}_\varepsilon((D, \text{DISJ}(D))) \leq \text{Samp}_\delta(D) + O(\sqrt{n})$. First, note that for any sampling protocol, if we condition on a particular transcript then the output distribution becomes product (Alice and Bob are independent after they stop communicating). Second, [17] proved that for every product distribution and every constant $\gamma > 0$, there exists a deterministic protocol that uses $O(\sqrt{n})$ bits of communication and computes DISJ with error probability $\leq \gamma$ on a random input from the distribution. Now to ε -sample $(D, \text{DISJ}(D))$, Alice and Bob can δ -sample D to obtain (x, y) , and then conditioned on that sampler's transcript, they can run the average-case protocol from [17] for the corresponding product distribution with error $\varepsilon - \delta$. A simple calculation shows this indeed gives statistical distance ε . \triangleleft

The upshot is that to get an improved bound, *the hardness of sampling $(D, \text{DISJ}(D))$ would come entirely from the hardness of just sampling D* . Thus such a result would not really be “about” the Set-Disjointness function, it would be about the distribution on inputs. Instead of abandoning this line of inquiry, we realize that if D itself is somehow defined in terms of DISJ , then a bound for sampling D would still be saying something about the complexity of Set-Disjointness. In fact, the proof in [7] actually shows something stronger than the previously-stated result: If D is instead defined as the uniform distribution over pairs of *disjoint* sets of size \sqrt{n} (which are 1-inputs of DISJ), then $\text{Samp}_\varepsilon(D) \geq \Omega(\sqrt{n})$. After this pivot, we are now facing a direction in which we can hope for an improvement. We prove that by removing the restriction on the sizes of the sets, the sampling problem becomes maximally hard. Our result holds for error $\varepsilon < 1$ that is exponentially close to 1, but the result is already new and interesting for constant $\varepsilon > 0$.

► **Theorem 1.** *Let U be the uniform distribution over the set of all $(x, y) \in \{0, 1\}^n \times \{0, 1\}^n$ with $x \wedge y = 0^n$. There exists a constant $\beta < 1$ such that $\text{Samp}_{1-\beta^n}(U) = \Omega(n)$.*

The proof from [7] was a relatively short application of the technique from [9], but for Theorem 1, harnessing known techniques for proving linear communication lower bounds turns out to be more involved.

For calibration, the uniform distribution over *all* (x, y) achieves statistical distance $1 - 0.75^n$ from U since there are 4^n inputs and 3^n disjoint inputs. We can do a little better: Suppose for each coordinate independently, Alice picks 0 with probability $\sqrt{1/3}$ and picks 1 with probability $1 - \sqrt{1/3}$, and Bob does the same. This again involves no communication, and it achieves statistical distance $1 - (2\sqrt{1/3} - 1/3)^n \leq 1 - 0.82^n$ from U . Theorem 1 shows that the constant 0.82 cannot be improved arbitrarily close to 1 without a lot of communication. (In the setting of lower bounds for circuit samplers, significant effort has gone into handling statistical distances exponentially close to the maximum possible [32, 13, 76].)

1.2 Interpreting the result

We first observe that our sampling model is equivalent to two other models. One of these we call (for lack of a better word) “synthesizing” the distribution D : Alice and Bob get inputs $x, y \in \{0, 1\}^n$ respectively, in addition to their private randomness, and their goal is to accept with probability exactly $D_{x,y}$. We let $\text{Synth}(D)$ denote the minimum communication cost of any synthesizing protocol for D , and $\text{Synth}_\varepsilon(D)$ denote the minimum of $\text{Synth}(D')$ over all D' with $\Delta(D, D') \leq \varepsilon$. The other model is the nonnegative rank of a matrix: $\text{rank}_+(D)$ is defined as the minimum k for which D can be written as a sum of k many nonnegative rank-1 matrices.

▷ Observation 2. For every distribution D , the following are all within $\pm O(1)$ of each other:

$$\text{Samp}(D), \quad \text{Synth}(D), \quad \log \text{rank}_+(D).$$

Proof. $\text{Synth}(D) \leq \text{Samp}(D) + 2$ since a synthesizing protocol can just run a sampling protocol and accept iff the result equals the given input (x, y) .

$\log \text{rank}_+(D) \leq \text{Synth}(D)$ since for each transcript of a synthesizing protocol, the matrix that records the probability of getting that transcript on each particular input has rank 1; summing these matrices over all accepting transcripts yields a nonnegative rank decomposition of D .

To see that $\text{Samp}(D) \leq \lceil \log \text{rank}_+(D) \rceil$, suppose $D = M^{(1)} + M^{(2)} + \dots + M^{(k)}$ is a sum of nonnegative rank-1 matrices. For each i , by scaling we can write $M_{x,y}^{(i)} = p_i u_x^{(i)} v_y^{(i)}$ for some distributions $u^{(i)}$ and $v^{(i)}$ over $\{0, 1\}^n$, where p_i is the sum of all entries of $M^{(i)}$. Since D is a distribution, $p := (p_1, \dots, p_k)$ is a distribution over $[k]$. To sample from D , Alice can privately sample $i \sim p$ and send it to Bob using $\lceil \log k \rceil$ bits, then Alice can sample $x \sim u^{(i)}$ and Bob can independently sample $y \sim v^{(i)}$ with no further communication. ◁

By this characterization, Theorem 1 can be viewed as a lower bound on the approximate nonnegative rank of the DISJ matrix, where the approximation is in ℓ_1 (which has an average-case flavor). In the recent literature, “approximate nonnegative rank” generally refers to approximation in ℓ_∞ (which is a worst-case requirement), and this model is equivalent to the so-called smooth rectangle bound and WAPP communication complexity [44, 55, 37].

2 Proof

2.1 Overview

Our proof of Theorem 1 is by a black-box reduction to the well-known *corruption lemma* for Set-Disjointness due to Razborov [62]. We start with a high-level overview.

For notation: Let $|z|$ denote the Hamming weight of a string $z \in \{0, 1\}^n$. For $\ell \in \mathbb{N}$, let U^ℓ be the uniform distribution over all $(x, y) \in \{0, 1\}^n \times \{0, 1\}^n$ with $|x \wedge y| = \ell$. Note that $U = U^0$. For a distribution D over $\{0, 1\}^n \times \{0, 1\}^n$ and an event $E \subseteq \{0, 1\}^n \times \{0, 1\}^n$, let $D_E := \sum_{(x,y) \in E} D_{x,y}$. For a randomized protocol Π , let $\text{acc}_\Pi(x, y)$ denote the probability that Π accepts (x, y) .

Step I: Uniform corruption

The corruption lemma states that if a rectangle $R \subseteq \{0, 1\}^n \times \{0, 1\}^n$ contains a noticeable fraction of *disjoint* pairs, then it must contain about as large a fraction of *uniquely intersecting* pairs. More quantitatively, there exist a constant $C > 0$ and two distributions D^ℓ , $\ell = 0, 1$, defined over disjoint ($\ell = 0$) and uniquely intersecting pairs ($\ell = 1$) such that for every rectangle R ,

$$\text{if } D_R^0 \geq 2^{-o(n)} \quad \text{then } D_R^1 \geq C \cdot D_R^0.$$

The original proof [62] defined D^ℓ as the uniform distribution over all pairs (x, y) with fixed sizes $|x| = |y| = \lceil n/4 \rceil$ and $|x \wedge y| = \ell$. For our purpose, we need the corruption lemma to hold relative to the aforementioned distributions U^ℓ , $\ell = 0, 1$, which have no restrictions on set sizes. We derive in Subsection 2.2 a corruption lemma for U^ℓ from the original lemma for D^ℓ . To do this, we exhibit a reduction that uses public randomness and no communication to transform a sample from D^ℓ into a sample from a distribution that is close to U^ℓ in a suitable sense, for $\ell = 0, 1$.

Step II: Truncate and scale

For simplicity, let us think about proving Theorem 1 for a small error $\varepsilon > 0$. Assume for contradiction there is some distribution D , $\Delta(U, D) \leq \varepsilon$, such that $\text{Synth}(D) \leq o(n)$ as witnessed by a private-randomness synthesizing protocol Π' with $\text{acc}_{\Pi'}(x, y) = D_{x, y}$. Note that the total acceptance probability over disjoint inputs is close to 1:

$$\sum_{x, y: |x \wedge y| = 0} \text{acc}_{\Pi'}(x, y) \geq 1 - \varepsilon \quad \text{and thus} \quad \mathbb{E}_{(x, y) \sim U^0} [\text{acc}_{\Pi'}(x, y)] \geq (1 - \varepsilon)3^{-n}.$$

Our eventual goal (in Step III) is to apply our corruption lemma to the transcript rectangles, but the above threshold $(1 - \varepsilon)3^{-n}$ is too low for this. To raise the threshold to $2^{-o(n)}$ as needed for corruption, we would like to scale up all the acceptance probabilities accordingly. To “make room” for the scaling, we first carry out a certain truncation step. Specifically, in Subsection 2.3 we transform Π' into a public-randomness protocol Π :

1. First, we **truncate** (using a *truncation lemma* [37]) the values $\text{acc}_{\Pi'}(x, y)$, which has the effect of decreasing some of them, but any $\text{acc}_{\Pi'}(x, y)$ that is under 3^{-n} remains approximately the same. This results in an intermediate protocol Π'' that still satisfies $\mathbb{E}_{(x, y) \sim U^0} [\text{acc}_{\Pi''}(x, y)] \geq \Omega((1 - \varepsilon)3^{-n})$ (using the assumption that $\Delta(U, D) \leq \varepsilon$).
2. Second, we **scale** (using the low cost of Π'') the truncated probabilities up by a large factor $3^n 2^{-o(n)}$. This results in a protocol Π with large typical acceptance probabilities:

$$\mathbb{E}_{(x, y) \sim U^0} [\text{acc}_{\Pi}(x, y)] \geq 2^{-o(n)}. \tag{1}$$

Step III: Iterate corruption

Because Π has such large acceptance probabilities (Equation 1), our corruption lemma can be applied: there is some constant $C' > 0$ such that

$$\mathbb{E}_{(x, y) \sim U^1} [\text{acc}_{\Pi}(x, y)] \geq C' \cdot \mathbb{E}_{(x, y) \sim U^0} [\text{acc}_{\Pi}(x, y)]. \tag{2}$$

Since Π is a truncated-and-scaled version of Π' , this allows us to infer that

$$\mathbb{E}_{(x, y) \sim U^1} [\text{acc}_{\Pi'}(x, y)] \geq \Omega((1 - \varepsilon)3^{-n}) \quad \text{and thus} \quad \sum_{x, y: |x \wedge y| = 1} \text{acc}_{\Pi'}(x, y) \geq \Omega((1 - \varepsilon)n)$$

using the fact that $|\text{supp}(U^1)| = n3^{n-1} = (n/3) \cdot |\text{supp}(U^0)|$. Thus for $\varepsilon = 1 - \omega(1/n)$, this means Π' must have placed a total probability mass > 1 on uniquely intersecting inputs, which is the sought contradiction.

To prove Theorem 1 for very large error $\varepsilon = 1 - \beta^n$, in Subsection 2.4 we iterate the above argument for U^ℓ over $0 \leq \ell \leq o(n)$. Namely, analogously to Equation 2, we show that the average acceptance probability of Π over $U^{\ell+1}$ is at least a constant times the average over U^ℓ . Meanwhile, the support sizes increase as $|\text{supp}(U^{\ell+1})| \geq \omega(1) \cdot |\text{supp}(U^\ell)|$ for $\ell \leq o(n)$. These facts together imply a large constant factor increase in the total probability mass that Π' places on $\text{supp}(U^{\ell+1})$ as compared to $\text{supp}(U^\ell)$. Starting with even a tiny probability mass over $\text{supp}(U^0)$, this iteration will eventually lead to a contradiction.

2.2 Step I: Uniform corruption

The goal of this step is to derive Lemma 3 from Lemma 2.

► **Lemma 2** (Corruption [62]). *For every rectangle $R \subseteq \{0, 1\}^n \times \{0, 1\}^n$ we have $D_R^1 \geq \frac{1}{45} D_R^0 - 2^{-0.017n}$ where, assuming $n = 4k - 1$, D^ℓ is the uniform distribution over all (x, y) with $|x| = |y| = k$ and $|x \wedge y| = \ell$.*

► **Lemma 3** (Uniform Corruption). *For every rectangle $R \subseteq \{0, 1\}^n \times \{0, 1\}^n$ we have $U_R^1 \geq \frac{1}{765}U_R^0 - 2^{-0.008n}$.*

Proof. Assume for convenience that $n/2$ has the form $4k - 1$ (otherwise use the nearest such number instead of $n/2$ throughout). We prove that Lemma 2 for $n/2$ implies Lemma 3 for n by the contrapositive. Thus, D^0 and D^1 are distributions over $\{0, 1\}^{n/2} \times \{0, 1\}^{n/2}$ while U^0 and U^1 are distributions over $\{0, 1\}^n \times \{0, 1\}^n$. Assume there exists a rectangle $R \subseteq \{0, 1\}^n \times \{0, 1\}^n$ such that $U_R^1 < \frac{1}{765}U_R^0 - 2^{-0.008n}$. We exhibit a distribution over rectangles $Q \subseteq \{0, 1\}^{n/2} \times \{0, 1\}^{n/2}$ such that $\mathbb{E}[D_Q^1] < \frac{1}{45}\mathbb{E}[D_Q^0] - 2^{-0.017n/2}$; by linearity of expectation this implies that there exists such a Q with $D_Q^1 < \frac{1}{45}D_Q^0 - 2^{-0.017n/2}$.

To this end, we define a distribution F over functions $f: \{0, 1\}^{n/2} \times \{0, 1\}^{n/2} \rightarrow \{0, 1\}^n \times \{0, 1\}^n$ of the form $f(x, y) = (f_1(x), f_2(y))$ and then let Q_f be the rectangle $f^{-1}(R) := \{(x, y) : f(x, y) \in R\}$. Let H be the distribution over $\{(v, w) \in \mathbb{N} \times \mathbb{N} : v + w \leq n\}$ obtained by sampling $(x, y) \sim U^0$ and outputting $(|x|, |y|)$; i.e., $H_{v,w} := \frac{n!}{v!w!(n-v-w)!} \cdot 3^{-n}$. To sample $f \sim F$:

1. Sample (v, w) from H conditioned on $v \geq k$, $w \geq k$, and $v + w \leq 2k + n/2$.
2. Sample a uniformly random permutation π of $[n]$.
3. Given $(x, y) \in \{0, 1\}^{n/2} \times \{0, 1\}^{n/2}$, define $(x', y') \in \{0, 1\}^n \times \{0, 1\}^n$ by letting

$$x'_i y'_i := \begin{cases} x_i y_i & \text{for the first } n/2 \text{ coordinates } i; \\ 10 & \text{for the next } v - k \text{ coordinates } i; \\ 01 & \text{for the next } w - k \text{ coordinates } i; \\ 00 & \text{for the remaining } n/2 - (v - k) - (w - k) \geq 0 \text{ coordinates } i. \end{cases}$$

4. Let $f(x, y) := (\pi(x'), \pi(y'))$ (i.e., permute the coordinates according to π).

For $\ell \in \{0, 1\}$ let $F(D^\ell)$ denote the distribution obtained by sampling $(x, y) \sim D^\ell$ and $f \sim F$ and outputting $f(x, y)$, and note that $F(D^\ell)_R = \mathbb{E}_F[D_{Q_f}^\ell]$. Now we claim that $F(D^\ell)$ and U^ℓ are close, in the following senses:

- (1) For every event E , $F(D^0)_E \geq U_E^0 - 2^{-0.01n}$.
- (2) For every event E , $F(D^1)_E \leq U_E^1 \cdot 17$.

Using R as the event E , we have

$$\begin{aligned} F(D^1)_R &\leq U_R^1 \cdot 17 \\ &< 17\left(\frac{1}{765}U_R^0 - 2^{-0.008n}\right) \\ &\leq 17\left(\frac{1}{765}(F(D^0)_R + 2^{-0.01n}) - 2^{-0.008n}\right) \\ &\leq \frac{1}{45}F(D^0)_R - 2^{-0.017n/2} \end{aligned}$$

as desired. To see (1), note that $F(D^0)$ is precisely U^0 conditioned on $v \geq k$, $w \geq k$, and $v + w \leq 2k + n/2$, and this conditioning event has probability $\geq 1 - 2^{-0.01n}$ by Chernoff bounds:

$$\begin{aligned} \mathbb{P}[v < k] &= \mathbb{P}[w < k] = \mathbb{P}[\text{Bin}(n, 1/3) < n/8 + 1/4] \leq 2^{-0.12n} \\ \mathbb{P}[v + w > 2k + n/2] &= \mathbb{P}[\text{Bin}(n, 2/3) > 3n/4 + 1/2] \leq 2^{-0.02n} \end{aligned}$$

Thus letting C be the complement of the conditioning event, we have $F(D^0)_E \geq U_{E \setminus C}^0 \geq U_E^0 - U_C^0 \geq U_E^0 - 2^{-0.01n}$. To see (2), consider any outcome $(x, y) \in \{0, 1\}^n \times \{0, 1\}^n$ with $|x \wedge y| = 1$. We have $U_{x,y}^1 = 1/(n3^{n-1})$. Abbreviating $a := |x|$ and $b := |y|$, assume $a \geq k$, $b \geq k$, and $a + b \leq 2k + n/2$ since otherwise $F(D^1)_{x,y} = 0$ and there would be nothing to prove. Henceforth consider the probability space with the randomness of D^1 and of F . Let I be the event that $F_1(D^1) \wedge F_2(D^1) = x \wedge y$, i.e., that the intersecting coordinate of $F(D^1)$ is the same as for (x, y) . We have

$$F(D^1)_{x,y} = \underbrace{\mathbb{P}[I]}_{(*)} \cdot \underbrace{\mathbb{P}[v = a \text{ and } w = b]}_{(**)} \cdot \underbrace{\mathbb{P}[F(D^1) = (x, y) \mid I \text{ and } v = a \text{ and } w = b]}_{(***)}.$$

For the three terms on the right side, we have

$$(*) = \frac{1}{n}, \quad (**) \leq H_{a,b}/(1-2^{-0.01n}) \leq \frac{n!}{a!b!(n-a-b)!} \cdot 3^{-n} \cdot 1.01, \quad (***) = 1/\frac{(n-1)!}{(a-1)!(b-1)!(n-a-b+1)!}.$$

We have

$$\frac{n!}{a!b!(n-a-b)!} / \frac{(n-1)!}{(a-1)!(b-1)!(n-a-b+1)!} = \frac{n \cdot (n-a-b+1)}{a \cdot b} \leq \frac{n \cdot (n-2k+1)}{k \cdot k} \leq \frac{n \cdot (n-2n/8+1)}{(n/8) \cdot (n/8)} = \left(\frac{3}{4} + \frac{1}{n}\right) \cdot 64.$$

Combining, we get

$$F(D^1)_{x,y} / U_{x,y}^1 = (*) \cdot (**) \cdot (***) \cdot n3^{n-1} \leq \frac{1.01}{3} \cdot \left(\frac{3}{4} + \frac{1}{n}\right) \cdot 64 \leq 17. \quad \blacktriangleleft$$

2.3 Step II: Truncate and scale

The goal of this step is to construct a truncated-and-scaled protocol Π from any given low-cost Π' that synthesizes a distribution close to U .

For a nonnegative matrix M , we define its *truncation* \bar{M} to be the same matrix but where each entry > 1 is replaced with 1.

► **Lemma 4** (Truncation Lemma [37]). *For every $2^n \times 2^n$ nonnegative rank-1 matrix M and every d there exists a $O(d + \log n)$ -communication public-randomness protocol Π such that for every (x, y) we have $\text{acc}_\Pi(x, y) \in \bar{M}_{x,y} \pm 2^{-d}$.*

Let $c \geq 1$ be the hidden constant in the big O in Lemma 4, and let $\delta := 0.00005/c$. Toward proving Theorem 1, suppose for contradiction $\text{Samp}(D) \leq \delta n$ for some distribution D with $\Delta(U, D) \leq 1 - 2^{-\delta n}$ (so $\beta := 2^{-\delta}$ in Theorem 1) and thus $\sum_{x,y: |x \wedge y|=0} \min(3^{-n}, D_{x,y}) \geq 2^{-\delta n}$. By Observation 2, $\text{Synth}(D) \leq \delta n + 2$, so consider a synthesizing protocol Π' for D with communication cost $\leq \delta n + 2$. Let A be the set of all accepting transcripts of Π' . For each $\tau \in A$ let N^τ be the nonnegative rank-1 matrix such that $N_{x,y}^\tau$ is the probability Π' generates τ on input (x, y) ; thus $D_{x,y} = \sum_{\tau \in A} N_{x,y}^\tau$. Let Π^τ be the public-randomness protocol from Lemma 4 applied to $M^\tau := 3^n N^\tau$ and $d := 15\delta n$. Let Π be the public-randomness protocol that picks a uniformly random $\tau \in A$ and then runs Π^τ . The communication cost of Π is $\leq c \cdot (d + \log n) \leq 0.001n$.

▷ **Claim 5.** For every input (x, y) we have $\frac{3^n}{|A|} \min(3^{-n}, D_{x,y}) - 2^{-d} \leq \text{acc}_\Pi(x, y) \leq \frac{3^n}{|A|} D_{x,y} + 2^{-d}$.

Proof. We have

$$\begin{aligned} \text{acc}_\Pi(x, y) &= \frac{1}{|A|} \sum_{\tau \in A} \text{acc}_{\Pi^\tau}(x, y) \\ &\in \frac{1}{|A|} \sum_{\tau \in A} (\bar{M}_{x,y}^\tau \pm 2^{-d}) \\ &\subseteq \frac{1}{|A|} \sum_{\tau \in A} \min(1, 3^n N_{x,y}^\tau) \pm 2^{-d} \\ &= \frac{3^n}{|A|} \sum_{\tau \in A} \min(3^{-n}, N_{x,y}^\tau) \pm 2^{-d}. \end{aligned}$$

From this it follows that:

$$\begin{aligned} \text{acc}_\Pi(x, y) &\geq \frac{3^n}{|A|} \min(3^{-n}, \sum_{\tau \in A} N_{x,y}^\tau) - 2^{-d} = \frac{3^n}{|A|} \min(3^{-n}, D_{x,y}) - 2^{-d} \\ \text{acc}_\Pi(x, y) &\leq \frac{3^n}{|A|} \sum_{\tau \in A} N_{x,y}^\tau + 2^{-d} = \frac{3^n}{|A|} D_{x,y} + 2^{-d}. \quad \blacktriangleleft \end{aligned}$$

51:8 A Lower Bound for Sampling Disjoint Sets

We can now formally state the large typical acceptance probability property (Equation 1 from the overview): writing $U_\Pi := \mathbb{E}_{(x,y) \sim U}[\text{acc}_\Pi(x,y)]$ (and similarly for other input distributions),

$$\begin{aligned}
 U_\Pi &\geq \frac{1}{3^n} \sum_{x,y: |x \wedge y|=0} \left(\frac{3^n}{|A|} \min(3^{-n}, D_{x,y}) - 2^{-d} \right) && \text{(by Claim 5)} \\
 &= \frac{1}{|A|} \sum_{x,y: |x \wedge y|=0} \min(3^{-n}, D_{x,y}) - 2^{-d} \\
 &\geq \frac{1}{|A|} 2^{-\delta n} - 2^{-15\delta n} \\
 &\geq \frac{1}{|A|} 2^{-\delta n - 1} && (3)
 \end{aligned}$$

where the last line follows because $|A| \leq 2^{\delta n + 2}$ and $2^{-2\delta n - 2}$ is at least twice $2^{-15\delta n}$.

2.4 Step III: Iterate corruption

Here we derive the final contradiction: Π' places an acceptance probability mass exceeding 1 on $\text{supp}(U^{\delta n})$. This is achieved by iterating our corruption lemma, starting with Equation 3 as the base case.

For $z \in \{0,1\}^n$ let U^z be the uniform distribution over all $(x,y) \in \{0,1\}^n \times \{0,1\}^n$ with $x \wedge y = z$ (so U^ℓ is the uniform mixture of all U^z with $|z| = \ell$; in particular, $U^0 = U^{0^n}$), and if $|z| < n$ then let \widehat{U}^z be the uniform mixture of $U^{z'}$ over all z' that can be obtained from z by flipping a single 0 to 1 (so $U^{\ell+1}$ is the uniform mixture of all \widehat{U}^z with $|z| = \ell$; in particular, $U^1 = \widehat{U}^{0^n}$).

▷ **Claim 6.** For every $z \in \{0,1\}^n$ with $|z| \leq n/2$ we have $\widehat{U}_\Pi^z \geq \frac{1}{765} U_\Pi^z - 2^{-0.003n}$.

Proof. Since all relevant inputs (x,y) have $x_i y_i = 11$ for all i such that $z_i = 1$, we can ignore those coordinates and think of \widehat{U}^z and U^z as U^1 and U^0 respectively, but defined on the remaining $n - |z| \geq n/2$ coordinates (instead of on all n coordinates). Thus by Lemma 3, for every outcome of the public randomness of Π and every accepting transcript, say corresponding to rectangle R , we have $\widehat{U}_R^z \geq \frac{1}{765} U_R^z - 2^{-0.008n/2}$. Summing over all the (at most $2^{0.001n}$ many) accepting transcripts, and then taking the expectation over the public randomness, yields the claim since $2^{0.001n} \cdot 2^{-0.008n/2} \leq 2^{-0.003n}$. ◁

▷ **Claim 7.** For every $\ell = 0, \dots, \delta n$ we have $U_\Pi^\ell \geq \frac{1}{|A|} 2^{-\delta n - 1 - 11\ell}$.

Proof. We prove this by induction on ℓ . The base case $\ell = 0$ is Equation 3. For the inductive step, assume the claim is true for ℓ . Since $U^{\ell+1}$ and U^ℓ are the uniform mixtures of \widehat{U}^z and U^z respectively over all z with $|z| = \ell$ (so $U_\Pi^{\ell+1} = \mathbb{E}_z[\widehat{U}_\Pi^z]$ and $U_\Pi^\ell = \mathbb{E}_z[U_\Pi^z]$), by linearity of expectation Claim 6 implies

$$U_\Pi^{\ell+1} \geq \frac{1}{765} U_\Pi^\ell - 2^{-0.003n} \geq \frac{1}{|A|} 2^{-\delta n - 1 - 11\ell - \log_2(765)} - 2^{-0.003n} \geq \frac{1}{|A|} 2^{-\delta n - 1 - 11(\ell+1)}$$

where the last inequality follows because $|A| \leq 2^{\delta n + 2}$ and $2^{-\delta n - 2 - \delta n - 1 - 11\delta n - \log_2(765)} \geq 2^{-14\delta n}$ is at least twice $2^{-0.003n}$, which gives $U_\Pi^{\ell+1} \geq \frac{1}{|A|} 2^{-\delta n - 1 - 11\ell - \log_2(765) - 1}$, and $\log_2(765) + 1 \leq 11$. ◁

Choosing $\ell = \delta n$ we have

$$U_\Pi^\ell - 2^{-d} \geq \frac{1}{|A|} 2^{-\delta n - 1 - 11\ell} - 2^{-15\delta n} \geq \frac{1}{|A|} 2^{-\delta n - 2 - 11\ell} \quad (4)$$

because $|A| \leq 2^{\delta n + 2}$ and $2^{-\delta n - 2 - \delta n - 1 - 11\delta n} \geq 2^{-14\delta n}$ is at least twice $2^{-15\delta n}$. Thus, for $\ell = \delta n$,

$$\begin{aligned}
\sum_{x,y} D_{x,y} &\geq \sum_{x,y:|x\wedge y|=\ell} D_{x,y} \\
&\geq \sum_{x,y:|x\wedge y|=\ell} \frac{|A|}{3^n} (\text{acc}_\Pi(x,y) - 2^{-d}) && \text{(by Claim 5)} \\
&= \frac{|A|}{3^n} \binom{n}{\ell} 3^{n-\ell} (U_\Pi^\ell - 2^{-d}) \\
&\geq \frac{|A|}{3^n} \binom{n}{\ell}^\ell 3^{n-\ell} \frac{1}{|A|} 2^{-\delta n - 2 - 11\ell} && \text{(using Equation 4)} \\
&= \left(\frac{n}{\ell \cdot 3 \cdot 2^{11}}\right)^\ell 2^{-\delta n - 2} \\
&= \left(\frac{1}{\delta \cdot 3 \cdot 2^{11} \cdot 2}\right)^{\delta n} / 4 \\
&\geq 1.6^{\delta n} \\
&> 1,
\end{aligned}$$

contradicting the fact that D is a distribution.

Abstract

The *noise sensitivity* of a Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is one of its fundamental properties. For noise parameter δ , the noise sensitivity is denoted as $NS_\delta[f]$. This quantity is defined as follows: First, pick $x = (x_1, \dots, x_n)$ uniformly at random from $\{0, 1\}^n$, then pick z by flipping each x_i independently with probability δ . $NS_\delta[f]$ is defined to equal $\Pr[f(x) \neq f(z)]$. Much of the existing literature on noise sensitivity explores the following two directions: (1) Showing that functions with low noise-sensitivity are structured in certain ways. (2) Mathematically showing that certain classes of functions have low noise sensitivity. Combined, these two research directions show that certain classes of functions have low noise sensitivity and therefore have useful structure.

The fundamental importance of noise sensitivity, together with this wealth of structural results, motivates the algorithmic question of approximating $NS_\delta[f]$ given an oracle access to the function f . We show that the standard sampling approach is essentially optimal for general Boolean functions. Therefore, we focus on estimating the noise sensitivity of *monotone* functions, which form an important subclass of Boolean functions, since many functions of interest are either monotone or can be simply transformed into a monotone function (for example the class of *unate* functions consists of all the functions that can be made monotone by reorienting some of their coordinates [21]).

Specifically, we study the algorithmic problem of approximating $NS_\delta[f]$ for monotone f , given the promise that $NS_\delta[f] \geq 1/n^C$ for constant C , and for δ in the range $1/n \leq \delta \leq 1/2$. For such f and δ , we give a randomized algorithm performing $O\left(\frac{\min(1, \sqrt{n\delta} \log^{1.5} n)}{NS_\delta[f]} \text{poly}\left(\frac{1}{\epsilon}\right)\right)$ queries and approximating $NS_\delta[f]$ to within a multiplicative factor of $(1 \pm \epsilon)$. Given the same constraints on f and δ , we also prove a lower bound of $\Omega\left(\frac{\min(1, \sqrt{n\delta})}{NS_\delta[f] \cdot n^\xi}\right)$ on the query complexity of any algorithm that approximates $NS_\delta[f]$ to within any constant factor, where ξ can be any positive constant. Thus, our algorithm's query complexity is close to optimal in terms of its dependence on n .

We introduce a novel *descending-ascending view* of noise sensitivity, and use it as a central tool for the analysis of our algorithm. To prove lower bounds on query complexity, we develop a technique that reduces computational questions about query complexity to combinatorial questions about the existence of “thin” functions with certain properties. The existence of such “thin” functions is proved using the probabilistic method. These techniques also yield new lower bounds on the query complexity of approximating other fundamental properties of Boolean functions: the *total influence* and the *bias*.

1 Introduction

Noise sensitivity is a property of any Boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ defined as follows: First, pick $x = (x_1, \dots, x_n)$ uniformly at random from $\{0, 1\}^n$, then pick z by flipping each x_i independently with probability δ . Here δ , the noise parameter, is a given positive constant no greater than $1/2$ (and at least $1/n$ in the interesting cases). With the above distributions on x and z , the noise sensitivity of f , denoted as $NS_\delta[f]$, is defined as follows:

$$NS_\delta[f] \stackrel{\text{def}}{=} \Pr[f(x) \neq f(z)] \quad (1)$$

Noise sensitivity was first explicitly defined by Benjamini, Kalai and Schramm in [3], and has been the focus of multiple papers: e.g. [3, 7, 8, 10, 12, 17, 22]. It has been applied to learning theory [4, 7, 8, 9, 10, 11, 15], property testing [1, 2], hardness of approximation [13, 16], hardness amplification [19], combinatorics [3, 12], distributed computing [18] and differential privacy [7]. Multiple properties and applications of noise sensitivity are summarized in [20] and [21]. Much of the existing literature on noise sensitivity explores the following directions: (1) Showing that functions with low noise-sensitivity are structured in certain ways. (2) Mathematically showing that certain classes of functions have low noise sensitivity. Combined, these two research directions show that certain classes of functions have low noise sensitivity and therefore have useful structure.

The fundamental importance of noise sensitivity, together with this wealth of structural results, motivates the algorithmic question of approximating $NS_\delta[f]$ given an oracle access to the function f . It can be shown that standard sampling techniques require $O\left(\frac{1}{NS_\delta[f]\epsilon^2}\right)$ queries to get a $(1 + \epsilon)$ -multiplicative approximation for $NS_\delta[f]$. In the full version of the paper, we show that this is optimal for a wide range of parameters of the problem. Specifically, it cannot be improved by more than a constant when ϵ is a sufficiently small constant, δ satisfies $1/n \leq \delta \leq 1/2$ and $NS_\delta[f]$ satisfies $\Omega\left(\frac{1}{2^n}\right) \leq NS_\delta[f] \leq O(1)$.

It is often the case that data possesses a known underlying structural property which makes the computational problem significantly easier to solve. A natural first such property to investigate is that of monotonicity, as a number of natural function families are made up of functions that are either monotone or can be simply transformed into a monotone function (for example the class of *unate* functions consists of all the functions that can be made monotone by reorienting some of their coordinates [21]). Therefore, we focus on estimating the noise sensitivity of monotone functions.

The approximation of the related quantity of total influence (henceforth just influence) of a monotone Boolean function in this model was previously studied by [24, 23]¹. Influence, denoted by $I[f]$, is defined as n times the probability that a random edge of the Boolean cube (x, y) is *influential*, which means that $f(x) \neq f(y)$. (This latter probability is sometimes referred to as the *average sensitivity*). It was shown in [24, 23] that one can approximate the influence of a monotone function f with only $\tilde{O}\left(\frac{\sqrt{n}}{I[f]\text{poly}(\epsilon)}\right)$ queries, which for constant ϵ beats the standard sampling algorithm by a factor of \sqrt{n} , ignoring logarithmic factors.

¹ [23] is the journal version of [24] and contains a different algorithm that yields sharper results. However, our algorithmic techniques build on the conference version [24].

Despite the fact that the noise sensitivity is closely connected to the influence [20, 21], the noise sensitivity of a function can be quite different from its influence. For instance, for the parity function of all n bits, the influence is n , but the noise sensitivity is $\frac{1}{2}(1 - (1 - 2\delta)^n)$ (such disparities also hold for monotone functions, see for example the discussion of influence and noise sensitivity of the majority function in [21]). Therefore, approximating the influence by itself does not give one a good approximation to the noise sensitivity.

The techniques in [24, 23] also do not immediately generalize to the case of noise sensitivity. The result in [24, 23] is based on the observation that given a descending² path on the Boolean cube, at most one edge in it can be influential. Thus, to check if a descending path of any length contains an influential edge, it suffices to check the function values at the endpoints of the path. By sampling random descending paths, [24, 23] show that one can estimate the fraction of influential edges, which is proportional to the influence.

The most natural attempt to relate these path-based techniques with the noise sensitivity is to view it in the context of the following process: first one samples x randomly, then one obtains z by taking a random walk from x by going through all the indices in an arbitrary order and deciding whether to flip each with probability δ . The intermediate values in this process give us a natural path connecting x to z . However, this path is in general not descending, so it can, for example, cross an even number of influential edges, and then the function will have the same value on the two endpoints of this path. This prevents one from immediately applying the techniques from [24, 23].

We overcome this difficulty by introducing our main conceptual contribution: the *descending-ascending view* of noise sensitivity. In the process above, instead of going through all the indices in an arbitrary order, we first go through the indices i for which $x_i = 1$ and only then through the ones for which $x_i = 0$. This forms a path between x and z that has first a descending component and then an ascending component. Although this random walk is more amenable to an analysis using the path-based techniques of [24, 23], there are still non-trivial sampling questions involved in the design and analysis of our algorithm.

An immediate corollary of our result is a query complexity upper bound on estimating the gap between the noise stability of a Boolean function and one. The noise stability of a Boolean function f depends on a parameter ρ and is denoted by $\text{Stab}_\rho[f]$ (for more information about noise stability, see [21]). One way $\text{Stab}_\rho[f]$ can be defined is as the unique quantity satisfying the functional relation $\frac{1}{2}(1 - \text{Stab}_{1-2\delta}[f]) = \text{NS}_\delta[f]$ for all δ . This implies that by obtaining an approximation for $\text{NS}_\delta[f]$, one also achieves an approximation for $1 - \text{Stab}_{1-2\delta}[f]$.

1.1 Results

Our main algorithmic result is the following:

► **Theorem 1.** *Let δ be a parameter satisfying:*

$$\frac{1}{n} \leq \delta \leq \frac{1}{\sqrt{n} \log^{1.5} n}$$

Suppose, $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is a monotone function and $\text{NS}_\delta[f] \geq \frac{1}{n^C}$ for some constant C .

Then, there is an algorithm that outputs an approximation to $\text{NS}_\delta[f]$ to within a multiplicative factor of $(1 \pm \epsilon)$, with success probability at least $2/3$. In expectation, the algorithm makes $O\left(\frac{\sqrt{n} \delta \log^{1.5} n}{\text{NS}_\delta[f] \epsilon^3}\right)$ queries to the function. Additionally, it runs in time polynomial in n .

² A path is *descending* if each subsequent vertex in it is dominated by all the previous ones in the natural partial order on the Boolean cube.

Note that computing noise-sensitivity using standard sampling³ requires $O\left(\frac{1}{NS_\delta[f]\epsilon^2}\right)$ samples. Therefore, for a constant ϵ , we have the most dramatic improvement if $\delta = \frac{1}{n}$, in which case, ignoring constant and logarithmic factors, our algorithm outperforms standard sampling by a factor of \sqrt{n} .

As in [24], our algorithm requires that the noise sensitivity of the input function f is larger than a specific threshold $1/n^C$. Our algorithm is not sensitive to the value of C as long as it is a constant, and we think of $1/n^C$ as a rough initial lower bound known in advance.

We next give lower bounds for approximating three different parameters of monotone Boolean functions: the bias, the influence and the noise sensitivity. A priori, it is not clear what kind of lower bounds one could hope for. Indeed, determining whether a given function is the all-zeros function requires $\Omega(2^n)$ queries in the general function setting, but only 1 query (of the all-ones input), if the function is promised to be monotone. Nevertheless, we show that such a dramatic improvement for approximating these quantities is not possible.

For monotone functions, we are not aware of previous lower bounds on approximating the bias or noise sensitivity. Our lower bound on approximating influence is not comparable to the lower bounds in [24, 23], as we will elaborate shortly.

We now state our lower bound for approximating the noise sensitivity. Here and everywhere else, to “reliably distinguish” means to distinguish with probability at least $2/3$.

► **Theorem 2.** *For all constants C_1 and C_2 satisfying $C_1 - 1 > C_2 \geq 0$, for an infinite number of values of n the following is true: For all δ satisfying $1/n \leq \delta \leq 1/2$, given a monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, one needs at least $\Omega\left(\frac{n^{C_2}}{e^{\sqrt{C_1 \log n/2}}}\right)$ queries to reliably distinguish between the following two cases: (i) f has noise sensitivity between $\Omega(1/n^{C_1+1})$ and $O(1/n^{C_1})$ and (ii) f has noise sensitivity larger than $\Omega(\min(1, \delta\sqrt{n})/n^{C_2})$.*

► **Remark 3.** For any positive constant ξ , we have that $e^{\sqrt{C_1 \log n/2}} \leq n^\xi$.

► **Remark 4.** The range of the parameter δ can be divided into two regions of interest. In the region $1/n \leq \delta \leq 1/(\sqrt{n} \log n)$, the algorithm from Theorem 1 can distinguish the two cases above with only $\tilde{O}(n^{C_2})$ queries. Therefore its query complexity is optimal up to a factor of $\tilde{O}(e^{\sqrt{C_1 \log n/2}})$. Similarly, in the region $1/(\sqrt{n} \log n) \leq \delta \leq 1/2$, the standard sampling algorithm can distinguish the two distributions above with only $\tilde{O}(n^{C_2})$ queries. Therefore in this region of interest, standard sampling is optimal up to a factor of $\tilde{O}(e^{\sqrt{C_1 \log n/2}})$.

We define the *bias* of a Boolean function as $B[f] \stackrel{\text{def}}{=} \Pr[f(x) = 1]$, where x is chosen uniformly at random from $\{0, 1\}^n$. It is arguably the most basic property of a Boolean function, so we consider the question of how quickly it can be approximated for monotone functions. To approximate the bias up to a multiplicative factor of $(1 \pm \epsilon)$ using standard sampling, one needs $O(1/(B[f]\epsilon^2))$ queries. We obtain a lower bound for this task similar to the previous theorem:

► **Theorem 5.** *For all constants C_1 and C_2 satisfying $C_1 - 1 > C_2 \geq 0$, for an infinite number of values of n the following is true: Given a monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, one needs at least $\Omega\left(\frac{n^{C_2}}{e^{\sqrt{C_1 \log n/2}}}\right)$ queries to reliably distinguish between the following two cases: (i) f has bias of $\Theta(1/n^{C_1})$ (ii) f has bias larger than $\Omega(1/n^{C_2})$.*

³ Standard sampling refers to the algorithm that picks $O\left(\frac{1}{NS_\delta[f]\epsilon^2}\right)$ pairs x and z as in the definition of noise sensitivity and computes the fraction of pairs for which $f(x) \neq f(z)$.

Finally, we prove a lower bound for approximating influence:

► **Theorem 6.** *For all constants C_1 and C_2 satisfying $C_1 - 1 > C_2 \geq 0$, for an infinite number of values of n the following is true: Given a monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, one needs at least $\Omega\left(\frac{n^{C_2}}{e^{\sqrt{C_1 \log n/2}}}\right)$ queries to reliably distinguish between the following two cases: (i) f has influence between $\Omega(1/n^{C_1})$ and $O(n/n^{C_1})$ (ii) f has influence larger than $\Omega(\sqrt{n}/n^{C_2})$.*

This gives us a new sense in which the algorithm family in [24, 23] is close to optimal, because for a function f with influence $\Omega(\sqrt{n}/n^{C_2})$ this algorithm makes $\tilde{O}(n^{C_2})$ queries to estimate the influence up to any constant factor.

Our lower bound is incomparable to the lower bound in [24], which makes the stronger requirement that $I[f] \geq \Omega(1)$, but gives a bound that is only a polylogarithmic factor smaller than the runtime of the algorithm in [24, 23]. There are many possibilities for algorithmic bounds that were compatible with the lower bound in [24, 23], but are eliminated with our lower bound. For instance, prior to this work, it was conceivable that an algorithm making as little as $O(\sqrt{n})$ queries could give a constant factor approximation to the influence of **any** monotone input function whatsoever. Our lower bound shows that not only is this impossible, no algorithm that makes $O(n^{C_2})$ queries for any constant C_2 can accomplish this either.

1.2 Algorithm overview

Here, we give the algorithm in Theorem 1 together with the subroutines it uses. Additionally, we give an informal overview of the proof of correctness and the analysis of running time and query complexity, which are presented in more detail in Section 3.

First of all, recall that $NS_\delta[f] = \Pr[f(x) \neq f(z)]$ by Equation 1. Using a standard pairing argument, we argue that $NS_\delta[f] = 2 \cdot \Pr[f(x) = 1 \wedge f(z) = 0]$. In other words, we can focus only on the case when the value of the function flips from one to zero.

We introduce the *descending-ascending view of noise sensitivity* (described more formally in Subsection 3.1), which, roughly speaking, views the noise process as decomposed into a first phase that operates only on the locations in x that are 1, and a second phase that operates only on the locations in x that are set to 0. Formally, we define the noise process D in Algorithm 1.

This process gives us a path from x to z that can be decomposed into two segments, such that the first part, P_1 , descends in the hypercube, and the second part P_2 ascends in the hypercube.

■ Algorithm 1 Process D .

1. Pick x uniformly at random from $\{0, 1\}^n$. Let S_0 be the set of indexes i for which $x_i = 0$, and conversely let S_1 be the rest of indexes.
2. **Phase 1:** go through all the indexes in S_1 in a random order, and flip each with probability δ . Form the descending path P_1 from all the intermediate results. Call the endpoint y .
3. **Phase 2:** start at y , and flip each index in S_0 with probability δ . As before, all the intermediate results form an ascending path P_2 , which ends in z .
4. Output P_1, P_2, x, y and z .

Since f is monotone, for $f(x) = 1$ and $f(z) = 0$ to be the case, it is necessary, though not sufficient, that $f(x) = 1$ and $f(y) = 0$, which happens whenever P_1 hits an influential edge. Therefore we break the task of estimating the probability of $f(x) \neq f(z)$ into computing the product of:

- The probability that P_1 hits an influential edge, specifically, the probability that $f(x) = 1$ and $f(y) = 0$, which we refer to as p_A .
- The probability that P_2 does not hit any influential edge, given that P_1 hits an influential edge: specifically, the probability that given $f(x) = 1$ and $f(y) = 0$, it is the case that $f(z) = 0$. We refer to this probability as p_B .

The above informal definitions of p_A and p_B ignore some technical complications. Specifically, the impact of certain “bad events” is considered in our analysis. We redefine p_A and p_B precisely in Subsection 3.2.1.

To define those bad events, we use the following two values, which we reference in our algorithms: t_1 and t_2 . Informally, t_1 and t_2 have the following meaning. A typical vertex x of the hypercube has Hamming weight $L(x)$ between $n/2 - t_1$ and $n/2 + t_1$. A typical Phase 1 path from process D will have length at most t_2 . To achieve this, we assign $t_1 \stackrel{\text{def}}{=} \eta_1 \sqrt{n \log n}$ and $t_2 \stackrel{\text{def}}{=} n\delta(1 + 3\eta_2 \log n)$, where η_1 and η_2 are certain constants.

We also define M to be the set of edges $e = (v_1, v_2)$, for which both $L(v_1)$ and $L(v_2)$ are between $n/2 - t_1$ and $n/2 + t_1$. Most of the edges in the hypercube are in M , which is used by our algorithm and the run-time analysis.

Our analysis requires that only $\delta \leq 1/(\sqrt{n} \log^{1.5} n)$ as in the statement of Theorem 1, however the utility of the ascending-descending view can be most clearly motivated when $\delta \leq 1/(\sqrt{n} \log^2 n)$. Specifically, given that $\delta \leq 1/(\sqrt{n} \log^2 n)$, it is the case that t_2 will be shorter than $O(\sqrt{n}/\log n)$. Therefore, typically, the path P_1 is also shorter than $O(\sqrt{n}/\log n)$. Similar short descending paths on the hypercube have been studied before: In [24], paths of such lengths were used to estimate the number of influential edges by analyzing the probability that a path would hit such an edge. One useful insight given by [24] is that the probability of hitting almost every single influential edge is roughly the same.

However, the results in [24] cannot be immediately applied to analyze P_1 , because (i) P_1 does not have a fixed length, but rather its lengths form a probability distribution, (ii) this probability distribution also depends on the starting point x of P_1 . We build upon the techniques in [24] to overcome these difficulties, and prove that again, roughly speaking, for almost every single influential edge, the probability that P_1 hits it depends very little on the location of the edge, and our proof also computes this probability. This allows us to prove that $p_A \approx \delta I[f]/2$. Then, using the algorithm in [24] to estimate $I[f]$, we thereby estimate p_A .

Regarding p_B , we estimate it by approximately sampling paths P_1 and P_2 that would arise from process D , conditioned on that P_1 hits an influential edge. To that end, we first sample an influential edge e that P_1 hits. Since P_1 hits almost every single influential edge with roughly the same probability, we do it by sampling e approximately uniformly from among influential edges. For the latter task, we build upon the result in [24] as follows: As we have already mentioned, the algorithm in [24] samples descending paths of a fixed length to estimate the influence. For those paths that start at an x for which $f(x) = 1$ and end at a z for which $f(z) = 0$, we add a binary search step in order to locate the influential edge e that was hit by the path.

Thus, we have the following algorithm \mathcal{A} (see Algorithm 2), which takes oracle access to a function f and an approximation parameter ϵ as input. In the case of success, it outputs an influential edge that is roughly uniformly distributed.

■ **Algorithm 2** Algorithm \mathcal{A} (given oracle access to a monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ and a parameter ϵ).

-
1. Assign $w = \frac{\epsilon}{3100\eta_1} \sqrt{\frac{n}{\log n}}$
 2. Pick x uniformly at random from $\{0, 1\}^n$.
 3. Perform a descending walk P_1 downwards in the hypercube starting at x . Stop at a vertex y either after w steps, or if you hit the all-zeros vertex. Query the value of f only at the endpoints x and y of this path.
 4. If $f(x) = f(y)$ output FAIL.
 5. If $f(x) \neq f(y)$ perform a binary search on the path P_1 and find an influential edge e_{inf} .
 6. If $e_{inf} \in M$ return e_{inf} . Otherwise output FAIL.
-

Finally, once we have obtained a roughly uniformly random influential edge e , we sample a path P_1 from among those that hit it. An obvious way to try to quickly sample such a path is to perform two random walks of lengths w_1 and w_2 in opposite directions from the endpoints of the edge, and then concatenate them into one path. However, to do this, one needs to somehow sample the lengths w_1 and w_2 . This problem is not trivial, since longer descending paths are more likely to hit an influential edge, which biases the distribution of the path lengths towards longer ones.

To generate w_1 and w_2 according to the proper distribution, we first sample a path P_1 hitting any edge at the same *layer*⁴ Λ_e as e . We accomplish this by designing an algorithm that uses rejection sampling. The algorithm samples short descending paths from some conveniently chosen distribution, until it gets a path hitting the desired layer.

We now describe the algorithm in more detail. Recall that we use $L(x)$ to denote the Hamming weight (which we also call the *level*) of x , which equals the number of indices i on which $x_i = 1$, and we use the symbol Λ_e to denote the whole *layer* of edges that have the same endpoint levels as e . The algorithm \mathcal{W} described in Algorithm 3 takes an influential edge e as an input and samples the lengths w_1 and w_2 .

■ **Algorithm 3** Algorithm \mathcal{W} (given an edge $e \stackrel{\text{def}}{=} (v_1, v_2)$ so $v_2 \preceq v_1$).

-
1. Pick an integer l uniformly at random among the integers in $[L(v_1), L(v_1) + t_2 - 1]$. Pick a vertex x randomly at level l .
 2. As in phase 1 of the noise sensitivity process, traverse in random order through the indices of x and for each index that equals to one, flip it with probability δ . The intermediate results form a path P_1 , and we call its endpoint y .
 3. If P_1 does not intersect Λ_e go to step 1.
 4. Otherwise, output $w_1 = L(x) - L(v_1)$ and $w_2 = L(v_2) - L(y)$.
-

Recall that t_2 has a technical role and is defined to be equal $n\delta(1 + 3\eta_2 \log n)$, where η_2 is a certain constant. t_2 is chosen to be long enough that it is longer than most paths P_1 , but short enough to make the sampling in \mathcal{W} efficient. Since the algorithm involves short descending paths, we analyze this algorithm building upon the techniques we used to approximate p_A .

⁴ We say that edges e_1 and e_2 are on the same layer if and only if their endpoints have the same Hamming weights. We denote the layer an edge e belongs to as Λ_e .

52:8 Approximating the Noise Sensitivity of a Monotone Boolean Function

After obtaining a random path going through the same layer as e , we show how to transform it, using the symmetries of the hypercube, into a random path P_1 going through e itself. Additionally, given the endpoint of P_1 , we sample the path P_2 just as in the process D .

Formally, the algorithm \mathcal{B} (see Algorithm 4) takes an influential edge e and returns a descending path P_1 that goes through e and an adjacent ascending path P_2 , together with the endpoints of these paths.

■ **Algorithm 4** Algorithm \mathcal{B} (given an influential edge $e \stackrel{\text{def}}{=} (v_1, v_2)$ so $v_2 \preceq v_1$).

1. Use $\mathcal{W}(e)$ to sample w_1 and w_2 .
 2. Perform an ascending random walk of length w_1 starting at v_1 and call its endpoint x . Similarly, perform a descending random walk starting at v_2 of length w_2 , call its endpoint y .
 3. Define P_1 as the descending path that results between x and y by concatenating the two paths from above, oriented appropriately, and edge e .
 4. Define P_2 just as in phase 2 of our process starting at y . Consider in random order all the zero indices y has in common with x and flip each with probability δ .
 5. Return P_1, P_2, x, y and z .
-

We then use sampling to estimate which fraction of the paths P_2 continuing these P_1 paths does not hit an influential edge. This allows us to estimate p_B , which, combined with our estimate for p_A , gives us an approximation for $NS_\delta[f]$.

Formally, we put all the previously defined subroutines together into the randomized Algorithm 5 that takes oracle access to a function f together with an approximation parameter ϵ and outputs an approximation to $NS_\delta[f]$:

■ **Algorithm 5** Algorithm for estimating noise sensitivity. (given oracle access to a monotone function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, and a parameter ϵ).

1. Using the algorithm from [24] as described in Theorem 14, compute an approximation to the influence of f to within a multiplicative factor of $(1 \pm \epsilon/33)$. This gives us \tilde{I} .
 2. Compute $\tilde{p}_A := \delta \tilde{I} / 2$.
 3. Initialize $\alpha := 0$ and $\beta := 0$. Repeat the following until $\alpha = \frac{768 \ln 200}{\epsilon^2}$.
 - Use algorithm \mathcal{A} from Lemma 20 repeatedly to successfully sample an edge e .
 - From Lemma 25 use the algorithm \mathcal{B} , giving it e as input, and sample P_1, P_2, x, y and z .
 - If it is the case that $f(x) = 1$ and $f(z) = 0$, then $\alpha := \alpha + 1$.
 - $\beta := \beta + 1$.
 4. Set $\tilde{p}_B = \frac{\alpha}{\beta}$.
 5. Return $2\tilde{p}_A \tilde{p}_B$.
-

1.3 Lower bound techniques

We use the same technique to lower bound the query complexity of approximating any of the following three quantities: the noise sensitivity, influence and bias.

For concreteness, let us first focus on approximating the bias. Recall that one can distinguish the case where the bias is 0 from the bias being $1/2^n$ using a single query. Nevertheless, we show that for the most part, no algorithm for estimating the bias can do much better than the random sampling approach.

We construct two probability distributions D_1^B and D_2^B that are relatively hard to distinguish but have drastically different biases. To create them, we fix some threshold l_0 and then construct a special monotone function F^B , which has the following two properties: (1) It has a high bias. (2) It equals to one on only a relatively small fraction of points on the level l_0 . We refer to functions satisfying (2) as “thin” functions. We will explain later how to obtain such a function F^B . We pick a function from D_2^B by taking F^B , randomly permuting the indices of its input, and finally “truncating” it by setting it to one on all values of x , which have Hamming weight greater than l_0 .

We form D_1^B even more simply. We take the all-zeros function and truncate it at the same threshold l_0 . The threshold l_0 is chosen in a way that this function in D_1^B has a sufficiently small bias. Thus D_1^B consists of only a single function.

The purpose of truncation is to prevent a distinguisher from gaining information by accessing the values of the function on the high-level vertices of the hypercube. Indeed, if there was no truncation, one could tell whether they have access to the all-zeros function by simply querying it on the all-ones input. Since F^B is monotone, if it equals to one on at least one input, then it has to equal one on the all-ones input.

The proof has two main lemmas: The first one is computational and says that if F^B is “thin” then D_1^B and D_2^B are hard to reliably distinguish. To prove the first lemma, we show that one could transform any adaptive algorithm for distinguishing D_1^B from D_2^B into an algorithm that is just as effective, is non-adaptive and queries points only on the layer l_0 .

To show this, we observe that, because of truncation, distinguishing a function in D_2^B from a function in D_1^B is in a certain sense equivalent to finding a point with level at most l_0 on which the given function evaluates to one. We argue that for this setting, adaptivity does not help. Additionally, if $x \preceq y$ and both of them have levels at most l_0 then, since f is monotone, $f(x) = 1$ implies that $f(y) = 1$ (but not necessarily the other way around). Therefore, for finding a point on which the function evaluates to one, it is never more useful to query x instead of y .

Once we prove that no algorithm can do better than a non-adaptive algorithm that only queries points on the level l_0 , we use a simple union bound to show that any such algorithm cannot be very effective for distinguishing our distributions.

Finally, to construct F^B , we need to show that there exist functions that are “thin” and simultaneously have a high bias. This is a purely combinatorial question and is proven in our second main lemma. We build upon Talagrand random functions that were first introduced in [25]. In [17] it was shown that they are very sensitive to noise, which was applied for property testing lower bounds [2]. A Talagrand random DNF consists of $2^{\sqrt{n}}$ clauses of \sqrt{n} indices chosen randomly with replacement. We modify this construction by picking the indices without replacement and generalize it by picking $2^{\sqrt{n}}/n^{C_2}$ clauses, where C_2 is a non-negative constant. We show that these functions are “thin”, so they are appropriate for our lower bound technique.

“Thinness” allows us to conclude that D_1^B and D_2^B are hard to distinguish from each other. We then prove that they have drastically different biases. We do the latter by employing the probabilistic method and showing that in expectation our random function has a large enough bias. We handle influence and noise sensitivity analogously, specifically by showing that that as we pick fewer clauses, the expected influence and noise sensitivity decrease proportionally. We prove this by dividing the points, where one of these random functions equals to one,

into two regions: (i) the region where only one clause is true and (ii) a region where more than one clause is true. Roughly speaking, we show that the contribution from the points in (i) is sufficient to obtain a good lower bound on the influence and noise sensitivity.

1.4 Possibilities of improvement?

In [23] (which is the journal version of [24]), it was shown that using the chain decomposition of the hypercube, one can improve the run-time of the algorithm to $O\left(\frac{\sqrt{n}}{\epsilon^2 I[f]}\right)$ and also improve the required lower bound on $I[f]$ to be $I[f] \geq \exp(-c_1 \epsilon^2 n + c_2 \log(n/\epsilon))$ for some constant c_1 and c_2 (it was $I[f] \geq 1/n^C$ for any constant C in [24]). Additionally, the algorithm itself was considerably simplified.

A hope is that techniques based on the chain decomposition could help improve the algorithm in Theorem 1. However, it is not clear how to generalize our approach to use these techniques, since the ascending-descending view is a natural way to express noise sensitivity in terms of random walks, and it is not obvious whether one can replace these walks with chains of the hypercube.

2 Preliminaries

2.1 Definitions

2.1.1 Fundamental definitions and lemmas pertaining to the hypercube

► **Definition 7.** We refer to the poset over $\{0, 1\}^n$ as the ***n*-dimensional hypercube**, viewing the domain as vertices of a graph, in which two vertices are connected by an edge if and only if the corresponding elements of $\{0, 1\}^n$ differ in precisely one index. For $x = (x_1, \dots, x_n)$ and $y = (y_1, \dots, y_n)$ in $\{0, 1\}^n$, we say that $x \preceq y$ if and only if for all i in $[n]$ it is the case that $x_i \leq y_i$.

► **Definition 8.** The **level of a vertex** x on the hypercube is the hamming weight of x , or in other words number of 1-s in x . We denote it by $L(x)$.

We define the set of edges that are in the same “layer” of the hypercube as a given edge:

► **Definition 9.** For an arbitrary edge e suppose $e = (v_1, v_2)$ and $v_2 \preceq v_1$. We denote Λ_e to be the set of all edges $e' = (v'_1, v'_2)$, so that $L(v_1) = L(v'_1)$ and $L(v_2) = L(v'_2)$.

The size of Λ_e is $L(v_1) \binom{n}{L(v_1)}$. The concept of Λ_e will be useful because we will deal with paths that are symmetric with respect to change of coordinates, and these have an equal probability of hitting any edge in Λ_e .

As we view the hypercube as a graph, we will often refer to paths on it. By referring to a path P we will, depending on the context, refer to its set of vertices or edges.

► **Definition 10.** We call a path **descending** if for every pair of consecutive vertices v_i and v_{i+1} , it is the case that $v_{i+1} \prec v_i$. Conversely, if the opposite holds and $v_i \prec v_{i+1}$, we call a path **ascending**. We consider an empty path to be vacuously both ascending and descending. We define the length of a path to be the number of edges in it, and denote it by $|P|$. We say we **take a descending random walk of length w starting at x** , if we pick a uniformly random descending path of length w starting at x .

Descending random walks over the hypercube were used in an essential way in [24] and were central for the recent advances in monotonicity testing algorithms [5, 6, 14].

► **Lemma 11** (Hypercube Continuity Lemma). *Suppose n is a sufficiently large positive integer, C_1 is a constant and we are given l_1 and l_2 satisfying $\frac{n}{2} - \sqrt{C_1 n \log(n)} \leq l_1 \leq l_2 \leq \frac{n}{2} + \sqrt{C_1 n \log(n)}$. If we denote $C_2 \stackrel{\text{def}}{=} \frac{1}{10\sqrt{C_1}}$, then for any ξ satisfying $0 \leq \xi \leq 1$, if it is the case that $l_2 - l_1 \leq C_2 \xi \sqrt{\frac{n}{\log(n)}}$, then, for large enough n , it is the case that $1 - \xi \leq \frac{\binom{n}{l_1}}{\binom{n}{l_2}} \leq 1 + \xi$*

Proof. See the full version of the paper. ◀

2.1.2 Fundamental definitions pertaining to Boolean functions

► **Definition 12.** *Let δ be a parameter and let x be selected uniformly at random from $\{0, 1\}^n$. Let $z \in \{0, 1\}^n$ be defined as follows:*

$$z_i = \begin{cases} x_i & \text{with probability } 1 - \delta \\ 1 - x_i & \text{with probability } \delta \end{cases}$$

*We denote this distribution of x and z by T_δ . Then we define the **noise sensitivity** of f as $NS_\delta[f] \stackrel{\text{def}}{=} \Pr_{(x,z) \in_R T_\delta}[f(x) \neq f(z)]$.*

► **Observation 13.** *For every pair of vertices a and b , the probability that for a pair x, z drawn from T_δ , it is the case that $(x, z) = (a, b)$, is equal to the probability that $(x, z) = (b, a)$.*

Therefore, $\Pr[f(x) = 0 \wedge f(z) = 1] = \Pr[f(x) = 1 \wedge f(z) = 0]$. Hence:

$$NS_\delta[f] = 2 \cdot \Pr[f(x) = 1 \wedge f(z) = 0]$$

2.1.3 Influence estimation

To estimate the influence, standard sampling would require $O\left(\frac{n}{I[f]\epsilon^2}\right)$ samples. However, from [24] we have:

► **Theorem 14.** *There is an algorithm that approximates $I[f]$ to within a multiplicative factor of $(1 \pm \epsilon)$ for a monotone $f : \{0, 1\}^n \rightarrow \{0, 1\}$. The algorithm requires that $I[f] \geq 1/n^{C'}$ for a constant C' that is given to the algorithm. It outputs a good approximation with probability at least 0.99 and in expectation requires $O\left(\frac{\sqrt{n} \log(n/\epsilon)}{I[f]\epsilon^3}\right)$ queries. Additionally, it runs in time polynomial in n .*

2.1.4 Bounds for the error parameter and the influence

The following observation allows us to assume that without loss of generality ϵ is not too small. A similar technique was also used in [24].

► **Observation 15.** *When $\epsilon < O(\sqrt{n}\delta \log^{1.5}(n))$ there is a simple algorithm that accomplishes the desired query complexity of $O\left(\frac{\sqrt{n}\delta \log^{1.5}(n)}{NS_\delta[f]\epsilon^3}\right)$. Namely, this can be done by the standard sampling algorithm that requires only $O\left(\frac{1}{NS_\delta[f]\epsilon^2}\right)$ samples. Thus, since we can handle the case when $\epsilon < O(\sqrt{n}\delta \log^{1.5}(n))$, we focus on the case when $\epsilon \geq H\sqrt{n}\delta \log^{1.5}(n) \geq H\frac{\log^{1.5} n}{\sqrt{n}}$, for any constant H .*

Additionally, throughout the paper whenever we need it, we will without loss of generality assume that ϵ is smaller than a sufficiently small positive constant.

We will also need a known lower bound on influence:

► **Observation 16.** For any function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ and $\delta \leq 1/2$ it is the case that $NS_\delta[f] \leq \delta I[f]$. Therefore it is the case that $I[f] \geq \frac{1}{n^\delta}$.

A very similar statement is proved in [17] and for completeness we prove it in the full version of the paper.

3 An improved algorithm for small values of the noise parameter

In this section we give a more in-depth motivation for the analysis of our algorithm, together with the statements of the main lemmas. For all proofs, the reader is referred to the full version.

3.1 Descending-ascending framework

The descending-ascending process

It will be useful to view noise sensitivity in the context of the noise process D (see Algorithm 1 for the definition). By inspection, x and z are distributed identically in D as in T_δ . Therefore from Observation 13:

$$NS_\delta[f] = 2 \cdot \Pr_D[f(x) = 1 \wedge f(z) = 0]$$

► **Observation 17.** Since the function is monotone, if $f(x) = 1$ and $f(z) = 0$, then it has to be that $f(y) = 0$.

3.2 Review of algorithm

Roughly speaking, our algorithm will break the task of estimating $NS_\delta[f]$ into estimating the probabilities⁵ $\Pr_D[f(x) = 1 \wedge f(y) = 0]$ and $\Pr_D[f(z) = 0 | f(x) = 1 \wedge f(y) = 0]$. To estimate the former, in Lemma 23 we will advantage of the fact that δ is small, so the path P_1 is typically short, and hence the same types of techniques can be applied as in the analysis of the influence estimation algorithm.

The situation here is different from that of influence estimation because (i) the length of the path is random (ii) this probability distribution of lengths depends on the starting vertex. However, we will prove there exists a value, call it p_1 , so that most influential edges are hit with probability close to p_1 . It depends on δ and $I[f]$, and we can estimate it quite efficiently by estimating $I[f]$.

In order to estimate $\Pr_D[f(z) = 0 | f(x) = 1 \wedge f(y) = 0]$ we will approximate the distribution D conditioned on $f(x) = 1 \wedge f(y) = 0$. To that end, we will first sample an influential edge e that P_1 goes through, and then among all the downwards paths going through e we will sample P_1 itself. The algorithm that samples an influential edge approximately uniformly is inspired by the algorithm that estimates influence.

3.2.1 Defining bad events and technical notation

In this section, we give the parameters that we use to determine the lengths of our walks, as well as the “middle” of the hypercube. Additionally, in this section we define some notation we use.

⁵ In the precise analysis there will be some bad events to take care of. For the sake of simplicity, we do not talk about them right now.

Define the following values:

$$t_1 \stackrel{\text{def}}{=} \eta_1 \sqrt{n \log n} \qquad t_2 \stackrel{\text{def}}{=} n\delta(1 + 3\eta_2 \log n)$$

Here η_1 and η_2 are large enough constants. Taking $\eta_1 = \sqrt{C} + 4$ and $\eta_2 = C + 2$ is sufficient for our purposes (recall that we were promised that $NS_\delta[f] \geq 1/n^C$ for a constant C).

Informally, t_1 and t_2 have the following intuitive meaning. A typical vertex x of the hypercube has $L(x)$ between $n/2 - t_1$ and $n/2 + t_1$. A typical Phase 1 path from process D will have length at most t_2 .

We define the “middle edges” M as the following set of edges:

$$M \stackrel{\text{def}}{=} \{e = (v_1, v_2) : \frac{n}{2} - t_1 \leq L(v_2) \leq L(v_1) \leq \frac{n}{2} + t_1\}$$

Denote by \overline{M} the rest of the edges.

We define two bad events in context of D , such that when neither of these events happen, we can show that the output has certain properties. The first one happens roughly when P_1 (from x to y , as defined by Process D) is much longer than it should be in expectation, and the second one happens when P_1 crosses one of the edges that are too far from the middle of the hypercube, which could happen because P_1 is long or because of a starting point that is far from the middle. More specifically:

- E_1 happens when both of the following hold (i) P_1 crosses an edge $e \in E_I$ and (ii) denoting $e = (v_1, v_2)$, so that $v_2 \preceq v_1$, it is the case that $L(x) - L(v_1) \geq t_2$.
- E_2 happens when P_1 contains an edge in $E_I \cap \overline{M}$.

While defining E_1 we want two things from it. First of all, we want its probability to be upper-bounded easily. Secondly, we want it not to complicate the sampling of paths in Lemma 24. There exists a tension between these two requirements, and as a result the definition of E_1 is somewhat convoluted.

We will approximate the noise sensitivity as the product of the following two quantities:

$$p_A \stackrel{\text{def}}{=} \Pr_D[f(x) = 1 \wedge f(y) = 0 \wedge \overline{E_1} \wedge \overline{E_2}]$$

$$p_B \stackrel{\text{def}}{=} \Pr_D[f(z) = 0 | f(x) = 1 \wedge f(y) = 0 \wedge \overline{E_1} \wedge \overline{E_2}]$$

Ignoring the bad events, p_A is the probability that P_1 hits an influential edge, and p_B is the probability that given that P_1 hits an influential edge P_2 does not hit an influential edge. From Observation (17), if and only if these two things happen, it is the case that $f(x) = 1$ and $f(z) = 0$. From this fact and the laws of conditional probabilities we have:

$$\Pr_D[f(x) = 1 \wedge f(z) = 0 \wedge \overline{E_1} \wedge \overline{E_2}] = \Pr_D[f(x) = 1 \wedge f(y) = 0 \wedge f(z) = 0 \wedge \overline{E_1} \wedge \overline{E_2}] = p_A p_B \quad (2)$$

We can consider for every individual edge e in $M \cap E_I$ the probabilities:

$$p_e \stackrel{\text{def}}{=} \Pr_D[e \in P_1 \wedge \overline{E_1} \wedge \overline{E_2}]$$

$$q_e \stackrel{\text{def}}{=} \Pr_D[f(x) = 1 \wedge f(z) = 0 | e \in P_1 \wedge \overline{E_1} \wedge \overline{E_2}] = \Pr_D[f(z) = 0 | e \in P_1 \wedge \overline{E_1} \wedge \overline{E_2}]$$

The last equality is true because $e \in P_1$ already implies $f(x) = 1$. Informally and ignoring the bad events again, p_e is the probability that $f(x) = 1$ and $f(y) = 0$ **because** P_1 hits e and not some other influential edge. Similarly, q_e is the probability $f(x) = 1$ and $f(z) = 0$ given that P_1 hits specifically e .

52:14 Approximating the Noise Sensitivity of a Monotone Boolean Function

Since f is monotone, P_1 can hit at most one influential edge. Therefore, the events of P_1 hitting different influential edges are disjoint. Using this, Equation (2) and the laws of conditional probabilities we can write:

$$p_A = \sum_{e \in E_I \cap M} p_e \quad (3)$$

Furthermore, the events that P_1 hits a given influential edge and then P_2 does not hit any are also disjoint for different influential edges. Therefore, analogous to the previous equation we can write:

$$p_{APB} = \Pr_D[(f(x) = 1) \wedge (f(z) = 0) \wedge \overline{E_1} \wedge \overline{E_2}] = \sum_{e \in E_I \cap M} p_e q_e \quad (4)$$

3.2.2 Bad events can be “ignored”

In the following, we will need to consider probability distributions in which bad events do not happen. For the most part, conditioning on the fact that bad events do not happen changes little in the calculations. In this subsection, we present two relatively simple lemmas that allow us to formalize these claims.

The following observation suggests that almost all influential edges are in M .

► **Observation 18.** *It is the case that:*

$$\left(1 - \frac{\epsilon}{310}\right) |E_I| \leq |M \cap E_I| \leq |E_I|$$

Proof. This is the case, because:

$$\begin{aligned} |\overline{M} \cap E_I| &\leq |\overline{M}| \leq 2^n \cdot 2 \exp(-2\eta_1^2 \log(n)) = \\ &2^{n-1} \cdot 4/n^{2\eta_1^2-1} \leq 2^{n-1} I[f]/n = |E_I|/n \leq \frac{\epsilon}{310} |E_I| \end{aligned} \quad (5)$$

The second inequality is the Hoeffding bound, then we used Observations 16 and 15. ◀

We now assert that ignoring these bad events does not distort our estimate for $NS_\delta[f]$.

► **Lemma 19.** *It is the case that:*

$$p_{APB} \leq \frac{1}{2} NS_\delta[f] \leq \left(1 + \frac{\epsilon}{5}\right) p_{APB}$$

Proof. See the full version of the paper. ◀

3.3 Main lemmas

Having rigorously defined our technical language, now we can state our main algorithmic lemmas, together with their motivation and our approach to proving them. We refer the reader to the full version of the paper for the proofs of these lemmas, the proof of the Theorem 1 using these lemmas, as well as the derivation of the lower bounds in Theorems 5, 6 and 2.

The first two lemmas allow the estimation of the probability that a certain descending random walk hits an influential edge. As we mentioned in the introduction, except for the binary search step, the algorithm in Lemma 20 is similar to the algorithm in [24]. In principle, we could have carried out much of the analysis of the algorithm in Lemma 20 by referencing

an equation in [24]. However, for subsequent lemmas, including Lemma 23, we build on the application of the Hypercube Continuity Lemma to the analysis of random walks on the hypercube. In the full version of the paper, we give a full analysis of the algorithm in Lemma 20, in order to demonstrate how the Hypercube Continuity Lemma (Lemma 11) can be used to analyze random walks on the hypercube, before handling the more complicated subsequent lemmas, including Lemma 23.

► **Lemma 20.** *There exists an algorithm \mathcal{A} (see Algorithm 2) that samples edges from $M \cap E_I$ so that for every two edges e_1 and e_2 in $M \cap E_I$:*

$$\left(1 - \frac{\epsilon}{70}\right) \Pr_{e \in_{R\mathcal{A}}} [e = e_2] \leq \Pr_{e \in_{R\mathcal{A}}} [e = e_1] \leq \left(1 + \frac{\epsilon}{70}\right) \Pr_{e \in_{R\mathcal{A}}} [e = e_2]$$

The probability that the algorithm succeeds is at least $\frac{1}{O(\sqrt{n} \log^{1.5} n / I[f] \epsilon)}$. If it succeeds, the algorithm makes $O(\log n)$ queries, and if it fails, it makes only $O(1)$ queries. In either case, it runs in time polynomial in n .

► **Remark 21.** Through the standard repetition technique, the probability of error can be decreased to an arbitrarily small constant, at the cost of $O\left(\frac{\sqrt{n} \log^{1.5} n}{I[f] \epsilon}\right)$ queries. Then, the run-time still stays polynomial in n , since $I[f] \geq 1/n^C$.

► **Remark 22.** The distribution \mathcal{A} outputs is point-wise close to the uniform distribution over $M \cap E_I$. We will also obtain such approximations to other distributions in further lemmas. Note that this requirement is stronger than closeness in L_1 norm.

The following lemma, roughly speaking, shows that just as in previous lemma, the probability that P_1 in D hits an influential edge e does not depend on where exactly e is, as long as it is in $M \cap E_I$. The techniques we use are similar to the ones in the previous lemma and it follows the same outline. However here we encounter additional difficulties for two reasons: first of all, the length of P_1 is not fixed, but it is drawn from a probability distribution. Secondly, this probability distribution depends on the starting point of P_1 .

► **Lemma 23.** *For any edge $e \in M \cap E_I$ it is the case that:*

$$\left(1 - \frac{\epsilon}{310}\right) \frac{\delta}{2^n} \leq p_e \leq \left(1 + \frac{\epsilon}{310}\right) \frac{\delta}{2^n}$$

While we will use Lemma 23 in order to estimate p_A , the next two lemmas are for estimating p_B . To that end, we will need to sample from a distribution of descending and ascending paths going through a given edge. Informally, the requirement on the distribution is that it should be close to the conditional distribution of such paths P_1 that would arise from process D , conditioned on going through e and satisfying \bar{E}_1 and \bar{E}_2 .

A first approach to sampling such P_1 would be to take random walks in opposite directions from the endpoints of the edge e and then concatenate them together. This is in fact what we do. However, difficulty comes from determining the appropriate lengths of the walks for the following reason. If P_1 is longer, it is more likely to hit the influential edge e . This biases the distribution of the descending paths hitting e towards the longer descending paths. In order to accommodate for this fact we used the following two-step approach:

1. Sample only the levels of the starting and ending points of the path P_1 . This is equivalent to sampling the length of the segment of P_1 before the edge e and after it. This requires careful use of rejection sampling together with the techniques we used to prove Lemmas 20 and 23. Roughly speaking, we use the fact that P_1 is distributed symmetrically with respect to the change of indices in order to reduce a question about the edge e to a question about the layer Λ_e . Then, we use the Lemma 11 to answer questions about random walks hitting a given layer. This is handled in Lemma 24.

2. Sample a path P_1 that has the given starting and ending levels and passes through an influential edge e . This part is relatively straightforward. We prove that all the paths satisfying these criteria are equally likely. We sample one of them randomly by performing two random walks in opposite directions starting at the endpoints of e . This all is handled in Lemma 25.

► **Lemma 24.** *There is an algorithm \mathcal{W} (see Algorithm 3) that takes as input an edge $e = (v_1, v_2)$ in $M \cap E_I$, so that $v_2 \preceq v_1$, and samples two non-negative numbers w_1 and w_2 , so that for any two non-negative w'_1 and w'_2 :*

$$\begin{aligned} & \left(1 - \frac{\epsilon}{70}\right) \Pr_{\mathcal{W}(e)} [(w_1 = w'_1) \wedge (w_2 = w'_2)] \\ & \leq \Pr_D [(L(x) - L(v_1) = w'_1) \wedge (L(v_2) - L(y) = w'_2) | (e \in P_1) \wedge \overline{E_1} \wedge \overline{E_2}] \\ & \leq \left(1 + \frac{\epsilon}{70}\right) \Pr_{\mathcal{W}(e)} [(w_1 = w'_1) \wedge (w_2 = w'_2)] \quad (6) \end{aligned}$$

The algorithm requires no queries to f and runs in time polynomial in n .

► **Lemma 25.** *There exists an algorithm \mathcal{B} (see Algorithm 4) with the following properties. It takes as input an edge $e = (v_1, v_2)$ in $M \cap E_I$, so that $v_2 \preceq v_1$ and outputs paths P_1 and P_2 together with hypercube vertices x, y and z . It is the case that x is the starting vertex of P_1 , y is both the starting vertex of P_2 and the last vertex of P_1 , and z is the last vertex of P_2 . Additionally, P_1 is descending and P_2 is ascending. Furthermore, for any pair of paths P'_1 and P'_2 we have:*

$$\begin{aligned} & \left| \Pr_{\mathcal{B}(e)} [(P_1 = P'_1) \wedge (P_2 = P'_2)] - \Pr_D [(P_1 = P'_1) \wedge (P_2 = P'_2) | (e \in P_1) \wedge \overline{E_1} \wedge \overline{E_2}] \right| \\ & \leq \frac{\epsilon}{70} \Pr_{\mathcal{B}(e)} [(P_1 = P'_1) \wedge (P_2 = P'_2)] \quad (7) \end{aligned}$$

It requires no queries to the function and takes computation time polynomial in n to draw one sample.

In the full version of this paper, we analyze the query complexity and the run-time of the Algorithm 5, thus proving Theorem 1. This is shown to be a relatively straightforward application of the four main technical lemmas we presented and discussed in this section.

Abstract

Random geometric graph (Gilbert, 1961) is a basic model of random graphs for spatial networks proposed shortly after the introduction of the Erdős-Rényi random graphs. The *geometric block model* (GBM) is a probabilistic model for community detection defined over random geometric graphs (RGG) similar in spirit to the popular *stochastic block model* which is defined over Erdős-Rényi random graphs. The GBM naturally inherits many desirable properties of RGGs such as transitivity (“friends having common friends”) and has been shown to model many real-world networks better than the stochastic block model. Analyzing the properties of a GBM requires new tools and perspectives to handle correlation in edge formation. In this paper, we study the necessary and sufficient conditions for community recovery over GBM in the connectivity regime. We provide efficient algorithms that recover the communities exactly with high probability and match the lower bound within a small constant factor. This requires us to prove new connectivity results for *vertex-random graphs* or *random annulus graphs* which are natural generalizations of random geometric graphs.

A vertex-random graph is a model of random graphs where the randomness lies in the vertices as opposed to an Erdős-Rényi random graph where the randomness lies in the edges. A vertex-random graph $G(n, [r_1, r_2])$, $0 \leq r_1 < r_2 \leq 1$ with n vertices is defined by assigning a real number in $[0, 1]$ randomly and uniformly to each vertex and adding an edge between two vertices if the “distance” between the corresponding two random numbers is between r_1 and r_2 . For the special case of $r_1 = 0$, this corresponds to random geometric graph in one dimension. We can extend this model naturally to higher dimensions; these higher dimensional counterparts are referred to as *random annulus graphs*. Random annulus graphs appear naturally whenever the well-known Goldilocks principle (“not too close, not too far”) holds in a network. In this paper, we study the connectivity properties of such graphs, providing both necessary and sufficient conditions. We show a surprising *long edge phenomena* for vertex-random graphs: the minimum gap for connectivity between r_1 and r_2 is significantly less when $r_1 > 0$ vs when $r_1 = 0$ (RGG). We then extend the connectivity results to high dimensions. These results play a crucial role in analyzing the GBM.

1 Introduction

Models of random graphs are ubiquitous with Erdős-Rényi graphs [12, 17] at the forefront. Studies of the properties of random graphs have led to many fundamental theoretical observations as well as many engineering applications. In an Erdős-Rényi graph $G(n, p)$, $n \in \mathbb{Z}_+$, $p \in [0, 1]$, the randomness lies in how the edges are chosen: each possible pair of vertices forms an edge independently with probability p . It is also possible to consider models of graphs where randomness lies in the vertices.

Keeping up with the simplicity of the Erdős-Rényi model, one can define a vertex-random graph (VRG) in the following way. Given two reals $0 \leq r_1 \leq r_2 \leq 1/2$, the vertex-random graph $\text{VRG}(n, [r_1, r_2])$ is a random graph with n vertices. Each vertex u is assigned a random point X_u selected uniformly from the circumference of a circle of perimeter 1. Two vertices u and v are connected by an edge, if and only if the distance of the corresponding points on the circle (the geodesic distance) is between r_1 and r_2 . This definition is by no means new. For the case of $r_1 = 0$, this is the random geometric graphs (RGG) in one dimension. Random Geometric graphs were defined first by [18] and constitute the first and simplest model of spatial networks. Since then, they have found wide-spread applications in modeling wireless (ad-hoc) communication networks [9, 19], information propagation in social networks [13, 31] etc., and have been studied extensively [4, 5, 6]. The definition of VRG has been previously mentioned in [9]. The interval $[r_1, r_2]$ is called the connectivity interval in VRGs.

Vertex random graphs inherit many desirable properties of RGGs such as vertices with high modularity and the degree associativity property (high degree nodes tend to connect), which in turn led to the popularity of RGGs [13, 31]. In addition, VRGs naturally arise whenever the Goldilocks principle (not too close, not too far) is applicable in networks. For example, in a co-purchase network, a person who bought a bike may buy similar products like a helmet along with it, but not another bike [15]. Understanding connectivity properties of VRGs can shed light in co-purchasing behavior and product recommendation. Interestingly, the connectivity properties of VRGs turn out to be crucial to develop and analyze community detection algorithms for the *geometric block model* [15].

Connectivity of Vertex Random Graph (VRG). Threshold properties of Erdős-Rényi graphs have been at the center of much interest, and in particular it is known that many graph properties exhibit sharp phase transition phenomena [14]. Random geometric graphs also exhibit similar threshold properties [26]. Our first contribution in this work is to identify such connectivity threshold for VRGs. Consider a $\text{VRG}(n, [0, r])$ defined above with $r = \frac{a \ln n}{n}$. It is known that $\text{VRG}(n, [0, r])$ is connected with high probability if and only if $a > 1$ (I.e., $\text{VRG}(n, [0, \frac{(1+\epsilon) \ln n}{n}])$ is connected for any $\epsilon > 0$). We will ignore this ϵ and just mention connectivity threshold as $\frac{\ln n}{n}$. Now let us consider the graph $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{\ln n}{n}])$, $b > 0$. Clearly this graph has less edges than $\text{VRG}(n, [0, \frac{\ln n}{n}])$. **Is this graph still connected?** Surprisingly, we show that the modified graph remains connected as long as $b \leq 0.5$. Therefore, $\text{VRG}(n, [\frac{0.5 \ln n}{n}, \frac{\ln n}{n}])$ is connected, but $\text{VRG}(n, [0, \frac{(1-\epsilon) \ln n}{n}])$ is not $\forall \epsilon > 0$.

Can we explain this striking shift in connectivity interval, when one goes from $b = 0$ to $b > 0$? Note that the $\text{VRG}(n, [\frac{0.5 \ln n}{n}, \frac{\ln n}{n}])$ is obtained from the $\text{VRG}(n, [0, \frac{\ln n}{n}])$ by deleting all “short-distance” edges. It turns out the “long-distance” edges are sufficient to maintain connectivity, because they can connect points over multiple hops in the graph. Another possible explanation is that connectivity threshold for VRG is not dictated by isolated nodes as is the case in Erdős-Rényi graphs. Thus, after the connectivity threshold has been achieved, removing short edges still retains connectivity.

The Geometric Block Model. We are motivated to study the threshold phenomena of vertex-random graphs, because it appears naturally in the analysis of the geometric block model (GBM) [15]. The geometric block model is a probabilistic generative model of communities and is a spatial analogue to the popular stochastic block model (SBM) [22, 10, 8, 2, 1, 20, 7, 24]. The SBM generalizes the Erdős-Rényi graphs in the following way. Consider a graph $G(V, E)$, where $V = V_1 \sqcup V_2 \sqcup \dots \sqcup V_k$ is a disjoint union of k clusters denoted by V_1, \dots, V_k . The edges of the graph are drawn randomly: there is an edge between $u \in V_i$ and $v \in V_j$ with probability $q_{i,j}$, $1 \leq i, j \leq k$. Given the adjacency matrix of such a graph, the task is to find the partition $V_1 \sqcup V_2 \sqcup \dots \sqcup V_k$ of V .

This model has been incredibly popular both in theoretical and practical domains of community detection. Recent theoretical works focus on characterizing sharp threshold of recovering the partition in the SBM. For example, when there are only two communities of exactly equal sizes, and the inter-cluster edge probability is $\frac{b \ln n}{n}$ and intra-cluster edge probability is $\frac{a \ln n}{n}$, it is known that exact recovery is possible if and only if $\sqrt{a} - \sqrt{b} > \sqrt{2}$ [1, 24]. The regime of the probabilities being $\Theta\left(\frac{\ln n}{n}\right)$ has been put forward as one of most interesting ones, because in an Erdős-Rényi random graph, this is the threshold for graph connectivity [4]. Note that the results are not only of theoretical interest, many real-world networks exhibit a “sparsely connected” community feature [23], and any efficient recovery algorithm for sparse SBM has many potential applications.

While the SBM is a popular model (because of its apparent simplicity), there are many aspects of real social networks, such as “transitivity rule” (“friends having common friends”) and other community structures that are not accounted for in SBM. Defining a block model over a random geometric graph, the geometric block model (GBM), circumvents this since GBMs naturally inherit the transitivity property of random geometric graphs. In a previous work [15], we showed GBMs model community structures better than an SBM in many real world networks (e.g. DBLP collaboration network, Amazon co-purchase network etc.). The GBM depends on the basic definition of the random geometric graph in the same way the SBM depends on Erdős-Rényi graphs. The two-cluster GBM with vertex set $V = V_1 \sqcup V_2$, $V_1 = V_2$ is a random graph defined in the following way. Suppose, $0 \leq r_d < r_s \leq 1/2$ be two real numbers. For each vertex $u \in V$ randomly and independently choose a point X_u from the circumference of a circle of unit perimeter. There will be an edge between u and v if and only if,

$$\begin{aligned} d_L(X_u, X_v) &\leq r_s \text{ when } u, v \in V_1 \text{ or } u, v \in V_2 \\ d_L(X_u, X_v) &\leq r_d \text{ when } u \in V_1, v \in V_2 \text{ or } u \in V_2, v \in V_1, \end{aligned}$$

where d_L denotes the geodesic distance. Let us denote this random graph as $\text{GBM}(r_s, r_d)$. Given this graph $\text{GBM}(r_s, r_d)$, the main problem of community detection is to recover the partition (i.e., V_1 and V_2). The GBM provides a systematic way to introduce correlation during edge formation, an important aspect in real networks that often renders a problem theoretically intractable. The tool set needed to recover communities under a GBM thus differs significantly than what has been used to analyze the SBM.

Motivated by the SBM literature, we here also look at the GBM in the connectivity regime, i.e., when $r_s = \frac{a \ln n}{n}$, $r_d = \frac{b \ln n}{n}$. Our first contribution in this part is to provide a lower bound that shows that it is impossible to recover the parts from $\text{GBM}\left(\frac{a \ln n}{n}, \frac{b \ln n}{n}\right)$ when $a - b < 1/2$. No lower bound for recovery was known before. We also derive a relation between a and b that defines a sufficient condition of recovery in $\text{GBM}\left(\frac{a \ln n}{n}, \frac{b \ln n}{n}\right)$, closely matching the lower bound. The analysis crucially exploits the connectivity properties of vertex-random graphs.

It is possible to generalize the GBM to include different distributions, different metric spaces and multiple parts. It is also possible to construct other type of spatial block models such as the one very recently being put forward in [28] which rely on the random dot product graphs [30]. In [28], edges are drawn between vertices randomly and independently as a function of the distance between the corresponding vertex random variables. In contrast, in GBM edges are drawn deterministically given the vertex random variables, and edges are dependent unconditionally. Moreover [28] only considers the recovery scenario where in addition to the graph, values of the vertex random variables are provided. Note that in GBM, we only observe the graph. In particular, it will be later clear that if we are given the corresponding random variables (locations) to the vertices in addition to the graph, then recovery of the partitions in GBM($\frac{a \ln n}{n}, \frac{b \ln n}{n}$) is possible if and only if $a - b > 0.5$ and $a > 1$, that is we can identify the recovery threshold exactly.

VRG in Higher Dimension: The Random Annulus Graphs. It is natural to ask similar question of connectivity for VRGs in higher dimension. In a VRG at dimension t , we may assign t -dimensional random vectors to each of the vertices, and use a standard metric such as the Euclidean distance to decide whether there should be an edge between two vertices. Formally, let us define the t -dimensional sphere as $S^t \equiv \{x \in \mathbb{R}^{t+1} \mid \|x\|_2 = 1\}$. Given two reals $0 \leq r_1 \leq r_2 \leq 2$, the random annulus graph $\text{RAG}_t(n, [r_1, r_2])$ is a random graph with n vertices. Each vertex u is assigned a random vector X_u selected randomly and uniformly from S^t . Two vertices u and v are connected by an edge, if and only if $r_1 \leq d(u, v) \equiv \|X_u - X_v\|_2 \leq r_2$. Note that for $t = 1$ an $\text{RAG}_1(n, [r_1, r_2])$ is nothing but a VRG as defined above, where we need to convert the Euclidean distance to the geodesic distance and scale the probabilities by a factor of 2π . The $\text{RAG}_t(n, [0, r])$ gives the standard definition of random geometric graphs in t dimensions (for example, see [6] or [26]).

We refer to high-dimensional VRGs as the random annulus graph (RAG) since here two vertices are connected iff one is within an “annulus” centered at the other. For the random annulus graphs, we extend our connectivity results of $t = 1$ to general t . In particular, we show that there exists an isolated vertex in the $\text{RAG}_t(n, [b(\frac{\ln n}{n})^{\frac{1}{t}}, a(\frac{\ln n}{n})^{\frac{1}{t}}])$ with high probability if and only if

$$a^t - b^t < \frac{\sqrt{\pi}(t+1)\Gamma(\frac{t+2}{2})}{\Gamma(\frac{t+3}{2})} \equiv \psi(t),$$

where $\Gamma(\cdot)$ is the gamma function. Computing the connectivity threshold of RAG exactly is highly challenging, and we have to use several approximations of high dimensional geometry. Our arguments crucially rely on VC dimensions of sets of geometric objects such as intersections of high dimensional annuluses and hyperplanes. Overall we find that the $\text{RAG}_t(n, [b(\frac{\ln n}{n})^{\frac{1}{t}}, a(\frac{\ln n}{n})^{\frac{1}{t}}])$ is connected with high probability if

$$(a/2)^t - b^t \geq 8(t+1)\psi(t) \text{ and } a > 2b.$$

Using the connectivity result for RAG_t , the results for the geometric block model can be extended to high dimensions. The latent feature space of nodes in most networks are high-dimensional. For example, road networks are two-dimensional whereas the number of features used in a social network may have much higher dimensions. In a “high-dimensional” GBM: for any $t > 1$, instead of assigning a random variable from $[0, 1]$ we assign a random vector $X_u \in S^t$ to each vertex u ; and two vertices in the same part is connected if and only if their Euclidean distance is less than r_s , whereas two vertices from different parts are connected if and only if their distance is less than r_d . We show the algorithm developed for one dimension extends to higher dimensions with nearly tight lower and upper bounds.

In this paper, we consistently refer to the $t = 1$ case for RAG as the vertex-random graph.

The paper is organized as follows. In Section 2, we provide the formal definitions and the main results of the paper. In Section 3, the sharp connectivity phase transition results for vertex-random graphs are proven. In Section 4, the connectivity results are proven for high dimensional random annulus graphs (details in full version [16]). Finally, in Section 5, a lower bound for the geometric block model as well as the main recovery algorithm are presented (details for the high-dimensional case in full version [16]).

2 Main Results

We formally define the random graph models, and state our results here.

► **Definition 1** (Vertex-Random Graph). *A vertex-random graph $\text{VRG}(n, [r_1, r_2])$ on n vertices has parameters n , and a pair of real numbers $r_1, r_2 \in [0, 1/2]$, $r_1 \leq r_2$. It is defined by assigning a number $X_i \in \mathbb{R}$ to vertex i , $1 \leq i \leq n$, where X_i 's are independent and identical random variables uniformly distributed in $[0, 1]$. There will be an edge between vertices i and j , $i \neq j$, if and only if $r_1 \leq d_L(X_i, X_j) \leq r_2$ where $d_L(X_i, X_j) \equiv \min\{|X_i - X_j|, 1 - |X_i - X_j|\}$.*

We choose $d_L(X_i, X_j) = \min\{|X_i - X_j|, 1 - |X_i - X_j|\}$ to ignore the boundary effect, although the results extend identically to the scenario when $d_L(X_i, X_j) = |X_i - X_j|$. One can also interpret X_i , $1 \leq i \leq n$, to be uniformly distributed on the perimeter of a circle with radius $\frac{1}{2\pi}$ and the distance $d_L(\cdot, \cdot)$ to be the geodesic distance. As a shorthand, for any two vertices u, v , let $d(u, v)$ denote $d_L(X_u, X_v)$ where X_u, X_v are the random variables corresponding to the vertices. We also use $d(u, v)$ to denote the distance between a vertex u (or the embedding of that vertex in $[0, 1]$) and a point $v \in [0, 1]$ naturally. Our main result regarding VRGs is summarized in the following theorem.

► **Theorem 2** (Connectivity threshold of vertex-random graphs). *The $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ is connected with probability $1 - o(1)$ if $a > 1$ and $a - b > 0.5$. On the other hand, the $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ is not connected with probability $1 - o(1)$ if $a < 1$ or $a - b < 0.5$.*

Only for the special case of $b = 0$, the connectivity result was known before [25, 26]. See also [27]. Generalization to $b > 0$ is both nontrivial and counter-intuitive (the minimum connectivity gap is no longer $a - b \geq 1$). Indeed, our analysis also leads to an alternate simple proof of connectivity for one-dimensional RGGs.

► **Definition 3** (The Random Annulus Graph). *Let us define the t -dimensional unit sphere as $S^t \equiv \{x \in \mathbb{R}^{t+1} \mid \|x\|_2 = 1\}$. A random annulus graph $\text{RAG}_t(n, [r_1, r_2])$ on n vertices has parameters $n, t \in \mathbb{Z}_+$, and a pair of real numbers $r_1, r_2 \in [0, 2]$, $r_1 \leq r_2$. It is defined by assigning a number $X_i \in S^t$ to vertex i , $1 \leq i \leq n$, where X_i 's are independent and identical random vectors uniformly distributed in S^t . There will be an edge between vertices i and j , $i \neq j$, if and only if $r_1 \leq \|X_i - X_j\|_2 \leq r_2$ where $\|\cdot\|_2$ denote the ℓ_2 norm.*

When from the context it is clear that we are in high dimensions, we use $d(u, v)$ to denote $\|X_u - X_v\|_2$ or just the ℓ_2 distance between the arguments¹. The following result summarizes the condition for the existence of isolated vertices in RAGs.

¹ If we substitute $t = 1$, then $\text{RAG}_1(n, [r_1, r_2])$ is a random graph where each vertex is associated with a random variable uniformly distributed in the unit circle. The distance between two vertices is the length of the chord connecting the random variables corresponding to the two vertices. If the length of the chord is $r \leq 2$, then the length of the corresponding (smaller) chord length of the corresponding arc between the vertices along the circumference of the circle is $2 \sin^{-1} \frac{r}{2}$. If we normalize the circumference of the circle by 2π , we obtain a random graph model that is equivalent to our definition of the vertex-random graphs. Since handling geodesic distances is more cumbersome in the higher dimensions, we resorted to Euclidean distance.

► **Theorem 4** (Zero-One law for Isolated Vertex in RAG). *For a random annulus graph $\text{RAG}_t(n, [r_1, r_2])$ where $r_2 = a\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}$ and $r_1 = b\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}$, there exists isolated nodes with probability $1 - o(1)$ if*

$$a^t - b^t < \frac{\sqrt{\pi}(t+1)\Gamma(\frac{t+2}{2})}{\Gamma(\frac{t+3}{2})} \equiv \psi(t),$$

where $\Gamma(x) = \int_0^\infty y^{x-1}e^{-y}dy$ is the gamma function, and there does not exist an isolated vertex with probability $1 - o(1)$ if $a^t - b^t > \psi(t)$.

As a corollary of the above, we observe an $\text{RAG}_t(n, [b\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}, a\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}])$ is not connected with probability $1 - o(1)$ if $a^t - b^t < \psi(t)$. Our main result provides a sufficient condition for the connectivity.

► **Theorem 5.** *A t dimensional random annulus graph $\text{RAG}_t(n, [b\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}, a\left(\frac{\ln n}{n}\right)^{\frac{1}{t}}])$ is connected with probability $1 - o(1)$ if $(a/2)^t - b^t \geq 8(t+1)\psi(t)$ and $a > 2b$.*

These connectivity results find immediate application in analyzing the geometric block model (GBM), a generative model for networks with underlying community structure.

► **Definition 6** (Geometric Block Model). *Given $V = V_1 \sqcup V_2, |V_1| = |V_2| = \frac{n}{2}$, choose a random variable X_u uniformly distributed in $[0, 1]$ for all $u \in V$. The geometric block model $\text{GBM}(r_s, r_d)$ with parameters $1/2 \geq r_s > r_d$ is a random graph where an edge exists between vertices u and v if and only if,*

$$\begin{aligned} d_L(X_u, X_v) &\leq r_s \text{ when } u, v \in V_1 \text{ or } u, v \in V_2 \\ d_L(X_u, X_v) &\leq r_d \text{ when } u \in V_1, v \in V_2 \text{ or } u \in V_2, v \in V_1. \end{aligned}$$

As a consequence of the connectivity lower bound on VRG, we are able to show community recovery lower bound, that is we show the recovery of the partition is not possible with high probability in $\text{GBM}(\frac{a \ln n}{n}, \frac{b \ln n}{n})$ whenever $a - b < 0.5$ or $a < 1$ (see, Theorem 18). If in addition the vertex locations are known, then we can show a matching lower and upper bounds: the recovery is possible if and only if $a - b > 0.5$ or $a > 1$ (formal statement in full version [16]).

Coming back to the actual recovery problem, our main contribution for GBM is to provide a simple and efficient algorithm that performs well in the connectivity regime and recovers the clusters exactly. The following theorem provides a weaker (but simpler to understand) bound.

► **Theorem 7** (Recovery algorithm for GBM). *Suppose we have a graph $G(V, E)$ generated according to $\text{GBM}(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n})$ and $b > \frac{1}{4 \ln 2 - 2}$, then there exists an efficient algorithm (see Algorithm 1) which recovers the correct partition in G with probability $1 - o(1)$ if $a - 8b > 1$.*

For the full range of parameter b , the (stronger) recovery guarantees for Algorithm 1 is discussed in Theorem 22 in Section 5. Table 1 lists some examples of the parameters when the proposed algorithm (Algorithm 1) can successfully recover the clusters. As can be anticipated, the connectivity results for RAGs apply to the ‘‘high dimensional’’ GBM.

■ **Table 1** Minimum value of a , given b for which Algorithm 1 resolves clusters correctly in the setting for $\text{GBM}(\frac{a \ln n}{n}, \frac{b \ln n}{n})$.

b	1	2	3	4	5	6	7
Minimum value of a	8.96	12.63	15.9	18.98	21.93	24.78	27.57

► **Definition 8** (The GBM in High Dimensions). *Given $V = V_1 \sqcup V_2, |V_1| = |V_2| = \frac{n}{2}$, choose a random vector X_u independently uniformly distributed in S^t for all $u \in V$. The geometric block model $\text{GBM}_t(r_s, r_d)$ with parameters $r_s > r_d$ is a random graph where an edge exists between vertices u and v if and only if,*

$$\begin{aligned} \|X_u - X_v\|_2 &\leq r_s \text{ when } u, v \in V_1 \text{ or } u, v \in V_2 \\ \|X_u - X_v\|_2 &\leq r_d \text{ when } u \in V_1, v \in V_2 \text{ or } u \in V_2, v \in V_1. \end{aligned}$$

We extend the algorithmic results to high dimensions.

► **Theorem 9.** *There exists a polynomial time efficient algorithm that recovers the partition from $\text{GBM}_t(r_s, r_d)$ with probability $1 - o(1)$ if $r_s = \Theta((\frac{\ln n}{n})^{\frac{1}{t}})$ and $r_s - r_d = \Omega((\frac{\ln n}{n})^{\frac{1}{t}})$. Moreover, any algorithm fails to recover the parts with probability at least $1/2$ if $r_s - r_d = o((\frac{\ln n}{n})^{\frac{1}{t}})$ or $r_s = o((\frac{\ln n}{n})^{\frac{1}{t}})$.*

3 Connectivity of Vertex-Random Graphs

In this section we give a proof of Theorem 2.

3.1 Sufficient condition for connectivity of VRG

► **Theorem 10.** *The vertex-random graph $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ is connected with probability $1 - o(1)$ if $a > 1$ and $a - b > 0.5$.*

To prove this theorem we use two main technical lemmas that show two different events happen with high probability simultaneously. First, we show that a $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ can be decomposed into union of cycles such that each of them cover $[0, 1]$. Second, we show there exists a vertex u_0 such that it has at least one neighbor in each cycle².

► **Lemma 11.** *A set of vertices $\mathcal{C} \subseteq V$ is called a cover of $[0, 1]$, if for any point y in $[0, 1]$ there exists a vertex $v \in \mathcal{C}$ such that $d(v, y) \leq \frac{a \ln n}{2n}$. A $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ is a union of cycles such that every cycle forms a cover of $[0, 1]$ as long as $a - b > 0.5$ and $a > 1$ with probability $1 - o(1)$.*

Let us consider a weaker condition $a - b > 1$ than the statement of Lemma 11. This will be much easier to prove and already establishes the connectivity result for RGG in one dimension. Note that since the points are on a circle, it is natural to define a right (clockwise) and a left (counterclockwise) direction. When $a - b > 1$, we show each vertex has at least one neighbor on both directions. To see this for each vertex u , assign two indicator $\{0, 1\}$ -random variables A_u^l and A_u^r , with $A_u^l = 1$ if and only if there is no node x to the left

² If the points are assumed to be present on a unit line $[0, 1]$, the same proof works with a difference that $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ can now be decomposed into a collection of paths that cover $[0, 1]$ and all these paths are connected through a vertex u_0 . This analysis requires us to handle the nodes present in the boundary region $- [0, \frac{a \ln n}{n}]$ and $[1 - \frac{a \ln n}{n}, 1]$ separately.

of node u such that $d(u, x) \in [\frac{b \ln n}{n}, \frac{a \ln n}{n}]$. Similarly, let $A_u^r = 1$ if and only if there is no node x to the right of node u such that $d(u, x) \in [\frac{b \ln n}{n}, \frac{a \ln n}{n}]$. Now define $A = \sum_u (A_u^l + A_u^r)$. We have,

$$\Pr(A_u^l = 1) = \Pr(A_u^r = 1) = \left(1 - \frac{(a-b) \ln n}{n}\right)^{n-1},$$

and,

$$\mathbb{E}[A] = 2n \left(1 - \frac{(a-b) \ln n}{n}\right)^{n-1} \leq 2n^{1-(a-b)}.$$

If $a - b > 1$ then $\mathbb{E}[A] = o(1)$ which implies, by invoking Markov inequality, that with high probability every node will have neighbors (connected by an edge in the VRG) on either side. Therefore every vertex will lie on a cycle that covers $[0, 1]$. This is true for every vertex, hence the graph is simply a union of cycles each of which is a cover of $[0, 1]$. The main technical challenge is to show that this conclusion remains valid even when $a - b > 0.5$, which is proved in Lemma 11 in Appendix A. Indeed, when $a - b > 0.5$, not every vertex will have neighbors on both sides; rather we need to analyze the connectivity via multi-hops to establish the desired result.

► **Lemma 12.** *Set two real numbers $k \equiv \lceil \frac{b}{(a-b)} \rceil + 1$ and $\epsilon < \frac{1}{2k}$. In an $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$, $0 < b < a$, with probability $1 - o(1)$ there exists a vertex u_0 and k nodes $\{u_1, u_2, \dots, u_k\}$ to the right of u_0 such that $d(u_0, u_i) \in [\frac{(i(a-b)-2i\epsilon) \ln n}{n}, \frac{(i(a-b)-(2i-1)\epsilon) \ln n}{n}]$ and another set of k nodes $\{v_1, v_2, \dots, v_k\}$ also to the right of u_0 such that $d(u_0, v_i) \in [\frac{((i(a-b)+b-(2i-1)\epsilon) \ln n}{n}, \frac{(i(a-b)+b-(2i-2)\epsilon) \ln n}{n})]$, for $i = 1, 2, \dots, k$. The arrangement of the vertices is shown in Figure 1.*

We delegate the proof of this lemma to Appendix A.

Proof of Theorem 10. We have shown that the two events mentioned in Lemmas 11 and 12 happen with high probability. Therefore they simultaneously happen under the condition $a > 1$ and $a - b > 0.5$. Now we will show that these events together imply that the graph is connected. To see this, consider the vertices $u_0, \{u_1, u_2, \dots, u_k\}$ and $\{v_1, v_2, \dots, v_k\}$ that satisfy the conditions of Lemma 12. We can observe that each vertex v_i has an edge with u_i and u_{i-1} , $i = 1, \dots, k$. This is because (see Figure 1 for a depiction)

$$d(u_i, v_i) \geq \frac{((i(a-b) + b - (2i-1)\epsilon) \ln n}{n} - \frac{i(a-b) - (2i-1)\epsilon \ln n}{n}}{n} = \frac{b \ln n}{n} \quad \text{and}$$

$$d(u_i, v_i) \leq \frac{i(a-b) + b - (2i-2)\epsilon \ln n}{n} - \frac{(i(a-b) - 2i\epsilon) \ln n}{n} = \frac{(b+2\epsilon) \ln n}{n}.$$

Similarly,

$$\begin{aligned} d(u_{i-1}, v_i) &\geq \frac{((i(a-b) + b - (2i-1)\epsilon) \ln n}{n} - \frac{(i-1)(a-b) - (2i-3)\epsilon \ln n}{n}}{n} \\ &= \frac{(a-2\epsilon) \ln n}{n} \quad \text{and} \end{aligned}$$

$$d(u_{i-1}, v_i) \leq \frac{i(a-b) + b - (2i-2)\epsilon \ln n}{n} - \frac{((i-1)(a-b) - 2(i-1)\epsilon) \ln n}{n} = \frac{a \ln n}{n}.$$

■ **Figure 1** The location of u_i and v_i relative to u scaled by $\frac{\ln n}{n}$ in Lemma 12. Edges stemming out of v_1, v_2, v_3 are shown as blue, red and violet respectively.

■ **Figure 2** The line segments where v_1, v_2, v_3 can have neighbors (scaled by $\frac{\log n}{n}$) in the proof of Theorem 10. The point t has to lie in one of these regions.

This implies that u_0 is connected to u_i and v_i for all $i = 1, \dots, k$. Using Lemma 11, the first event implies that the connected components are cycles spanning the entire line $[0, 1]$. Now consider two such disconnected components, one of which consists of the nodes $u_0, \{u_1, u_2, \dots, u_k\}$ and $\{v_1, v_2, \dots, v_k\}$. There must exist a node t in the other component (cycle) such that t is on the right of u_0 and $d(u_0, t) \equiv \frac{x \ln n}{n} \leq \frac{a \ln n}{n}$. If $x \leq b$, then there exists an i such that $i \leq k$ and $i(a - b) + b - a - (2i - 2)\epsilon \leq x \leq i(a - b) - (2i - 1)\epsilon$ (see Figure 2). Thus, when $x \leq b$, we can calculate the distance between t and v_i as

$$d(t, v_i) \geq \frac{(i(a - b) + b - (2i - 1)\epsilon) \ln n}{n} - \frac{(i(a - b) - (2i - 1)\epsilon) \ln n}{n} = \frac{b \ln n}{n}$$

and

$$d(t, v_i) \leq \frac{(i(a - b) + b - (2i - 2)\epsilon) \ln n}{n} - \frac{(i(a - b) + b - a - (2i - 2)\epsilon) \ln n}{n} = \frac{a \ln n}{n}.$$

Therefore t is connected to v_i when $x \leq b$. If $x > b$ then t is already connected to u_0 . Therefore the two components (cycles) in question are connected. This is true for all cycles and hence there is only a single component in the entire graph. Indeed, if we consider the cycles to be disjoint super-nodes, then we have shown that there must be a star configuration. ◀

The following result is an immediate corollary of the connectivity upper bound.

► **Corollary 13.** Consider a random graph $G(V, E)$ is being generated as a variant of the VRG where each $u, v \in V$ forms an edge if and only if $d(u, v) \in [0, c\frac{\ln n}{n}] \cup [b\frac{\ln n}{n}, a\frac{\ln n}{n}]$, $0 < c < b < a$. This graph is connected with probability $1 - o(1)$ if $a - b + c > 1$ or if $a - b > 0.5, a > 1$.

3.2 Necessary condition for connectivity of VRG

► **Theorem 14** (VRG connectivity lower bound). The $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ is not connected with probability $1 - o(1)$ if $a < 1$ or $a - b < 0.5$.

Proof. First of all, it is known that $\text{VRG}(n, [0, \frac{a \ln n}{n}])$ is not connected with high probability when $a < 1$ [25, 26]. Therefore $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ must not be connected with high probability when $a < 1$ as the connectivity interval is a strict subset of the previous case, and $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ can be obtained from $\text{VRG}(n, [0, \frac{a \ln n}{n}])$ by deleting all the edges that has the two corresponding random variables separated by distance less than $\frac{b \ln n}{n}$.

Next we will show that if $a - b < 0.5$ then there exists an isolated vertex with high probability. It would be easier to think of each vertex as a uniform random point in $[0, 1]$. Define an indicator variable A_u for every node u which is 1 when node u is isolated and 0 otherwise. We have,

$$\Pr(A_u = 1) = \left(1 - \frac{2(a-b) \ln n}{n}\right)^{n-1}.$$

Define $A = \sum_u A_u$, and hence

$$\mathbb{E}[A] = n \left(1 - \frac{2(a-b) \ln n}{n}\right)^{n-1} = n^{1-2(a-b)-o(1)}.$$

Therefore, when $a - b < 0.5$, $\mathbb{E}[A] = \Omega(1)$. To prove this statement with high probability we can show that the variance of A is bounded. Since A is a sum of indicator random variables, we have that

$$\begin{aligned} \text{Var}(A) &\leq \mathbb{E}[A] + \sum_{u \neq v} \text{Cov}(A_u, A_v) \\ &= \mathbb{E}[A] + \sum_{u \neq v} (\Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1) \Pr(A_v = 1)). \end{aligned}$$

Now, consider the scenario when the vertices u and v are at a distance more than $\frac{2a \ln n}{n}$ apart (happens with probability $1 - \frac{4a \ln n}{n}$). Then the region in $[0, 1]$ that is between distances $\frac{b \ln n}{n}$ and $\frac{a \ln n}{n}$ from both of the vertices is empty and therefore $\Pr(A_u = 1 \cap A_v = 1) = \left(1 - \frac{4(a-b) \ln n}{n}\right)^{n-2}$. When the vertices are within distance $\frac{2a \ln n}{n}$ of one another, then $\Pr(A_u = 1 \cap A_v = 1) \leq \Pr(A_u = 1)$. Therefore,

$$\begin{aligned} \Pr(A_u = 1 \cap A_v = 1) &\leq \left(1 - \frac{4a \ln n}{n}\right) \left(1 - \frac{4(a-b) \ln n}{n}\right)^{n-2} + \frac{4a \ln n}{n} \Pr(A_u = 1) \\ &\leq \left(1 - \frac{4a \ln n}{n}\right) n^{-4(a-b)+o(1)} + \frac{4a \ln n}{n} n^{-2(a-b)+o(1)}. \end{aligned}$$

Consequently for large enough n ,

$$\begin{aligned} \Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1) \Pr(A_v = 1) &\leq \left(1 - \frac{4a \ln n}{n}\right) n^{-4(a-b)+o(1)} \\ &\quad + \frac{4a \ln n}{n} n^{-2(a-b)+o(1)} - n^{-4(a-b)+o(1)} \leq \frac{8a \ln n}{n} \Pr(A_u = 1). \end{aligned}$$

Now,

$$\text{Var}(A) \leq \mathbb{E}[A] + \binom{n}{2} \frac{8a \ln n}{n} \Pr(A_u = 1) \leq \mathbb{E}[A](1 + 4a \ln n).$$

By using Chebyshev bound, with probability at least $1 - \frac{1}{\ln n}$,

$$A > n^{1-2(a-b)} - \sqrt{n^{1-2(a-b)}(1 + 4a \ln n) \ln n},$$

which imply for $a - b < 0.5$, there will exist isolated nodes with high probability. \blacktriangleleft

4 Connectivity of High Dimensional Random Annulus Graphs: Proof of Theorem 5

In this section we provide a proof sketch of Theorem 5 to establish the sufficient condition of connectivity of random annulus graphs. The details of the proof and the necessary conditions are provided in the full version [16].

Note, here $r_1 \equiv b \left(\frac{\ln n}{n}\right)^{1/t}$ and $r_2 \equiv a \left(\frac{\ln n}{n}\right)^{1/t}$. To show the upper bound for connectivity, the very first step is to define a *pole* which is a vertex that is connected to all vertices within a distance of r_2 from itself. We show such a pole exists with high probability in Lemma 15. This is a significant generalization of Lemma 12 from Section 3. We prove there exist annuli of suitably small radii around a node u_0 such that they are each non-empty and the vertices in these annuli are connected to each other along with u_0 . Moreover the center of the annuli are collinear. Every point within distance r_2 from u_0 is then shown to be connected to at least one vertex in these constructed annuli.

► **Lemma 15.** *In a $\text{RAG}_t \left(n, \left[b \left(\frac{\ln n}{n}\right)^{1/t}, a \left(\frac{\ln n}{n}\right)^{1/t} \right] \right)$, $0 < b < a$, with probability $1 - o(1)$ there exists a pole.*

Next, Lemma 16 shows that for every vertex u and every hyperplane L passing through u and not too close to the tangent hyperplane at u , there will be a neighbor of u on either side of the plane. Therefore, there should be a neighbor towards the direction of the pole. In order to formalize this, let us define a few regions associated with a node u and a hyperplane $L : w^T x = \beta$ passing through u .

$$\mathcal{R}_L^1 \equiv \{x \in S^t \mid r_1 \leq d(u, x) \leq r_2, w^T x \leq \beta\}$$

$$\mathcal{R}_L^2 \equiv \{x \in S^t \mid r_1 \leq d(u, x) \leq r_2, w^T x \geq \beta\}$$

$$\mathcal{A}_L \equiv \{x \mid x \in S^t, w^T x = \beta\}.$$

Informally, \mathcal{R}_L^1 and \mathcal{R}_L^2 represent the partition of the annulus on either side of the hyperplane L and \mathcal{A}_L represents the region on the sphere lying on L .

► **Lemma 16.** *If we sample n nodes from S^t according to $\text{RAG}_t \left(n, \left[b \left(\frac{\ln n}{n}\right)^{1/t}, a \left(\frac{\ln n}{n}\right)^{1/t} \right] \right)$, then for every node u and every hyperplane L passing through u such that \mathcal{A}_L is not all within distance r_2 of u , node u has a neighbor on both sides of the hyperplane L with probability at least $1 - \frac{1}{n}$ provided $(a/2)^t - b^t \geq \frac{8\sqrt{\pi}(t+1)^2 \Gamma(\frac{t+2}{2})}{\Gamma(\frac{t+3}{2})}$ and $a > 2b$.*

The proof of this lemma is quite challenging. Since, we do not know the location of the pole, we need to show that every point has a neighbor on both sides of the plane L no matter what the orientation of the plane. Since the number of possible orientations is uncountably infinite, we

cannot use a union-bound type argument. To show this we have to rely on the VC Dimension of the family of sets $\{x \in S^t \mid r_1 \leq \|u-x\|_2 \leq r_2, w^T x \geq \beta, \mathcal{A}_{L:w^T x=\beta} \text{ not all within } r_2 \text{ of } u\}$ for all hyperplanes L (which can be shown to be less than $t+1$). We rely on the celebrated result of [21] (we derive a continuous version of it), see full version [16], to deduce our conclusion.

For a node u and its corresponding location $X_u = (u_1, u_2, \dots, u_{t+1})$, define the particular hyperplane $L_u^* : x_1 = u_1$ which is normal to the line joining $u_0 \equiv (1, 0, \dots, 0)$ and the origin and passes through u . We now need one more lemma that will help us prove Theorem 5.

► **Lemma 17.** *For a particular node u and corresponding hyperplane L_u^* , if every point in $\mathcal{A}_{L_u^*}$ is within distance r_2 from u , then u must be within r_2 of u_0 .*

Proof of Theorem 5. We consider an alternate (rotated but not shifted) coordinate system by multiplying every vector by an orthonormal matrix such that the new position of the pole is the $t+1$ -dimensional vector $(1, 0, \dots, 0)$ where only the first coordinate is non-zero. Let the $t+1$ dimensional vector describing any node u in this new coordinate system be $\hat{u} = (\hat{u}_1, \hat{u}_2, \dots, \hat{u}_{t+1})$. Now consider the hyperplane $L : x_1 = \hat{u}_1$ and if u is not connected to the pole already, then by Lemma 16 and Lemma 17, the node u has a neighbor u_2 which has a higher first coordinate ($\hat{u}_2 > \hat{u}_1$). The same analysis applies for u_2 and hence we have a path where the first coordinate of every node is higher than the previous node. Since the number of nodes is finite, this path cannot go on indefinitely and at some point, one of the nodes is going to be within r_2 of the pole and will be connected to the pole. Therefore every node is going to be connected to the pole and hence our theorem is proved. ◀

5 The Geometric Block Model

In this section, we prove a necessary condition for exact cluster recovery of the GBM and give an efficient algorithm that matches that within a constant factor. Very interestingly, our algorithm is based on a simple triangle counting method, whose variants are used as popular heuristics for community recovery in many real networks [3, 29, 11]. This further validates the suitability of GBMs as a community detection model.

5.1 Immediate consequence of VRG connectivity

The following lower bound for GBM can be obtained as a consequence of Theorem 2.

► **Theorem 18 (Impossibility in GBM).** *Any algorithm to recover the partition in $\text{GBM}(\frac{a \ln n}{n}, \frac{b \ln n}{n})$ will give incorrect output with probability $1 - o(1)$ if $a - b < 0.5$ or $a < 1$.*

Proof. Consider the scenario that not only the geometric block model graph $\text{GBM}(\frac{a \ln n}{n}, \frac{b \ln n}{n})$ was provided to us, but also the random values $X_u \in [0, 1]$ for all vertex u in the graph were provided. We will show that we will still not be able to recover the correct partition of the vertex set V with probability at least 0.5 (with respect to choices of X_u , $u, v \in V$ and any randomness in the algorithm).

In this situation, the edge (u, v) where $d_L(X_u, X_v) \leq \frac{b \ln n}{n}$ does not give any new information than X_u, X_v . However the edges (u, v) where $\frac{b \ln n}{n} \leq d_L(X_u, X_v) \leq \frac{a \ln n}{n}$ are informative, as existence of such an edge will imply that u and v are in the same part. These edges constitute a vertex-random graph $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$. But if there are more than two components in this vertex-random graph, then it is impossible to separate out the vertices into the correct two parts, as the connected components can be assigned to any of the two parts and the VRG along with the location values $(X_u, u \in V)$ will still be consistent.

What remains to be seen that $\text{VRG}(n, [\frac{b \ln n}{n}, \frac{a \ln n}{n}])$ will have $\omega(1)$ components with high probability if $a - b < 0.5$ or $a < 1$. This is certainly true when $a - b < 0.5$ as we have seen in Theorem 14, there can indeed be $\omega(1)$ isolated nodes with high probability. On the other hand, when $a < 1$, just by using an analogous argument it is possible to show that there are $\omega(1)$ vertices that do not have any neighbors on the left direction (counterclockwise). We delegate the proof of this claim as Lemma 19. If there are k such vertices, there must be at least $k - 1$ disjoint candidates. This completes the proof. \blacktriangleleft

► **Lemma 19.** *A random geometric graph $G(n, \frac{a \ln n}{n})$ will have $\omega(1)$ disconnected components for $a < 1$.*

Proof. Define an indicator random variable A_u for a node u which is 1 if it does not have a neighbor on its left. We must have that $\Pr(A_u) = \left(1 - \frac{a \ln n}{n}\right)^{n-1}$. Therefore we must have that $\sum_u \mathbb{E}A_u = n^{1-a} = \Omega(1)$ if $a < 1$. This statement also holds true with high probability. To show this we need to prove that the variance of $\sum_u \mathbb{E}A_u$ is bounded. We have

$$\begin{aligned} \text{Var}(A) &< \mathbb{E}[A] + \sum_{u \neq v} \text{Cov}(A_u, A_v) \\ &= \mathbb{E}[A] + \sum_{u \neq v} \Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1)\Pr(A_v = 1) \end{aligned}$$

Now, consider the scenario when the vertices u and v are at a distance more than $\frac{2a \ln n}{n}$ apart (happens with probability at least $1 - \frac{4a \ln n}{n}$). Then the region in $[0, 1]$ that is within distance $\frac{a \ln n}{n}$ from both of the vertices is empty and therefore $\Pr(A_u = 1 \cap A_v = 1) = \Pr(A_u = 1)\Pr(A_v = 1|A_u = 1) \leq \Pr(A_u = 1)\Pr(A_v = 1) = (\Pr(A_u = 1))^2$. When the vertices are within distance $\frac{2a \ln n}{n}$ of one another, then $\Pr(A_u = 1 \cap A_v = 1) \leq \Pr(A_u = 1)$. Therefore,

$$\Pr(A_u = 1 \cap A_v = 1) \leq \left(1 - \frac{4a \ln n}{n}\right)(\Pr(A_u = 1))^2 + \frac{4a \ln n}{n} \Pr(A_u = 1).$$

Consequently,

$$\begin{aligned} \Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1)\Pr(A_v = 1) &\leq \left(1 - \frac{4a \ln n}{n}\right)(\Pr(A_u = 1))^2 \\ &\quad + \frac{4a \ln n}{n} \Pr(A_u = 1) - (\Pr(A_u = 1))^2 \leq \frac{4a \ln n}{n} \Pr(A_u = 1). \end{aligned}$$

Now,

$$\text{Var}(A) \leq \mathbb{E}[A] + \binom{n}{2} \frac{4a \ln n}{n} \Pr(A_u = 1) \leq \mathbb{E}[A](1 + 2a \ln n).$$

By using Chebyshev bound, with probability at least $1 - \frac{1}{\ln n}$,

$$A > n^{1-a} - \sqrt{n^{1-a}(1 + 2a \ln n) \ln n},$$

Now, observe that if there exist k nodes with no neighbor on one side, then there must exist $k - 1$ disconnected components. Hence the number of components in $G(n, \frac{a \ln n}{n})$ is $\omega(1)$. \blacktriangleleft

Indeed, when the locations X_u associated with every vertex u is provided, it is also possible to recover the partition when $a - b > 0.5$ and $a > 1$, matching the above lower bound exactly. Similar impossibility result extends to higher dimensional GBM from the necessary condition on connectivity of RAG.

5.2 A Recovery Algorithm for GBM

We now turn our attention to an efficient recovery algorithm for GBM. Intriguingly, we show a simple triangle counting based algorithm works well for GBM and recovers the communities in the connectivity regime.

■ **Algorithm 1** Community recovery in GBM.

Require: GBM $G = (V, E)$, r_s, r_d

- 1: **for** $(u, v) \in E$ **do**
- 2: **if** $\text{process}(u, v, r_s, r_d) = \text{false}$ **then**
- 3: $E.\text{remove}((u, v))$
- 4: **end if**
- 5: **end for**
- 6: **return** $\text{connectedComponent}(V, E)$

■ **Algorithm 2** process .

Require: u, v, r_s, r_d

Ensure: true/false

{Comment: When $a > 2b$, $t_1 = \min\{t : (2b + t) \ln \frac{2b+t}{2b} - t > 1\}$, $t_2 = \min\{t : (2b - t) \ln \frac{2b-t}{2b} + t > 1$ and $E_S = (2b + t_1) \frac{\ln n}{n}$ and $E_D = (2b - t_2) \frac{\ln n}{n}$ }

- 1: $\text{count} \leftarrow |\{z : (z, u) \in E, (z, v) \in E\}|$
- 2: **if** $\frac{\text{count}}{n} \geq E_S(r_d, r_s)$ or $\frac{\text{count}}{n} \leq E_D(r_d, r_s)$ **then**
- 3: **return** true
- 4: **end if**
- 5: **return** false

Suppose we are given a graph $G = (V : |V| = n, E)$ with two disjoint parts, $V_1, V_2 \subseteq V$ generated according to $\text{GBM}(r_s, r_d)$. The algorithm (Algorithm 1) goes over all edges $(u, v) \in E$. It counts the number of triangles containing the edge (u, v) by calling the process function that counts the number of common neighbors of u and v .

process outputs “true” if it is confident that the nodes u and v belong to the same cluster and “false” otherwise. More precisely, if the count is within some prescribed values E_S and E_D , it returns “false”. Note that the thresholds E_S and E_D refer to the maximum and minimum value of triangle-count for an “inter-cluster” edge. The algorithm removes the edge on getting a “false” from process function. After processing all the edges of the network, the algorithm is left with a reduced graphs (with certain edges deleted from the original). It then finds the connected components in the graph and returns them as the parts V_1 and V_2 .

It would have been natural to consider two thresholds E_D and E_S and if the triangle count of an edge is closer to E_S than E_D , then the two end-points are assigned to the same cluster and otherwise in separate clusters. Indeed such a natural algorithm has been analyzed in [15]. On the other hand, here we remove an edge if the triangle count lies in an interval. This is apparently non-intuitive, but gives a significant improvement over the previously known bound (see Figure 3).

Figure 3 The minimum gap between a and b permitted by our algorithm vs the previously known bound of [15].

5.3 Analysis of Algorithm 1

Given a graph $G(V, E) \equiv GBM(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n})$ with two clusters $V = V_1 \sqcup V_2$, and a pair of vertices $u, v \in V$, the events $\mathcal{E}_z^{u,v}, z \in V$ of any other vertex z being a common neighbor of both u and v given $(u, v) \in E$ are dependent; however given the distance between the corresponding random variables $d_L(X_u, X_v) = x$, the events are independent. This is a crucial observation that lets us overcome the difficulty of handling correlated edge formation.

Moreover, given the distance between two nodes u and v are the same, the probabilities of $\mathcal{E}_z^{u,v} \mid (u, v) \in E$ are different when u and v are in the same cluster and when they are in different clusters. Therefore the count of the common neighbors are going to be different, and substantially separated with high probability for two vertices in cases when they are from the same cluster or from different clusters. However, this may not be the case, if we do not restrict the distance to be the same and look at the entire range of possible distances.

The distribution of the number of common neighbors given $(u, v) \in E$ and $d(u, v) = x$ is given in Table 2 (follows from Lemma 23 and Lemma 24 from Appendix). As throughout this paper, we have assumed that there are only two clusters of equal size. In the table, $u \sim v$ means u and v are in the same cluster and $\text{Bin}(n, p)$ denotes a binomial random variable with mean np .

Table 2 Distribution of triangle count for an edge (u, v) conditioned on the distance between them $d(u, v) = d_L(X_u, X_v) = x$, when there are two equal sized clusters.

$(u, v) \in E$ $d(u, v) = x$	Distribution of count ($r_s > 2r_d$)		Distribution of count ($r_s \leq 2r_d$)	
	$u \sim v, x \leq r_s$	$u \not\sim v, x \leq r_d$	$u \sim v, x \leq r_s$	$u \not\sim v, x \leq r_d$
Motif : $z \mid (z, u) \in E, (z, v) \in E$	$\text{Bin}(\frac{n}{2} - 2, 2r_s - x) + \mathbb{1}\{x \leq 2r_d\} \text{Bin}(\frac{n}{2}, 2r_d - x)$	$\text{Bin}(n - 2, 2r_d)$	$\text{Bin}(\frac{n}{2} - 2, 2r_s - x) + \text{Bin}(\frac{n}{2}, 2r_d - x)$	$\text{Bin}(n - 2, \min(r_s + r_d - x, 2r_d))$

At this point in a $GBM(r_s, r_d)$ for any edge u, v that does not belong to the same part, the expected total number of common neighbors of u and v does not depend on their distance. In Lemma 20, we show that in this case the normalized total number of common neighbors is concentrated around $2r_d$.

► **Lemma 20.** *Suppose we are given a graph $G(V, E)$ generated according to $\text{GBM}(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n}), a \geq 2b$. Our algorithm with $E_S = (2b + t_1) \frac{\ln n}{n}$ and $E_D = (2b - t_2) \frac{\ln n}{n}$, deletes all the edges $(u, v) \in E$ such that u and v are in different parts with probability at least $1 - o(1)$, where*

$$t_1 = \min\{t : (2b + t) \ln \frac{2b + t}{2b} - t > 1\}, \quad t_2 = \min\{t : (2b - t) \ln \frac{2b - t}{2b} + t > 1\}.$$

Therefore, when Algorithm 1 finishes processing all the edges, all the “inter-cluster” edges are removed with high probability. However some of the “in-cluster” edges are also deleted, namely, those that have a count of common neighbors between E_S and E_D . In the next lemma, we show the necessary condition on the “in-cluster” edges such that they do not get removed by Algorithm 1.

► **Lemma 21.** *Suppose we are given a graph $G(V, E)$ generated according to $\text{GBM}(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n}), a \geq 2b$. Define t_1, t_2, E_D, E_S as in Lemma 20. Consider an edge $(u, v) \in E$ where u, v belong to the same part of the GBM and let $d(u, v) \equiv x \equiv \frac{\theta \ln n}{n}$. Suppose θ satisfies either of the following conditions:*

1. $\frac{1}{2} \left((4b + 2t_1) \ln \frac{4b + 2t_1}{2a - \theta} + 2a - \theta - 4b - 2t_1 \right) > 1$ and $0 \leq \theta \leq 2a - 4b - 2t_1$
 2. $\frac{1}{2} \left((4b - 2t_2) \ln \frac{4b - 2t_2}{2a - \theta} + 2a - \theta - 4b + 2t_2 \right) > 1$ and $a \geq \theta \geq \max\{2b, 2a - 4b + 2t_2\}$.
- Then Algorithm 1 with $E_S = (2b + t_1) \frac{\ln n}{n}$ and $E_D = (2b - t_2) \frac{\ln n}{n}$ will not remove this edge with probability at least $1 - O(\frac{1}{n(\ln n)^2})$.

Now we are in a position to prove our main theorem from this part.

► **Theorem 22.** *Suppose we are given a graph $G(V, E)$ generated according to $\text{GBM}(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n}), a \geq 2b$. Define t_1, t_2, E_S and E_D as in Lemma 20, and θ_1 and θ_2 as in Lemma 21. Then Algorithm 1 recovers the correct partition in G with probability $1 - o(1)$ if $a - \theta_2 + \theta_1 > 2$ OR $a - \theta_2 > 1, a > 2$.*

Proof. From Lemma 20, we know that after Algorithm 1 has processed all the edges, the edges with end-points in different parts of the GBM are all deleted with probability $1 - o(1)$. Moreover, from Lemma 21, an intra-cluster edge (u, v) will continue to exist if $d(u, v) \in [0, \theta_1] \cup [\theta_2, a]$ (by simply applying a union bound over at most $O(n \log n)$ edges). From Corollary 13, it is evident that each of the two parts of size $\frac{n}{2}$ each will be connected if either $a - \theta_2 + \theta_1 > 2$ or $a - \theta_2 > 1$ and $a > 2$. ◀

Theorem 7 is a weaker version of Theorem 22 which we obtain by setting specific values.

Proof of Theorem 7. Following the proof of Theorem 22, when $E_D = 0$ and $E_S = (2b + t_1) \frac{\ln n}{n}$, after Algorithm 1 processes all the edges, an edge between a pair u and v will continue to exist if $d(u, v) \in [0, \theta_1]$ which is equivalent to setting $\theta_2 \leq a$. Consider the case when $b > \frac{1}{4 \ln 2 - 2}$. Note that from Theorem 22, $t_1 = \min\{t : (2b + t) \ln \frac{2b + t}{2b} - t > 1\}$. We see that $t = 2b$ satisfies the above condition since, $(2b + t) \ln \frac{2b + t}{2b} - t = 4b \ln 2 - 2b > 1$. This shows that $t_1 \leq 2b$. Similarly, from Theorem 22,

$$\theta_1 = \max\{\theta : \frac{1}{2} \left((4b + 2t_1) \ln \frac{4b + 2t_1}{2a - \theta} + 2a - \theta - 4b - 2t_1 \right) > 1 \text{ and } 0 \leq \theta \leq 2a - 4b - 2t_1.\}$$

When $t_1 \leq 2b$, the expression $\theta \leq 2a - 4b - 2t_1$ is satisfied for all values of $\theta \leq 2a - 8b$. Hence, we choose $\theta = 2a - 16b$ to simplify the other expression and get the following chain of equations:

$$\begin{aligned} & \frac{1}{2} \left((4b + 2t_1) \ln \frac{4b + 2t_1}{2a - \theta} + 2a - \theta - 4b - 2t_1 \right) \\ & \geq \frac{1}{2} \left((4b + 2t_1) \ln \frac{4b + 2t_1}{2a - \theta} + 2a - \theta - 8b \right) = \frac{1}{2} \left((4b + 2t_1) \ln \frac{4b + 2t_1}{2a - \theta} \right) + 4b \\ & \geq \frac{1}{2} \left((4b) \ln \frac{4b}{2a - \theta} \right) + 4b \geq \frac{1}{2} \left((4b) \ln \frac{4b}{16b} \right) + 4b = -2b \ln 4 + 4b \end{aligned}$$

which is greater than 1 whenever b satisfies $b > \frac{1}{4-4\ln 2}$. However, since we assumed that $b > \frac{1}{2(2\ln 2-1)}$, the condition $b > \frac{1}{4-4\ln 2}$ is automatically satisfied as $\frac{1}{2(2\ln 2-1)} > \frac{1}{4-4\ln 2}$. This implies that $\theta_1 > 2a - 16b$.

Using, $\theta_1 > 2a - 16b$ and $\theta_2 = a$, the final condition of Theorem 22, $a - \theta_2 + \theta_1 > 2$ is satisfied whenever $\theta_1 > 2$ that is, $2a - 16b > 2$. Hence, whenever $2a - 16b > 2$, or, $a - 8b > 1$, Algorithm 1 will recover the correct partition with probability $1 - o(1)$. ◀

A Proof of Lemma 11 and Lemma 12

Proof of Lemma 11. The proof of this lemma is somewhat easily explained if we consider a weaker result (a stronger condition) with $a - b > 2/3$. Let us first briefly describe this case.

Consider a node u and assume without loss of generality that the position of u is 0 (i.e. $X_u = 0$). Associate four indicator $\{0, 1\}$ -random variables $A_u^i, i = 1, 2, 3, 4$ which take the value of 1 if and only if there does not exist any node x such that

1. $d(u, x) \in [b \frac{\ln n}{n}, a \frac{\ln n}{n}] \cup [0, \frac{a-b}{2} \frac{\ln n}{n}]$ for $i = 1$
2. $d(u, x) \in [b \frac{\ln n}{n}, a \frac{\ln n}{n}] \cup [-\frac{a-b}{2} \frac{\ln n}{n}, -b \frac{\ln n}{n}]$ for $i = 2$
3. $d(u, x) \in [-a \frac{\ln n}{n}, -b \frac{\ln n}{n}] \cup [-\frac{a+b}{2} \frac{\ln n}{n}, 0]$ for $i = 3$
4. $d(u, x) \in [-a \frac{\ln n}{n}, -b \frac{\ln n}{n}] \cup [b \frac{\ln n}{n}, \frac{a+b}{2} \frac{\ln n}{n}]$ for $i = 4$.

The intervals representing these random variables are shown in Figure 4.

Notice that $\Pr(A_u^i = 1) \leq \max\left\{\left(1 - 1.5(a - b)\frac{\ln n}{n}\right)^{n-1}, \left(1 - a\frac{\ln n}{n}\right)^{n-1}\right\}$ and therefore $\sum_{i,u} \mathbb{E}A_u^i \leq 4 \max\{n^{1-1.5(a-b)}, n^{1-a}\} = 4n^{\min\{1-1.5(a-b), 1-a\}}$. This means that for $a - b \geq 0.67$ and $a \geq 1$, $\sum_{i,u} \mathbb{E}A_u^i = o(1)$. Hence there exist vertices in all the regions described above for every node u with high probability.

Now, A_u^1 and A_u^2 being zero implies that either there is a vertex in $[b\frac{\ln n}{n}, a\frac{\ln n}{n}]$ or there exists two vertices v_1, v_2 in $[0, \frac{a-b}{2}\frac{\ln n}{n}]$ and $[-\frac{a-b}{2}\frac{\ln n}{n}, -b\frac{\ln n}{n}]$ respectively (see, Figure 4). In the second case, u is connected to v_2 and v_2 is connected to v_1 . Therefore u has nodes on left (v_2) and right (v_1) and u is connected to both of them through one hop in the graph.

Similarly, A_u^3 and A_u^4 being zero implies that either there exists a vertex in $[-a\frac{\ln n}{n}, -b\frac{\ln n}{n}]$ or again u will have vertices on left and right and will be connected to them. So, when all the four $A_u^i, i = 1, 2, 3, 4$ are zero together:

- $A_u^1 = A_u^2 = 0$ implies there is a neighbor of u on either sides or there is a single node in $[b\frac{\ln n}{n}, a\frac{\ln n}{n}]$
- $A_u^3 = A_u^4 = 0$ implies there is a neighbor of u on either sides or there is a single node in $[-a\frac{\ln n}{n}, -b\frac{\ln n}{n}]$

This shows that when $A_u^1 = A_u^2 = 0$ and $A_u^3 = A_u^4 = 0$ guarantee a node on only one side of u , there are nodes in $[b\frac{\ln n}{n}, a\frac{\ln n}{n}]$ and $[-a\frac{\ln n}{n}, -b\frac{\ln n}{n}]$. But in that case u has direct neighbors on both its left and right. We can conclude that every vertex u is connected to a vertex v on its right and a vertex w on its left such that $d(u, v) \in [0, a\frac{\ln n}{n}]$ and $d(u, w) \in [-a\frac{\ln n}{n}, 0]$; therefore every vertex is part of a cycle that covers $[0, 1]$.

■ **Figure 4** Representation of four different random variables for Lemma 11.

We can now extend this proof to the case when $a - b > 0.5$.

Let c be large number to be chosen specifically later. Consider a node u and assume that the position of u is 0. Now consider the four different regions $[-a\frac{\ln n}{n}, -b\frac{\ln n}{n}]$, $[-(a-b)\frac{\ln n}{n}, 0]$, $[b\frac{\ln n}{n}, a\frac{\ln n}{n}]$ and $[0, a - b\frac{\ln n}{n}]$ around u each divided into $L \equiv 2^c$ patches (intervals) of size $\theta = \frac{a-b}{2^c}$ in the following way:

1. $I_u^i = [\frac{(-a+(i-1)\theta) \ln n}{n}, \frac{(-a+i\theta) \ln n}{n}]$
2. $J_u^i = [\frac{(-(a-b)+(i-1)\theta) \ln n}{n}, \frac{(-(a-b)+i\theta) \ln n}{n}]$
3. $K_u^i = [\frac{(b+(i-1)\theta) \ln n}{n}, \frac{(b+i\theta) \ln n}{n}]$
4. $M_u^i = [\frac{((i-1)\theta) \ln n}{n}, \frac{i\theta \ln n}{n}]$

where $i = 1, 2, 3, \dots, L$. Note that any vertex in $\cup I_u^i \cup K_u^i$ is connected to u . See, Figure 5 for a depiction.

Consider a $\{0, 1\}$ -indicator random variable X_u that is 1 if and only if there does not exist any node in a region formed by union of any $2L - 1$ patches amongst the ones described above. Notice that when $a < 2b$, the patches do not overlap and the total size of $2L - 1$

■ **Figure 5** Pictorial representation of $I_u^i, J_u^i, K_u^i, M_u^i$ and their connectivity as described in Lemma 11. The colored lines show the regions that are connected to each other.

patches is $\frac{2^{c+1}-1}{2^c} \frac{(a-b) \ln n}{n}$ and when $a \geq 2b$, the patches can overlap and the total size of the $2L-1$ patches is going to be more than $\min\{\frac{2^{c+1}-1}{2^c} \frac{(a-b) \ln n}{n}, \frac{a \ln n}{n}\}$. Since there are $\binom{4L}{2L-1} \leq n^{\frac{4L}{\ln n}}$ possible regions that consists of $2L-1$ patches,

$$\begin{aligned} \sum_u \mathbb{E}X_u &\leq n \binom{4L}{2L-1} \left(1 - \min\left\{\frac{2^{c+1}-1}{2^c} \frac{(a-b) \ln n}{n}, \frac{a \ln n}{n}\right\}\right)^{n-1} \\ &\leq \max\{n^{1-\frac{2^{c+1}-1}{2^c}(a-b)+\frac{4L}{\ln n}}, n^{1-a+\frac{4L}{\ln n}}\}. \end{aligned}$$

At this point we can choose $c = c_n = o(\ln n)$ such that $\lim_n c_n = \infty$. Hence when $a-b > \frac{1}{2}$ and $a > 1$, for every vertex u there exists at least one patch amongst every $2L-1$ patches in $\cup I_u^i \cup J_u^j \cup K_u^k, i, j, k = 1, 2, \dots, L$ that contains a vertex.

Consider a collection of patches $\cup_i I_u^i \cup_j K_u^j, i, j = 1, 2, \dots, L$. We know that there exist two patches amongst these I_u^i s and K_u^j s that contain at least one vertices. If one of I_u^i s and one of K_u^j s contain two vertices, we found one neighbor of u on both left and right directions (see, Figure 5).

We consider the other case now. Without loss of generality assume that there are no vertex in all I_u^i s and there exist at least two patches in K_u^i s that contain at least one vertex each. Hence, there exists at least one of $\{K_u^i \mid i \in \{1, 2, \dots, L-1\}\}$ that contains a vertex. Similarly, we can also conclude in this case that there exists at least one of $\{J_u^i \mid i \in \{2, 3, \dots, L\}\}$ which contain a node. Assume J_u^ϕ to be the left most patch in $\cup J_u^i \mid i \in \{1, 2, \dots, L\}$ that contains a vertex (see, Figure 5). From our previous observation, we can conclude that $\phi \geq 2$.

We can observe that any vertex in J_u^j is connected to the vertices in patches $K_u^k, \forall k < j$. This is because for two vertices $v \in J_u^j$ and $w \in K_u^k$, we have

$$\begin{aligned} d(v, w) &\geq \frac{(b + (k-1)\theta) \ln n}{n} - \frac{(-(a-b) + j\theta) \ln n}{n} = \frac{(a + (k-j-1)\theta) \ln n}{n}; \\ d(v, w) &\leq \frac{(b + k\theta) \ln n}{n} - \frac{(-(a-b) + (j-1)\theta) \ln n}{n} = \frac{(a + (k-j+1)\theta) \ln n}{n}. \end{aligned}$$

Consider a collection of $2L-1$ patches $\{\cup I_u^i \cup J_u^j \cup K_u^k \mid i, j, k \in \{1, \dots, L\}, j > \phi, k \leq \phi-1\}$ where $\phi \geq 2$. This is a collection of $2L-1$ patches out of which one must have a vertex and since none of $\{J_u^j \mid j > \phi\}$ and I_u^i can contain a vertex, one of $\{K_u^k \mid k \leq \phi-1\}$ must contain the vertex. Recall that the vertex in J_u^ϕ is connected to any node in K_u^k for any $k \leq \phi-1$ and therefore u has a node to the right direction and left direction that are connected to u . Therefore every vertex is part of a cycle and each of the circles covers $[0, 1]$. ◀

Proof of Lemma 12. Recall that we want to show that there exists a node u_0 and k nodes $\{u_1, u_2, \dots, u_k\}$ to the right of u_0 such that $d(u_0, u_i) \in [\frac{(i(a-b)-2i\epsilon)\ln n}{n}, \frac{(i(a-b)-(2i-1)\epsilon)\ln n}{n}]$ and exactly k nodes $\{v_1, \dots, v_k\}$ to the right of u_0 such that $d(u_0, v_i) \in [\frac{((i(a-b)+b-(2i-1)\epsilon)\ln n}{n}, \frac{(i(a-b)+b-(2i-2)\epsilon)\ln n}{n}]$, for $i = 1, 2, \dots, k$ and ϵ is a constant less than $\frac{1}{2k}$ (see Figure 1 for a depiction). Let A_u be an indicator $\{0, 1\}$ -random variable for every node u which is 1 if u satisfies the above conditions and 0 otherwise. We will show $\sum_u A_u \geq 1$ with high probability. We have,

$$\begin{aligned} \Pr(A_u = 1) &= n(n-1) \dots (n-(2k-1)) \left(\frac{\epsilon \ln n}{n}\right)^{2k} \left(1 - 2k\epsilon \frac{\ln n}{n}\right)^{n-2k} \\ &= c_0 n^{-2k\epsilon} (\epsilon \ln n)^{2k} \prod_{i=0}^{2k-1} (1 - i/n) = c_1 n^{-2k\epsilon} (\epsilon \ln n)^{2k} \end{aligned}$$

where c_0, c_1 are just absolute constants independent of n (recall k is a constant). Hence,

$$\sum_u \mathbb{E}A_u = c_1 n^{1-2k\epsilon} (\epsilon \ln n)^{2k} \geq 1$$

as long as $\epsilon \leq \frac{1}{2k}$. Now, in order to prove $\sum_u A_u \geq 1$ with high probability, we will show that the variance of $\sum_u A_u$ is bounded from above. This calculation is very similar to the one in the proof of Theorem 14. Recall that if $A = \sum_u A_u$ is a sum of indicator random variables, we must have

$$\text{Var}(A) \leq \mathbb{E}[A] + \sum_{u \neq v} \text{Cov}(A_u, A_v) = \mathbb{E}[A] + \sum_{u \neq v} \Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1) \Pr(A_v = 1).$$

Now first consider the case when vertices u and v are at a distance of at least $\frac{2(a+b)\ln n}{n}$ apart (happens with probability $1 - \frac{4(a+b)\ln n}{n}$). Then the region in $[0, 1]$ that is within distance $\frac{(a+b)\ln n}{n}$ from both u and v is the empty-set. In this case, $\Pr(A_u = 1 \cap A_v = 1) = n(n-1) \dots (n-(4k-1)) \left(\frac{\epsilon \ln n}{n}\right)^{4k} \left(1 - 4k\epsilon \frac{\ln n}{n}\right)^{n-4k} = c_2 n^{-4k\epsilon} (\epsilon \ln n)^{4k}$, where c_2 is a constant.

In all other cases, $\Pr(A_u = 1 \cap A_v = 1) \leq \Pr(A_u = 1)$. Therefore,

$$\begin{aligned} \Pr(A_u = 1 \cap A_v = 1) &\leq \left(1 - \frac{4(a+b)\ln n}{n}\right) c_2 n^{-4k\epsilon} (\epsilon \ln n)^{4k} \\ &\quad + \frac{4(a+b)\ln n}{n} c_1 n^{-2k\epsilon} (\epsilon \ln n)^{2k} \end{aligned}$$

and

$$\begin{aligned} \text{Var}(A) &\leq c_1 n^{1-2k\epsilon} (\epsilon \ln n)^{2k} + \binom{n}{2} \left(\Pr(A_u = 1 \cap A_v = 1) - \Pr(A_u = 1) \Pr(A_v = 1) \right) \\ &\leq c_1 n^{1-2k\epsilon} (\epsilon \ln n)^{2k} + c_3 n^{1-2k\epsilon} (\ln n)^{2k+1} \leq c_4 n^{1-2k\epsilon} (\ln n)^{2k+1} \end{aligned}$$

where c_3, c_4 are constants. Again invoking Chebyshev's inequality, with probability at least $1 - \frac{1}{\ln n}$

$$A > c_1 n^{1-2k\epsilon} (\epsilon \ln n)^{2k} - \sqrt{c_4 n^{1-2k\epsilon} (\ln n)^{2k+2}}. \quad \blacktriangleleft$$

B Missing Proofs of Section 5

► **Lemma 23.** For any two vertices $u, v \in V_i : (u, v) \in E, i = 1, 2$ belonging to the same cluster with $d_L(X_u, X_v) = x$, the count of common neighbors $C_{u,v} \equiv |\{z \in V : (z, u), (z, v) \in E\}|$ is a random variable distributed according to $\text{Bin}(\frac{n}{2} - 2, 2r_s - x)$ when $r_s \geq x > 2r_d$ and according to $\text{Bin}(\frac{n}{2} - 2, 2r_s - x) + \text{Bin}(\frac{n}{2}, 2r_d - x)$ when $x \leq \min(2r_d, r_s)$, where $\text{Bin}(n, p)$ is a binomial random variable with mean np .

Proof. Without loss of generality, assume $u, v \in V_1$. For any vertex $z \in V$, let $\mathcal{E}_z^{u,v} \equiv \{(u, z), (v, z) \in E\}$ be the event that z is a common neighbor. For $z \in V_1$,

$$\begin{aligned} \Pr(\mathcal{E}_z^{u,v}) &= \Pr((z, u) \in E, (z, v) \in E) \\ &= 2r_s - x, \end{aligned}$$

since $d_L(X_u, X_v) = x$. For $z \in V_2$, we have,

$$\begin{aligned} \Pr(\mathcal{E}_z^{u,v}) &= \Pr((z, u), (z, v) \in E) \\ &= \begin{cases} 2r_d - x & \text{if } x < 2r_d \\ 0 & \text{otherwise} \end{cases}. \end{aligned}$$

Now since there are $\frac{n}{2} - 2$ points in $V_1 \setminus \{u, v\}$ and $\frac{n}{2}$ points in V_2 , we have the statement of the lemma. ◀

In a similar way, we can prove.

► **Lemma 24.** For any two vertices $u \in V_1, v \in V_2 : (u, v) \in E$ belonging to different clusters with $d_L(X_u, X_v) = x$, the count of common neighbors $C_{u,v} \equiv |\{z \in V : (z, u), (z, v) \in E\}|$ is a random variable distributed according to $\text{Bin}(n - 2, 2r_d)$ when $r_s > 2r_d$ and according to $\text{Bin}(n - 2, \min(r_s + r_d - x, 2r_d))$ when $r_s \leq 2r_d$ and $x \leq r_d$.

Proofs of Lemma 20 and Lemma 21

Proof of Lemma 20. Here we will use the fact that for $a \geq 1$, the number of edges in $\text{GBM}(r_s \equiv \frac{a \ln n}{n}, r_d \equiv \frac{b \ln n}{n})$ is $O(n \ln n)$ with probability $1 - \frac{1}{n^{\Theta(1)}}$. Consider any vertex $u \in V_1$ (symmetrically for $u \in V_2$), since the vertices are thrown uniformly at random in $[0, 1]$, the probability that a $v \in V_1, v \neq u$, is a neighbor of u is $\frac{a \ln n}{n}$, and for $v \in V_2$, the corresponding probability is $\frac{b \ln n}{n}$. Therefore, the expected degree of u is $\frac{(a+b)}{2} \ln n$. By a simple Chernoff bound argument, the degree of u is therefore $O(\ln n)$ with probability $1 - \frac{1}{n^c}$ for $c \geq 2$. By union bound over all the vertices, the total number of edges is $O(n \ln n)$ with probability $1 - \frac{1}{n}$.

Let Z denote the random variable that equals the number of common neighbors of two nodes $u, v \in V : (u, v) \in E$ such that u, v are from different parts of the GBM. Using Lemma 24, we know that Z is sampled from the distribution $\text{Bin}(n - 2, 2r_d)$, where $r_d = \frac{b \ln n}{n}$. Therefore,

$$\Pr(Z \geq nE_S) \leq \sum_{i=nE_S}^n \binom{n}{i} (2r_d)^i (n - 2r_d)^{n-i} \leq \exp\left(-nD\left((2b + t_1) \frac{\ln n}{n} \parallel \frac{2b \ln n}{n}\right)\right),$$

where $D(p \parallel q) \equiv p \ln \frac{p}{q} + (1 - p) \ln \frac{1-p}{1-q}$ is the KL divergence between Bernoulli(p) and Bernoulli(q) distributions. It is easy to see that,

$$nD\left(\frac{\alpha \ln n}{n} \parallel \frac{\beta \ln n}{n}\right) = \left(\alpha \ln \frac{\alpha}{\beta} + (\alpha - \beta)\right) \ln n - o(\ln n).$$

Therefore $\Pr(Z \geq nE_S) \leq \frac{1}{n(\ln n)^2}$ because $(2b + t_1) \ln \frac{2b+t_1}{2b} - t_1 > 1$. Similarly, we have that

$$\begin{aligned} \Pr(Z \leq nE_D) &\leq \sum_{i=0}^{nE_D} \binom{n}{i} (2r_d)^i (n - 2r_d)^{n-i} \leq \exp(-nD((2b-t)\frac{\ln n}{n} \parallel \frac{2b \ln n}{n})) \\ &\leq \frac{1}{n(\ln n)^2}. \end{aligned}$$

So all of the inter-cluster edges will be removed by Algorithm 1 with probability $1 - O(\frac{n \ln n}{n(\ln n)^2}) = 1 - o(1)$, as with probability $1 - o(1)$ the total number of edges in the graph is $O(n \ln n)$. ◀

Proof of Lemma 21. Let Z be the number of common neighbors of u, v . Recall that, u and v are in the same cluster. We know from Lemma 24 that Z is sampled from the distribution $\text{Bin}(\frac{n}{2} - 2, 2r_s - x) + \text{Bin}(\frac{n}{2}, 2r_d - x)$ when $x \leq 2r_d$, and from the distribution $\text{Bin}(\frac{n}{2} - 2, 2r_s - x)$ when $x \geq 2r_d$. We have,

$$\begin{aligned} \Pr(Z \leq nE_S) &= \begin{cases} \sum_{i=0}^{nE_S} \binom{\frac{n}{2}-2}{i} (2r_s - x)^i (1 - 2r_s + x)^{\frac{n}{2}-i-2} \\ \times \sum_{j=0}^{nE_S-i} \binom{\frac{n}{2}}{j} (2r_d - x)^j (1 - 2r_d + x)^{\frac{n}{2}-j} & \text{if } x \leq 2r_d \\ \sum_{i=0}^{nE_S} \binom{\frac{n}{2}-2}{i} (2r_s - x)^i (1 - 2r_s + x)^{\frac{n}{2}-i} & \text{otherwise} \end{cases} \\ &\leq e^{-\frac{n}{2}D(2E_S \parallel \frac{(2a-\theta) \ln n}{n})} \text{ since } 2a - \theta \geq 4b + 2t_1 \\ &\leq e^{-\frac{n}{2}D(\frac{(4b+2t_1) \ln n}{n} \parallel \frac{(2a-\theta) \ln n}{n})} \leq \frac{1}{n \ln^2 n}, \end{aligned}$$

because of Condition 1 of this lemma. Therefore, this edge will not be deleted with high probability.

Similarly, let us find the probability of $Z \geq nE_D = (2b - t_2) \ln n$. Let us just assume the worst case when $\theta \leq 2b$: that the edge is being deleted (see Condition 2, this is prohibited if that condition is satisfied). Otherwise, $\theta > 2b$ and,

$$\begin{aligned} \Pr(Z \geq nE_D) &= \sum_{i=nE_D}^n \binom{\frac{n}{2}-2}{i} (2r_s - x)^i (1 - 2r_s + x)^{\frac{n}{2}-i-2} \\ &\leq e^{-\frac{n}{2}D(2E_D \parallel \frac{(2a-\theta) \ln n}{n})} \text{ if } 2a - \theta \leq 4b - 2t_2 \\ &= e^{-\frac{n}{2}D(\frac{(4b-2t_2) \ln n}{n} \parallel \frac{(2a-\theta) \ln n}{n})} \leq \frac{1}{n \ln^2 n} \end{aligned}$$

because of Condition 2 of this lemma. ◀

A Local Stochastic Algorithm for Separation in Heterogeneous Self-Organizing Particle Systems

Abstract

We present and rigorously analyze the behavior of a distributed, stochastic algorithm for *separation* and *integration* in *self-organizing particle systems*, an abstraction of programmable matter. Such systems are composed of individual computational *particles* with limited memory, strictly local communication abilities, and modest computational power. We consider *heterogeneous* particle systems of two different colors and prove that these systems can collectively *separate* into different color classes or *integrate*, indifferent to color. We accomplish both behaviors with the same fully distributed, local, stochastic algorithm. Achieving separation or integration depends only on a single global parameter determining whether particles prefer to be next to other particles of the same color or not; this parameter is meant to represent external, environmental influences on the particle system. The algorithm is a generalization of a previous distributed, stochastic algorithm for *compression* (PODC '16) that can be viewed as a special case of separation where all particles have the same color. It is significantly more challenging to prove that the desired behavior is achieved in the heterogeneous setting, however, even in the bichromatic case we focus on. This requires combining several new techniques, including the *cluster expansion* from statistical physics, a new variant of the *bridging* argument of Miracle, Pascoe and Randall (RANDOM '11), the *high-temperature expansion* of the Ising model, and careful probabilistic arguments.

1 Introduction

Across many disciplines spanning computational, physical, and social sciences, heterogeneous systems self-organize into both separated (or segregated) and integrated states. Examples include molecules exhibiting attractive and repulsive forces, distinct types of bacteria competing for resources while collaborating towards common goals (e.g., [35, 39]), social insects tolerating or aggressing towards those from other colonies (e.g., [20, 30]), and inherent human biases that influence how we form and maintain social groups (e.g., [16, 37]). In each of these, individuals are of different “types”: integration occurs when the ensemble gathers together without much preference about the type of their neighbors, while separation occurs when individuals cluster with others of the same type. Here, we investigate these fundamental behaviors of separation or integration as they apply to *programmable matter*, a material that can alter its physical properties based on user input or stimuli from its environment. Instead of studying a particular instantiation of programmable matter, of which there are many [1, 7, 31, 36], we abstractly envision these systems as collections of simple, active computational *particles* that individually execute local distributed algorithms to collectively achieve some emergent behavior. We consider *heterogeneous* particle systems in which particles have immutable *colors*. We seek local, distributed algorithms that, when run by each particle independently and concurrently, result in emergent, self-organizing *separation* or *integration* of color classes.

This work uses the *stochastic approach to self-organizing particle systems* first used for *compression*, where (monochromatic) particles self-organize to gather together as tightly as possible [6]. Using this stochastic approach, one first defines an energy function where desired configurations have the lowest energy values. One then designs a Markov chain whose long run behavior favors these low energy configurations. This Markov chain is carefully designed so that all its transition probabilities can be computed locally, allowing it to be translated to a fully local distributed algorithm each particle can run independently. The resulting collective, emergent behavior of this distributed algorithm is thus described by the long run behavior of the Markov chain. Using this stochastic approach, we previously extended our compression algorithm [6] to an algorithm for *shortcut bridging* [2] – or maintaining bridge structures that balance the tradeoff between bridge efficiency and cost – and developed the theoretical basis for an experimental study in swarm robotics [32]. While the process of designing distributed algorithms for self-organizing particle systems via this stochastic approach is fairly well-understood, proving that such algorithms achieve their desired objectives remains quite challenging. In particular, it is not enough to know the desired configurations have the highest long-run probability; there may be so many other, lower probability configurations that they collectively outweigh the desirable ones. This energy/entropy trade-off has been studied in various Markov chains for the purposes of proving slow mixing, but we analyze it directly to show our algorithms achieve the desired objectives with high probability.

Here, we focus on separation and integration in heterogeneous systems. Our inspiration comes from the classical Ising model in statistical physics [18, 38], where the vertices of a graph are assigned positive and negative “spins” and there are rules governing the probability that adjacent vertices have the same spin. Connected to the Ising model is classical work from stochastic processes on the Schelling model of segregation [33, 34], which explores how individuals’ micro-motives can induce macro-level phenomena like racial segregation in residential neighborhoods. Recent variants of this model from computer science have investigated the degree of individual bias required to induce such segregation [5, 17], and a related distributed algorithm has been developed [29]. Our work differs from those on

the Ising and Schelling models because of natural physical constraints on systems of self-organizing, active particles like ours. For example, interpreting particles of one color to be vertices with positive spin and particles of another color to be particles with negative spin, this acts like an Ising model, but on a graph that evolves as particles move. Despite these obstacles, we apply ideas developed for rigorously analyzing the Ising and similar models to prove our distributed algorithm for separation and integration accomplishes the desired goals.

While we are interested in distributed algorithms, it is worth noting that efficient stochastic algorithms for separation can be challenging even with centralized Markov chains. Separation of a region into equitably sized, compact districts has been widely explored recently in the context of gerrymandering, where the aim is to sample colorings of a weighted graph from an appropriately defined stationary distribution [10, 15]. Heuristics for random districting have been discussed in the media, but there are still no known rigorous, efficient algorithms.

1.1 Results

We present a distributed algorithm for self-organizing separation and integration that takes as input two bias parameters, λ and γ . Setting $\lambda > 1$ corresponds to particles favoring having more neighbors; this is known to cause compression in homogeneous systems when λ is large enough [6]. For separation in the heterogeneous setting, we introduce a second parameter γ , where $\gamma > 1$ corresponds to particles favoring having more neighbors *of their own color*. We then investigate for what values of λ and γ our algorithm yields compression and separation. Informally, a particle system is separated if there is a subset of particles such that (i) the boundary between this subset and the rest of the system is small, (ii) a large majority of particles in this subset are of the same color, say c , and (iii) very few particles with color c exist outside of this subset. This notion of separation (defined formally in Definition 3) captures what it means for a system to have large monochromatic regions of particles.

We prove that for any $\lambda > 1$ and $\gamma > 4^{5/4} \sim 5.66$ such that $\lambda\gamma > 2(2 + \sqrt{2})e^{0.0003} \sim 6.83$, our algorithm accomplishes separation with high probability.¹ However, we prove the opposite for some values of γ close to one; counterintuitively, this even includes some values of $\gamma > 1$, the regime where particles favor having like-colored neighbors. Formally, we prove that for any $\lambda > 1$ and $\gamma \in (79/81, 81/79)$ such that $\lambda(\gamma + 1) > 2(2 + \sqrt{2})e^{0.00003} \sim 6.83$, our algorithm fails to achieve separation (i.e., it achieves integration) with high probability.

1.2 Proof Techniques

Because our distributed algorithm is based on a Markov chain, we can use standard tools such as detailed balance to understand its long-term behavior and prove its convergence to a unique probability distribution π over particle system configurations. This stationary distribution π depends on the input parameters λ and γ . Our main contribution is analyzing π for various ranges of λ and γ , showing that a configuration drawn from distribution π is either very likely (for large γ) or very unlikely (for γ close to one) to be separated.

To show separation occurs when λ and γ are both large, we modify the proof technique of *bridging* introduced by Miracle, Pascoe, and Randall [28]. To show separation does not occur when λ is large and γ is small (close to one), we use a probabilistic argument, a Chernoff-type bound, and a decomposition of configurations into different regions. These arguments – both

¹ We say an event A occurs with high probability (w.h.p.) if $\Pr[A] \geq 1 - c^n$, where $0 < c < 1$ and $\delta > 0$ are constants and n is the number of particles. Our w.h.p. results all have $\delta \in \{1/2, 1/2 - \varepsilon\}$, for arbitrarily small $\varepsilon > 0$.

for large and small γ – require that the particle system is compressed; i.e., that the system has perimeter $\Theta(\sqrt{n})$. However, the arguments from [6] showing compression occurs for homogeneous systems when λ is large do not extend to the heterogeneous setting.

We instead turn to the *cluster expansion* from statistical physics to show our separation algorithm achieves compression for large enough γ . The cluster expansion was first introduced in 1937 by Mayer [27], though a more modern treatment can be found in the textbook [12] where it is used to derive several properties of statistical physics models including the Ising and hard-core models. In the past year, the cluster expansion has received renewed attention in the computer science community due to the recent work of Helmuth, Perkins, and Regts that uses the cluster expansion to develop approximate counting and sampling algorithms for low-temperature statistical physics models on lattices including the Potts and hard-core models [14]. Subsequent work has considered similar techniques on expander graphs [19] and random regular bipartite graphs [23]. Inspired by the interpolation method of Barvinok [3, 4], these works give algorithms for estimating partition functions that explicitly calculate the first $\log n$ coefficients of the cluster expansion. We use the cluster expansion differently, to separate the volume and surface contributions to a partition function.

The cluster expansion is a power series representation of $\ln Z$ where Z is a *polymer partition function*. We relate each of our quantities of interest to a particular polymer partition function, and then use a version of the Kotecký-Preiss condition [21] to show that the power series in the cluster expansion is convergent for the ranges of parameters we are interested in. We then use this convergent cluster expansion to split our polymer partition functions into a *volume term*, depending only on the size of the region of interest, and a *surface term*, depending only on its perimeter. This separation into volume and surface terms turns out to be the key to our compression argument, both for large γ and for γ close to one. While splitting partition functions into volume and surface terms is not a new idea in the statistical physics literature (for example, Section 5.7.1 of [12] uses it to derive an explicit expression for the infinite volume pressure of the Ising model on \mathbb{Z}^d with large magnetic field), we are the first to bring this approach into the computer science literature. We are hopeful it will be useful beyond its specific applications in this paper.

2 Background

We begin by defining our amoebot model for programmable matter and stating a few key results. We then extend the amoebot model to heterogeneous particle systems and formally define what it means for a system to be separated or integrated. We conclude with the necessary terminology and results on Markov chains.

2.1 The Amoebot Model

In the *amoebot model*, introduced in [9] and fully described in [8], programmable matter consists of individual, homogeneous computational elements called *particles*. In its geometric variant, particles are assumed to occupy nodes of the triangular lattice $G_\Delta = (V, E)$ and can move along its edges (see Figure 1a). Each node in V can be occupied by at most one particle at a time. Each particle occupies either a single node in V (i.e., it is *contracted*) or a pair of adjacent nodes in V (i.e., it is *expanded*), as in Figure 1b. Particles move via a series of *expansions* and *contractions*: a contracted particle can expand into an unoccupied adjacent node to become expanded, and completes its movement by contracting to once again occupy a single node.

■ **Figure 1** (a) A section of the triangular lattice G_Δ . (b) Expanded and contracted particles (black dots) on G_Δ (gray lattice). Particles with a black line between their nodes are expanded.

Two particles occupying adjacent nodes are said to be *neighbors*. Each particle is *anonymous*, lacking a unique identifier, but can locally identify each of its neighboring locations and can determine which of these are occupied by particles. Each particle has a constant-size local memory that it can write to and its neighbors can read from for communication. In particular, a particle stores whether it is contracted or expanded in its memory. Particles do not have any access to global information such as a shared compass, coordinate system, or estimate of the size of the system.

The system progresses through *atomic actions* according to the standard asynchronous model of computation from distributed computing (see, e.g., [25]). A classical result under this model states that for any concurrent asynchronous execution of atomic actions, there exists a sequential ordering of actions producing the same end result, provided conflicts that arise in the concurrent execution are resolved. In the amoebot model, an atomic action corresponds to the activation of a single particle. Once activated, a particle can (i) perform a constant amount of computation involving information it reads from its local memory and its neighbors' memories, (ii) write to its local memory, and (iii) perform at most one expansion or contraction. Conflicts involving simultaneous particle expansions into the same unoccupied node are assumed to be resolved arbitrarily such that at most one particle moves to some unoccupied node at any given time. Thus, while in reality many particles may be active concurrently, it suffices when analyzing algorithms under the amoebot model to consider a sequence of activations where only one particle is active at a time.

2.2 Terminology and Results for Homogeneous Particle Systems

We now recall the relevant terminology and notation from our previous work on compression [6]. A particle system *arrangement* is the set of vertices of the triangular lattice G_Δ occupied by particles. Two arrangements are equivalent if they are translations of each other; we define a particle system *configuration* to be an equivalence class of arrangements. An *edge* of a configuration is an edge of G_Δ where both endpoints are occupied by particles. A configuration is *connected* if for any two particles in the system, there is a path of such edges between them. A configuration has a *hole* if there is a maximal, finite, connected component of unoccupied vertices in G_Δ .

As we justify with Lemma 6, our analysis will focus on connected, hole-free configurations. The *boundary* of such a configuration σ is the closed walk \mathcal{P} on edges of σ that encloses all particles of σ and no unoccupied vertices of G_Δ . The *perimeter* $p(\sigma)$ of configuration σ is the length of this walk, also denoted $|\mathcal{P}|$. The following bounds the number of configurations with a given perimeter.

► **Lemma 1** ([6], Lemma 4.3). *For any $\nu > 2 + \sqrt{2}$, there is an integer $n_1(\nu)$ such that for all $n \geq n_1(\nu)$, the number of connected, hole-free particle system configurations with n particles and perimeter k is at most ν^k .*

Let $p_{\min}(n)$ be the minimum possible perimeter for a configuration of n particles; it is easy to see that $p_{\min}(n) = \Theta(\sqrt{n})$. Given any $\alpha > 1$, a configuration of n particles is said to be α -compressed if $p(\sigma) \leq \alpha \cdot p_{\min}(n)$. The following lemma establishes a concrete upper bound on $p_{\min}(n)$.

► **Lemma 2.** *For any $n \geq 1$, there is a connected, hole-free particle system configuration of n particles with perimeter at most $2\sqrt{3}\sqrt{n}$. That is, $p_{\min}(n) \leq 2\sqrt{3}\sqrt{n}$.*

Proof. This lemma follows easily from noting that hexagonal configurations of n particles have perimeter on the order of $2\sqrt{3}\sqrt{n}$; a proof can be found in Appendix A.1. ◀

2.3 Heterogeneous Particle Systems

Generalizing previous work on the amoebot model in which all particles are homogeneous and indistinguishable, we assume that each particle P has a fixed *color* $c(P) \in \{c_1, \dots, c_k\}$ that is visible to itself and its neighbors, where $k \ll n$ is a constant. We extend the definition of *configuration* given in Section 2.2 to include both the vertices of G_Δ occupied by particles as well as the colors of those particles. An edge of configuration σ with endpoints occupied by particles P and Q is *homogeneous* if $c(P) = c(Q)$ and *heterogeneous* otherwise.

We further extend the original model by allowing neighboring particles to exchange their positions in a *swap move*. Swap moves have no meaning in homogeneous systems as all particles are indistinguishable, but they grant heterogeneous systems flexibility in allowing particles trapped in the interior of the system to move freely.² These swap moves are not necessary for the correctness of our algorithm or our rigorous analysis, but enable faster convergence in practice.

In this paper, we study heterogeneous systems with $k = 2$ color classes. As discussed in Section 5, our algorithm performs well in practice for larger values of k and we expect our proof techniques would generalize without needing significant new ideas. However, this generalization would be cumbersome; thus, for simplicity, we restrict our attention to systems with colors $\{c_1, c_2\}$. For 2-heterogeneous systems, we can formally define separation with respect to having large monochromatic regions.

► **Definition 3.** *For $\beta > 0$ and $\delta \in (0, 1/2)$, a 2-heterogeneous particle system configuration σ is said to be (β, δ) -separated if there is a subset of particles R such that:*

1. *There are at most $\beta\sqrt{n}$ edges of σ with exactly one endpoint in R ;*
2. *The density of particles of color c_1 in R is at least $1 - \delta$; and*
3. *The density of particles of color c_1 not in R is at most δ .*

Unpacking this definition, β controls how small a boundary there is between the monochromatic region R and the rest of the system, with smaller β requiring smaller boundaries. The δ parameter expresses the tolerance for having particles of the wrong color within the monochromatic region R : small values of δ require stricter separation of the color classes, while larger values of δ allow for more integrated configurations. Notably, R does not need to be connected.

2.4 Markov Chains

A thorough treatment of Markov chains can be found in the standard textbook [22]. A *Markov chain* is a memoryless random process on a state space Ω ; for our purposes, Ω is finite and discrete. We focus on discrete time Markov chains, where one transition occurs

² In domains where physical swap moves are unrealistic, colors could be treated as in-memory attributes that could be exchanged by neighboring particles to simulate a swap move.

per *iteration* (or *step*). Because of its stochasticity, we can completely describe a Markov chain by its transition matrix M , which is an $|\Omega| \times |\Omega|$ matrix where for $x, y \in \Omega$, $M(x, y)$ is the probability, if in state x , of transitioning to state y in one step. The t -step transition probability $M^t(x, y)$ is the probability of transitioning from x to y in exactly t steps.

A Markov chain is *ergodic* if it is both *irreducible* (i.e., for all $x, y \in \Omega$ there is a t such that $M^t(x, y) > 0$) and *aperiodic* (i.e., for all $x \in \Omega$, $\gcd\{t : M^t(x, x) > 0\} = 1$). A *stationary distribution* of a Markov chain is a probability distribution π over Ω such that $\pi M = \pi$. Any finite, ergodic Markov chain converges to a unique stationary distribution given by $\pi(y) = \lim_{t \rightarrow \infty} M^t(x, y)$ for any $x, y \in \Omega$; importantly, for such chains this distribution is independent of starting state x . To verify π' is the unique stationary distribution of a finite ergodic Markov chain, it suffices to check that $\pi'(x)M(x, y) = \pi'(y)M(y, x)$ for all $x, y \in \Omega$ (the *detailed balance condition*; see, e.g., [11]).

Given a state space Ω , a set of allowable transitions between states, and a desired stationary distribution π on Ω , the Metropolis-Hastings algorithm [13] gives a Markov chain on Ω with those transitions that converges to π . For separation, the state space contains particle configurations and transitions correspond to configurations that differ by one particle move; the stationary distribution π favors well-separated configurations; and we calculate transition probabilities according to the Metropolis-Hastings algorithm (using a *Metropolis filter*). Importantly, we choose π so that these transition probabilities can be calculated by an individual particle using only information in its local neighborhood.

3 The Separation Algorithm

We now present our stochastic, local, distributed algorithm for separation. Our algorithm achieves separation by biasing particles towards moves that both gain them more neighbors overall and more like-colored neighbors. We use two bias parameters to control this preference: $\lambda > 1$ corresponds to particles favoring having more neighbors, and $\gamma > 1$ corresponds to particles favoring having more neighbors of their own color.

In order to leverage powerful techniques from Markov chain analysis and statistical physics to prove the correctness of our algorithm, we design our algorithm to follow certain invariants. First, assuming the initial particle system configuration is connected, our algorithm ensures it remains connected; this is necessary because particles have strictly local communication abilities so a disconnected particle is unable to communicate with or even find the rest of the particles. Second, our algorithm eventually eliminates all holes in the configuration, and no new holes are ever formed. This is necessary because our proof techniques only apply to hole-free configurations. Third, once all holes have been eliminated, all moves allowed by our algorithm are *reversible*: if a particle moves from node u to an adjacent node v in one step, there is a nonzero probability that it moves back to u in the next step. Finally, the moves allowed by our algorithm suffice to transform any connected, hole-free configuration into any other connected, hole-free configuration.

Our algorithm uses two locally-checkable properties that ensure particles do not disconnect the system or form a hole when moving (our first two invariants). We use the following notation. For a location ℓ – i.e., a node of the triangular lattice G_Δ – let $N_i(\ell)$ denote the particles of color c_i occupying locations adjacent to ℓ . For neighboring locations ℓ and ℓ' , let $N_i(\ell \cup \ell')$ denote the set $N_i(\ell) \cup N_i(\ell')$, excluding particles occupying ℓ and ℓ' . When ignoring color, let $N(\ell) = \bigcup_i N_i(\ell)$; define $N(\ell \cup \ell')$ analogously. Let $S = N(\ell) \cap N(\ell')$ denote the set of particles adjacent to both locations. A particle can move from location ℓ to ℓ' if one of the following are satisfied:

► **Property 4.** $|\mathbb{S}| \in \{1, 2\}$ and every particle in $N(\ell \cup \ell')$ is connected to exactly one particle in \mathbb{S} by a path through $N(\ell \cup \ell')$.

► **Property 5.** $|\mathbb{S}| = 0$, and both $N(\ell) \setminus \{\ell'\}$ and $N(\ell') \setminus \{\ell\}$ are nonempty and connected.

Note these properties do not need to be verified for swap moves, since swap moves do not change the set of occupied locations and thus cannot disconnect the system or create a hole.

We now define the Markov chain \mathcal{M} for separation. The state space Ω of \mathcal{M} is the set of all connected heterogeneous particle system configurations of n contracted particles, and Algorithm 1 defines its transition probabilities. We note that \mathcal{M} , a centralized Markov chain, can be directly translated to a fully distributed, local, asynchronous algorithm \mathcal{A} that can be run by each particle independently and concurrently to achieve the same system behavior. This translation is much the same as for previous algorithms developed using the stochastic approach to self-organizing particle systems [2, 6]; we refer the interested reader to those papers for details. Importantly, this translation is only possible because all probability calculations and property checks in \mathcal{M} use strictly local information available to the particles involved. Simulations of \mathcal{M} can be found in Section 3.2.

■ **Algorithm 1** Markov Chain \mathcal{M} for Separation and Integration.

Beginning at any connected configuration σ_0 of n particles, repeat:

- 1: Choose a particle P uniformly at random; let c_i be its color and ℓ its location.
 - 2: Choose a neighboring location ℓ' and $q \in (0, 1)$ each uniformly at random.
 - 3: **if** ℓ' is unoccupied **then**
 - 4: P expands to occupy both ℓ and ℓ' .
 - 5: Let $e = |N(\ell)|$ (resp., $e_i = |N_i(\ell)|$) be the number of neighbors (resp., of color c_i) P had when contracted at location ℓ , and define $e' = |N(\ell')|$ and $e'_i = |N_i(\ell')|$ analogously.
 - 6: **if** (i) $e \neq 5$, (ii) ℓ and ℓ' satisfy Property 4 or 5, and (iii) $q < \lambda^{e'-e} \cdot \gamma^{e'_i - e_i}$ **then**
 - 7: P contracts to ℓ' .
 - 8: **else** P contracts back to ℓ .
 - 9: **else if** ℓ' is occupied by particle Q of color c_j **then**
 - 10: **if** $q < \gamma^{|N_i(\ell') \setminus \{P\}| - |N_i(\ell)| + |N_j(\ell) \setminus \{Q\}| - |N_j(\ell')|}$ **then** P and Q perform a swap move.
-

3.1 The Stationary Distribution of Markov Chain \mathcal{M}

In this section, we prove that Markov chain \mathcal{M} maintains the four invariants described previously and then characterize its stationary distribution.

► **Lemma 6.** *If the particle system is initially connected, it remains connected throughout the execution of \mathcal{M} . Moreover, \mathcal{M} eventually eliminates any holes in the initial configuration, after which no holes are ever introduced again.*

Proof. This follows directly from analogous results for compression [6]. Although the separation and compression algorithms assign different probabilities to particle moves, the set of allowed movements is exactly the same, excluding swap moves that do not change the set of occupied nodes of G_Δ , so they cannot disconnect the system or introduce a hole. ◀

► **Lemma 7.** *Once all holes have been eliminated, every possible particle move is reversible; that is, if there is a positive probability of moving from configuration σ to configuration τ , then there is a positive probability of moving from τ to σ .*

Proof. Suppose, for example, that a particle P moves from location ℓ to ℓ' . In the next time step, it is possible for P to be chosen again (Step 1) and for ℓ to be chosen as the position to explore (Step 2). Because Properties 4 and 5 are symmetric with respect to ℓ and ℓ' , whichever was satisfied in the forward move will also be satisfied in this reverse move. Finally, the probability checked in Condition (iii) of Step 7 is always nonzero, so all together there is a nonzero probability that P moves back to ℓ in this reverse move. Swap moves can be shown to be reversible in a similar way. ◀

► **Lemma 8.** *Markov chain \mathcal{M} is ergodic on the space of connected, hole-free configurations.*

Proof Sketch. One can show that \mathcal{M} is irreducible (i.e., the moves of \mathcal{M} suffice to transform any configuration to any other configuration) similarly to the proof of the same fact for compression [6]: it is first shown that any configuration can be reconfigured into a straight line; then, the line can be sorted by the color of the particles; finally, by reversibility (Lemma 7), the line can be reconfigured into any configuration. Additionally, it is easy to see that \mathcal{M} is aperiodic: at each iteration of \mathcal{M} , there is a nonzero probability that the configuration does not change. Thus, because \mathcal{M} is irreducible and aperiodic, we conclude it is ergodic. ◀

Because \mathcal{M} is finite and ergodic, it converges to a unique stationary distribution π that we now characterize. For a configuration σ , let $h(\sigma)$ be the number of heterogeneous edges in σ .

► **Lemma 9.** *For $Z = \sum_{\sigma} (\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)}$, the stationary distribution of \mathcal{M} is:*

$$\pi(\sigma) = \begin{cases} (\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)} / Z & \text{if } \sigma \text{ is connected and hole-free;} \\ 0 & \text{otherwise.} \end{cases}$$

Proof Sketch. By Lemma 6, when \mathcal{M} starts at a connected configuration it eventually reaches and remains in the set of configurations that are connected and hole-free. Thus, disconnected configurations and configurations with holes have zero weight at stationarity. In Appendix A.2, we show using detailed balance that the unique stationary distribution of \mathcal{M} can be written, for σ connected and hole-free, as $\pi(\sigma) = \lambda^{e(\sigma)} \cdot \gamma^{a(\sigma)} / Z_e$ where $e(\sigma)$ is the number of edges and $a(\sigma)$ is the number of homogeneous edges of σ and $Z_e = \sum_{\sigma} \lambda^{e(\sigma)} \cdot \gamma^{a(\sigma)}$. This can be rewritten as in the lemma using two facts: (i) since every edge is either homogeneous or heterogeneous, $e(\sigma) = a(\sigma) + h(\sigma)$; and (ii) for any connected, hole-free configuration σ , $e(\sigma) = 3n - p(\sigma) - 3$, a result shown in [6]. ◀

The remainder of this paper will be spent analyzing this stationary distribution.

3.2 Simulations

We supplement our rigorous results with simulations that show separation occurs for even better values of λ and γ than our proofs guarantee, indicating that our proven bounds are likely not tight. We simulated \mathcal{M} on heterogeneous particle systems with two colors, using 50 particles of each color. Figure 2 shows the progression of \mathcal{M} over time with bias parameters $\lambda = 4$ and $\gamma = 4$, the regime in which particles prefer to have more neighbors, especially those of their own color. The simulation ran for nearly 70 million iterations, but much of the system's compression and separation occurs in the first million iterations. Separation still occurs even when swap moves are disallowed, but takes much longer to achieve.

Figure 3 compares the resulting system configurations after running \mathcal{M} from the same initial configuration for the same number of iterations, varying only the values of λ and γ . We observe four distinct phases: compressed-separated, compressed-integrated, expanded-separated, and expanded-integrated. We rigorously verify the compressed-separated behavior

■ **Figure 2** A 2-heterogeneous particle system of 100 particles starting from an arbitrary initial configuration after (from left to right) 0; 50,000; 1,050,000; 17,050,000; and 68,250,000; iterations of \mathcal{M} with $\lambda = 4$ and $\gamma = 4$.

	$\gamma = 5.20$ (Separation)	$\gamma = 0.58$ (Integration)
$\lambda = 5.20$ (Compression)		
$\lambda = 0.58$ (Expansion)		

■ **Figure 3** A 2-heterogeneous particle system of 100 particles starting in the leftmost configuration of Figure 2 after 50,000,000 iterations of \mathcal{M} for various values of the parameters λ and γ .

(i.e., when λ and γ are large), and do the same for the compressed-integrated behavior (i.e., when λ is large and γ is small). We do not give proofs for expanded configurations; in fact, our current definition of separation may not accurately capture what occurs in expanded configurations.

4 Summary of Results and Proofs

Here we summarize our results and proofs; details have been omitted due to length constraints.

We want to know for which values of λ and γ separation does or does not occur. Our proof techniques only apply to compressed configurations, so we must first show that Markov chain \mathcal{M} achieves compression for the values of λ and γ we are interested in. Previous proofs of compression in homogeneous particle systems break down for heterogeneous systems, so we utilize the *cluster expansion* to overcome this obstacle. The cluster expansion comes from statistical physics and allows us to rewrite a sum over collections of disjoint objects in terms of a sum over collections of overlapping objects. This latter sum is often much easier to work with. For the cluster expansion to be useful, the formal power series it involves must be convergent. We highly recommend Chapter 5 of [12] to learn more about the cluster expansion. Here we present only the relevant definitions and results from this chapter.

In a *polymer model*, we consider a finite set Γ , the elements of which are called *polymers*. We will consider polymers that are collections of edges of G_Δ having certain properties; for large γ , our polymers are minimal cut sets that we call *loops*, and when γ is close to one, our polymers are connected edge sets with an even number of edges incident on each vertex. Formally, polymers only need to satisfy:

- Each polymer $\xi \in \Gamma$ has a real *weight* $w(\xi)$.³
- There is a notion of pairwise *compatibility* for polymers.

Polymers are typically compatible when they are well-separated in some sense. Our loop polymers will be compatible when they share no edges, and our even polymers will be compatible when they are not incident on any of the same vertices. We say a collection of polymers $\Gamma' \subseteq \Gamma$ is *compatible* if all polymers in Γ' are pairwise compatible.

The *polymer partition function* is defined as:

$$\Xi = \sum_{\substack{\Gamma' \subseteq \Gamma \\ \text{compatible}}} \prod_{\xi \in \Gamma'} w(\xi).$$

Many partition functions of spin systems, such as the Ising model or the hard-core lattice gas model, can be written in this form as polymer partition functions. Such an abstract sum can sometimes be hard to analyze, but the *cluster expansion* gives a way of rewriting this expression in terms of a sum over subsets $\Gamma' \subseteq \Gamma$ where many polymers are incompatible; because incompatible polymers “touch”, we can enumerate such collections more easily and thus such sums are often easier to work with

Formally, consider an ordered multiset $X = \{\xi_1, \xi_2, \dots, \xi_m\} \subseteq \Gamma$. Let H_X be the *incompatibility graph* on vertex set $\{1, 2, \dots, m\}$ where $i \sim j$ whenever ξ_i and ξ_j are incompatible. We say that the X is a *cluster* if H_X is connected.⁴ Let $|X| = m$ denote the number of polymers in cluster X (with polymers counted with the appropriate multiplicities).

The *cluster expansion* is the formal power series for $\ln \Xi$ given in Equation 2. Often this power series does not converge, but the *Kotecky-Preiss condition* guarantees convergence and is often easy to verify [21]. The following theorem states the Kotecky-Preiss condition (Equation 1) and the cluster expansion of Ξ .

► **Theorem 10** ([12], Chapter 5). *Let Γ be a finite set of polymers ξ with real weights $w(\xi)$ and a notion of pairwise compatibility. If there exists a function $a : \Gamma \rightarrow \mathbb{R}_{>0}$ such that for all $\xi^* \in \Gamma$,*

$$\sum_{\substack{\xi \in \Gamma: \\ \xi, \xi^* \text{ incompatible}}} |w(\xi)| e^{a(\xi)} \leq a(\xi^*), \tag{1}$$

then the polymer partition function Ξ satisfies

$$\ln \Xi = \sum_{X: \text{cluster}} \frac{1}{|X|!} \left(\sum_{\substack{G \subseteq H_X: \\ \text{connected,} \\ \text{spanning}}} (-1)^{|E(G)|} \right) \left(\prod_{\xi \in X} w(\xi) \right), \tag{2}$$

where $G \subseteq H_X$ means G is a subgraph of H_X .

³ In general $w(\xi)$ can be complex, but for our purposes it will always be a (positive or negative) real number.

⁴ Many sources define clusters to be unordered multisets, necessitating additional combinatorial terms in the cluster expansion; for simplicity, we assume clusters are ordered.

The cluster expansion is derived and this theorem is proved in Chapter 5 of [12], for a slightly different (but equivalent) definition of a cluster.

We apply the cluster expansion twice, with two different notions of polymers and compatibility. In both cases, our polymers will be connected edge sets $\xi \subseteq E(G_\Delta)$, and we use that to state a general result here. Let Γ be an infinite set of such polymers that is invariant under translation and rotation of polymers. Two polymers in Γ will be compatible if they are well-separated in the model-dependent sense described above. Polymers are incompatible when they are “too close”; for a polymer $\xi \in \Gamma$, let $[\xi] \subseteq E(G_\Delta)$ be the minimal edge set such that if ξ' is not compatible with ξ , then ξ' must contain an edge of $[\xi]$. We use brackets, consistent with the notation of [12], because this is a type of *closure* of a polymer. For our loop polymers, which are compatible if they share no edges, $[\xi] = \xi$. For our even polymers, which are compatible if they are not incident on any of the same vertices, $[\xi]$ is all edges that share an endpoint with an edges of ξ . We denote the size of this edge set as $||[\xi]||$.

We will be interested in some finite region $\Lambda \subseteq E(G_\Delta)$, and we say $\Gamma_\Lambda \subseteq \Gamma$ is all polymers of Γ whose edges are contained in Λ . Let $\partial\Lambda$ be an edge set such that a cluster containing an edge in Λ and an edge not in Λ must contain an edge of $\partial\Lambda$. We will consider loop polymers with edges from $E_{\mathcal{P}}^{int}$, the set of edges with at least one endpoint strictly inside boundary \mathcal{P} , so in this case we use $\Lambda = E_{\mathcal{P}}^{int}$ and $\partial\Lambda$ the edges in \mathcal{P} . For even polymers, we use $\Lambda = E_{\mathcal{P}}$, all edges on or inside \mathcal{P} , and $\partial\Lambda$ is all edges with one endpoint on \mathcal{P} and the other outside.

The following states the key fact about the cluster expansion that we will need. Namely, when a certain mild condition is satisfied, we can use the cluster expansion to give upper and lower bounds on the polymer partition function for Λ in terms of a volume term, depending only on $|\Lambda|$, and a surface term, depending only on $|\partial\Lambda|$.

► **Theorem 11.** *Let Γ be an infinite set of polymers $\xi \subseteq E(G_\Delta)$ that is closed under translation and rotation, and let $\Lambda \subseteq E(G_\Delta)$ be finite. If there is a constant c such that for any edge $e \in E(G_\Delta)$,*

$$\sum_{\substack{\xi \in \Gamma: \\ e \in \xi}} |w(\xi)| e^{c||[\xi]||} \leq c,$$

then for any Λ the partition function

$$\Xi_\Lambda := \sum_{\substack{\Gamma' \subseteq \Gamma_\Lambda \\ \text{compatible}}} \prod_{\xi \in \Gamma'} w(\xi)$$

satisfies

$$e^{\psi|\Lambda| - c|\partial\Lambda|} \leq \Xi_\Lambda \leq e^{\psi|\Lambda| + c|\partial\Lambda|},$$

for some constant $\psi \in [-c, c]$ that is independent of Λ .

We prove this theorem in Appendix A.3.

This result is the key step needed to show that when λ and γ are both large, compression occurs; as our techniques for establishing separation first require configurations to be compressed, this is a necessary first step. For compression, we look at the *partition function* $Z_{\mathcal{P}}$ for different fixed boundaries \mathcal{P} , where $Z_{\mathcal{P}}$ is the sum over all configurations σ with boundary \mathcal{P} of their weights $(\lambda\gamma)^{-|\mathcal{P}|} \cdot \gamma^{-h(\sigma)}$. We cannot analyze $Z_{\mathcal{P}}$ directly, so we instead relate $Z_{\mathcal{P}}$ to a specific polymer partition function $\Xi_{\mathcal{P}}^{\mathcal{C}}$ which does have a cluster expansion. Using the sufficient condition of Theorem 10, we show the cluster expansion for $\Xi_{\mathcal{P}}^{\mathcal{C}}$ is convergent

when $\gamma > 4^{5/4}$. We then use this expression of $\ln \Xi_{\mathcal{P}}^{\mathcal{L}}$ as a convergent power series and Theorem 11 to bound $\Xi_{\mathcal{P}}^{\mathcal{L}}$ in terms of a *volume term*, depending only on the number of particles n , and a *surface term*, depending only on $|\mathcal{P}|$, the length of boundary \mathcal{P} .

► **Lemma 12.** *When $\gamma > 4^{5/4}$, for $c = 0.0001$, there exists a constant $\psi \in [-c, c]$ that depends on γ but is independent of \mathcal{P} such that*

$$e^{(3n-3)\psi-3c|\mathcal{P}|} \leq \Xi_{\mathcal{P}}^{\mathcal{L}} \leq e^{(3n-3)\psi+3c|\mathcal{P}|}.$$

This means, in particular, that the ratios of $\Xi_{\mathcal{P}}^{\mathcal{L}}$ and $\Xi_{\mathcal{P}'}^{\mathcal{L}}$ for different boundaries \mathcal{P} and \mathcal{P}' that enclose the same number n of particles can be bounded by an expression that is exponential in the lengths of these boundaries but independent of n . This is essential to our compression argument, which will focus on boundaries of various lengths. We note that it is straightforward, using the previous lemma, to get similar bounds on $Z_{\mathcal{P}}$, the quantity we are actually interested in. We use this to apply a Peierls argument similar to the one used to show compression in [6]. This argument relates the total weight of undesirable configurations – those with boundaries longer than $\alpha \cdot p_{\min}$ for some constant $\alpha > 1$ – to the weight of configurations with minimum perimeter, p_{\min} . The result is as follows.

► **Theorem 13.** *Consider algorithm \mathcal{M} when there are n total particles of two different colors. For $c = 0.0001$, when constants $\alpha > 1$, $\lambda > 1$, and $\gamma > 4^{5/4}$ satisfy*

$$\frac{2(2 + \sqrt{2})e^{3c}}{\lambda\gamma} \left(e^{3c} \lambda \gamma^{3/2} \right)^{1/\alpha} < 1,$$

when n is sufficiently large then for \mathcal{M} with parameters λ and γ , configurations drawn from distribution π are α -compressed with probability at least $1 - \zeta\sqrt{n}$ for some constant $\zeta < 1$.

One corollary is that if $\lambda > 1$ and $\gamma > 4^{5/4}$ such that $\lambda\gamma > 2(2 + \sqrt{2})e^{0.0003} \sim 6.83$, there exists a constant α such that a configuration drawn from the stationary distribution π of \mathcal{M} is α -compressed with high probability. (Recall, we say an event A occurs with high probability, or w.h.p., if $\Pr[A] \geq 1 - c^{n^\delta}$, where $0 < c < 1$ and $\delta > 0$ are constants. Unless we explicitly state otherwise, it will always be the case that $\delta = 1/2$.) Conversely, for any $\alpha > 1$, there exist λ and γ such that \mathcal{M} with these parameter values achieves α -compression at stationarity w.h.p.

We next show, again when λ and γ are large enough, that separation provably occurs. By the previous theorem, it suffices to show this among compressed configurations. We use a technique known as *bridging* that was developed to analyze molecular mixtures called *colloids* [28]. Adapting the bridging approach to our setting required several new innovations to overcome obstacles such as the irregular shapes of particle system configurations, the non-self-duality of the triangular lattice, the interchangeability between color classes, and other technicalities related to interfaces between particles of different colors. The main result of this section is the following theorem. Recall that for a fixed boundary \mathcal{P} , the probability distribution $\pi_{\mathcal{P}}$ is over colored particle configurations with this boundary where $\pi_{\mathcal{P}}(\sigma)$ is proportional to $\gamma^{-h(\sigma)}$.

► **Theorem 14.** *Let \mathcal{P} be the boundary of n particles with $|\mathcal{P}| \leq \alpha p_{\min}$. For any $\beta > 2\sqrt{3}\alpha$ and any $\delta < 1/2$, if γ is large enough that*

$$3^{\frac{2\alpha\sqrt{3}}{\beta}} 4^{\frac{1+3\delta}{4\delta}} \gamma^{-1+\frac{2\alpha\sqrt{3}}{\beta}} < 1$$

then for sufficiently large n a configuration drawn from $\pi_{\mathcal{P}}$ is (β, δ) -separated with probability at least $1 - \zeta\sqrt{n}$ for some constant $\zeta < 1$.

Combining this with the previous theorem, we see that for any $\lambda > 1$ and $\gamma > 4^{5/4} \sim 5.66$ such that $\lambda\gamma > 2(2 + \sqrt{2})e^{0.0003} \sim 6.83$, there exist constants β and δ such that for large enough n , \mathcal{M} provably achieves (β, δ) -separation at stationarity w.h.p. Furthermore, for any $\beta > 2\sqrt{3}$ and any $\delta < 1/2$, there are values for λ and γ such that for large enough n , \mathcal{M} provably achieves (β, δ) -separation at stationarity w.h.p.

We are also able to show that there are some values of γ close to one for which separation does not occur. This counterintuitively includes values where $\gamma > 1$ and particles have a preference for being next to particles of the same color. As we did for large values of γ , we first show that when λ is large and γ is close to one, compression provably occurs. The polymer partition function $\Xi_{\mathcal{P}}^{\mathcal{L}}$ from above does not have a convergent cluster expansion when γ is close to one, so we cannot use it to show compression. Instead, we carefully relate $Z_{\mathcal{P}}$ to a different polymer partition function $\Xi_{\mathcal{P}}^{HT}$ by considering the *high temperature expansion*, which rewrites a sum over configurations with a fixed boundary as a sum over even edge sets within that boundary. The high-temperature expansion is well-studied for the Ising model (see, e.g., [12], Section 3.7.3). We show $\Xi_{\mathcal{P}}^{HT}$ has a convergent cluster expansion when γ is close to one. We then use the cluster expansion for this high temperature representation, much the same as above, to show compression provably occurs.

► **Theorem 15.** *Consider algorithm \mathcal{M} when there are n total particles of two different colors. For $a = 10^{-5}$, when constants $\alpha > 1$, $\lambda > 1$, and $\gamma \in (79/81, 81/79)$ satisfy*

$$\frac{2(2 + \sqrt{2})e^{3a}}{\lambda(\gamma + 1)} \left(\frac{\lambda(\gamma + 1)}{2e^{-3a} \left(\frac{79}{81}\right)} \right)^{1/\alpha} < 1$$

when n is sufficiently large then for \mathcal{M} with parameters λ and γ , configurations drawn from \mathcal{M} 's stationary distribution π are α -compressed with probability at least $1 - \zeta^{\sqrt{n}}$ for some constant $\zeta < 1$.

This theorem implies that for any $\lambda > 1$ and $\gamma \in (79/81, 81/79)$ such that $\lambda(\gamma + 1) > 2(2 + \sqrt{2})e^{0.00003} \sim 6.83$, there exists a constant α such that a configuration drawn from the stationary distribution π of \mathcal{M} is α -compressed w.h.p. Conversely, for any $\alpha > 1$ and any $\gamma \in (79/81, 81/79)$, for large enough λ algorithm \mathcal{M} with parameters λ and γ achieves α -compression at stationarity w.h.p.

Once we have shown that compression occurs for large λ and γ near one, we show that among these compressed configurations a large amount of separation between color classes is very unlikely. We prove this with a probabilistic argument in which we find a set of polynomially many events such that if separation occurs, then at least one of these events occurs. We then show that each event occurs with probability at most $\zeta^{n^{1/2-\varepsilon}}$ for some $\zeta < 1$ and arbitrarily small $\varepsilon > 0$, which via a union bound over the polynomial number of events implies separation is very unlikely.

► **Theorem 16.** *Let \mathcal{P} be any α -compressed boundary. Let $\delta < 1/4$ and γ close enough to one such that there exists a $\mu \in (\delta/(1 - 2\delta), 1/2)$ where*

$$\left(\frac{\mu}{1 - \mu} \right)^{(\mu - \delta/(1 - 2\delta))/11} < \gamma < \left(\frac{1 - \mu}{\mu} \right)^{(\mu - \delta/(1 - 2\delta))/11}.$$

For any β and any $c < 1/4$, there is a constant $\zeta < 1$ such that the probability a particle configuration drawn at random from $\pi_{\mathcal{P}}$ is (β, δ) -separated is at most $\zeta^{n^{2c}}$.

Combining this with the results above, we see that for $\lambda > 1$ and $\gamma \in (79/81, 81/79)$ such that $\lambda(\gamma + 1) > 2(2 + \sqrt{2})e^{0.00003} \sim 6.83$, there are constants β and δ such that the probability \mathcal{M} with parameters λ and γ achieves (β, δ) -separation at stationarity is at most $\zeta^{n^{1/2-\varepsilon}}$,

where $\varepsilon > 0$ and $\zeta < 1$. Conversely, for any $\beta > 0$ and any $\delta < 1/4$, there exists λ and γ such that \mathcal{M} with these parameters achieves (β, δ) -separation at stationarity with probability at most $\zeta^{n^{1/2-\varepsilon}}$ for $\varepsilon > 0$ and $\zeta < 1$.

5 Conclusion

We considered separation with two colors, but expect our proofs to generalize in a straightforward way to heterogeneous systems with more colors using insights that generalize cluster expansion polymers from the Ising model to the Potts model (see the notion of a *contour* in Pirogov-Sinai theory, e.g., in Chapter 7 of [12]). The proofs would follow the same strategy for two colors, requiring little additional insight but a fairly large amount of technical detail.

We note that, as with previous papers using stochastic, distributed algorithms for programmable matter, we are unable to give any nontrivial bounds on the mixing time of our Markov chain \mathcal{M} . The difficulties in proving polynomial upper bounds on the mixing time are unsurprising, given similarities between \mathcal{M} and a well-studied open problem in statistical physics about the mixing time of Glauber dynamics of the Ising model on \mathbb{Z}^2 with plus boundary conditions starting from the all minus state [24, 26] (see remarks concluding [6]). However, the mixing time may not be the best bound for characterizing when compression and separation occur. Simulations show that both compression and separation occur fairly quickly (Figure 2), although the algorithm continues to gradually achieve more compression and separation, confirming we likely achieve these goals well before converging to stationarity.

We believe the stochastic approach to self-organizing particle systems, used here to develop a distributed algorithm for separation and integration in programmable matter, is much more broadly applicable. This approach can potentially be applied to any objective described by a global energy function (where the desirable configurations have low energy values), provided changes in energy due to particle movements can be calculated with only local information. Choosing the correct global energy function is the key; translating the energy function into a Markov chain and then into a distributed algorithm is, by now, fairly routine (see [2, 6]). However, proving that the stationary distribution has our desired properties with high probability remains challenging, requiring application-specific proof techniques.

Last, we believe the proof techniques developed here extend beyond our current work. For separation and integration, the key ingredient is the cluster expansion, used recently to develop efficient low-temperature approximations and sampling algorithms, and the related Pirogov-Sinai theory, used to show slow mixing of certain Markov chains. Here, however, we used a completely different aspect of the cluster expansion by separating partition functions into surface and volume terms. The cluster expansion and Pirogov-Sinai theory have been widely used in statistical physics for many purposes, and we believe there are many more ways a thorough understanding of these methods can benefit computer science.

A Appendix

Here we include the proofs of some of our claims that were omitted from the main body of this paper for conciseness and clarity. We do not include any detailed proofs of our technical results due to length constraints.

A.1 Proof of Lemma 2

Recall that Lemma 2 states that for any $n \geq 1$, there is a connected, hole-free particle configuration of n particles with perimeter at most $2\sqrt{3}\sqrt{n}$. That is, $p_{\min}(n) \leq 2\sqrt{3}\sqrt{n}$.

Proof. The lemma can easily be verified for $n \leq 6$. For $n \geq 7$, we begin with the case where $n = 3\ell^2 + 3\ell + 1$ for some integer $\ell \geq 1$. A regular hexagon with side length ℓ can be decomposed into six triangles, each with $\ell(\ell + 1)/2$ particles, and a single center vertex, for $3\ell^2 + 3\ell + 1$ total particles; see Figure 4a. Such a hexagon has perimeter 6ℓ . We see that

$$p_{\min}(3\ell^2 + 3\ell + 1) \leq 6\ell \leq 2\sqrt{3}\sqrt{3\ell(\ell + 1)} \leq 2\sqrt{3}\sqrt{n - 1} \leq 2\sqrt{3}\sqrt{n}.$$

Now we consider $n = 3\ell^2 + 3\ell + 1 + k$, for integers ℓ and k , where $k \in [1, 6\ell + 6)$. As $(3\ell^2 + 3\ell + 1) + 6\ell + 6 = 3(\ell + 1)^2 + 3(\ell + 1) + 1$, this covers all possible values of n . We construct a particle configuration on $n = 3\ell^2 + 3\ell + 1 + k$ particles by first constructing a regular hexagon of side length ℓ and then adding the remaining k particles around the outside of this hexagon in a single layer, completing one side before beginning the next; see Figure 4b, where $\ell = 3$ and $k = 6$. For $k \leq \ell$, the perimeter of this configuration is $6\ell + 1$. More generally, the perimeter increases by one when particles begin to be added to a new side of the hexagon, and so for $i = 2, 3, 4, 5, 6$, for $(i - 1)\ell + (i - 2) < k \leq i\ell + (i - 1)$ the perimeter of this configuration is $6\ell + i$. We see that (using $i \leq 6$ and $\ell \geq 1$), for any $i = 1, 2, 3, 4, 5, 6$,

$$\begin{aligned} p_{\min}(3\ell^2 + 3\ell + 1 + k) &\leq 6\ell + i \leq 2\sqrt{3}\sqrt{\left(\sqrt{3}\ell + \frac{i}{2\sqrt{3}}\right)^2} = 2\sqrt{3}\sqrt{3\ell^2 + \frac{i^2}{12} + i} \\ &\leq 2\sqrt{3}\sqrt{3\ell^2 + 3 + i} \\ &\leq 2\sqrt{3}\sqrt{3\ell^2 + 3\ell + 1 + i - 1} \\ &\leq 2\sqrt{3}\sqrt{3\ell^2 + 3\ell + 1 + k} = 2\sqrt{3}\sqrt{n}. \end{aligned}$$

This concludes our proof. ◀

A.2 Detailed Balance Proof that π is the Stationary Distribution of \mathcal{M}

Recall that Lemma 9 states that the stationary distribution of \mathcal{M} is given by $\pi(\sigma) = 0$ if σ is disconnected or has holes, and by $\pi(\sigma) = (\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)}/Z$ otherwise, where $Z = \sum_{\sigma} (\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)}$. Here, we analyze the necessary cases to verify this with detailed balance.

■ **Figure 4** (a) The regular hexagon with side length $\ell = 3$ with $3\ell^2 + 3\ell + 1$ total particles. (b) A configuration with $n = 3\ell^2 + 3\ell + 1 + k$ particles for $\ell = 3$ and $k = 6$ with perimeter $20 < 2\sqrt{3}\sqrt{n}$.

Proof. We first verify that $\pi(\sigma) = \lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)} / Z_e$ – where $\epsilon(\sigma)$ is the number of edges of σ , $a(\sigma)$ is the number of homogeneous edges of σ , and $Z_e = \sum_{\sigma} \lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}$ – is the stationary distribution by detailed balance. We then show that this form of π can be rewritten as in the lemma.

Consider any two connected, hole-free configurations σ, τ that differ by one move of some particle from location ℓ in σ to a neighboring location ℓ' in τ . By examining \mathcal{M} , we see that the probability of transitioning from σ to τ is:

$$M(\sigma, \tau) = \min \left\{ 1, \lambda^{|N(\ell')| - |N(\ell)|} \cdot \gamma^{|N_i(\ell')| - |N_i(\ell)|} \right\} / 6n.$$

A similar analysis shows:

$$M(\tau, \sigma) = \min \left\{ 1, \lambda^{|N(\ell)| - |N(\ell')|} \cdot \gamma^{|N_i(\ell)| - |N_i(\ell')|} \right\} / 6n.$$

Without loss of generality, suppose $\lambda^{|N(\ell')| - |N(\ell)|} \cdot \gamma^{|N_i(\ell')| - |N_i(\ell)|} < 1$, meaning $M(\sigma, \tau)$ is this value over $6n$ and $M(\tau, \sigma) = 1/6n$. Because the only edges that differ in σ and τ are incident to ℓ or ℓ' ,

$$\begin{aligned} \pi(\sigma)M(\sigma, \tau) &= \frac{\lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \cdot \frac{1}{n} \cdot \frac{1}{6} \cdot \lambda^{|N(\ell')| - |N(\ell)|} \cdot \gamma^{|N_i(\ell')| - |N_i(\ell)|} \\ &= \frac{\lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \cdot \frac{1}{n} \cdot \frac{1}{6} \cdot \lambda^{\epsilon(\tau) - \epsilon(\sigma)} \cdot \gamma^{a(\tau) - a(\sigma)} \\ &= \frac{\lambda^{\epsilon(\tau)} \cdot \gamma^{a(\tau)}}{Z_e} \cdot \frac{1}{n} \cdot \frac{1}{6} \cdot 1 = \pi(\tau)M(\tau, \sigma) \end{aligned}$$

Thus, detailed balance is satisfied for particle moves that are not swaps.

Suppose instead that σ and τ differ by a swap move of particle P with color c_i at location ℓ in σ and particle Q with color c_j at neighboring location ℓ' in σ . This move could occur if P or Q is chosen in Step 1 of \mathcal{M} , so:

$$M(\sigma, \tau) = \min \left\{ 1, \gamma^{|N_i(\ell') \setminus \{P\}| - |N_i(\ell)| + |N_j(\ell) \setminus \{Q\}| - |N_j(\ell')|} \right\} / 3n.$$

Similarly, because τ has P at location ℓ' and Q at location ℓ , we have:

$$M(\tau, \sigma) = \min \left\{ 1, \gamma^{|N_i(\ell) \setminus \{P\}| - |N_i(\ell')| + |N_j(\ell') \setminus \{Q\}| - |N_j(\ell)|} \right\} / 3n.$$

Without loss of generality, suppose that $\gamma^{|N_i(\ell') \setminus \{P\}| - |N_i(\ell)| + |N_j(\ell) \setminus \{Q\}| - |N_j(\ell')|} < 1$, so $M(\sigma, \tau)$ is this value over $3n$ and $M(\tau, \sigma) = 1/3n$. Then,

$$\begin{aligned} \pi(\sigma)M(\sigma, \tau) &= \frac{\lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \cdot \frac{2}{n} \cdot \frac{1}{6} \cdot \gamma^{|N_i(\ell') \setminus \{P\}| - |N_i(\ell)| + |N_j(\ell) \setminus \{Q\}| - |N_j(\ell')|} \\ &= \frac{\lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \cdot \frac{2}{n} \cdot \frac{1}{6} \cdot \gamma^{(|N_i(\ell') \setminus \{P\}| + |N_j(\ell) \setminus \{Q\}|) - (|N_i(\ell)| + |N_j(\ell')|)} \\ &= \frac{\lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \cdot \frac{2}{n} \cdot \frac{1}{6} \cdot \gamma^{a(\tau) - a(\sigma)} \\ &= \frac{\lambda^{\epsilon(\tau)} \cdot \gamma^{a(\tau)}}{Z_e} \cdot \frac{2}{n} \cdot \frac{1}{6} \cdot 1 = \pi(\tau)M(\tau, \sigma) \end{aligned}$$

In both cases, detailed balance is satisfied, so we conclude the stationary distribution π (which is only non-zero over connected, hole-free configurations) is given by $\pi(\sigma) = \lambda^{\epsilon(\sigma)} \cdot \gamma^{a(\sigma)} / Z_e$.

Since every edge of σ is either homogeneous or heterogeneous, we have $e(\sigma) = a(\sigma) + h(\sigma)$. From [6], we have $e(\sigma) = 3n - p(\sigma) - 3$, where n is the number of particles in the system. Thus, we can rewrite this unique stationary distribution as follows:

$$\begin{aligned} \pi(\sigma) &= \frac{\lambda^{e(\sigma)} \cdot \gamma^{a(\sigma)}}{Z_e} \\ &= \frac{\lambda^{e(\sigma)} \cdot \gamma^{a(\sigma)}}{\sum_{\sigma} \lambda^{e(\sigma)} \cdot \gamma^{a(\sigma)}} \\ &= \frac{(\lambda\gamma)^{-3n+3} \cdot (\lambda\gamma)^{e(\sigma)} \cdot \gamma^{a(\sigma)-e(\sigma)}}{(\lambda\gamma)^{-3n+3} \cdot \sum_{\sigma} (\lambda\gamma)^{e(\sigma)} \cdot \gamma^{a(\sigma)-e(\sigma)}} \\ &= \frac{(\lambda\gamma)^{e(\sigma)-3n+3} \cdot \gamma^{a(\sigma)-e(\sigma)}}{\sum_{\sigma} (\lambda\gamma)^{e(\sigma)-3n+3} \cdot \gamma^{a(\sigma)-e(\sigma)}} \\ &= \frac{(\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)}}{\sum_{\sigma} (\lambda\gamma)^{-p(\sigma)} \cdot \gamma^{-h(\sigma)}}. \end{aligned}$$

This concludes our proof. ◀

A.3 Proof of Boundary-Volume Decomposition of Cluster Expansion

In this section we provide the proof of Theorem 11, which is our decomposition of a polymer partition function into boundary and volume terms via the cluster expansion. For the sake of clarity we restate this theorem here, including all of its hypotheses and assumptions.

► **Theorem 11.** *Let Γ be an infinite set of polymers $\xi \subseteq E(G_{\Delta})$ that is closed under translation and rotation, and let $\Lambda \subseteq E(G_{\Delta})$ be finite. If there is a constant c such that for any edge $e \in E(G_{\Delta})$,*

$$\sum_{\substack{\xi \in \Gamma: \\ e \in \xi}} |w(\xi)| e^{c|\xi|} \leq c, \quad (3)$$

then for any Λ the partition function

$$\Xi_{\Lambda} := \sum_{\substack{\Gamma' \subseteq \Gamma_{\Lambda} \\ \text{compatible}}} \prod_{\xi \in \Gamma'} w(\xi)$$

satisfies

$$e^{\psi|\Lambda|-c|\partial\Lambda|} \leq \Xi_{\Lambda} \leq e^{\psi|\Lambda|+c|\partial\Lambda|},$$

for some constant $\psi \in [-c, c]$ that is independent of Λ .

Proof. We follow the same outline as the proof of the same fact for the Ising model in Section 5.7.1 of [12].

Let \mathcal{X} be all clusters comprised of polymers from Γ , and let \mathcal{X}_{Λ} be all clusters of polymers in Γ_{Λ} . Note that Equation 3 implies the hypothesis of Theorem 10 (Equation 1) is satisfied, with function $a : \Gamma \rightarrow \mathbb{R}$ given by $a(\xi) = c|\xi|$:

$$\sum_{\substack{\xi \in \Gamma: \\ \xi, \xi^* \text{ incompatible}}} |w(\xi)| e^{a(\xi)} \leq \sum_{e \in [\xi^*]} \sum_{\substack{\xi \in \Gamma: \\ e \in \xi}} |w(\xi)| e^{c|\xi|} \leq c|[\xi^*]|.$$

Because this hypothesis is satisfied for all $\xi^* \in \Gamma$, it certainly holds when we restrict our attention to polymers in Γ_Λ . By Theorem 10, because Γ_Λ is a finite set, this means the cluster expansion for Ξ_Λ converges:

$$\ln \Xi_\Lambda = \sum_{X \in \mathcal{X}_\Lambda} \Psi(X)$$

Let $\bar{X} = \cup_{\xi \in X} \xi$ be the *support* of cluster X and $|\bar{X}|$ the size of this support. Using Equation 3 and standard techniques (see [12], the proof of Theorem 5.4 and Equation (5.29)), the translation and rotation invariance of Γ imply that for any edge $e \in E(G_\Delta)$,

$$\sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}}} |\Psi(X)| \leq c. \quad (4)$$

The proof of this fact is the reason we need a slightly stronger hypothesis (Equation 3) than is needed to guarantee the cluster expansion converges (Equation 1).

For any cluster $X \in \mathcal{X}_\Lambda$, it trivially holds that $1 = (\sum_{e \in \Lambda} \mathbf{1}_{e \in \bar{X}}) / |\bar{X}|$. We can use this fact to rewrite the cluster expansion for Ξ_Λ :

$$\begin{aligned} \ln \Xi_\Lambda &= \sum_{X \in \mathcal{X}_\Lambda} \Psi(X) = \sum_{\substack{X \in \mathcal{X}: \\ \bar{X} \subseteq \Lambda}} \Psi(X) = \sum_{e \in \Lambda} \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}, \\ \bar{X} \subseteq \Lambda}} \frac{1}{|\bar{X}|} \Psi(X) \\ &= \sum_{e \in \Lambda} \left(\sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}}} \frac{1}{|\bar{X}|} \Psi(X) - \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}, \\ \bar{X} \not\subseteq \Lambda}} \frac{1}{|\bar{X}|} \Psi(X) \right) \\ &= \left(\sum_{e \in \Lambda} \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}}} \frac{1}{|\bar{X}|} \Psi(X) \right) - \left(\sum_{e \in \Lambda} \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}, \\ \bar{X} \not\subseteq \Lambda}} \frac{1}{|\bar{X}|} \Psi(X) \right). \end{aligned} \quad (5)$$

The two infinite sums in parentheses above are absolutely convergent by Equation 4, so this difference is well-defined.

To analyze the first term of Equation 5, we note that by the translation and rotation invariance of Γ , the sum

$$\psi := \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}}} \frac{1}{|\bar{X}|} \Psi(X)$$

is independent of e and of Λ and only depends on our particular polymer model; this is the value ψ that appears in the statement of the theorem, and by Equation 4, $|\psi| \leq c$. We conclude the first term of Equation 5 is $\psi|\Lambda|$.

54:22 Stochastic Separation in Self-Organizing Particle Systems

To analyze the second term of Equation 5, recall if cluster X satisfies both $e \in \bar{X}$ for some $e \in \Lambda$ and $\bar{X} \not\subseteq \Lambda$, then \bar{X} must contain some edge $f \in \partial\Lambda$. We rewrite the absolute value of this second sum as

$$\begin{aligned} \left| \sum_{e \in \Lambda} \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}, \\ \bar{X} \not\subseteq \Lambda}} \frac{1}{|\bar{X}|} \Psi(X) \right| &\leq \sum_{e \in \Lambda} \sum_{\substack{X \in \mathcal{X}: \\ e \in \bar{X}, \\ \bar{X} \not\subseteq \Lambda}} \frac{1}{|\bar{X}|} |\Psi(X)| \\ &\leq \sum_{f \in \partial\Lambda} \sum_{\substack{X \in \mathcal{X}: \\ f \in \bar{X}}} |\bar{X} \cap \Lambda| \frac{1}{|\bar{X}|} |\Psi(X)| \\ &\leq \sum_{f \in \partial\Lambda} \sum_{\substack{X \in \mathcal{X}: \\ f \in \bar{X}}} |\Psi(X)| \leq c |\partial\Lambda|. \end{aligned}$$

The last inequality above follows from Equation 4 and the translation and rotation invariance of Λ .

We conclude that Equation 5 implies

$$\psi|\Lambda| - c|\partial\Lambda| \leq \ln \Xi_\Lambda \leq \psi|\Lambda| + c|\partial\Lambda|.$$

Exponentiation proves the theorem. ◀

The Large-Error Approximate Degree of AC^0

Abstract

We prove two new results about the inability of low-degree polynomials to uniformly approximate constant-depth circuits, even to slightly-better-than-trivial error. First, we prove a tight $\tilde{\Omega}(n^{1/2})$ lower bound on the threshold degree of the SURJECTIVITY function on n variables. This matches the best known threshold degree bound for any AC^0 function, previously exhibited by a much more complicated circuit of larger depth (Sherstov, FOCS 2015). Our result also extends to a $2^{\tilde{\Omega}(n^{1/2})}$ lower bound on the sign-rank of an AC^0 function, improving on the previous best bound of $2^{\Omega(n^{2/5})}$ (Bun and Thaler, ICALP 2016).

Second, for any $\delta > 0$, we exhibit a function $f: \{-1, 1\}^n \rightarrow \{-1, 1\}$ that is computed by a circuit of depth $O(1/\delta)$ and is hard to approximate by polynomials in the following sense: f cannot be uniformly approximated to error $\varepsilon = 1 - 2^{-\Omega(n^{1-\delta})}$, even by polynomials of degree $n^{1-\delta}$. Our recent prior work (Bun and Thaler, FOCS 2017) proved a similar lower bound, but which held only for error $\varepsilon = 1/3$.

Our result implies $2^{\Omega(n^{1-\delta})}$ lower bounds on the complexity of AC^0 under a variety of basic measures such as discrepancy, margin complexity, and threshold weight. This nearly matches the trivial upper bound of $2^{O(n)}$ that holds for every function. The previous best lower bound on AC^0 for these measures was $2^{\Omega(n^{1/2})}$ (Sherstov, FOCS 2015). Additional applications in learning theory, communication complexity, and cryptography are described.

1 Introduction

The *threshold degree* of a Boolean function $f: \{-1, 1\}^n \rightarrow \{-1, 1\}$, denoted $\deg_{\pm}(f)$, is the least degree of a real polynomial p that sign-represents f , i.e., $p(x) \cdot f(x) > 0$ for all $x \in \{-1, 1\}^n$. A closely related notion is the ε -approximate degree of f , denoted $\widetilde{\deg}_{\varepsilon}(f)$, which is the least degree of a real polynomial p such that $|p(x) - f(x)| \leq \varepsilon$ for all $x \in \{-1, 1\}^n$.

The parameter setting $\varepsilon = 1$ is a degenerate case: $\widetilde{\text{deg}}_1(f) = 0$ because the constant 0 function approximates any Boolean f to error $\varepsilon = 1$. However, as soon as ε is strictly less than 1, ε -approximate degree is a highly non-trivial notion with a rich mathematical theory. In particular, it is easily seen that

$$\text{deg}_{\pm}(f) = \lim_{\varepsilon \nearrow 1} \widetilde{\text{deg}}_{\varepsilon}(f).$$

In other words, threshold degree is equivalent to the notion of ε -approximate degree when ε is permitted to be *arbitrarily* close to (but strictly less than) 1.¹

In this paper, we are concerned with proving ε -approximate degree lower bounds when either:

- ε is *arbitrarily* close to 1, or
- ε is *exponentially* close to 1 (i.e., $\varepsilon = 1 - 2^{-n^{1-\delta}}$ for some constant $\delta > 0$).

The former parameter regime captures threshold degree, while we refer to the latter as *large-error* approximate degree. While the approximate and threshold degree of a function f capture simple statements about its approximability by polynomials, these quantities relate intimately to the complexity of computing f in concrete computational models. Specifically, the query complexity models UPP^{dt} and PP^{dt} , and the communication models UPP^{cc} , PP^{cc} , are all defined (cf. Section 2) as natural analogs of the Turing machine class PP , which in turn captures probabilistic computation with arbitrarily small advantage over random guessing. It is known that the threshold degree of f is equivalent to its complexity $\text{UPP}^{\text{dt}}(f)$, while a fundamental matrix-analytic analog of threshold degree known as *sign-rank* characterizes UPP^{cc} . Similarly, large-error approximate degree characterizes the query complexity measure PP^{dt} , in the following sense: for any $d > 0$, $\widetilde{\text{deg}}_{1-2^{-d}}(f) \geq \Omega(d) \iff \text{PP}^{\text{dt}}(f) \geq \Omega(d)$. Section 2 elaborates on these models and their many applications in learning theory, circuit complexity, and cryptography.

Our Results in a Nutshell. We prove two results about the threshold degree and large-error approximate degree of functions in AC^0 .² First, we prove a tight $\tilde{\Omega}(n^{1/2})$ lower bound on the threshold degree (i.e., UPP^{dt} complexity) of a natural function called **SURJECTIVITY**, which is computed by a depth three circuit with logarithmic bottom fan-in. This matches the previous best threshold degree lower bound for any AC^0 function, due to Sherstov [34]. Our analysis is much simpler than Sherstov’s, which takes up the bulk of a (70+)-page manuscript [34]. An additional advantage of our analysis is that our lower bound on the threshold degree of **SURJECTIVITY** “lifts” to give a lower bound for the communication analog UPP^{cc} as well. In particular, we obtain an $\Omega(n^{1/2})$ UPP^{cc} lower bound for a related AC^0 function; this improves over the previous best UPP^{cc} lower bound for AC^0 , of $\Omega(n^{2/5})$ [12].

Second, we give nearly optimal bounds on the large-error approximate degree (and hence, PP^{dt} complexity) of AC^0 . For any constant $\delta > 0$, we show that there is an AC^0 function with ε -approximate degree $\Omega(n^{1-\delta})$, where $\varepsilon = 1 - 2^{-\Omega(n^{1-\delta})}$. This result lifts to an analogous PP^{cc} lower bound.

¹ It is known that for any $d > 0$, there are functions of threshold degree d that cannot be approximated by degree d polynomials to error better than $1 - 2^{-\tilde{\Omega}(n^d)}$ [27], and this bound is tight [7]. Hence, threshold degree is also equivalent to the notion of ε -approximate degree for some value of ε that is *doubly-exponentially* close to 1.

² AC^0 is the non-uniform class of sequences of functions computed by polynomial size Boolean circuits of constant depth.

■ **Table 1** Comparison of our new bounds for AC^0 to prior work in roughly chronological order. The circuit depth column lists the depth of the Boolean circuit used to exhibit the bound, δ denotes an arbitrarily small positive constant, and k an arbitrary positive integer. All Boolean circuits are polynomial size.

To summarize our results succinctly:

- We prove a $\tilde{\Omega}(n^{1/2})$ lower bound on the **UPP** complexity of SURJECTIVITY in the query setting, and of a related AC^0 function in the communication setting.
- We prove a $\Omega(n^{1-\delta})$ lower bound on the **PP** complexity of some AC^0 circuit of depth $O(1/\delta)$, in both the query and communication settings.

Table 1 compares our new lower bounds for AC^0 to the long line of prior works with similar goals.

Context and Prior Work. The study of both large-error approximate degree and threshold degree has led to many breakthrough results in theoretical computer science, especially in the algorithmic and complexity-theoretic study of constant depth circuits. For example, threshold degree upper bounds are at the core of many of the fastest known PAC learning algorithms. This includes the notorious case of polynomial size CNF formulas on n variables, for which the fastest known algorithm [19] runs in time $\exp(\tilde{O}(n^{1/3}))$ owing to a $\tilde{O}(n^{1/3})$ upper bound on the threshold degree of any such formula. This upper bound is tight, matching a classic $\Omega(n^{1/3})$ lower bound of Minsky and Papert [23] for the following read-once CNF: $AND_{n^{1/3}} \circ OR_{n^{2/3}}$ (here, we use subscripts to clarify the number of inputs on which a function is defined).

In complexity theory, breakthrough results of Sherstov [29, 31] and Buhrman et al. [7] used lower bounds on large-error approximate degree to show that there are AC^0 functions with polynomial PP^{cc} complexity. One notable implication of these results is that Allender’s [1] classic simulation of AC^0 functions by depth-three majority circuits is optimal. (This resolved an open problem of Krause and Pudlák [20].) A subsequent, related breakthrough of Razborov and Sherstov [28] used Minsky and Papert’s lower bound on the threshold degree of $AND_{n^{1/3}} \circ OR_{n^{2/3}}$ to prove the first polynomial UPP^{cc} lower bound for a function in AC^0 , answering an old open question of Babai et al. [2].

These breakthrough lower bounds raised the intriguing possibility that AC^0 functions could be *maximally* hard for the UPP^{cc} and PP^{cc} communication models, as well as for related complexity measures. Nevertheless, the quantitative parameters achieved in these works are far from actually showing that this is the case. Indeed, the following basic questions about the complexity of AC^0 remain open.

► **Problem 1.** *Is there an AC^0 function $F: \{-1, 1\}^{n \times n} \rightarrow \{-1, 1\}$ with UPP^{cc} complexity $\Omega(n)$?*

► **Problem 2.** *Is there an AC^0 function $F: \{-1, 1\}^{n \times n} \rightarrow \{-1, 1\}$ with PP^{cc} complexity $\Omega(n)$?*

An affirmative answer to either question would be tight: *Every* function $F: \{-1, 1\}^n \times \{-1, 1\}^n \rightarrow \{-1, 1\}$ has UPP^{cc} and PP^{cc} complexity at most n . Obtaining an affirmative answer to Open Problem 1 is harder than for Open Problem 2, since $UPP^{cc}(f) \leq PP^{cc}(f)$ for all f .

Guided by these open problems, a sequence of works has established quantitatively stronger and more general lower bounds for AC^0 functions [9–13, 33, 34]. In addition to making partial progress toward resolving these questions, the techniques developed in these works have found fruitful applications in new domains. For example, Bouland et al. [6] built on techniques from a number of aforementioned works [9, 10, 12, 33] to resolve several old open questions about the relativized power of statistical zero knowledge proofs and their variants. As another example, our recent prior works [8, 13] built on the same line of work to resolve or nearly resolve a number of longstanding open questions in quantum query complexity. Finally, large-error and threshold degree lower bounds on AC^0 functions have recently proved instrumental in the development of cryptographic secret-sharing schemes with reconstruction procedures in AC^0 [4, 5, 14]. We thus believe that the new techniques developed in this work will find further applications, perhaps in unexpected areas.

Prior to our work, the best known result toward a resolution of Open Problem 1 was a $\Omega(n^{2/5})$ lower bound on UPP^{cc} complexity of an AC^0 function [12], while the best known result toward Open Problem 2 was a $\Omega(n^{1/2})$ bound on the PP^{cc} complexity of a very complicated AC^0 circuit [34].

1.1 Our Results In Detail

1.1.1 Resolving the Threshold Degree of SURJECTIVITY

Surjectivity and its History. Let R be a power of 2 and $n = N \log R$. The function $SURJECTIVITY_n$ ($SURJ_{R,N}$ for short) is defined as follows. Given an input in $\{-1, 1\}^n$, $SURJ_{R,N}$ interprets the input as a list of N numbers (s_1, \dots, s_N) from a range $[R] := \{1, \dots, R\}$, and evaluates to -1 if and only if every element of the range $[R]$ appears at least once in the list.³ $SURJ_{R,N}$ is computed by an AC^0 circuit of depth three and logarithmic bottom fan-in, since it is equivalent to the AND_R (over all range items $r \in [R]$) of the OR_N (over all inputs $i \in [N]$) of “Is input s_i equal to r ?”, where the quoted question is computed by a conjunction of width $\log R$ over the input bits.

$SURJ_{R,N}$ has been studied extensively in the contexts of quantum query complexity and approximate degree. Beame and Machmouchi [3] showed that computing $SURJ_{R,N}$ for $R = N/2 + 1$ requires $\tilde{\Omega}(n)$ quantum queries, making it the only known AC^0 function with linear quantum query complexity. Meanwhile, the $(1/3)$ -approximate degree of $SURJ_{R,N}$ was

³ As is standard, we associate -1 with logical TRUE and $+1$ with logical FALSE throughout.

recently shown to be $\tilde{\Theta}(R^{1/4} \cdot N^{1/2})$. The lower bound is from our prior work [8], while the upper bound was shown by Sherstov [35], with a different proof given in [8]. In particular, when $R = N/2$, $\widetilde{\deg}_{1/3}(\text{SURJ}_{R,N}) = \tilde{\Theta}(N^{3/4})$. Our prior works [8, 13] built directly on the approximate degree lower bound for $\text{SURJ}_{R,N}$ to give near-optimal lower bounds on the $(1/3)$ -approximate degree of AC^0 (see Section 3.3 for details).

Our Result. In spite of the progress described above, the threshold degree $\text{SURJ}_{R,N}$ remained open. For $R < N/2$, an upper bound of $\tilde{O}(\min\{R, N^{1/2}\})$ follows from standard techniques. The best known lower bound was $\Omega(\min\{R, N^{1/3}\})$, obtained by a reduction to Minsky and Papert’s threshold degree lower bound for $\text{AND}_{n^{1/3}} \circ \text{OR}_{n^{2/3}}$. In this work, we settle the threshold degree of $\text{SURJ}_{R,N}$, showing that the known upper bound is tight up to logarithmic factors.

► **Theorem 3.** *For $R < N/2$, the threshold degree of $\text{SURJ}_{R,N}$ is $\tilde{\Theta}(\min\{R, N^{1/2}\})$. In particular, if $R = N^{1/2}$, $\text{deg}_{\pm}(\text{SURJ}_{R,N}) = \tilde{\Theta}(N^{1/2})$.*

In addition to resolving a natural question in its own right, Theorem 3 matches the best prior threshold degree lower bound for AC^0 , previously proved in [34] for a much more complicated function computed by a circuit of strictly greater depth. Furthermore, with some extra effort, our lower bound for $\text{SURJ}_{R,N}$ extends to give a $\tilde{\Omega}(n^{1/2})$ lower bound on the UPP^{cc} complexity of a related AC^0 function, yielding progress on Open Question 1 (cf. Section 1). In contrast, Sherstov’s $\Omega(n^{1/2})$ threshold degree lower bound for AC^0 [34] is not known to extend to UPP^{cc} complexity. As stated in Section 1, the best previous UPP^{cc} lower bound for an AC^0 function was $\Omega(n^{2/5})$.

► **Corollary 4.** *There is an AC^0 function $F: \{-1, 1\}^{n \times n} \rightarrow \{-1, 1\}$ such that $\text{UPP}^{\text{cc}}(F) \geq \tilde{\Omega}(n^{1/2})$.*

1.1.2 AC^0 Has Nearly Maximal PP^{cc} Complexity

In our second result, for any constant $\delta > 0$, we exhibit an AC^0 function $f: \{-1, 1\}^n \rightarrow \{-1, 1\}$ with $\widetilde{\deg}_{\varepsilon}(f) = \Omega(n^{1-\delta})$ for some $\varepsilon = 1 - 2^{-\Omega(n^{1-\delta})}$. This is a major strengthening of our prior works [8, 13], which proved a similar result for $\varepsilon = 1/3$. By combining this large-error approximate degree lower bound with a “query-to-communication lifting theorem” for PP [31], we obtain a $\Omega(n^{1-\delta})$ bound on the PP^{cc} complexity of an AC^0 function, nearly resolving Open Question 2 from the previous section.

► **Theorem 5.** *For any constant $\delta > 0$, there is an AC^0 function $F: \{-1, 1\}^{n \times n} \rightarrow \{-1, 1\}$ with $\text{PP}^{\text{cc}}(F) = \Omega(n^{1-\delta})$.*

The best previous lower bound for the PP^{cc} complexity of an AC^0 function was $\Omega(n^{1/2})$ [34].

2 Algorithmic and Complexity-Theoretic Applications

To introduce the applications of our results, we begin by defining the query complexity quantities UPP^{dt} and PP^{dt} and the communication complexity quantities UPP^{cc} and PP^{cc} .

Query Models. In randomized query complexity, an algorithm aims to evaluate a known Boolean function f on an unknown input $x \in \{-1, 1\}^n$ by reading as few bits of x as possible. We say that the *query cost* of a randomized algorithm is the maximum number of bits it queries for any input x .

- UPP^{dt} considers “unbounded error” randomized algorithms, which means that on any input x , the algorithm outputs $f(x)$ with probability strictly greater than $1/2$. $UPP^{dt}(f)$ is the minimum query cost of any unbounded error algorithm for f .
- $PP^{dt}(f)$ captures “large” (rather than unbounded) error algorithms. If a randomized query algorithm outputs $f(x)$ with probability $1/2 + \beta$ for all x , then the PP -cost of the algorithm is the sum of the query cost and $\log(1/\beta)$. $PP^{dt}(x)$ is the minimum PP -cost of any randomized query algorithm for f .

Communication Models. UPP^{cc} and PP^{cc} consider the standard two-party setup where Alice holds an input x and Bob holds an input y , and they run a private-coin randomized communication protocol to compute a function $f(x, y)$, while minimizing the number of bits they exchange. In direct analogy to the query complexity measures above, we say that the *communication cost* of a randomized protocol is the maximum number of bits Alice and Bob exchange on any input (x, y) .

- $UPP^{cc}(f)$ [26] is the minimum communication cost of any randomized protocol that outputs $f(x, y)$ with probability strictly greater than $1/2$ on all inputs (x, y) .
- $PP^{cc}(f)$ [2] is the minimum PP -cost of a protocol for f , where the PP -cost of a protocol that outputs $f(x, y)$ with probability $1/2 + \beta$ for all (x, y) is the sum of the communication cost and $\log(1/\beta)$.

We now give an overview of the applications of Theorem 5 and Corollary 4.

2.1 Applications of Theorem 5

PP^{cc} is known to be equivalent to two measures of central importance in learning theory and communication complexity, namely *margin complexity* [22] and *discrepancy* [18]. Hence, Theorem 5 implies that AC^0 has nearly maximal complexity under both measures. Below, we highlight four additional applications.

- **Communication Complexity.** The PP^{cc} communication model can efficiently simulate almost every two-party communication model, including P (i.e., deterministic communication), BPP (randomized communication), BQP (quantum), and P^{NP} . The only well-studied exceptions are UPP^{cc} , and communication analogs of the polynomial hierarchy (the latter of which we do not know how to prove lower bounds against). Hence, in showing that AC^0 has essentially maximal PP^{cc} complexity, we subsume or nearly subsume all previous results on the communication complexity of AC^0 .
- **Cryptography.** Bogdanov et al. [4] observed that for any $f: \{-1, 1\}^n \rightarrow \{-1, 1\}$ and $d > 0$, if one shows that $\widetilde{\deg}_\varepsilon(f) \geq d$, then one obtains a scheme for sharing a secret bit $b \in \{-1, 1\}$ among n parties such that any subset of d shares provides no reconstruction advantage, yet applying f to all n shares yields b with probability at least $1/2 + \varepsilon/2$. They combined this with known approximate degree lower bounds for AC^0 functions to get secret sharing schemes with reconstruction procedures in AC^0 . Via this connection, an immediate corollary of Theorem 5 is a nearly optimal secret sharing scheme in AC^0 : for any desired constant $\delta > 0$, any subset of $n^{1-\delta}$ shares provides no reconstruction advantage, yet all n shares can be successfully reconstructed (by applying an AC^0 function) with probability $1 - 2^{-n^{1-\delta}}$.
- **Learning Theory.** Valiant [38] introduced the *evolvability* model in an effort to quantify how (and which) mechanisms can evolve in realistic population sizes within realistic time periods. Feldman [15] showed that the “weak evolvability” of a class of functions $\mathcal{F} = \{\phi_1, \dots, \phi_{|\mathcal{F}|}\}$ is characterized by the PP^{cc} complexity of the function $F(x, y) = \phi_x(y)$. Hence, a consequence of Theorem 5 is that there are AC^0 functions that are nearly

maximally hard to evolve (i.e., for any constant $\delta > 0$, there are AC^0 functions that require either $2^{n^{1-\delta}}$ generations, or populations of size $2^{n^{1-\delta}}$ to evolve, even if one only wants to evolve a mechanism that has advantage just $2^{-n^{1-\delta}}$ over random guessing).

We also obtain a nearly optimal $2^{n^{1-\delta}}$ lower bound on the *threshold weight* of an AC^0 function. Threshold weight is another central quantity underlying many algorithmic results in learning theory. Our results rule out the possibility that algorithms based on threshold weight bounds can PAC learn AC^0 in time significantly faster than 2^n .

- **Circuit Complexity.** If $\text{PP}^{\text{cc}}(f) \geq d$, then f is not computable by Majority-of-Threshold circuits of size $2^{\Omega(d)}$ [24]. Hence, by showing that AC^0 has nearly maximal PP^{cc} complexity, we show that there are AC^0 functions that are not computed by Majority-of-Threshold circuits of size $2^{n^{1-\delta}}$. That is, AC^0 has essentially no non-trivial simulation by Majority-of-Threshold circuits (in contrast, AC^0 can be efficiently simulated by depth-three Majority circuits [1]).

2.2 Applications of Corollary 4

As indicated in Section 1, $\text{UPP}^{\text{cc}}(F)$ is known to be characterized by (the logarithm of) the *sign-rank* of the matrix $[F(x, y)]_{x, y \in \{-1, 1\}^{n \times n}}$ [26].⁴ Hence, Corollary 4 implies an $\exp(\tilde{\Omega}(n^{1/2}))$ lower bound on the sign-rank of AC^0 function. Below, we highlight two additional applications of Corollary 4, based on the following connections between communication complexity, circuit complexity, and learning theory.

In communication complexity, UPP^{cc} is the most powerful two-party model against which we know how to prove lower bounds. In circuit complexity, if $\text{UPP}^{\text{cc}}(f) \geq d$, then f cannot be computed by Threshold-of-Majority circuits of size $2^{\Omega(d)}$ [17]. (Threshold-of-Majority circuits represent the most powerful class of threshold circuits against which we can prove superpolynomial lower bounds.) In learning theory, it is commonly assumed that data can be classified by a halfspace in many dimensions; the UPP^{cc} -complexity of a concept class precisely captures how many dimensions are needed. To connect this to a previously mentioned example, Klivans and Servedio [19] observed that an upper bound of d on the UPP^{cc} complexity of a concept class \mathcal{C} yields a PAC learning for \mathcal{C} running in time $2^{O(d)}$. They used this result to give a $2^{\tilde{O}(n^{1/3})}$ -time algorithm for PAC-learning CNFs. This remains the state-of-the-art algorithm for this fundamental problem. Accordingly, Corollary 4 has the following implications.

- **Circuit Complexity.** There are AC^0 functions that are not computable by Threshold-of-Majority Circuits of size $2^{\tilde{\Omega}(n^{1/2})}$.
- **Learning Theory.** UPP^{cc} -based learning algorithms cannot learn AC^0 in time better than $2^{\tilde{\Omega}(n^{1/2})}$.

3 Techniques

3.1 The SURJECTIVITY Lower Bound

For a function f_n , let $f^{\leq N}$ denote the partial function obtained by restricting f to the domain of inputs of Hamming weight at most N . The ε -approximate degree of $f^{\leq N}$, denoted $\widehat{\text{deg}}_\varepsilon(f^{\leq N})$, is the least degree of a real polynomial p such that

$$|p(x) - f(x)| \leq \varepsilon \text{ for all inputs } x \text{ of Hamming weight at most } N. \quad (1)$$

⁴ The sign-rank of a matrix M with entries in $\{\pm 1\}$ is the least rank of a real matrix M' that agrees in sign with M entry-wise.

Note that Property (1) allows p to *behave arbitrarily* on inputs x of Hamming weight more than N . Similarly, the threshold degree of $f^{\leq N}$ is the least degree of a real polynomial p such that

$$p(x) \cdot f(x) > 0 \text{ for all inputs } x \text{ of Hamming weight at most } N.$$

Our prior work [13] showed the ε -approximate (respectively, threshold) degree of $SURJ_{R,N}$ is *equivalent* to the ε -approximate (respectively, threshold) degree of $(AND_R \circ OR_N)^{\leq N}$. Hence, the main technical result underpinning our threshold degree lower bound for $SURJ$ is the following theorem about the threshold degree of $(AND_R \circ OR_N)^{\leq N}$ (we have made no effort to optimize the logarithmic factors).

► **Theorem 6.** *Let $R = N^{1/2}$. Then $\deg_{\pm} \left((AND_R \circ OR_N)^{\leq N} \right) = \Omega(N^{1/2} / \log^{3/2} N)$.*

Discussion. Theorem 6 is a substantial strengthening of the classic result of Minsky and Papert [23] mentioned above, which established that the total function $MP_{N^{1/2},N} := AND_{N^{1/2}} \circ OR_N$ on $n = N^{3/2}$ inputs has threshold degree $\Omega(N^{1/2})$. Theorem 6 establishes that Minsky and Papert’s lower bound holds even under the promise that the input has Hamming weight at most $N = n^{2/3}$. That is, any polynomial that sign-represents $AND_{n^{1/3}} \circ OR_{n^{2/3}}$ on inputs of Hamming weight at most $n^{2/3}$ has degree $\tilde{\Omega}(n^{1/3})$, *even when p is allowed to behave arbitrarily on inputs of Hamming weight larger than $n^{2/3}$.*

Proof overview for Theorem 6 and comparison to prior work. Like much recent work on approximate and threshold degree lower bounds, our proof makes use of *dual polynomials*. A dual polynomial is a dual solution to a certain linear program capturing the approximate or threshold degree of any function, and acts as a certificate of the high approximate or threshold degree of the function.

A dual polynomial that witnesses the fact that $\deg_{\pm}(f_M) \geq d$ is a function $\psi: \{-1, 1\}^M \rightarrow \{-1, 1\}$ satisfying three properties:

- $\psi(x) \cdot f(x) \geq 0$ for all $x \in \{-1, 1\}^M$. If ψ satisfies this condition, we say ψ agrees in sign with f .
- $\sum_{x \in \{-1, 1\}^M} |\psi(x)| = 1$. If ψ satisfies this condition, it is said to have ℓ_1 -norm equal to 1.
- For all polynomials $p: \{-1, 1\}^M \rightarrow \mathbb{R}$ of degree at most d , $\sum_{x \in \{-1, 1\}^M} p(x) \cdot \psi(x) = 0$. If ψ satisfies this condition, it is said to have *pure high degree* at least d .

A dual witness for the fact that $\widetilde{\deg}_{\varepsilon}(f_M) \geq d$ is similar, except that the first condition is replaced with:

- $\sum_{x \in \{-1, 1\}^M} \psi(x) \cdot f(x) > \varepsilon$. If ψ satisfies this condition, it is said to be ε -*correlated* with f . If $\psi(x) \cdot f(x) < 0$, we say that ψ *makes an error* at x .

Sherstov [34] reproved Minsky and Papert’s result by constructing an explicit dual witness for $MP_{N^{1/2},N}$, via a two-step process. First, Sherstov started with a dual witness ψ_{base} for the fact that

$$\widetilde{\deg}_{\varepsilon}(MP_{N^{1/2},N}) = \Omega(N^{1/2}), \text{ for } \varepsilon = 1 - 2^{-N^{1/2}}.$$

The function ψ_{base} was introduced in our prior work [10], where it was constructed by combining a dual witness for $AND_{N^{1/2}}$ with a dual witness for OR_N via a technique called dual block composition [21, 32, 37].

Unfortunately, ψ_{base} falls short of witnessing Minsky and Papert’s threshold degree lower bound because it makes errors on some inputs. In the second step of Sherstov’s construction [34], he adds in a correction term that zeros out the errors of ψ_{base} , without disturbing the sign of ψ_{base} on any other inputs, and without lowering its pure high degree.

Theorem 6 asserts that $\text{MP}_{N^{1/2}, N}^{\leq N}$ satisfies the same threshold degree lower bound as $\text{MP}_{N^{1/2}, N}$ itself. To prove Theorem 6, we need to construct a dual witness ψ that not only improves Minsky and Papert’s classic lower bound for $\text{MP}_{N^{1/2}, N}$, but also satisfies the extra condition that:

$$\psi(x) = 0 \text{ for all inputs } x \text{ of Hamming weight more than } N. \quad (2)$$

To accomplish this, we apply a novel strategy that can be thought of as a three-step process. First, like Sherstov, we start with ψ_{base} . Second, we modify ψ_{base} to obtain a dual witness ψ'_{base} that places significant mass on all inputs of Hamming weight at most d , for some $d = \tilde{\Omega}(N^{1/2})$ (details of the construction of ψ'_{base} are described two paragraphs hence). More specifically, we ensure that ψ'_{base} satisfies:

$$|\psi'_{\text{base}}(x)| \gg n^{-d} \text{ for all inputs } x \text{ of Hamming weight at most } d. \quad (3)$$

We refer to this property by saying that ψ'_{base} is “smooth” or “large” on all inputs of Hamming weight at most d . Note that, in modifying ψ_{base} to obtain ψ'_{base} , we do *not* correct the errors that ψ_{base} makes, nor do we ensure that ψ'_{base} is supported on inputs of Hamming weight at most N .

Third, we add in a correction term, very different than Sherstov’s correction term, that not only zeros out the errors of ψ'_{base} , but also zeros out any mass it places on inputs of Hamming weight more than N . While the general technique we use to construct this correction term appeared in our prior works [8, 13], the novelty in our construction and analysis is two-fold. First, the technique was used in our prior work only to zero out mass placed on inputs of Hamming weight more than N (i.e., to ensure that Equation (2) is satisfied), not to correct errors. Second, and more importantly, we crucially exploit the largeness of ψ'_{base} on inputs of Hamming weight at most d to ensure that the correction term does not disturb the sign of ψ'_{base} on any inputs other than those on which it is deliberately being zeroed out. This is what enables us to obtain a threshold degree lower bound, whereas our prior works [8, 13] were only able to obtain ε -approximate degree lower bounds for ε bounded away from 1.

Our “smoothing followed by correction” approach appears to be significantly more generic than the correction technique of [34]. For example, prior work of Bouland et al. [6] proved an $\Omega(n^{1/4})$ lower bound on the threshold degree of a certain function denoted $\text{GAPMAJ}_{n^{1/4}} \circ \text{PTP}_{n^{3/4}}$, and used this result to give an oracle separating the oracle complexity classes SZK and UPP, thereby answering an open question of Watrous from 2002. Our techniques can be used to give a much simpler proof of this result, as well as several others appearing in the literature (for brevity, we omit the details of these simpler proofs of prior results). We are confident that our technique will find additional applications in the future.

Details of the smoothing step. As stated above, the dual witness ψ_{base} from our prior work does not satisfy the property we need (cf. Equation (3)) of being “large” on all inputs of Hamming weight at most $d = \tilde{\Omega}(N^{1/2})$.

Fortunately, we observe that although ψ_{base} is *not* large on all inputs of Hamming weight at most d , it *is* large on one very special input of low Hamming weight, namely the ALL-FALSE input. That is, $\psi_{\text{base}}(\mathbf{1}) \geq 2^{-d}$. So we just need a way to “bootstrap” this largeness property

on $\mathbf{1}$ to a largeness property on all inputs of Hamming weight at most d . Put another way, we need to be able to treat other inputs of Hamming weight at most d as if they actually have Hamming weight 0. But $\text{MP}_{N^{1/2}, N} := \text{AND}_{N^{1/2}} \circ \text{OR}_N$ has a property that enables precisely this: we can fix the inputs to any constant fraction c of the OR gates to an arbitrary value in $\text{OR}^{-1}(-1)$, and the remaining function of the unrestricted inputs is $\text{AND}_{(1-c) \cdot R} \circ \text{OR}_N$. This is “almost” the same function as $\text{AND}_R \circ \text{OR}_N$; we have merely slightly reduced the top fan-in, which does not substantially lower the threshold degree of the resulting function.

We exploit the above observation to achieve the following: for each input x of Hamming weight at most d , we build a dual witness ν_x targeted at x (i.e., that essentially treats x as if it is the ALL-FALSE input). We do this as follows. Let T be the set of all OR gates that are fed one or more -1 s by x , and let $S \subseteq [N^{1/2} \cdot N]$ be the union of the inputs to each of the OR gates in T . Let ψ_{base} be the dual witness for $\text{AND}_{N^{1/2}-|T|} \circ \text{OR}_N$ given in our prior work [10]. We let

$$\nu_x(y) = \begin{cases} \psi_{\text{base}}(y_{\bar{S}}) & \text{if } y_S = x_S \\ 0 & \text{otherwise,} \end{cases}$$

where $y_{\bar{S}}$ denotes the set of all the coordinates of y other than those in S .

The dual witness ψ'_{base} is then defined to be the average of the ν_x 's, over all inputs x of Hamming weight at most d . This averaged dual witness ψ'_{base} has all of the same useful properties as ψ_{base} , and additionally satisfies the key requirement captured by Equation (3).

3.2 Extension to UPP^{cc} : Proof of Corollary 4

Building on the celebrated framework of Forster [16], Razborov and Sherstov [28] developed techniques to translate threshold degree lower bounds into sign-rank lower bounds. Specifically, they showed that, in order for a threshold degree lower bound of the form $\text{deg}_{\pm}(f_n) \geq d$ to translate into a UPP^{cc} lower bound for a related function F , it suffices for the threshold degree lower bound for f_n to be exhibited by a dual witness ϕ satisfying the following smoothness condition:

$$|\phi(x)| \geq 2^{-O(d)} \cdot 2^{-n} \text{ for all but a } 2^{-\Omega(d)} \text{ fraction of inputs } x \in \{-1, 1\}^n. \quad (4)$$

Note that this is a different smoothness condition than the one satisfied by the dual witness ψ'_{base} discussed above for $\text{MP}_{N^{1/2}, N}$ (cf. Equation (3)): on inputs x of Hamming weight at most d , $|\psi'_{\text{base}}(x)|$ is always at least $n^{-d} \gg 2^{-d} \cdot 2^{-n}$, whereas on inputs x of Hamming weight more than d , $|\psi'_{\text{base}}(x)|$ may be 0. In words, $|\psi'_{\text{base}}(x)|$ is *very large* on inputs x of Hamming weight at most d , but may not be large at all on inputs of larger Hamming weight. In contrast, Equation (4) requires a dual witness to be “somewhat large” (within a $2^{-O(d)}$ factor of uniform) on *nearly all* inputs.

In summary, our construction of a dual witness for $\text{MP}_{N^{1/2}, N}^{\leq N}$ that is sketched in the previous subsection is not sufficient to apply Razborov and Sherstov’s framework to $\text{SURJ}_{R, N}$, for two reasons. First, the dual witness we construct for $\text{MP}_{N^{1/2}, N}^{\leq N}$ is not smooth in the sense of Equation (4), as it is only “large” on inputs of Hamming weight at most d . Second, to apply Razborov and Sherstov’s framework to $\text{SURJ}_{R, N}$, we actually need to give a smooth dual witness for $\text{SURJ}_{R, N}$ itself, not for $\text{MP}_{N^{1/2}, N}^{\leq N}$. Note that $\text{SURJ}_{R, N}$ is defined over the domain $\{-1, 1\}^n$ where $n = N \log R$, while $\text{MP}_{N^{1/2}, N}^{\leq N}$ is defined over subset of $\{-1, 1\}^{NR}$ consisting of inputs of Hamming weight at most N .

We address both of the above issues as follows. First, we show how to turn our dual witness μ for $\text{MP}_{N^{1/2}, N}^{\leq N}$ into a dual witness $\hat{\sigma}$ for the fact that $\text{deg}_{\pm}(\text{SURJ}_{R, N}) \geq d$, such that $\hat{\sigma}$ inherits the “largeness” property of μ on inputs of Hamming weight at most d . Second, we transform

$\hat{\sigma}$ into a dual witness τ for the fact that $\text{deg}_{\pm}(\text{SURJ}_{R,N} \circ \text{AND}_{\log^2 n} \circ \text{PARITY}_{\log^3 n}) \geq d$, such that τ satisfies the smoothness condition given in Equation (4). We conclude that $\text{SURJ}_{R,N} \circ \text{AND}_{\log^2 n} \circ \text{PARITY}_{\log^3 n}$ can be transformed into a related function F (on $\tilde{O}(n)$ inputs, and which is also in AC^0) that has sign-rank $\exp(\tilde{\Omega}(n^{1/2}))$.

3.3 The PP^{cc} Bound: Proof of Theorem 5

As mentioned in Section 1.1.2, the core of Theorem 5 is to exhibit an AC^0 function f such that $\widetilde{\text{deg}}_{\varepsilon}(f) = \Omega(n^{1-\delta})$ for some $\varepsilon = 1 - 2^{-\Omega(n^{1-\delta})}$. To accomplish this, we prove a hardness amplification theorem that should be understood in the context of a weaker result from our prior work [13].

As stated in Section 3.1, for $\varepsilon = 1/3$, our prior work [13] showed how to take any Boolean function f_n in AC^0 with ε -approximate degree d and transform it into a related function g on roughly the same number of variables, such that g is still in AC^0 , and g has significantly higher ε' -approximate degree for some $\varepsilon' \approx 1/3$. This was done in a two-step process. First, we showed that in order to construct a “harder” function g , it is sufficient to identify an AC^0 function G defined on $\text{poly}(n)$ inputs such that for some $\ell = n \cdot \text{polylog}(n)$, $\widetilde{\text{deg}}_{\varepsilon'}(G^{\leq \ell}) \gg d$.⁵ Second, we exhibited such a G . In our prior works [8, 13], for general functions f_n , the function G was $f_n \circ \text{AND}_r \circ \text{OR}_{m'}$, where $r = 10 \log n$, and $m' = \Theta(n/d)$.

We would like to prove a similar result, but we require that G have larger ε' -approximate degree than f_n , where ε' is exponentially closer to 1 than is ε itself. Unfortunately, the definition of G from our prior works [8, 13] does not necessarily result in such a function. For example, if $f_n = \text{OR}_n$ (or any polylogarithmic DNF for that matter), then the function $G = f_n \circ \text{AND}_r \circ \text{OR}_{m'}$ is also a DNF of polylogarithmic width, and it is not hard to see that all such DNFs have ε -approximate degree at most $\text{polylog}(n)$ for some $\varepsilon = 1 - 1/n^{\text{polylog}(n)}$.

To address this situation, we change the definition of G . Rather than defining $G := f_n \circ \text{AND}_r \circ \text{OR}_{m'}$, we define $G = \text{GAPMAJ}_t \circ f_z \circ \text{AND}_r \circ \text{OR}_m$ for appropriately chosen settings of the parameters t, z, r , and m . Here, GAPMAJ_t denotes any function evaluating to 1 on inputs of Hamming weight at most $t/3$, -1 on inputs of Hamming weight at least $2t/3$, and taking any value in $\{-1, 1\}$ on all other inputs (such functions are also called *approximate majorities*, and it is known that there are approximate majorities computable in AC^0). GAPMAJ has also played an important role in related prior work [6, 13].

In order to show that $\widetilde{\text{deg}}_{\varepsilon'}(G^{\leq \ell}) \gg \widetilde{\text{deg}}_{\varepsilon}(f_n)$ for an ε' that is exponentially closer to 1 than is ε , we require a more delicate construction of a dual witness than our prior works [8, 13]. After all, our prior works only required a dual witness for $G^{\leq \ell}$ with correlation at least $1/3$ with G^{ℓ} , while we require a dual witness achieving correlation with $G^{\leq \ell}$ that is exponentially close to 1. Roughly speaking, whereas our prior works [8, 13] were able to get away with exclusively using the simple and clean technique called dual block composition for constructing dual witnesses, we use a closely related but more involved construction introduced by Sherstov [30]. (Sherstov introduced his construction to prove that approximate degree satisfies a type of direct-sum theorem.)

More specifically, suppose that for some positive integer k , f_z has $\varepsilon(z)$ -approximate degree at least $d(z) = z^{k/(k+1)}$, where $\varepsilon(z) = 1 - 2^{-z^{k/(k+1)}}$. In our definition of G , we set $t = n^{1/(k+2)}$, $z = n^{(k+1)/(k+2)}$, $r = 10 \log n$, and $m = n^{2/(k+2)}$, and we build a dual witness for $G^{\leq \ell}$ via a multi-step construction.

⁵ This step was also used in the analysis of $\text{SURJ}_{R,N}$ outlined in Section 3.2 above, where G was the function $\text{AND}_R \circ \text{OR}_N$.

In Step 1, we take dual witnesses ψ_{f_z} , ψ_{AND_r} , and ψ_{OR_m} for f_z , AND_r , and OR_m respectively, and we combine them using the technique of Sherstov [30], to give a dual witness γ for $f_z \circ AND_r \circ OR_m$ satisfying the following properties: γ has pure high degree at least $D(n) = n^{(k+1)/(k+2)} = d(n)^{(k+1)/k} \gg d(n)$, and γ 's correlation with $f_z \circ AND_r \circ OR_m$ is $\varepsilon'' \approx \varepsilon(z)$. That is, γ witnesses the fact that the ε'' -approximate degree of $f_z \circ AND_r \circ OR_m$ is much larger than the $\varepsilon(n)$ -approximate degree of f_n itself.

This step of the construction is in contrast to our prior work, which constructed a dual witness for $f_n \circ AND_r \circ OR_m$ via direct dual block composition of ψ_{f_n} , ψ_{AND_r} , and ψ_{OR_m} . Direct dual block composition does not suffice for us because it would yield a dual witness with significantly worse correlation with $f_z \circ AND_r \circ OR_m$ than $\varepsilon(z)$.

While achieving correlation $\varepsilon'' \approx \varepsilon(z)$ is an improvement over what would obtain from direct dual block composition, it is still significantly farther from 1 than is $\varepsilon(n)$, i.e., $1 - \varepsilon'' \gg 1 - \varepsilon(n)$. And we ultimately need to construct a dual witness for $G^{\leq \ell}$ that is significantly *closer* to 1 than is $\varepsilon(n)$. To address this issue, in Step 2 of our construction, we use dual block composition to turn γ into a dual witness η for $G = \text{GAPMAJ}_t \circ f_z \circ AND_r \circ OR_m$ satisfying the following properties: η has the same pure high degree as γ , and moreover η has correlation at least $\varepsilon' = 1 - 2^{-\Omega(n^{(k+1)/(k+2)})}$ with G .

However, after Step 2, we are still not done, because η places some mass on inputs of Hamming weight as large as $t \cdot z \cdot r \cdot m \gg \ell$. Hence η is only a dual witness to the high ε' -approximate degree of G , not the high ε' -approximate degree of $G^{\leq \ell}$ (recall that any dual witness for $G^{\leq \ell}$, must evaluate to 0 on all inputs of Hamming weight larger than ℓ , cf. Equation (2)). Nonetheless, as in our prior work [8, 13], we are able to argue that η places *very little* mass on inputs of Hamming weight more than ℓ , and thereby invoke techniques from our prior work [8, 13] to zero out this mass. The reason this final step of the argument is not immediate from our prior work [8, 13] is as follows. Although prior work has developed a precise understanding of how much mass is placed on inputs of Hamming weight more than ℓ by dual witnesses constructed via basic dual block composition, the dual witness γ for $f_z \circ AND_r \circ OR_m$ that we constructed in Step 1 was *not* built by invoking pure dual block composition. Our key observation is that Sherstov's technique that we invoked to construct γ is "similar enough" to vanilla dual block composition that the precise understanding of dual block composition developed in our prior work can be brought to bear on our dual witness η .

In summary, there are two main technical contributions in our proof of Theorem 5. The first is the identification of a hardness amplification construction for ε -approximate degree that not only amplifies the degree against which the lower bound holds, but also the error parameter ε . The second is constructing a dual polynomial to witness the claimed lower bound, using techniques more involved and delicate than the vanilla dual block composition technique that sufficed in our prior works [8, 13].

4 Subsequent Work and Discussion

Subsequent to our work, Sherstov and Wu [36] have made major progress toward resolving Open Problem 1 by showing nearly optimal threshold degree and sign-rank lower bounds for AC^0 . Specifically, for every $k \geq 1$, they exhibit a family of depth- k AC^0 circuits with threshold degree $\tilde{\Omega}(n^{(k-1)/(k+1)})$. This generalizes Minsky and Papert's lower bound of $\Omega(n^{1/3})$ on the threshold degree of DNF, as well as our lower bound of $\tilde{\Omega}(n^{1/2})$ for the depth-3 SURJECTIVITY function. Sherstov and Wu, moreover, show that for any positive constant $\delta > 0$ there is a family of AC^0 circuits with depth $O(1/\delta)$ and sign-rank $\exp(\tilde{\Omega}(n^{1-\delta}))$. This gives an almost optimal improvement to our sign-rank lower bound of $\exp(\tilde{\Omega}(n^{1/2}))$ on an AC^0 function.

As in our proof of Theorem 5, as well as our prior work [13], Sherstov and Wu obtain their threshold degree lower bound for AC^0 by recursively applying a new hardness amplification theorem. Their hardness amplification theorem shows how to convert a function f_z into a new function g_n , computable by circuits with slightly higher depth and roughly the same size, but with polynomially larger threshold degree. Again as in the proof of Theorem 5, in order to obtain such a g , it suffices to construct a function G with $\deg_{\pm}(G^{\leq n}) \gg \deg_{\pm}(f)$. Starting from a function f_z with threshold degree $z^{(k-1)/(k+1)}$, the function G that they identify as sufficient for this purpose is $G = f_z \circ \text{MP}_{r,r^2}$, where $z = n^{(k+1)/(k+3)}$ and $r = n^{2/(k+3)}$. When f_z is a trivial function, this recovers our lower bound of $\tilde{\Omega}(n^{1/2})$ for SURJECTIVITY. Hence, their construction in full can be viewed as a generalization of our Theorem 6 that is amenable to recursive application. This requires several technical new ideas in the construction of the dual witness. However, we remain optimistic that the simplicity of our analysis for SURJECTIVITY will nonetheless lead to future applications of our techniques.

Sherstov and Wu’s sign-rank lower bound follows from a similar high-level (though more technically demanding) strategy, where they show that *smooth* threshold degree also obeys such a hardness amplification theorem.

While these new results resolve the most glaring question raised in the initial version of this work, a number of interesting directions remain for further study. A common feature of our large-error approximate degree lower bound and Sherstov and Wu’s threshold degree and sign-rank lower bounds for AC^0 is that, in order to obtain lower bounds of the form $\Omega(n^{1-\delta})$, we must consider functions computed by circuits of depth $\Theta(1/\delta)$. This contrasts with the situation for bounded error approximate degree [13], where a lower bound of $\Omega(n^{1-\delta})$ can be obtained at depth only $\widetilde{O}(\log(1/\delta))$. Can one show that there are AC^0 functions f of depth $O(\log(1/\delta))$ with $\widetilde{\deg}_{\varepsilon}(f) = \Omega(n^{1-\delta})$ for $\varepsilon = 1 - 2^{-\Omega(n^{1-\delta})}$ or with $\deg_{\pm}(f) = \Omega(n^{1-\delta})$? There is a common underlying reason why our construction and Sherstov and Wu’s construction both require circuits of depth $\Theta(1/\delta)$ and not $\Theta(\log(1/\delta))$: a component of the hardness amplifier in both constructions (in our case, $\text{GAPMAJ}_{n^{1/(k+1)}}$, and in Sherstov and Wu’s case, the top gate of MP_{r,r^2}) is used to amplify error but does not amplify degree. In contrast, in the construction of [13] for lower bounding bounded-error approximate degree, up to a logarithmic factor, all of the hardness amplifier is used to amplify degree.

We would also like to highlight the question of proving sublinear *upper bounds* on the threshold degree of AC^0 . Given the surprising $O(R^{1/4} \cdot N^{1/2})$ upper bound on the $(1/3)$ -approximate degree of $\text{SURJ}_{R,N}$ from recent works [8,35], we have begun to seriously entertain the possibility that for every function f computable by AC^0 of depth k , there is some constant $\delta(k) > 0$ such that the threshold degree (and possibly even $(1/3)$ -approximate degree) of f is $O(n^{1-\delta})$. Unfortunately, we cannot currently even show that this is true for depth three circuits of quadratic size. Any progress in this direction would be very interesting, and we believe that such progress would likely lead to new circuit lower bounds.

Abstract

String matching is the problem of deciding whether a given n -bit string contains a given k -bit pattern. We study the complexity of this problem in three settings.

- **Communication complexity.** For small k , we provide near-optimal upper and lower bounds on the communication complexity of string matching. For large k , our bounds leave open an exponential gap; we exhibit some evidence for the existence of a better protocol.
- **Circuit complexity.** We present several upper and lower bounds on the size of circuits with threshold and DeMorgan gates solving the string matching problem. Similarly to the above, our bounds are near-optimal for small k .
- **Learning.** We consider the problem of learning a hidden pattern of length at most k relative to the classifier that assigns 1 to every string that contains the pattern. We prove optimal bounds on the VC dimension and sample complexity of this problem.

1 Introduction

One of the most fundamental and frequently encountered tasks by minds and machines is that of detecting patterns in perceptual inputs. A basic example is the *string matching* problem, where given a string $x \in \{0, 1\}^n$ and a pattern $y \in \{0, 1\}^k$, $k \leq n$, the goal is to

decide whether x contains y as a substring. Formally, denoting by $x[i, j]$ the bits of x in the interval $[i, j] := \{i, i + 1, \dots, j\}$, we define a Boolean function by

$$\text{SM}_{n,k}(x, y) := 1 \quad \text{iff} \quad x[i, i + k - 1] = y \text{ for some } i \in [n - k + 1].$$

String matching is well-studied in the context of traditional algorithms: it can be computed in linear time [7, 25, 15] (with some lower bounds given by [40]). It has also been studied in more modern algorithmic frameworks such as streaming [37], sketching [3], and property testing [5]. See Section 2 for more related work.

In this work we study the $\text{SM}_{n,k}$ problem in three models of computation, where it appears to have received relatively little attention.

1. *Communication complexity*: How many bits of communication are required to compute $\text{SM}_{n,k}$ when the input (x, y) is adversarially split between two players?
2. *Circuit complexity*: How many gates are needed to compute $\text{SM}_{n,k}$ by DeMorgan circuits (possibly in low depth)? How about threshold circuits?
3. *Learning*: How many labeled samples of strings must be observed in order to (PAC) learn a classifier assigning 1 to a string if and only if it contains a (fixed) hidden pattern y ? What is the VC dimension of this problem?

1.1 Results: Communication Complexity

We first show bounds on the randomized two-party communication complexity of $\text{SM}_{n,k}$. (For standard textbooks on communication complexity, see [26, 22].) The only related prior work we are aware of is Bar-Yossef et al. [3] who studied the *one-way* communication complexity of string matching; our focus is on *two-way* communication. Our bounds are near-optimal for small k , but for large $k \geq \Omega(n)$, we leave open a mysterious exponential gap. Our protocols work regardless of how the input bits (x, y) are bipartitioned between the players, whereas our lower bound is proved relative to some fixed hard partition.

- **Theorem 1** (Communication Complexity). *For the $\text{SM}_{n,k}(x, y)$ problem:*
- **Upper bound**: *Under any bipartition of the input bits, there is a protocol of cost*
 - Deterministic: $O(\log k \cdot n/k)$ if $k \leq \sqrt{n}$;
 - Randomized: $O(\log n \cdot \sqrt{n})$ if $k \geq \sqrt{n}$.
 - **Lower bound**: *For $k \geq 2$ there is a bipartition of the input bits such that every randomized protocol requires $\Omega(\log \log k \cdot n/k)$ bits of communication, even for the fixed pattern $y = 1^k$.*

► **Remark 2**. Note that the most natural bipartition, where Alice gets x and Bob gets y , is easy. Indeed, for such partition there is a randomized $O(\log n)$ -bit protocol, where Bob sends to Alice a hash of y , and Alice compares it with the hashes of the substrings $x[1, k]$, $x[2, k+1], \dots, x[n-k+1, n]$. Under this bipartition, by setting $k = n$, one can also recover the usual *equality* problem, which is well-known to have deterministic communication complexity $\Omega(n)$. This explains why nontrivial protocols for large k need randomness.

A better protocol?

For simplicity of discussion, consider the case $k = n/2$.

What is the randomized communication complexity of $\text{SM}_{n, n/2}$?

Our bounds, $\Omega(\log \log n)$ and $O(\log n \cdot \sqrt{n})$, leave open a huge gap. We conjecture that the answer is closer to the lower bound. As formal evidence we show that problems closely related to $\text{SM}_{n, n/2}$ admit efficient “unambiguous randomized” (aka U-BPP) communication protocols.

A classic result [51] says that any “unambiguous deterministic” (aka U-P) protocol can be efficiently simulated by a deterministic one, that is, $U\text{-P} = P$ in communication complexity. A randomized analogue of this, $U\text{-BPP} = BPP$, turns out to be false as a consequence of the recent breakthrough of Chattopadhyay et al. [9]. One can nevertheless interpret our U-BPP protocols as evidence for the existence of improved randomized protocols.

Techniques

Our lower bound in Theorem 1 requires proving a tight randomized lower bound for composed functions of the form $OR \circ GT$ (where GT is the *greater-than* function), which answers a question of Watson [50]. We observe that the lower bound follows by a minor modification of existing *information complexity* techniques [8]. For upper bounds, the role of periods in strings plays a central role (Section 3.1). We go on to discuss a natural *period finding* problem, and conjecture that it is easy for randomized protocols. See Section 3.4 for details.

The communication complexity and circuit complexity of $SM_{n,k}$ are related. As we soon demonstrate, our study of the communication complexity of $SM_{n,k}$ results with circuit lower bounds for threshold circuits computing $SM_{n,k}$.

1.2 Results: Circuit Complexity

Threshold circuits

A threshold circuit is a circuit whose gates compute *linear threshold functions* (LTFs). Recall that an LTF outputs 1 on an m -bit input x if and only if $\sum_{i \in [m]} a_i x_i \geq \theta$ for some fixed coefficient vector $a \in \mathbb{R}^m$, and $\theta \in \mathbb{R}$. The study of threshold circuits is often motivated by its connection to neural networks [17, 36, 35, 32, 33]. The case of *low-depth* threshold circuits is also interesting. In particular, one line of work [47, 38, 46] has focused on efficient low-depth threshold implementations of arithmetic primitives (addition, comparison, multiplication). As for lower bounds, [17] show an exponential-in- n lower bound for the *mod-2 inner-product* function against depth-2 threshold circuits of low weight (see [12] for an extension). Superlinear lower bounds on the number of gates of arbitrary depth-2 as well as low-weight depth-3 threshold circuits were proven recently by Kane and Williams [24].

It is important that we measure the size of a threshold circuit as the *number of gates* (excluding inputs), in which case even superconstant lower bounds are meaningful. For example, it is easy to implement the equality function (namely $SM_{n,n}$) using three threshold gates (albeit, with exponential weights). Thus, in contrast to the case of bounded fanin circuits, proving linear or even nonconstant lower bounds on the number of gates is not straightforward. Indeed, there are few explicit examples of functions with superconstant lower bounds [16], and proving them is considered challenging [43]. Indeed, Jukna [22] writes “even proving non-constant lower bounds . . . is a nontrivial task”.

We show that $SM_{n,k}$ admits a linear-size implementation at low depth. Thereafter we focus on its fine-grained complexity, seeking to establish lower bounds as close to $\Omega(n)$ as possible.

► **Theorem 3** (Threshold circuits). *For the $SM_{n,k}(x, y)$ problem:*

- **Upper bound:** *There is a depth-2 threshold circuit of size $O(n - k)$.*
- **Lower bound for unbounded depth:** *Any threshold circuit must be of size*

$$\begin{aligned} &\Omega\left(\frac{n \log \log k}{k \log n}\right) && \text{if } k > 1; \\ &\Omega(\sqrt{n/k}) && \text{if } k \geq 2.1 \cdot \log n. \end{aligned}$$

The second lower bound is stronger than the first one in the regime $k = \Omega(n \cdot (\frac{\log \log n}{\log n})^2)$. We note that for $k \leq \text{polylog}(n)$, we have nearly linear lower bounds for unbounded-depth threshold circuits computing $\text{SM}_{n,k}$. We stress that there are no restrictions on the weights of the threshold gates in these lower bounds. We are not able to prove $\Omega(n)$ lower bounds even for depth-2 threshold circuits. Proving such lower bounds (or constructing a threshold circuit of size $o(n)$) remains open. We can prove strong lower bounds for depth-2 circuits in some special cases (see Section 4.3).

Techniques

In Section 4.2 we obtain lower bounds for threshold circuits from the lower bounds on communication complexity of $\text{SM}_{n,k}$ using a connection between threshold complexity and circuit complexity outlined by [34]. We also prove lower bounds for threshold circuits by reducing the problem of computing a “sparse hard” function to computing $\text{SM}_{n,k}$. Perhaps surprisingly, we show that the string matching problem can encode a truth table of an arbitrary sparse (few preimages of 1) Boolean function.

DeMorgan circuits

We consider usual DeMorgan circuits (AND, OR, NOT gates) of *unbounded fan-in* and show upper and lower bounds on the circuit complexity of $\text{SM}_{n,k}$. We emphasize again that we measure the size of a circuit as the *number of gates* (excluding inputs). For example, the n -bit AND can be computed with a circuit of size 1.

We start by analyzing the case of low-depth circuits.

► **Theorem 4** (Depth-2 DeMorgan circuits). *For the $\text{SM}_{n,k}(x, y)$ problem:*

- **Depth-2 upper bound:** *There is a depth-2 DeMorgan circuit of size $O(n \cdot 2^k)$.*
- **Depth-2 lower bound:** *Any depth-2 DeMorgan circuit must be of size*

$$\begin{array}{ll} \Omega(n \cdot 2^k) & \text{if } 1 < k \leq \sqrt{n} ; \\ \Omega(2^{2\sqrt{n-k+1}}) & \text{if } k \geq \sqrt{n}. \end{array}$$

For $k \leq \sqrt{n}$, our depth-2 results are optimal (up to a constant factor). For large k , say $k = n/2$, there is (similarly as for communication) a huge gap in our bounds: $2^{\Omega(\sqrt{n})}$ versus $2^{O(n)}$. We do not know what bound to conjecture here as the correct answer.

For DeMorgan circuits, the celebrated Håstad’s switching lemma [19] established exponential lower bounds for bounded depth circuits computing explicit functions (e.g., majority, parity). We note that in contrast to the parity function, the string matching function admits a polynomial size circuit of depth 3. It is unclear (to us) how to leverage known tools for proving lower bounds for small depth circuits (such as the switching lemma) towards proving super linear lower bounds for small depth DeMorgan circuits computing $\text{SM}_{n,k}$. Whether the string matching problem can be computed by a depth 3 (or even unrestricted) DeMorgan circuit of size $O(n)$ remains open.

Next, we prove that the circuit complexity of $\text{SM}_{n,k}$ for general DeMorgan circuits (unrestricted depth and fan-in) must be $\Omega(n)$. We also include a relatively straightforward upper bound (which may have been discovered before; [14] claims an upper bound $O(n \log^2 n)$ without a proof).

► **Theorem 5** (General DeMorgan circuits). *For the $\text{SM}_{n,k}(x, y)$ problem:*

- **Upper bound:** *There is a DeMorgan circuit of size $O(nk)$ and depth 3.*
- **Lower bound:** *Any DeMorgan circuit must be of size at least $n/2$.*

Techniques

We prove the lower bound on DNF by exhibiting an explicit set of inputs to $SM_{n,k}$ each of which requires a separate clause in any DNF. Our lower bound for CNF involves estimating the size of maxterms of $SM_{n,k}$. For the lower bound against circuits of unrestricted depth, we adjust the gate elimination technique to the case of unbounded fan-in circuits. See Section 5 for details.

1.3 Results: Learning

Finally, we seek to understand the sample complexity of PAC-learning the string matching function $SM_{n,\ell}(x, \sigma)$, where x is an arbitrary string of length n and σ is a *fixed* pattern of length $\ell \leq k$. Towards this goal we prove (almost) tight bounds on the VC dimension of the class of these functions. The VC dimension essentially determines the sample complexity needed to learn the pattern σ from a set of i.i.d. samples in the PAC learning framework. We formalize these notions below.

Let Σ be a fixed finite alphabet of size $|\Sigma| \geq 2$.¹ By Σ^n we denote the set of strings over Σ of length n , and by $\Sigma^{\leq k}$ we denote the set of strings of length at most k . We study the VC dimension of the class of functions, where each function is identified with a pattern of length at most k , and outputs 1 only on the strings containing this pattern. Recall that the length of the pattern $k = k(n) \leq n$ can be a function of n . We now define the set of functions we wish to learn:

► **Definition 6.** For a fixed finite alphabet Σ and an integer $k > 0$, let us define the class of Boolean functions $\mathcal{H}_{k,\Sigma}$ over Σ^n as follows. Every function $h_\sigma \in \mathcal{H}_{k,\Sigma}$ is parameterized by a pattern $\sigma \in \Sigma^{\leq k}$ of length at most k . Hence, $|\mathcal{H}_{k,\Sigma}| = \frac{|\Sigma|^{k+1}-1}{|\Sigma|-1}$. For a string $s \in \Sigma^n$, $h_\sigma(s) = 1$ if and only if s contains σ as a substring.

To analyze the sample complexity required to learn a function from $\mathcal{H}_{k,\Sigma}$ we first define VC dimension.

► **Definition 7.** Let \mathcal{F} be a class of functions from a set D to $\{0,1\}$, and let $S \subseteq D$. A dichotomy of S is one of the possible labellings of the points of S using a function from \mathcal{F} . S is shattered by \mathcal{F} if \mathcal{F} realizes all $2^{|S|}$ dichotomies of S . The VC dimension of \mathcal{F} , $VC(\mathcal{F})$, is the size of the largest set S shattered by \mathcal{F} .

In particular, $VC(\mathcal{H}_{k,\Sigma}) = d$ if and only if there is a set S of d strings of length n such that for every $S' \subseteq S$, there exists a pattern $P_{S'}$ of length at most k occurring in all the strings in S' and not occurring in all the strings in $S \setminus S'$.

A class of functions \mathcal{F} is PAC-learnable² with accuracy ε and confidence $1 - \delta$ in $\Theta\left(\frac{VC(\mathcal{F}) + \log(1/\delta)}{\varepsilon}\right)$ samples [6, 11, 18], and is agnostic PAC-learnable in $\Theta\left(\frac{VC(\mathcal{F}) + \log(1/\delta)}{\varepsilon^2}\right)$ samples [2, 44]. Thus, tight bounds on the VC dimension of a class of functions give tight bounds on its sample complexity.

Our main result is a tight bound on the VC dimension of $\mathcal{H}_{k,\Sigma}$ (up to low order terms). That is:

¹ In contrast to the circuit and communication setting, for the learning problem we consider nonbinary alphabets.

² For a precise definition of PAC learning, see Definition 36.

► **Theorem 8.** *Let Σ be a finite alphabet of size $|\Sigma| \geq 2$, then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}) = \min(\log |\Sigma|(k - O(\log k)), \log n + O(\log \log n)) .$$

It follows that the sample complexity of learning patterns is $O(\log n)$. We also show that there are efficient polynomial time algorithms solving this learning problem. See Corollary 37 for details.

Techniques

We prove our upper bound on the VC dimension by a double counting argument. This argument uses Sperner families to show that shattering implies a “large” family of non-overlapping patterns, which, on the other hand, is constrained by the length n of the strings that we shatter. The lower bound is materialized by the idea to have 2^d patterns $P = \{p_0 \dots p_{2^d-1}\}$ and d strings such that the i th string is a concatenation of all patterns with the binary expansion of their index having the i th bit equal 1. We construct a family of patterns T with the property that for any pair of distinct strings $\alpha, \beta \in T$, their concatenation $\alpha\beta$ does not contain a string $\gamma \in T, \gamma \neq \alpha, \beta$. Using this family (with some additional technical requirements) we are able to show that P shatters a set of d strings implying our lower bound on the VC dimension.

Circuit complexity

Upper bounds on the circuit complexity of 2D image matching problem under projective transformations was studied in [42]. In this problem, which is considerably more complicated than the pattern matching problems we study, the goal is to find a projective transformation f such that $f(A)$ “resembles”³ B for two images A, B . Here, images are 2D square arrays of dimension n containing discrete values (colors). In particular, it is proven that this image matching problem is in TC^1 (it admits a threshold circuit of polynomial size and logarithmic depth in n). These results concern a different problem than the string matching considered here, and do not seem to imply the upper bounds we obtain for circuits solving the string matching problem.

The idea to lower bound the circuit complexity of Boolean functions that arise in feature detection was studied in [29, 30]. These works assumed a setting with two types of features, a and b , with detectors corresponding to the two types situated on a 1D or 2D grid. The binary outputs of these features are represented by an array of n positions: a_1, \dots, a_n (where $a_i = 1$ if the feature a is detected in position i , and $a_i = 0$ otherwise) and an array b_1, \dots, b_n which is analogously defined with respect to b . The Boolean function P_{LR}^n outputs 1 if there exist i, j with $i < j$ such that $a_i = b_j = 1$, and 0 otherwise. This function is advocated in [30] as a simple example of a detection problem in vision that requires to identify spatial relationship among features. It is shown that this problem can be solved by $O(\log n)$ threshold gates. A 2-dimensional analogue where the indices $i = (i_1, i_2)$ and $j = (j_1, j_2)$ represent two-dimensional coordinates and one is interested whether there exist indices i and j such that $a_i = b_j = 1$ and j is above and to the right of the location i is studied in [30]. Recently, the two-dimensional version was studied in [48] where a $O(\sqrt{n})$ -gate threshold implementation

³ We refer to [42] for the precise definition of distance used there.

was given along with a lower bound of $\Omega(\sqrt{n/\log n})$ for the size of any threshold circuit for this problem. We remark that the problem studied in [29, 30, 48] is different from ours, and different proof ideas are needed for establishing lower bounds in our setting.

Learning patterns

The language of all strings (of arbitrary length) containing a fixed pattern is regular and can be recognized by a finite automaton. There is a large literature on learning finite automata (e.g., [1, 13, 41]). This literature is mostly concerned with various active learning models and it does not imply our bounds on the sample complexity of learning $\mathcal{H}_{k,\Sigma}$.

Motivated by computer vision applications, several works have considered the notion of *visual concepts*: namely a set of shapes that can be used to classify images in the PAC-learning framework [27, 45]. Their main idea is that occurrences of shapes (such as lines, squares etc.) in images can be used to classify images and that furthermore the representational class of DNF's can represent occurrences of shapes in images. For example, it is easy to represent the occurrence of a fixed pattern of length k in a string of size n as a DNF with $n - k$ clauses (see e.g., Lemma 24). We note that these works do not study the VC dimension of our pattern matching problems (or VC bounds in general). We also observe that no polynomial algorithm is known for learning DNF's and that there is some evidence that the problem of learning DNF is intractable [10]. Hence the result in [27, 45] do not imply that our pattern learning problem (represented as a DNF) can be done in polynomial time.

3 Communication Complexity

In this section we prove Theorem 1, and also discuss the possibility of a better upper bound.

► **Theorem 1** (Communication Complexity). *For the $SM_{n,k}(x, y)$ problem:*

- **Upper bound:** *Under any bipartition of the input bits, there is a protocol of cost*
 - Deterministic: $O(\log k \cdot n/k)$ if $k \leq \sqrt{n}$;
 - Randomized: $O(\log n \cdot \sqrt{n})$ if $k \geq \sqrt{n}$.
- **Lower bound:** *For $k \geq 2$ there is a bipartition of the input bits such that every randomized protocol requires $\Omega(\log \log k \cdot n/k)$ bits of communication, even for the fixed pattern $y = 1^k$.*

3.1 Periods in strings

We say a string $x \in \{0, 1\}^n$ has *period* $p \in \{0, 1\}^i$ of *order* i if x is a prefix of a high enough power p^m (for some $m \geq 1$). Equivalently, x has a period of order i iff $x[i+1, n] = x[1, n-i-1]$. A classic lemma characterizes the orders of short periods in a string.

► **Lemma 9** ([31]). *If x has periods of orders i, j , $i + j \leq |x|$, then there is one of order $\gcd(i, j)$.*

In particular, all periods of order $\leq n/2$ are powers of some *primitive period* (shortest period of order $\leq n/2$). It is natural to ask: how many bits of communication are required to decide whether a string has a primitive period? We will discuss this in Section 3.4.

3.2 Upper bound

We start by describing an $O(\log k \cdot n/k)$ -bit deterministic protocol for $SM_{n,k}$ assuming the pattern y is fixed (known to both players). This immediately gives a protocol of cost $O(k + \log k \cdot n/k)$ when y is *not* fixed: Alice and Bob simply exchange all bits of the k -bit pattern and then run the protocol that assumes y is fixed. When $k \leq \sqrt{n}$ this yields the first upper bound claimed in Theorem 1.

► **Lemma 10.** For every fixed pattern $y \in \{0, 1\}^k$ the function $x \mapsto \text{SM}_{n,k}(x, y)$ admits a deterministic protocol of cost $O(\log k \cdot n/k)$ under any bipartition of the input x .

Next we supply the protocol for the second upper bound in Theorem 1.

► **Lemma 11.** For $k \geq \sqrt{n}$ the function $\text{SM}_{n,k}$ admits a randomized protocol of cost $O(\log n \cdot \sqrt{n})$ under any bipartition of the input (x, y) .

► **Remark 12.** For $k \geq \sqrt{n \log n}$ the above protocol can be optimized to have cost $O(\sqrt{n \log n})$. Namely, consider a prefix p (and intervals) of length $\Theta(\sqrt{n \log n})$ rather than $\Theta(\sqrt{n})$.

3.3 Lower bound

Next we prove a lower bound of $\Omega(\log \log k \cdot n/k)$, for every $k \leq n$, on the randomized communication complexity of $\text{SM}_{n,k}$. As a warm-up, we first observe that a reduction from the ubiquitous set-disjointness function yields a randomized lower bound of $\Omega(n/k)$ for $\text{SM}_{n,k}$. We then show how to improve this by a factor of $\log \log k$.

Recall that in the m -bit set-disjointness problem, Alice is given $a \in \{0, 1\}^m$, Bob is given $b \in \{0, 1\}^m$, and their goal is to compute $\text{Disj}_m(a, b) := (\text{OR}_m \circ \text{AND}_2)(a, b) = \bigvee_{i \in [m]} (a_i \wedge b_i)$. It is well known that this function has communication complexity $\Omega(m)$ even against randomized protocols [23, 39, 4].

► **Observation 13.** $\text{Disj}_{\Omega(n/k)}$ reduces to $\text{SM}_{n,k}$ (under some bipartition of input bits).

To improve the above, we give a reduction from a slightly harder function, $\text{OR}_m \circ \text{GT}_\ell: [\ell]^m \times [\ell]^m \rightarrow \{0, 1\}$, which maps $(a, b) \mapsto \bigvee_{i \in [m]} \text{GT}_\ell(a_i, b_i)$ where $\text{GT}_\ell: [\ell] \times [\ell] \rightarrow \{0, 1\}$ is the *greater-than* function given by $\text{GT}_\ell(a, b) := 1$ iff $a \geq b$. The claimed lower bound $\Omega(\log \log k \cdot n/k)$ for $\text{SM}_{n,k}$ follows from the following two lemmas. As mentioned in the introduction, Lemma 15 was conjectured by [50].

► **Lemma 14.** $\text{OR}_{\Omega(n/k)} \circ \text{GT}_{\Omega(k)}$ reduces to $\text{SM}_{n,k}$ (under some bipartition of input bits).

► **Lemma 15.** $\text{OR}_m \circ \text{GT}_\ell$ has randomized communication complexity $\Omega(m \cdot \log \log \ell)$ for any m, ℓ .

3.4 A better protocol?

As bonus results, we give some evidence for the existence of an improved randomized protocol for $\text{SM}_{n,k}$ when k is large. We first define what *unambiguous randomized* (aka $\text{U} \cdot \text{BPP}$, or unambiguous Merlin–Arthur) protocols are; they generalize the notion of unambiguous deterministic protocols (aka $\text{U} \cdot \text{P}$) introduced by Yannakakis [51].

► **Definition 16** ($\text{U} \cdot \text{BPP}$ protocols). An unambiguous randomized protocol Π computes a function $F(x, y)$ as follows. In the first phase the players nondeterministically guess a witness string $z \in \{0, 1\}^{c_1}$, and then in the second phase they run a randomized (error $\leq 1/3$) protocol of cost c_2 to decide whether to accept the witness z . The correctness requirement is that for every $(x, y) \in F^{-1}(1)$ there needs to be a unique witness that is accepted; for every $(x, y) \in F^{-1}(0)$ no witness should be accepted. The cost of Π is defined as $c_1 + c_2$.

Unambiguous randomized protocols have not been studied before in communication complexity. However, the recent breakthrough of Chattopadhyay et al. [9] (who disproved the log-approximate-rank conjecture of [28]) is closely related. It is not hard to see that the function $F(x, y)$ they study (of the form $\text{Sink} \circ \text{XOR}$) admits an $O(\log n)$ -cost $\text{U} \cdot \text{BPP}$ protocol.

The authors proved that the usual randomized (aka BPP) communication complexity of F is high, $n^{\Omega(1)}$. Consequently, there is no generic simulation of a U·BPP protocol by a BPP protocol. By contrast, Yannakakis [51, Lemma 1] showed that U·P protocols can be made deterministic efficiently.

Our first bonus result is an efficient U·BPP protocol for determining if a given string has a primitive period. We do not know whether there is an efficient randomized protocol.

► **Lemma 17.** *Suppose the bits of $x \in \{0,1\}^n$ are split between two players. There is an U·BPP protocol of cost $O(\log^2 n)$ for deciding whether x has a primitive period (and to compute its order).*

If we let R_{pf} denote the randomized communication complexity of the above period finding problem, then we can interpret Lemma 17 as evidence that $R_{\text{pf}} \leq \text{polylog}(n)$. Assuming period finding is indeed easy, we can then provide similar evidence for the easiness of $\text{SM}_{n,k}$ for large k .

► **Lemma 18.** *$\text{SM}_{n,0.9n}$ admits an U·BPP protocol of cost $O(\log n) + R_{\text{pf}}$.*

4 Threshold Circuits

In this section we prove Theorem 3.

► **Theorem 3** (Threshold circuits). *For the $\text{SM}_{n,k}(x, y)$ problem:*

- **Upper bound:** *There is a depth-2 threshold circuit of size $O(n - k)$.*
- **Lower bound for unbounded depth:** *Any threshold circuit must be of size*

$$\Omega\left(\frac{n \log \log k}{k \log n}\right) \quad \text{if } k > 1;$$

$$\Omega(\sqrt{n/k}) \quad \text{if } k \geq 2.1 \cdot \log n.$$

In Section 4.1 we prove the upper bound, in Section 4.2 we give the lower bounds. Finally, in Section 4.3 we study the complexity of $\text{SM}_{n,k}$ in the models of restricted threshold circuits.

4.1 Upper bound

We start with a construction giving the upper bound of Theorem 3.

► **Lemma 19.** *There is a depth-2 threshold circuit of size $O(n - k)$ computing $\text{SM}_{n,k}$.*

4.2 Lower bounds

In order to prove the first lower bound of $\Omega\left(\frac{n \log \log k}{k \log n}\right)$ we use the classical result on communication complexity of threshold gates [34], and the lower bound on communication complexity of $\text{SM}_{n,k}$ from Theorem 1.

Nisan and Safra [34] proved that for *any* bipartition of the n input bits, the ϵ -error randomized communication complexity of a threshold gate (with arbitrary weights) has communication complexity $O(\log n/\epsilon)$. From this they concluded that for any function f , a lower bound of m on the randomized communication complexity for *some* bipartition of the input implies a lower bound of $\Omega(m/\log n)$ on the threshold complexity of f . Now the lower bound of $\Omega(n \log \log k/k)$ from Theorem 1 implies the lower bound of $\Omega\left(\frac{n \log \log k}{k \log n}\right)$ on the size of an unbounded depth threshold circuit computing $\text{SM}_{n,k}$.

Below we prove the second lower bound stated in Theorem 3. The lower bound is shown via a reduction from a hard function $f: \{0,1\}^{k/2-1} \rightarrow \{0,1\}$ which has n/k preimages of 1: $|f^{-1}(1)| = n/k$. First, we prove the desired lower bound for the case where k is even

and n is a multiple of k . In the end of this section we explain how to adjust the proof to the remaining cases. Let ℓ and t be integers such that $k = 2\ell + 2$ and $n = t \cdot k$. Let $F_{\ell,t} = \{f: \{0,1\}^\ell \rightarrow \{0,1\} : |f^{-1}(1)| = t\}$ be the class of Boolean functions of ℓ inputs which have exactly t preimages of 1.

We prove this lower bound via a reduction from a hard function $f \in F_{\ell,t}$. Specifically, we show that if $\text{SM}_{n,k}$ can be solved by a circuit of size s , then every function $f \in F_{\ell,t}$ also has a circuit of size s computing it. Then, we show that there are functions in $F_{\ell,t}$ that require large threshold circuits, which implies the corresponding lower bound for the $\text{SM}_{n,k}$ function.

The reduction

Given a string $a \in \{0,1\}^\ell$ define $\text{dup}(a) \in \{0,1\}^k$ to be the string obtained from a by repeating each bit of a twice, and concatenating it with 01 in the end. (Note that $2\ell + 2 = k$ by the choice of ℓ). For example $\text{dup}(010) = 00110001$.

► **Observation 20.** *Given a function $f \in F_{\ell,t}$ define $x_f \in \{0,1\}^{tk}$ to be the concatenation of $\text{dup}(a)$ for all $a \in f^{-1}(1)$ in the lexicographic order on $\{0,1\}^\ell$. Note that $|x_f| = tk = n$. Then, for any $y \in \{0,1\}^\ell$ it holds that $f(y) = 1$ if and only if $\text{SM}_{n,k}(x_f, \text{dup}(y)) = 1$.*

Indeed, it is immediate to see that if $f(y) = 1$ then $\text{SM}_{n,k}(x_f, \text{dup}(y)) = 1$. Duplicating every bit in a and adding 01 to the end of the resulting pattern are done to ensure that if $f(y) = 0$ there will not be a copy of $\text{dup}(y)$ in x_f .

Given the observation above, it is not difficult to see that any lower bound on the size of a circuit computing $f \in F_{\ell,t}$ implies a lower bound on $\text{SM}_{n,k}$.

► **Proposition 21.** *Let C be a threshold circuit computing $\text{SM}_{n,k}$. Then for every $f \in F_{\ell,t}$, there exists a threshold circuit C' computing f such that $|C'| \leq |C|$.*

In order to complete the proof of Theorem 3, we need to show that there exists a function $f \in F_{\ell,t}$ that requires large threshold circuits. For this, we compare the number of small threshold circuits (see, for example, [22, 24]) with the number of functions in $F_{\ell,t}$.

► **Proposition 22.** *Let $\ell \in \mathbb{N}$ be sufficiently large, and let $t \in \mathbb{N}$. There exists a function $f \in F_{\ell,t}$ such that any threshold circuit (with no restrictions on its depth) computing f must be of size at least $\Omega(\sqrt{t - t \log t / \ell})$.*

We now derive the desired lower bound on the size of threshold circuits computing the string matching function. Plugging in $k = 2\ell + 2$ and $n = tk$, we get the lower bound of $s \geq \Omega(\sqrt{\frac{n}{k} - \frac{2n}{k^2} \cdot \log(\frac{n}{k})}) = \Omega(\sqrt{\frac{n}{k}})$ assuming $k \geq \Omega(\log n)$.

Now we describe how this proof can be adopted for the case when n is not a multiple of k and the case of odd k . First, in order to handle the case of pattern of *odd* length, one can add the string 010 (instead of 01) to the end of $\text{dup}(a)$. If n is not a multiple of k , then in the reduction above we can pad the string x_f with zeros in the end, and the reduction still satisfies the property that $f(y) = 1$ if and only if $\text{SM}_{n,k}(x_f, \text{dup}(y)) = 1$ as in Observation 20, and the same lower bound holds (up to a constant factor in the asymptotics).

4.3 Depth-2 Circuits

In Theorem 23 we prove lower bounds for some restricted classes of depth-2 circuits computing $\text{SM}_{n,k}$. These results should be contrasted with the upper bounds of Theorem 3 and Theorem 5. Namely, there exists an $\text{LTF} \circ \text{LTF}$ circuit of size $O(n-k)$ and an $\text{OR} \circ \text{AND} \circ \text{OR}$ circuit of size $O(nk)$ computing $\text{SM}_{n,k}$.

We recall a few definitions. Let ELTF denote the class of *exact* threshold functions (that is, the functions which output 1 on an m -bit input x if and only if $\sum_{i \in [m]} a_i x_i = \theta$ for some fixed coefficient vector $a \in \mathbb{R}^m$, and $\theta \in \mathbb{R}$). Similarly, EMAJ denotes the class of exact majorities which output 1 if and only if the sum of their m Boolean inputs is exactly $m/2$. By SYM we denote the class of all symmetric Boolean functions. For two classes of functions \mathcal{C}_1 and \mathcal{C}_2 , by $\mathcal{C}_1 \circ \mathcal{C}_2$ we denote the class of depth-2 circuits where the output gate is from \mathcal{C}_1 and the gates of the first layer are from \mathcal{C}_2 . For a class of circuits \mathcal{C} and a function f , by $\mathcal{C}(f)$ we denote the minimal size of a circuit from \mathcal{C} computing f .

In proving lower bounds for $\text{SM}_{n,k}$ a simple yet useful property is that Observation 13 can be applied to circuits as well. This allows to reduce the disjointness problem to string matching, and get lower bounds for $\text{SM}_{n,k}$ via known circuit lower bounds for disjointness. The point is that a circuit C with strings of length roughly mk for $\text{SM}_{n,k}$ (and patterns of length k) can be used to solve disjointness on strings of length m by feeding C with the string $x := a_1 b_1 1^{k-2} 0 a_2 b_2 1^{k-2} 0 \dots a_n b_n 1^{k-2} 0$ and the pattern $y = 1^k$. Hence a lower bound of $s(n)$ for circuits computing disjointness implies a lower bound of $\Omega(s(n/k))$ for circuits computing $\text{SM}_{n,k}$.

► **Theorem 23.** *For every $1 < k \leq n$,*

1. $\text{OR} \circ \text{LTF}(\text{SM}_{n,k}) \geq \Omega(n - k)$;
2. $\text{AND} \circ \text{LTF}(\text{SM}_{n,k}) \geq 2^{\Omega(n/k)}$;
3. $\text{AND} \circ \text{OR} \circ \text{XOR}(\text{SM}_{n,k}) \geq 2^{\Omega(n/k)}$;
4. $\text{ELTF} \circ \text{SYM}(\text{SM}_{n,k}) \geq 2^{\Omega(n/k)}$;
5. $\text{EMAJ} \circ \text{ELTF}(\text{SM}_{n,k}) \geq 2^{\Omega(n/k)}$.

5 DeMorgan Circuits

In this section we prove Theorem 4 and Theorem 5.

► **Theorem 4** (Depth-2 DeMorgan circuits). *For the $\text{SM}_{n,k}(x, y)$ problem:*

- **Depth-2 upper bound:** *There is a depth-2 DeMorgan circuit of size $O(n \cdot 2^k)$.*
- **Depth-2 lower bound:** *Any depth-2 DeMorgan circuit must be of size*

$$\begin{array}{ll} \Omega(n \cdot 2^k) & \text{if } 1 < k \leq \sqrt{n} ; \\ \Omega(2^{2\sqrt{n-k+1}}) & \text{if } k \geq \sqrt{n}. \end{array}$$

► **Theorem 5** (General DeMorgan circuits). *For the $\text{SM}_{n,k}(x, y)$ problem:*

- **Upper bound:** *There is a DeMorgan circuit of size $O(nk)$ and depth 3.*
- **Lower bound:** *Any DeMorgan circuit must be of size at least $n/2$.*

In Section 5.1 we give upper bounds for both theorems, in Section 5.2 we prove lower bounds for depth-2 circuits, and in Section 5.3 we provide a lower bound for the unbounded depth case.

5.1 Upper Bounds

We first give a DNF with $2^k(n - k + 1)$ clauses computing $\text{SM}_{n,k}$, and in Lemma 26 we will prove that this DNF is essentially optimal.

► **Lemma 24.** *For any $k \leq n$ there exists a DeMorgan circuit of depth 2 and size $(n - k + 1) \cdot 2^k + 1$ computing $\text{SM}_{n,k}$.*

Now we show that already in depth 3, one can compute $\text{SM}_{n,k}$ by a much smaller circuit. This Lemma is likely to have been discovered multiple times, we attribute it to folklore.

► **Lemma 25.** *There exists a DeMorgan circuit of depth 3 and size $O(nk)$ computing $SM_{n,k}$.*

5.2 Lower bounds for depth 2

We may assume wlog that every optimal circuit of depth 2 is either a CNF or a DNF. First, we show that in the class of DNFs, the construction from Lemma 24 is optimal (up to a constant factor).

► **Lemma 26.**

For every $k > 2$, the DNF-size of $SM_{n,k}$ is at least

$$\text{DNF}(SM_{n,k}) \geq 2^{k-2}(n-k+1).$$

Now we will prove lower bounds for CNFs computing $SM_{n,k}$. We will need the following definition.

► **Definition 27.** *A maxterm of a Boolean function f is a set of variables of f , such that some assignment to those variables makes f output 0 irrespective of the assignment to the other variables. The width of a maxterm is the number of variables in it.*

First we find the minimal width of maxterms of $SM_{n,k}$.

► **Lemma 28.** *For any $k \leq n$, every maxterm of $SM_{n,k}$ has width at least*

$$\begin{array}{ll} 2\sqrt{n-k+1} & \text{for all } k; \\ k + \frac{n-k+1}{k} & \text{if } k \leq \sqrt{n-k+1}. \end{array}$$

Next we prove tight bounds on the number of non-satisfying inputs of $SM_{n,k}$.

► **Lemma 29.** *For $k \leq n$, let Z denote the set of preimages of 0 of $SM_{n,k}$. That is,*

$$Z = \{(x, y) \in \{0, 1\}^{n+k} : SM_{n,k}(x; y) = 0\}.$$

Then

$$\begin{array}{ll} |Z| = \Theta(2^{n+k}) & \text{if } k \geq \log n + 1; \\ |Z| \geq \Omega(2^n(1-2^{-k})^n) & \text{for all } k. \end{array}$$

► **Lemma 30.** *For every k , the CNF-size of $SM_{n,k}$ is at least*

$$\begin{array}{ll} \text{CNF}(SM_{n,k}) \geq \Omega\left(2^{\frac{n}{10k}}\right) & \text{if } 1 < k \leq \log n + 1; \\ \text{CNF}(SM_{n,k}) \geq \Omega\left(2^{k+n/k}\right) & \text{if } \log n + 1 \leq k \leq \sqrt{n}; \\ \text{CNF}(SM_{n,k}) \geq \Omega\left(2^{2\sqrt{n-k+1}}\right) & \text{if } k \geq \sqrt{n}. \end{array}$$

Discussion

Lemma 26 and Lemma 30 together give the lower bounds of Theorem 4. We observe a curious behavior of CNFs and DNFs for $SM_{n,k}$. For $k \leq \sqrt{n}$, an optimal depth-2 circuit for $SM_{n,k}$ is a DNF. It can also be shown that for $k \geq n - O(\frac{n}{\log n})$, an optimal circuit is a CNF. (Indeed, in order to certify that $SM_{n,k}(x, y) = 0$, it suffices to give mismatches for each of the $(n-k+1)$ shifts of the pattern y in x . This amounts to $k^{O(n-k+1)} < n \cdot 2^k$ clauses.) We leave the exact CNF complexity of $SM_{n,k}$ for the regime $k > \sqrt{n}$ as an open problem. One way to prove a stronger lower bound in this regime would be to give a lower bound on the width of every maxterm. This approach does not lead to stronger lower bounds

because there exist maxterms of width $2\sqrt{n}$. To see this, consider an assignment where the first \sqrt{n} characters of the pattern y are fixed to zeros, and all indices divisible by \sqrt{n} in the text x are fixed to ones. While we cannot prove a stronger lower bound on the width of “most” maxterms, we know that some maxterms must have width at least $n - k + 1$. Indeed, consider the text $x = 0^n$ and pattern $y = 10^{k-1}$. Every clause which outputs 0 on this pair, must assign the first $(n - k + 1)$ positions of x to 0.

We remark that weaker lower bounds of $2^{\Omega(\sqrt{n/k})}$ and $2^{0.08n/k}$ on the size of CNF computing $\text{SM}_{n,k}$ follow from the reduction from Disjointness in Observation 13 and the known lower bound on the depth-3 complexity of Iterated Disjointness [20] and Disjointness [21].

5.3 Lower bound for unbounded depth

Now we prove the lower bound of Theorem 5. For circuits with fan-in 2, a linear lower bound follows from the observation that $\text{SM}_{n,k}$ essentially depends on all of its inputs. In the next lemma, we use an extension of the gate elimination technique to show that even in the class of DeMorgan circuits with *unbounded fan-in*, $\text{SM}_{n,k}$ still requires linear size.

► **Lemma 31.** *For $k > 1$, any DeMorgan circuit computing $\text{SM}_{n,k}$ has size at least $n/2$.*

6 Learning

6.1 VC dimension

In this section we prove Theorem 8.

► **Theorem 8.** *Let Σ be a finite alphabet of size $|\Sigma| \geq 2$, then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}) = \min(\log |\Sigma|(k - O(\log k)), \log n + O(\log \log n)).$$

We begin by upper bounding the VC dimension. In the proof we will use the following folklore construction of a Sperner system.

► **Definition 32.** *A system \mathcal{F} of subsets of $\{1, \dots, n\}$ is called a Sperner system if no set in \mathcal{F} contains another one:*

$$\forall A, B \in \mathcal{F}: A \neq B \implies A \not\subseteq B.$$

For any n , there exists a Sperner system of size $\binom{n}{\lfloor n/2 \rfloor}$. Indeed, one can take \mathcal{F} to be the family of all sets of size exactly $\lfloor n/2 \rfloor$.

► **Lemma 33.** *Let Σ be a finite alphabet of size $|\Sigma| \geq 2$, then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}) \leq \min(\lceil k \log |\Sigma| \rceil, \log n + 0.5 \log \log n + 2).$$

To lower bound the VC dimension of $\mathcal{H}_{k,\Sigma}$ we need the following lemma.

► **Lemma 34.** *Let m be an integer $m \geq 1$, and Σ be an alphabet of size $|\Sigma| \geq 2$. There exists a set T_m of at least $|\Sigma|^{m-1}$ strings from $\Sigma^{m + \lceil \log m \rceil + 2}$ with the following property. For any two distinct strings $\tau_1, \tau_2 \in T_m$, their concatenation $\tau = \tau_1 \circ \tau_2$ doesn't contain any string from $T_m \setminus \{\tau_1, \tau_2\}$ as a substring.*

► **Lemma 35.** *Let Σ be a finite alphabet of size $|\Sigma| \geq 2$, then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}) \geq \min((k - \log k - 5) \log |\Sigma|, \log n - \log \log n).$$

This concludes the proof of Theorem 8.

6.2 Learning $\mathcal{H}_{k,\Sigma}$

In this section we discuss an efficient algorithm for learning the hypothesis class $\mathcal{H}_{k,\Sigma}$. For completeness we state the definition of PAC learning:

Let \mathcal{D} be a distribution over Σ^n . Suppose we are trying to learn h_σ for $\sigma \in \Sigma^{\leq k}$. Given $\tau \in \Sigma^{\leq k}$, the loss of h_τ with respect to h_σ is defined as

$$L_{\mathcal{D},\sigma}(\tau) = \Pr_{x \sim \mathcal{D}} [h_\tau(x) \neq h_\sigma(x)].$$

Following the notion of PAC-learning [49, 44], we can now define what we mean by learning $\mathcal{H}_{k,\Sigma}$.

► **Definition 36.** *An algorithm \mathcal{A} is said to PAC-learn $\mathcal{H}_{k,\Sigma}$ if for every distribution \mathcal{D} over Σ^n and every $h_\sigma \in \mathcal{H}_{k,\Sigma}$ for all $\epsilon, \delta \in (0, 1/2)$ the following holds. Given $m := m(\epsilon, \delta, n, k)$ i.i.d. samples $(x_1, h_\sigma(x_1)), \dots, (x_m, h_\sigma(x_m))$ where each x_i is sampled according to the distribution \mathcal{D} , \mathcal{A} returns with probability at least $1 - \delta$ a function $h_\tau \in \mathcal{H}_{k,\Sigma}$ such that $L_{\mathcal{D},\sigma}(\tau) \leq \epsilon$. Here the probability is taken with respect to the m i.i.d. samples as well as the possible random choices made by the algorithm \mathcal{A} .*

Throughout, we refer to δ as the confidence parameter and ϵ as the accuracy parameter.

In Definition 36 we consider the *realizable* case. Namely there exists $h_\sigma \in \mathcal{H}_{k,\Sigma}$ that we want to learn. One can also consider the *agnostic* case. Consider a distribution \mathcal{D} over $\Sigma^n \times \{0, 1\}$. We now define the loss of h_τ as

$$L_{\mathcal{D}}(\tau) = \Pr_{x \sim \mathcal{D}} [h_\tau(x) \neq y],$$

namely the measure under \mathcal{D} of all pairs $(x, y) \in \Sigma^n \times \{0, 1\}$ with $h_\tau(x) \neq y$ [44]. In the agnostic case we wish to find, given m i.i.d. samples $(x_1, h(x_1)), \dots, (x_m, h(x_m))$, a pattern $\sigma' \in \Sigma^{\leq k}$ such that $L_{\mathcal{D}}(\sigma') \leq \min_{\tau} L_{\mathcal{D}}(\tau) + \epsilon$ (where the minimum is taken over all $\tau \in \Sigma^{\leq k}$). Thus agnostically PAC-learning generalizes the realizable case where $\min_{\tau} L_{\mathcal{D}}(\tau) = 0$.

Recall that a function $h_\sigma \in \mathcal{H}_{k,\Sigma}$ (parameterized by the pattern σ of length at most k) can be learned with error ϵ and confidence δ by considering $m = O(\text{VC}(\mathcal{H}_{k,\Sigma}))$ samples $(x_1, h_\sigma(x_1)), \dots, (x_m, h_\sigma(x_m))$ (where the constant in the O term depends on ϵ, δ) and following the ERM (expected risk minimization) rule: Finding σ' that minimizes the loss

$$L(h_{\sigma'}) := \frac{|\{i \in [m] : h_{\sigma'}(x_i) \neq h_\sigma(x_i)\}|}{m}.$$

In words, to PAC learn h_σ we simply look for a string σ' of length at most k such that the fraction of sample points that are misclassified by $h_{\sigma'}$ is minimized (the ERM rule applies both for the agnostic and realizable settings).

By Lemma 33, the number of samples needed to PAC-learn h_σ is at most $O(\log n)$ (ignoring the dependency on ϵ, δ). Clearly we can implement the ERM by considering all possible substrings of length at most k that occur in the $m = O(\log n)$ strings $x_1 \dots x_m$ and finding the substring σ' minimizing $L(h_{\sigma'})$. The number of such substrings is at most $O(\log n \sum_{i=1}^k (n - k + 1)) \leq O(kn \log n)$. Since for every substring we can check whether it occurs in a string of length n in time $O(n)$, we can implement the ERM rule by going over every substring η of length at most k and checking for every string x_i (with $i \in [m]$) whether η occurs in x_i . By keeping track of the pattern which has minimal classification error with respect to the sample $(x_1, h_\sigma(x_1)), \dots, (x_m, h_\sigma(x_m))$ we can thus implement the ERM rule in time $O(kn^2 \log^2 n)$.

We can do better if the number of substrings of length at most k which is upper bounded by $2^{|\Sigma|^k}$ is smaller than $(n-k+1) \log n$. Suppose for example, that $k \leq \frac{\log n}{\log |\Sigma|}$. By Lemma 33, the VC-dimension of $\mathcal{H}_{k,\Sigma}$ is then upper bounded by $k \log |\Sigma|$. Hence in this case we can assume the number of strings m in our sample is at most $k \log |\Sigma|$, and we can implement the ERM rule in time $O(|\Sigma|^k k n \log |\Sigma|)$. When $k, |\Sigma|$ are constants independent of n we can thus learn h_σ in time $O(n)$.

We summarize this discussion with the following corollary:

► **Corollary 37.** *The hypothesis class $\mathcal{H}_{k,\Sigma}$ is PAC-learnable in time $O(kn^2 \log^2 n)$, where the O symbol contains constants depending on ϵ, δ but not on n, k . If $k, |\Sigma|$ are constants independent of n , then $\mathcal{H}_{k,\Sigma}$ can be learned in time $O(n)$.*

A Learning – Extensions

Infinite alphabet

So far we have been considering the case of finite alphabet Σ . For an infinite Σ the VC dimension is essentially $\log n$ for every value of $k \geq 1$. Note that the upper bound of $\text{VC}(\mathcal{H}_{k,\Sigma}) \leq \log n + 0.5 \log \log n + 2$ from Lemma 33 holds even for infinite alphabets Σ . Indeed, this upper bound counts the number of different patterns which have to occur in one string and compares it to the length of the string n . In the following lemma we give a lower bound of $\log n$ for all values of $k \geq 1$.

► **Lemma 38.** *Let Σ be an infinite alphabet, and $k \geq 1$. Then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}) = (1 + o(1)) \log n .$$

Learning multiple patterns

In this section we make a few simple observations regarding the VC dimension of classifiers defined by the occurrences of multiple patterns. The main observation is that learning a *constant* number of patterns does not change the asymptotics of the VC dimension so long as the number of patterns is upper bounded by the length of the pattern k . Let us consider two natural classes $\mathcal{H}_{k,\Sigma}^{\text{and}}$ and $\mathcal{H}_{k,\Sigma}^{\text{or}}$ of multi-pattern Boolean functions over Σ^n . Each function $h_{\sigma}^{\text{and}} \in \mathcal{H}_{k,\Sigma}^{\text{and}}$ is parameterized by $c > 0$ patterns $\sigma = (\sigma_1, \dots, \sigma_c) \in (\Sigma^{\leq k})^c$. Now, for an $s \in \Sigma^n$, $h_{\sigma}^{\text{and}}(s) = 1$ if and only if s contains *each* $\sigma_i, 1 \leq i \leq c$ as a substring (for brevity we omit from notation the dependence of $\mathcal{H}_{k,\Sigma}^{\text{and}}$ and $\mathcal{H}_{k,\Sigma}^{\text{or}}$ on c). Similarly, a function $h_{\sigma}^{\text{or}} \in \mathcal{H}_{k,\Sigma}^{\text{or}}$ takes the value one: $h_{\sigma}^{\text{or}}(s) = 1$ if and only if s contains *at least one* σ_i as a substring. We stress that we assume that the set of patterns $\sigma_i, i \in [c]$ are distinct.

An upper bound on the VC dimension of $\mathcal{H}_{k,\Sigma}^{\text{and}}$ and $\mathcal{H}_{k,\Sigma}^{\text{or}}$ follows at once from the following Lemma proved in [6] (Lemma 3.2.3).

► **Lemma 39.** *Let $\mathcal{H}_1, \dots, \mathcal{H}_c$ be classes of functions of VC dimension at most $\forall i: \text{VC}(\mathcal{H}_i) \leq d$. Let*

$$\begin{aligned}\mathcal{H}^{\text{and}} &= \{f_{h_1, \dots, h_c}(x) = h_1(x) \wedge \dots \wedge h_c(x) : h_1 \in \mathcal{H}_1, \dots, h_c \in \mathcal{H}_c\}, \\ \mathcal{H}^{\text{or}} &= \{f_{h_1, \dots, h_c}(x) = h_1(x) \vee \dots \vee h_c(x) : h_1 \in \mathcal{H}_1, \dots, h_c \in \mathcal{H}_c\}.\end{aligned}$$

Then $\text{VC}(\mathcal{H}^{\text{and}}) = O(dc \log c)$ and $\text{VC}(\mathcal{H}^{\text{or}}) = O(dc \log c)$.

We now turn to the lower bound. Our result here is rather modest: We show that the lower bound on the VC dimension of a single pattern also holds for $\mathcal{H}_{k,\Sigma}^{\text{and}}$ and $\mathcal{H}_{k,\Sigma}^{\text{or}}$ provided that the number c of (distinct) patterns is not too large. Let us see that the lower bounds of Lemma 35 hold for $\mathcal{H}_{k,\Sigma}^{\text{and}}$ and $\mathcal{H}_{k,\Sigma}^{\text{or}}$. Indeed, for the class $\mathcal{H}_{k,\Sigma}^{\text{and}}$, we use the construction from Lemma 35, where for every pattern σ in that construction we consider a set of k patterns $\{\sigma^1, \dots, \sigma^k\}$. We define $\sigma^i = \sigma_1 \dots \sigma_i$ to be the prefix of length i of σ . For example, for the pattern 11010 we take the patterns $\{1, 11, 110, 1101, 11010\}$. We remark that we obtain k distinct subpatterns of σ . Since every string from the shattered set contains σ if and only if it contains every pattern from $\{\sigma^1, \dots, \sigma^k\}$, all dichotomies are realized by the “last” pattern $\sigma^k = \sigma$. Since $c \leq k$, we take c longest patterns $\{\sigma^{k-c+1}, \dots, \sigma^k\}$, and our construction gives a shattered set of size

$$\text{VC}(\mathcal{H}_{k,\Sigma}^{\text{and}}) \geq \min(\log |\Sigma|(k - O(\log k)), \log n + O(\log \log n)) .$$

For the class $\mathcal{H}_{k,\Sigma}^{\text{or}}$, we can take $T'_m \subseteq T_m$ with $|T'_m| = |T_m|/2$ and shatter a set of size $d - 1$. Now for every $\sigma \in T'_m$ define a c -tuple of patterns by adding to σ $c - 1$ patterns in $T_m \setminus T'_m$ (where $c \leq 2^{d-1} - 1$ because $c \leq k$). Since none of the strings in the shattered set contains a pattern from $T_m \setminus T'_m$, all dichotomies are realized by the “first” pattern σ_1 . Again, our construction from Lemma 35 gives a shattered set of size $\min(\log |\Sigma|(k - O(\log k)), \log n + O(\log \log n)) - 1$.

To conclude, we have proved:

► **Theorem 40.** *Let $1 \leq c \leq k$ be a fixed constant. Then*

$$\text{VC}(\mathcal{H}_{k,\Sigma}^{\text{and}}), \text{VC}(\mathcal{H}_{k,\Sigma}^{\text{or}}) = \Theta(\min(\log |\Sigma|(k - O(\log k)), \log n + O(\log \log n))) .$$

Patterns of length k

One can also consider learning patterns of length *exactly* k . We consider this case separately since it seems that getting tight bounds on VC-dimension in this case is a harder task. In particular, we are not able to get tight bounds for the regime $k = n^{1-o(1)}$ and leave this as an open question.

For a fixed *finite* alphabet Σ and an integer $k > 0$, the class of functions $\mathcal{E}_{k,\Sigma}$ over Σ^n is defined as follows. Every Boolean function $h_\sigma \in \mathcal{E}_{k,\Sigma}$ is parameterized by a pattern $\sigma \in \Sigma^k$ of length exactly k . Therefore, $|\mathcal{E}_{k,\Sigma}| = |\Sigma|^k$. For a string $s \in \Sigma^n$, $h_\sigma(s) = 1$ if and only if s contains σ as a substring. We use a simple double counting argument to prove:

► **Lemma 41.** $\text{VC}(\mathcal{E}_{k,\Sigma}) \leq \min(k \log |\Sigma|, \log(n - k + 1) + 1)$.

Now we prove the following lower bound:

► **Lemma 42.** *Let Σ be a finite alphabet of size $|\Sigma| \geq 2$, then*

$$\text{VC}(\mathcal{E}_{k,\Sigma}) \geq \min((k - \log k - 5) \log |\Sigma|, \log n - \log k).$$

We remark that for the case of patterns of length *at most* k , Lemma 33 and Lemma 35 give essentially tight bounds for all regimes of the parameters. Here, in the case of patterns of length *exactly* k , we have a gap between lower and upper bounds for the regime $k = n^{1-o(1)}$.

2D patterns

Our bounds for learning one dimensional strings generalize to the 2D case. Here we have an $n \times n$ image over an alphabet Σ and an $m \times m$ pattern σ where $m \leq k \leq n$. An image is classified as 1 if and only if it contains σ .

► **Definition 43.** *For a fixed finite alphabet Σ and an integer $k > 0$, let us define the class of Boolean functions $\mathcal{G}_{k,\Sigma}$ over $\Sigma^{n \times n}$ as follows. Every function $g_\sigma \in \mathcal{G}_{k,\Sigma}$ is parameterized by a square 2D pattern $\sigma \in \Sigma^{m \times m}$ of dimension $m \leq k$. For a 2D image $s \in \Sigma^{n \times n}$ of dimension n , $g_\sigma(s) = 1$ if and only if s contains σ as a consecutive sub-matrix (sub-image).*

We give tight bounds (up to low order terms) on $\text{VC}(\mathcal{G}_{k,\Sigma})$. Since the proofs are very similar to the 1D case, we only sketch the arguments here.

Since $|\mathcal{G}_{k,\Sigma}| = \sum_{1 \leq i \leq k} |\Sigma|^{i^2} + 1 \leq \sum_{1 \leq i \leq k} |\Sigma|^{ik} + 1 < 2|\Sigma|^{k^2}$, we have that $\text{VC}(\mathcal{G}_{k,\Sigma}) \leq \lceil k^2 \log |\Sigma| \rceil$. Suppose that $\mathcal{G}_{k,\Sigma}$ shatters a set of d 2D images from $\Sigma^{n \times n}$. By considering a Sperner system over $\{1, \dots, d-1\}$ of size $D = \binom{d-1}{\lfloor (d-1)/2 \rfloor}$ and adding the element d to each subset, we get a family of $D = \binom{d-1}{\lfloor (d-1)/2 \rfloor}$ patterns all lying in a single $n \times n$ image such that no pattern contains another one. We have that the bottom right corners of all these patterns are distinct, and thus $\frac{2^{d-1}}{\sqrt{2^{d-1}}} \leq D \leq n^2$ implying that $d \leq 2 \log n + 0.5 \log \log n + 3$. Hence,

$$\text{VC}(\mathcal{G}_{k,\Sigma}) \leq \min(\lceil k^2 \log |\Sigma| \rceil, 2 \log n + 0.5 \log \log n + 3).$$

For the lower bound, the main observation is that we can generalize Lemma 34 to the two dimensional case having a set R_m of $(m + 2\lceil \log m \rceil + 2) \times (m + 2\lceil \log m \rceil + 2)$ 2D patterns of cardinality $|\Sigma|^{m^2-1}$ such that for any four distinct patterns $\alpha_1, \alpha_2, \alpha_3, \alpha_4$ from R_m , their concatenation (fitting the four patterns into a $2(m + 2\lceil \log m \rceil + 2) \times 2(m + 2\lceil \log m \rceil + 2)$ square image in each of the $4!$ possible ways) does not contain any $\alpha_5 \neq \alpha_i$ for $1 \leq i \leq 4$ from R_m . We achieve this by taking all $m \times m$ templates not containing the all 0 2D square template of size $(2\lceil \log m \rceil + 1) \times (2\lceil \log m \rceil + 1)$, padding them by an all zero strip of width $2\lceil \log m \rceil + 1$ on the right and bottom, and then adding a boundary of ones on those two sides. Similarly to Lemma 34, it can be verified that R_m satisfies the desired condition.

We now set

$$m = \left\lfloor \min \left(k - 2 \log k - 4, \sqrt{\frac{2 \log n}{\log |\Sigma|} - \frac{3 \log \log n}{\log |\Sigma|}} \right) \right\rfloor.$$

Let R_m be a set of $|\Sigma|^{m^2-1}$ templates whose construction was described in the paragraph above and set $d = \lfloor (m^2 - 1) \log |\Sigma| \rfloor$. Since $|R_m| = |\Sigma|^{m^2-1} \geq 2^d$, we can choose 2^d distinct 2D patterns $q_0 \dots q_{2^d-1}$ from R_m . The dimension of each pattern q_i is $m + 2\lceil \log m \rceil + 2$ which by the choice of m is at most k .

56:20 String Matching: Communication, Circuits, and Learning

Define a set of $n \times n$ images $Y := \{y_0 \dots y_{d-1}\}$ where y_i is an image containing all the patterns q_j from R_m such that the binary expansion of j equals 1 in the i th location. This way, each image from Y must contain at most 2^{d-1} patterns, while we can fit $\left\lfloor \frac{n}{m+2^{\lceil \log m \rceil + 2}} \right\rfloor^2$ patterns into an image of size $n \times n$. It can be verified that for the chosen values of m and d , $2^{d-1} \leq \left\lfloor \frac{n}{m+2^{\lceil \log m \rceil + 2}} \right\rfloor^2$. Thus, we have that each y_i can be padded to an $n \times n$ image if necessary by assigning 1 to all unassigned positions. Finally, it follows in a similar fashion to the 1D case that the set of patterns $q_0 \dots q_{2^d-1}$ shatters Y . Hence R_m shatters Y . Since $|Y| = d$ the VC dimension of the set of all 2D patterns of dimensions at most k is at least d .

We conclude this discussion with the following Theorem:

► **Theorem 44.**

$$\text{VC}(\mathcal{G}_{k,\Sigma}) = \min \left((k - O(\log k))^2 \log |\Sigma|, 2 \log n - O(\log \log n) \right) .$$

Efficient Black-Box Identity Testing for Free Group Algebras

Abstract

Hrubeš and Wigderson [12] initiated the study of noncommutative arithmetic circuits with division computing a noncommutative rational function in the *free skew field*, and raised the question of rational identity testing. For noncommutative *formulas* with inverses the problem can be solved in deterministic polynomial time in the *white-box* model [10, 13]. It can be solved in randomized polynomial time in the *black-box* model [8], where the running time is polynomial in the size of the formula. The complexity of identity testing of noncommutative rational functions, in general, remains open for noncommutative circuits with inverses.

We solve the problem for a natural special case. We consider expressions in the free group algebra $\mathbb{F}\langle X, X^{-1} \rangle^1$ where $X = \{x_1, x_2, \dots, x_n\}$. Our main results are the following.

1. Given a degree d expression f in $\mathbb{F}\langle X, X^{-1} \rangle$ as a black-box, we obtain a randomized $\text{poly}(n, d)$ algorithm to check whether f is an identically zero expression or not. The technical contribution is an Amitsur-Levitzki type theorem [1] for $\mathbb{F}\langle X, X^{-1} \rangle$. This also yields a deterministic identity testing algorithm (and even an expression reconstruction algorithm) that is polynomial time in the sparsity of the input expression.
2. Given an expression f in $\mathbb{F}\langle X, X^{-1} \rangle$ of degree D and sparsity s , as black-box, we can check whether f is identically zero or not in randomized $\text{poly}(n, \log s, \log D)$ time. This yields a randomized polynomial-time algorithm when D and s are exponential in n .

1 Introduction

Noncommutative computation is an important sub-area of arithmetic circuit complexity. In the usual arithmetic circuit model for noncommutative computation, the arithmetic operations are addition and multiplication, where each circuit input is either a variable from $X = \{x_1, x_2, \dots, x_n\}$ or a scalar from a prescribed field \mathbb{F} . Each multiplication gate in the circuit respects the order of its inputs since the variables x_i are noncommuting. Such circuits compute precisely noncommutative polynomials in the *free noncommutative ring* denoted by $\mathbb{F}\langle X \rangle$.

Analogous to commutative arithmetic computation, the central questions are to show circuit size lower bounds for explicit noncommutative polynomials and derandomization of polynomial identity testing (PIT) for noncommutative circuits (or subclasses of circuits). There is nontrivial progress on these problems unlike in the commutative case. Nisan [16] has shown that any algebraic branching program (ABP) computing the $n \times n$ noncommutative Determinant or Permanent polynomial requires exponential (in n) size. Raz and Shpilka [17] have shown a deterministic polynomial-time PIT for noncommutative ABPs in the white-box model. A quasi-polynomial time derandomization is also known for the black-box model [9]. However, for general circuits there are no better results (either lower bound or PIT) than known in the commutative setting.

The randomized polynomial-time PIT algorithm for noncommutative circuits computing a polynomial of polynomially bounded degree [6] follows from the Amitsur-Levitzki theorem [1] which states that a nonzero polynomial $p \in \mathbb{F}\langle X \rangle$ of degree $< 2k$ cannot be an identity for the ring $\mathbb{M}_k(\mathbb{F})$ of $k \times k$ matrices over \mathbb{F} . It is also known [2] that a nonzero noncommutative polynomial does not vanish on matrices of dimension logarithmic in the sparsity of the polynomial. This yields a randomized polynomial-time identity test for noncommutative circuits computing polynomials of exponential degree and exponential sparsity.

Hrubeš and Wigderson [12] initiated the study of noncommutative computation with inverses. In the commutative world, it suffices to consider additions and multiplications. By Strassen's result [20] (extended to finite fields [11]), divisions can be efficiently replaced by polynomially many additions and multiplications. However, divisions in noncommutative computation are more intricate [12]. In the same paper [12], the authors introduce *rational identity testing*: Given a noncommutative formula involving addition, multiplication and division gates, efficiently check if the resulting rational expression is identically zero in the free skew-field of noncommutative rational functions. They show that it is reducible to the following SINGULAR problem:

Given a matrix $A_{n \times n}$ where the entries are linear forms over noncommuting variables $\{x_1, x_2, \dots, x_n\}$, is A invertible in the free skew-field?

In the white-box model the problem is in deterministic polynomial time [10, 13], and in randomized polynomial time in the black-box model [8]. Specifically, for rational formulas of size s , random matrix substitutions of dimension linear in s suffices to test if the rational expression is identically zero [8].

The complexity of identity testing for general rational expressions remains open. For example, given a noncommutative circuit involving addition, multiplication and division gates, no efficient algorithm (even randomized!) is known to check if the resulting rational expression is identically zero in the free skew-field of noncommutative rational functions. In order to precisely formulate the problem, we define classes of rational expressions based on Bergman's definition [5] of *inversion height* which we now recall and elaborate upon with some notation.

► **Definition 1** ([5]). *Let X be a set of free noncommuting variables. Polynomials in the free ring $\mathbb{F}\langle X \rangle$ are defined to be rational expressions of height 0. A rational expression of height $i + 1$ is inductively defined to be a polynomial in rational expressions of height at most i , and inverses of such expressions.*

Let $\mathcal{E}_{d,0}$ denote all polynomials of degree at most d in the free ring $\mathbb{F}\langle X \rangle$. We inductively define rational expressions in $\mathcal{E}_{d,i+1}$ as follows: Let f_1, f_2, \dots, f_r and g_1, g_2, \dots, g_s be rational expressions in $\mathcal{E}_{d,i}$ in the variables x_1, x_2, \dots, x_n . Let $f(y_1, y_2, \dots, y_s, z_1, z_2, \dots, z_r)$ be a degree- d polynomial in $\mathbb{F}\langle X \rangle$. Then $f(g_1, g_2, \dots, g_s, f_1^{-1}, f_2^{-1}, \dots, f_r^{-1})$ is a rational expression (of inversion height $i + 1$) in $\mathcal{E}_{d,i+1}$.

Black-box identity testing for rational expressions is not well understood in general. In particular, no efficient randomized algorithm seems to be known even for identity testing of the class $\mathcal{E}_{d,1}$. One source of difficulty is the subtle behaviour of rational expressions when evaluated on matrix algebras. For example, a surprising result of Bergman [5, Proposition 5.1] shows that there are rational expressions that are nonzero over a dense subset of 2×2 matrices but evaluate to zero on dense subsets of 3×3 matrices.

► **Remark 2.** In this connection, we note that Hrubeš and Wigderson [12] have observed that testing if a *correct* rational expression Φ (see [12], Section 2) is not identically zero is equivalent to testing if the rational expression Φ^{-1} is *correct*. I.e. testing if a correct rational expression of *inversion height* i is identically zero or not can be reduced to testing if a rational expression of *inversion height* $i + 1$ is correct or not. Furthermore, testing if a rational expression of *inversion height one* is correct can be done by applying (to each inversion operation in this expression) a theorem of Amitsur (see [18, 15]) which implies that a nonzero degree $2d - 1$ noncommutative polynomial evaluated on $d \times d$ matrices will be invertible with high probability. However, this does not yield an efficient randomized identity testing algorithm for rational expressions of inversion height one. Because that requires testing correctness of expressions of inversion height two which is a question left open in their paper [12, Section 9].

Free Group Algebras

This motivates the study of black-box identity testing for rational expressions in the *free group algebra* $\mathbb{F}\langle X, X^{-1} \rangle$ which is a natural subclass of rational expressions of inversion height one, as we explain next.

We consider expressions in the free group algebra $\mathbb{F}\langle X, X^{-1} \rangle$, where $(X, X^{-1})^*$ denotes the free group generated by the n generators $X = \{x_1, x_2, \dots, x_n\}$ and their inverses

$$X^{-1} = \{x_1^{-1}, x_2^{-1}, \dots, x_n^{-1}\}.$$

Elements of the free group $(X, X^{-1})^*$ are words in X, X^{-1} . The only relations satisfied by the generators is $x_i x_i^{-1} = x_i^{-1} x_i = 1$ for all i . Thus, the elements in the free group $(X, X^{-1})^*$ are the *reduced words* which are words to which the above relations are not applicable.

The elements of the *free group algebra* $\mathbb{F}\langle X, X^{-1} \rangle$ are \mathbb{F} -linear combinations of the form

$$f = \sum_w \alpha_w w, \quad \alpha_w \in \mathbb{F},$$

where each $w \in (X, X^{-1})^*$ is a reduced word. The *degree* of the expression f is defined as the maximum length of a word w such that $\alpha_w \neq 0$. The expression f is said to have *sparsity* s if there are s many reduced words w such that $\alpha_w \neq 0$ in f . We also use the notation $[w]f$ to denote the coefficient α_w of the reduced word w in the expression f .

The free noncommutative ring $\mathbb{F}\langle X \rangle$ is a subalgebra of $\mathbb{F}\langle X, X^{-1} \rangle$. Clearly, the elements of $\mathbb{F}\langle X, X^{-1} \rangle$ are a special case of rational expressions of *inversion height one*. I.e., we note that:

► **Proposition 3.** $\mathbb{F}\langle X, X^{-1} \rangle \subset \cup_{d>0} \mathcal{E}_{d,1}$.

Note that the rational expressions in $\mathbb{F}\langle X, X^{-1} \rangle$ allows inverses only of the variables x_i , whereas the *free skew field* $\mathbb{F}\langle\langle X \rangle\rangle$ contains all possible rational expressions (with inverses at any nested level).

Our results

Our main goal is to obtain black-box identity tests for rational expressions in the free group algebra $\mathbb{F}\langle X, X^{-1} \rangle$.

Our first result is an Amitsur-Levitzki type theorem [1] for $\mathbb{F}\langle X, X^{-1} \rangle$. Let A be an associative algebra with identity over \mathbb{F} . An expression $f \in \mathbb{F}\langle X, X^{-1} \rangle$ is an *identity* for A if

$$f(a_1, \dots, a_n) = 0,$$

for all $a_i \in A$ such that a_i^{-1} is defined for each $i \in [n]$.

► **Theorem 4.** *Let \mathbb{F} be any field of characteristic zero and $f \in \mathbb{F}\langle X, X^{-1} \rangle$ be a nonzero expression of degree d . Then f is not an identity for the matrix algebra $\mathbb{M}_{2d}(\mathbb{F})$.*

The following corollary is immediate.

► **Corollary 5** (Black-box identity testing in free group algebras). *There is a black-box randomized $\text{poly}(n, d)$ identity test for degree d expressions in $\mathbb{F}\langle X, X^{-1} \rangle$.*

If the black-box contains a sparse expression, we show efficient deterministic algorithms for identity testing and interpolation algorithm.

► **Theorem 6** (Reconstruction for sparse expressions). *Let \mathbb{F} be any field of characteristic zero and f is an expression in $\mathbb{F}\langle X, X^{-1} \rangle$ of degree d and sparsity s given as black-box. Then we can reconstruct f in deterministic $\text{poly}(n, d, s)$ time with matrix-valued queries to the black-box.*

Nonzero polynomials in $\mathbb{F}\langle X \rangle$ of sparsity s cannot vanish on $O(\log s)$ dimensional matrix algebras [2]. We obtain a similar result for $\mathbb{F}\langle X, X^{-1} \rangle$: nonzero expressions in $\mathbb{F}\langle X, X^{-1} \rangle$ of degree D and sparsity s do not vanish on $O(\log s)$ dimensional matrices. It yields a randomized polynomial-time identity test if the black-box contains an expression f of exponential degree and exponential sparsity.

► **Theorem 7.** *Let \mathbb{F} be any field of characteristic zero. Then, a degree- D expression $f \in \mathbb{F}\langle X, X^{-1} \rangle$ of sparsity s is not an identity for the matrix algebra $\mathbb{M}_k(\mathbb{F})$ for $k \geq c \log s$ for some small constant c .*

► **Corollary 8.** *Given a degree- D expression $f \in \mathbb{F}\langle X, X^{-1} \rangle$ of sparsity s as black box, we can check whether f is identically zero or not in randomized $\text{poly}(n, \log D, \log s)$ time.*

► **Remark 9.** We have stated our results for fields of characteristic zero for simplicity. With suitable modifications, the results easily extend to fields of positive characteristic as discussed in Section 4.

Each of our proofs typically involves the construction of a nondeterministic substitution automaton \mathcal{A} . Consider any expression $f \in \mathbb{F}\langle X, X^{-1} \rangle$. For \mathcal{A} , let M_i denote its transition matrix for variable $x_i \in X$. The automaton \mathcal{A} has the property that $f \neq 0$ iff a specified entry of the matrix $f(M_1, M_2, \dots, M_n)$ is nonzero. This entry will actually be a commutative polynomial (or a ratio of two commutative polynomials). Automata constructions for noncommutative PIT have been used before [4, 3, 2]. In this work, an important difference is that we have to deal with \mathbb{F} -linear combinations of words in $\{X, X^{-1}\}$. Thus, if M_i is the transition matrix for x_i then M_i^{-1} will be substituted for x_i^{-1} . Hence, in the construction we have to ensure M_i is invertible. Furthermore, when the automaton reads x_i^{-1} its state transition will be governed by M_i^{-1} . In order to ensure that the final output matrix is nonzero, the transition matrices for the x_i have to be chosen carefully, taking into account the above aspects.

Organization

The paper is organized as follows. In Section 2, we prove Theorem 4, Corollary 5, and Theorem 6. In Section 3, we prove Theorem 7 and Corollary 8. Finally, in Section 4, we discuss suitable modifications to extend our results for finite fields.

2 An Amitsur-Levitzki Type Theorem

The main idea in our proof is to efficiently encode expressions in $\mathbb{F}\langle X, X^{-1} \rangle$ as polynomials in a suitable commutative ring preserving the identity. Let $\mathbb{F}[Y, Z]$ denote the commutative ring $\mathbb{F}[y_{ij}, z_{ij}]_{i \in [n], j \in [d]}$ for $n, d \in \mathbb{N}$, where $Y = \{y_{ij} \mid i \in [n], j \in [d]\}$ and $Z = \{z_{ij} \mid i \in [n], j \in [d]\}$.

► **Definition 10.** Define a map $\varphi : \mathbb{F}\langle X, X^{-1} \rangle \rightarrow \mathbb{F}[Y, Z]$ such that φ is identity on \mathbb{F} , and for each reduced word $w = x_{i_1}^{b_1} x_{i_2}^{b_2} \dots x_{i_d}^{b_d}$,

$$\varphi(x_{i_1}^{b_1} x_{i_2}^{b_2} \dots x_{i_d}^{b_d}) = \prod_{j=1}^d (\mathbb{1}_{[b_j=1]} \cdot y_{i_j j} + \mathbb{1}_{[b_j=-1]} \cdot z_{i_j j}),$$

where $\mathbb{1}_{[b_j=b]} = 1$ if $b_j = b$ and $\mathbb{1}_{[b_j=b]} = 0$ otherwise.

By linearity the map φ is defined on all expressions in $\mathbb{F}\langle X, X^{-1} \rangle$. We observe the following properties of φ .

1. The map φ is injective on the reduced words $(X, X^{-1})^*$. I.e., it maps each reduced word $w \in (X, X^{-1})^*$ to a unique monomial over the commuting variables $Y \cup Z$.
2. Consequently, φ is identity preserving. I.e., an expression f in $\mathbb{F}\langle X, X^{-1} \rangle$ is identically zero if and only if its image $\varphi(f)$ is the zero polynomial in $\mathbb{F}[Y, Z]$.
3. φ preserves the sparsity of the expression. I.e., f in $\mathbb{F}\langle X, X^{-1} \rangle$ is s -sparse iff $\varphi(f)$ in $\mathbb{F}[Y, Z]$ is s -sparse.
4. Given the image $\varphi(f) \in \mathbb{F}[Y, Z]$ in its sparse description (i.e., as a linear combination of monomials), we can efficiently recover the sparse description of $f \in \mathbb{F}\langle X, X^{-1} \rangle$.

Given polynomials $f, f' \in \mathbb{F}[Y, Z]$, we say f and f' are *weakly equivalent*, if for each monomial m , $[m]f = 0$ if and only if $[m]f' = 0$, where $[m]f$ denotes the coefficient of monomial m in f .

Given a black-box expression f in $\mathbb{F}\langle X, X^{-1} \rangle$, we show how to evaluate it on suitable matrices and obtain a polynomial in $\mathbb{F}[Y, Z]$ that is *weakly equivalent to* $\varphi(f)$ as a specific entry of the resulting matrix. The matrix substitutions are based on automata constructions.

Similar ideas have been used earlier to design PIT algorithms for noncommutative polynomials [4]. However, since we are dealing with rational expressions, some difficulties arise. The matrix substitutions for the variables x_1, \dots, x_n are obtained as the corresponding transition matrices M_i of the automaton. The matrix substitution for x_i^{-1} will be M_i^{-1} . Therefore, we must ensure that the transition matrices M_i are invertible and sufficiently structured to be useful for the identity testing.

We first illustrate our construction for an example degree-2 expression $f = x_1x_2^{-1} + x_2x_1^{-1}$, where $X = \{x_1, x_2\}$.

The basic “building block” for the transition matrix M_i is the 2×2 block matrix

$$\begin{bmatrix} 0 & y_{ij} \\ \frac{1}{z_{ij}} & 0 \end{bmatrix},$$

whose inverse is

$$\begin{bmatrix} 0 & z_{ij} \\ \frac{1}{y_{ij}} & 0 \end{bmatrix}.$$

When the 2×2 block is the j^{th} diagonal block in M_i , the corresponding automaton will go from state $2j - 1$ to state $2j$ replacing x_i by y_{ij} (or if x_i^{-1} occurs, it will replace it by z_{ij}).

We will keep the transition matrix M_i for x_i a block diagonal matrix with such 2×2 invertible blocks as the principal minors along the diagonal. In order to ensure this we introduce two new variables $W = \{w_1, w_2\}$ and substitute x_i by the word $w_i x_i w_i$ in the expression. This will ensure that we do not have two consecutive x_i in the resulting reduced words. In fact, between two X variables (or their inverses) we will have inserted exactly two W variables (or their inverses). Now, we define M_i for the above example as

$$M_i = \begin{bmatrix} 0 & y_{i1} & 0 & 0 \\ \frac{1}{z_{i1}} & 0 & 0 & 0 \\ 0 & 0 & 0 & y_{i2} \\ 0 & 0 & \frac{1}{z_{i2}} & 0 \end{bmatrix}, \quad M_i^{-1} = \begin{bmatrix} 0 & z_{i1} & 0 & 0 \\ \frac{1}{y_{i1}} & 0 & 0 & 0 \\ 0 & 0 & 0 & z_{i2} \\ 0 & 0 & \frac{1}{y_{i2}} & 0 \end{bmatrix}.$$

The corresponding transitions of the automaton is shown in Figure 1.

■ **Figure 1** The transition diagram of the automaton for x variables.

We now describe the transition matrices N_i for w_i . The matrix N_i is also a 4×4 block diagonal matrix. There are three blocks along the diagonal. The first and third are 1×1 blocks of the identity. The second one is a 2×2 block for w_i -transitions from state q_2 to state q_3 . It ensures that for any subword $w_1^{b_1} w_2^{b_2}$, $b_i \in \{1, -1\}$, in the resulting product matrix $N_1^{b_1} N_2^{b_2}$ the $(1, 2)^{\text{th}}$ entry of the 2×2 block is nonzero. The corresponding transitions of the automaton is depicted in Figure 2.

■ **Figure 2** The transition diagram of the automaton for w variables.

$$N_i = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & i & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad N_i^{-1} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & -i & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad N_i^{b_1} N_j^{b_2} = \begin{bmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & b_1 i + b_2 j & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

Hence, evaluating $f(N_1 M_1 N_1, N_2 M_2 N_2)$ we obtain (a polynomial weakly equivalent to) $\varphi(f)$ at the $(1, 4)^{th}$ entry. The complete automaton is depicted in figure 3.

■ **Figure 3** The transition diagram of the automaton.

We now explain the general construction. For $f \in \mathbb{F}\langle X, X^{-1} \rangle$ let $H_\ell(f)$ denote the degree- ℓ homogeneous part of f . We will denote by $\varphi(\widehat{H_\ell(f)})$ an arbitrary polynomial in $\mathbb{F}[Y, Z]$ weakly equivalent to $\varphi(H_\ell(f))$.

► **Lemma 11.** *Let $f \in \mathbb{F}\langle X, X^{-1} \rangle$ be a nonzero expression of degree d . There is an n -tuple of $2d \times 2d$ matrices (M_1, M_2, \dots, M_n) whose entries are either scalars, or variables $u \in Y \cup Z$, or their inverses $1/u$, such that*

$$(f(M_1, \dots, M_n))_{1,2d} = \varphi(\widehat{H_d(f)}).$$

Furthermore, for each degree- d reduced word of $m = x_{i_1}^{b_1} x_{i_2}^{b_2} \dots x_{i_d}^{b_d}$ in $\mathbb{F}\langle X, X^{-1} \rangle$,

$$[\varphi(m)]\varphi(\widehat{H_d(f)}) = [m]f \cdot \prod_{j=1}^{d-1} (b_j \cdot i_j + b_{j+1} \cdot i_{j+1}). \tag{1}$$

Proof. Let e_{ij} , for $i, j \in [k]$, be the $(i, j)^{th}$ elementary matrix in $\mathbb{M}_k(\mathbb{F})$: its $(i, j)^{th}$ entry is 1 and other entries are 0.

We now define the transition matrices of the NFA for variables $\{w_i : 1 \leq i \leq n\}$ and $\{x_i : 1 \leq i \leq n\}$. For each $i \in [n]$, define 2×2 matrix $N'_i = e_{11} + e_{22} + i \cdot e_{12}$. Now N_i is a $2d \times 2d$ matrix defined as the block diagonal matrix,

$$N'_i = \begin{bmatrix} 1 & i \\ 0 & 1 \end{bmatrix}, \quad N_i = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 & 0 \\ 0 & N'_i & 0 & \dots & 0 & 0 \\ 0 & 0 & N'_i & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & N'_i & 0 \\ 0 & 0 & 0 & \dots & 0 & 1 \end{bmatrix}.$$

$$N'^{-1}_i = \begin{bmatrix} 1 & -i \\ 0 & 1 \end{bmatrix}, \quad N^{-1}_i = \begin{bmatrix} 1 & 0 & 0 & \dots & 0 & 0 \\ 0 & N'^{-1}_i & 0 & \dots & 0 & 0 \\ 0 & 0 & N'^{-1}_i & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & N'^{-1}_i & 0 \\ 0 & 0 & 0 & \dots & 0 & 1 \end{bmatrix}.$$

Each $M_i, 1 \leq i \leq n$ is the $2d \times 2d$ block diagonal matrix where each 2×2 block $M'_{i,j}, 1 \leq j \leq d$ is a 2×2 matrix defined as $M'_{i,j} = y_{ij} \cdot e_{12} + \frac{1}{z_{ij}} \cdot e_{21}$. Their inverses have a similar structure.

$$M'_{i,p} = \begin{bmatrix} 0 & y_{ip} \\ \frac{1}{z_{ip}} & 0 \end{bmatrix}, \quad M_i = \begin{bmatrix} M'_{i,1} & 0 & 0 & \dots & 0 \\ 0 & M'_{i,2} & 0 & \dots & 0 \\ 0 & 0 & M'_{i,3} & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & M'_{i,d} \end{bmatrix}.$$

$$M'^{-1}_{i,p} = \begin{bmatrix} 0 & z_{ip} \\ \frac{1}{y_{ip}} & 0 \end{bmatrix}, \quad M^{-1}_i = \begin{bmatrix} M'^{-1}_{i,1} & 0 & 0 & \dots & 0 \\ 0 & M'^{-1}_{i,2} & 0 & \dots & 0 \\ 0 & 0 & M'^{-1}_{i,3} & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & M'^{-1}_{i,d} \end{bmatrix}.$$

The corresponding NFA is depicted in Figure 4. We substitute each x_{i_j} by the $2d \times 2d$ matrix $N_{i_j} M_{i_j} N_{i_j}$. Each $x_{i_j}^{-1}$ is substituted by its inverse matrix $N_{i_j}^{-1} M_{i_j}^{-1} N_{i_j}^{-1}$.

Correctness:

Consider a degree- d reduced word $m = x_{i_1}^{b_1} x_{i_2}^{b_2} \dots x_{i_d}^{b_d}$.

Following the automaton construction of Figure 4, $x_{i_j}^{b_j}$ occurring at position j is substituted by $(\mathbb{1}_{[b_j=1]} y_{i_j} + \mathbb{1}_{[b_j=-1]} z_{i_j})$. Moreover, for each position $j \in [d-1]$, the adjacent pair $x_{i_j}^{b_j} x_{i_{j+1}}^{b_{j+1}}$ produces a scalar factor $(b_j \cdot i_j + b_{j+1} \cdot i_{j+1})$ due to the product $N_{i_j}^{b_j} N_{i_{j+1}}^{b_{j+1}}$. Consequently, it follows that

$$(m(M_1, \dots, M_n))_{1,2d} = \prod_{j=1}^{d-1} (b_j \cdot i_j + b_{j+1} \cdot i_{j+1}) \prod_{j=1}^d (\mathbb{1}_{[b_j=1]} y_{i_j} + \mathbb{1}_{[b_j=-1]} z_{i_j}).$$

As φ is a linear map, the lemma follows. ◀

■ **Figure 4** The transition diagram of the automaton.

2.1 Black-box identity testing for circuits in free group algebras

Proof of Theorem 4. The proof follows easily from Lemma 11. Lemma 11 says that if $f \in \mathbb{F}\langle X, X^{-1} \rangle$ is nonzero of degree d then the $(1, 2d)$ entry of the matrix $p(N_1 M_1 N_1, \dots, N_n M_n N_n)$ is a nonzero polynomial in $\mathbb{F}[Y, Z]$. Hence f can not be an identity for $M_{2d}(\mathbb{F})$. ◀

Proof of Corollary 5. The identity testing algorithm follows from Theorem 4. We can randomly substitute for the variables and apply the Schwartz-Zippel-Demillo-Lipton Theorem [19, 21, 7]. This completes the proof of the Corollary 5. ◀

2.2 Reconstruction of sparse expressions

If the black-box contains an s -sparse expression in $\mathbb{F}\langle X, X^{-1} \rangle$, we give a $\text{poly}(s, n, d)$ deterministic interpolation algorithm (which also gives a deterministic identity testing for such expressions). We use a result of Klivans-Spielman [14, Theorem11] that constructs a test set in deterministic polynomial time for sparse commutative polynomials, which is used for the interpolation algorithm.

Proof of Theorem 6. Let the black-box expression f be s -sparse of degree d . By Lemma 11, a polynomial $\varphi(\widehat{H_d(f)})$ in $\mathbb{F}[Y, Z]$ is obtained at the $(1, 2d)^{\text{th}}$ entry of the matrix $f(M_1, \dots, M_n)$, where $M_i \in M_{2d}(\mathbb{F}[Y, Z])$ is as defined in Lemma 11. By Definition 10, $\varphi(f) \in \mathbb{F}[Y, Z]$ is s -sparse and has $2nd$ variables. Let $\mathcal{H}_{2nd,d,s}$ be the corresponding test set from [14] to interpolate a polynomial of degree d and s -sparse over $2nd$ variables. Querying the black-box on $M_1(\vec{h}), M_2(\vec{h}), \dots, M_n(\vec{h})$ for each $\vec{h} \in \mathcal{H}_{2nd,d,s}$ we can interpolate the commutative polynomial $\varphi(\widehat{H_d(f)})$ and obtain an expression for $\varphi(\widehat{H_d(f)}) = \sum_{t=1}^s c_{m_t} m_t$ as a sum of monomials.

We will now adjust the extra scalar factors for each monomial in $\varphi(\widehat{H_d(f)})$ to obtain $\varphi(H_d(f))$. We can adjust this for each monomial as Lemma 11 shows that the extra scalar factor for the word $m = x_{i_1}^{b_1} x_{i_2}^{b_2} \dots x_{i_\ell}^{b_\ell}$ is just $\alpha_{\varphi(m)} = \prod_{j=1}^{\ell-1} (b_j \cdot i_j + b_{j+1} \cdot i_{j+1})$. So we construct $\varphi(H_d(f)) = \sum_{t=1}^s \frac{c_{m_t}}{\alpha_{m_t}} m_t$ by removing the factors α_{m_t} for each monomial m_t . We now *invert* the map φ (using the 4th property of Definition 10) on every monomial m_t to obtain $H_d(f)$ as a sum of degree d reduced words. This yields the expression for highest degree homogeneous component of f . We can repeat the above procedure on $f - H_d(f)$ and reconstruct the remaining homogeneous components of f . ◀

3 Black-box Identity Testing for Expressions of Exponential Degree and Exponential Sparsity

It is known [2] that a nonzero noncommutative polynomial of sparsity s cannot be an *identity* for $O(\log s)$ dimensional matrix algebras. In this section, we show a similar result for free group algebras. In particular, we prove that the dimension of the matrix algebra for which a nonzero free group algebra expression f does not vanish is logarithmic in the sparsity of f . It yields a randomized $\text{poly}(\log D, \log s, n)$ time identity testing algorithm when the black-box contains an expression of degree D and sparsity s .

We first recall the notion of *isolating index set* from [2].

► **Definition 12.** Let $\mathcal{M} \subseteq \{X, X^{-1}\}^D$ be a subset of reduced words of degree D . An index set $I \subseteq [D]$ is an *isolating index set* for \mathcal{M} if there is a word $m \in \mathcal{M}$ such that for each $m' \in \mathcal{M} \setminus \{m\}$ there is an index $i \in I$ for which $m[i] \neq m'[i]$. I.e. no other word in \mathcal{M} agrees with m on all positions in the index set I . We say m is an *isolated word*.

In the following lemma we show that \mathcal{M} has an isolating index set of size $\log |\mathcal{M}|$. The proof is identical to [2]. Nevertheless, we give the simple details for completeness as we deal with both variables and their inverses.

► **Lemma 13** ([2]). Let $\mathcal{M} \subseteq \{X, X^{-1}\}^D$ be reduced degree- D words. Then \mathcal{M} has an *isolating index set* of size k which is bounded by $\log |\mathcal{M}|$.

Proof. The words $m \in \mathcal{M}$ are indexed, where $m[i]$ denotes the variable (or the inverse of a variable) in the i^{th} position of m . Let $i_1 \leq D$ be the first index such that not all words agree on the i_1^{th} position. Let

$$S_j^+ = \{m : m[i_1] = x_j\}$$

$$S_j^- = \{m : m[i_1] = x_j^{-1}\}.$$

For some j , $|S_j^+|$ or $|S_j^-|$ is of size at most $|\mathcal{M}|/2$. Let S_j^b denote that subset, $b \in \{+, -\}$. We replace \mathcal{M} by S_j^b and repeat the same argument for at most $\log |\mathcal{M}|$ steps. Clearly, by this process, we identify a set of indices $I = \{i_1, \dots, i_{k'}\}$, $k' \leq \log |\mathcal{M}|$ such that the set shrinks to a singleton set $\{m\}$. Clearly, I is an isolating index set as witnessed by the *isolating word* m . ◀

Proof of Theorem 7

Proof. Let $k = 4(k' + 1)$ where k' is the size of the isolating set I . As in Section 2, we substitute each x_i by $w_i x_i w_i$, where $w_i, i \in [n]$ are n new variables. The transition matrices for w_i and x_i are denoted by N_i and M_i respectively.

For $1 \leq i \leq n$, we define $k \times k$ matrix N_i as a block diagonal matrix of $k' + 1$ many copies of a 4×4 matrix N'_i where $N'_i = I_4 + i(e_{12} + e_{34} + e_{32} + e_{14})$.

$$N'_i = \begin{bmatrix} 1 & i & 0 & i \\ 0 & 1 & 0 & 0 \\ 0 & i & 1 & i \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad N_i = \begin{bmatrix} N'_i & 0 & 0 & \dots & 0 \\ 0 & N'_i & 0 & \dots & 0 \\ 0 & 0 & N'_i & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & N'_i \end{bmatrix},$$

$$N_i'^{-1} = \begin{bmatrix} 1 & -i & 0 & -i \\ 0 & 1 & 0 & 0 \\ 0 & -i & 1 & -i \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad N_i^{-1} = \begin{bmatrix} N_i'^{-1} & 0 & 0 & \dots & 0 \\ 0 & N_i'^{-1} & 0 & \dots & 0 \\ 0 & 0 & N_i'^{-1} & \dots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \dots & N_i'^{-1} \end{bmatrix}.$$

Notice that

$$N_i'^{b_1} N_j'^{b_2} = \begin{bmatrix} 1 & (b_1 i + b_2 j) & 0 & (b_1 i + b_2 j) \\ 0 & 1 & 0 & 0 \\ 0 & (b_1 i + b_2 j) & 1 & (b_1 i + b_2 j) \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

We now define the $k \times k$ transition matrix M_i as a block diagonal matrix,

$$M_{i,j}' = \begin{bmatrix} 0 & y_{ij} \\ \frac{1}{z_{ij}} & 0 \end{bmatrix}, \quad M_{\xi_i}' = \begin{bmatrix} 0 & \xi_i \\ \frac{1}{\xi_i} & 0 \end{bmatrix},$$

$$M_i = \begin{bmatrix} 1 & 0 & 0 & 0 & \dots & 0 & 0 \\ 0 & M_{\xi_1}' & 0 & 0 & \dots & 0 & 0 \\ 0 & 0 & M_{i,1}' & 0 & \dots & 0 & 0 \\ 0 & 0 & 0 & M_{\xi_2}' & \dots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & \dots & M_{\xi_{k'+1}}' & 0 \\ 0 & 0 & 0 & 0 & \dots & 0 & 1 \end{bmatrix}.$$

These matrices can be seen as the transitions of a suitable NFA. We sketch the construction of this NFA.

Let $I = \{i_1, \dots, i_{k'}\}$ be an isolating set such that $i_1 < \dots < i_{k'}$. Intuitively, the NFA does one of two operations on each symbol (a variable or its inverse) of the input expression: a *Skip* or an *Encode*. In a *Skip* stage, the NFA deals with positions that are not part of the (guessed) isolating index set. In this stage, the NFA substitutes the w_i variables by suitable scalars (coming from the N_i' matrices) and x_i variables by block variables $\{\xi_1, \dots, \xi_{k'+1}\}$. The NFA nondeterministically decides whether the *Skip* stage is over and it enters the *Encode* stage for a guessed index of the isolating set. It substitutes x_i and x_i^{-1} variables by y_{ij} and z_{ij} respectively. Fig. 5 summarizes the action of the NFA.

■ **Figure 5** The transition diagram of the automaton.

57:12 Efficient Black-Box Identity Testing for Free Group Algebras

Define \hat{f} in $\mathbb{F}(Y, Z, \bar{\xi})$ to be rational function we obtain at the $(1, k)^{th}$ entry by evaluating the expression $f(N_1 M_1 N_1, \dots, N_n M_n N_n)$. Notice that, the isolating word m of degree D will be of following form $m = W_1 x_{i_1}^{b_{i_1}} W_2 x_{i_2}^{b_{i_2}} \dots W'_k x_{i'_k}^{b_{i'_k}} W_{k'+1}$ where each subword $W_j = x_{j_1}^{b_{j_1}} x_{j_2}^{b_{j_2}} \dots x_{j_{\ell_j}}^{b_{j_{\ell_j}}}$ is of length $\ell_j \geq 0$, where some of the W_j could be the empty word as well.

We refer to an NFA transition $q_i \rightarrow q_j$ as a *forward edge* if $i < j$ and a *backward edge* if $i > j$. We classify the backward edges in three categories based on the substitution on the edge-label. We say, a backward edge is of *type A* if a variable is substituted by a scalar value; a backward edge is of *type B* if a variable is substituted by $\frac{1}{\xi_j}$ for some j ; a backward edge is of *type C* if a variable is substituted by $\frac{1}{y_{ij}}$ or $\frac{1}{z_{ij}}$ for some i, j .

Consider a walk of the NFA on an input word m that reaches state k using only *type A* backward edges. In that case, m is substituted by $\alpha \cdot \hat{m}$ where \hat{m} is a monomial over $\{Y, Z, \xi\}$ of same degree,

$$\hat{m} = \prod_{j=1}^{k'+1} \xi_j^{\ell_j} \cdot \prod_{j=1}^{k'} ([b_{i_j} = 1] y_{i_j j} + [b_{i_j} = -1] z_{i_j j}).$$

and α is some nonzero constant obtained as a product of $[m]f$ with the scalars obtained as substitutions from the edges involving the w_i variables in the *Skip* stages. Indeed, as we can see from the entries of product matrices $N_i^{b_{i_1}} \cdot N_j^{b_{i_2}}$, where $b_1, b_2 \in \{-1, 1\}$, the scalar α is a product of $[m]f$ with terms of the form $b_1 i + b_2 j$, for $i \neq j$, each of which is nonzero for any reduced word.

■ **Figure 6** The transition diagram of the automaton at *Encode* stage.

▷ **Claim 14.**

$$[\hat{m}] \hat{f} \neq 0 \text{ iff } [m]f \neq 0.$$

Proof. It suffices to show that for any word $m' \neq m$, where m' has degree $\leq D$, no walks of the NFA accepting m' generate \hat{m} after substitution. For a computation path J , the monomial m_J in \hat{f} has two parts, let us call it *skip_J* and *encode_J* where *skip_J* is a monomial over $\{\xi_1, \dots, \xi_{k'+1}\}$ and *encode_J* is a monomial over $\{y_{ij}, z_{ij}\}_{i \in [n], j \in [k']}$. If the computation path J (which is different from the computation path described above for \hat{m}) uses only *type A* backward edges, then necessarily $m_J \neq \hat{m}$ from the definition of *isolating index set*. This argument is analogous to the argument given in [2].

Now consider a walk J which involves backward edges of other types. Let us first consider those walks that take backward edges only of *type A* and *type B*. Such a walk still produces a monomial over $\{y_{ij}, z_{ij}\}_{i \in [n], j \in [k']}$ and $\{\xi_i\}_{1 \leq i \leq k'+1}$ because division only by ξ_i variables

² Recall that $k = 4(k' + 1)$ where k' is the size of an isolating set.

Figure 7 The transition diagram of the automaton at *Skip* stage.

occur in the resulting expression. Since \hat{m} is of highest degree, the total degree of these monomials is strictly lesser than degree of \hat{m} . For those walks that take at least one backward edge of *type C*, a rational expression in $\{y_{ij}, z_{ij}\}_{i \in [n], j \in [k']}$ and $\{\xi_i\}_{1 \leq i \leq k'+1}$ is produced (as there is division by y_{ij} or z_{ij} variables). As the sum of the degree of the numerator and degree of the denominator is bounded by the total degree, the degree of the numerator is smaller than degree of \hat{m} .

Thus the $(1, k)^{th}$ entry of the output matrix is of the form $\sum_{i=1}^{N_1} c_i m_i + \sum_{j=1}^{N_2} r_j$ where $\{m_1, \dots, m_{N_1}\}$ are monomials arising from different walks (w.l.o.g. assume that $m_1 = \hat{m}$) and $\{r_1, \dots, r_{N_2}\}$ are the rational expressions from the other walks (due to the backward edges of *type C*). Note that, denominator in each r_j is a monomial over Y, Z of degree at most D . Let $L = \prod_{i=1}^n \prod_{j=1}^{k'} y_{i,j}^D \cdot z_{i,j}^D$. Now, we have,

$$\sum_{i=1}^{N_1} c_i m_i + \sum_{j=1}^{N_2} r_j = \frac{1}{L} \cdot \left(\sum_{i=1}^{N_1} c_i m_i L + \sum_{j=1}^{N_2} p_j \right).$$

Since $\hat{m}L \neq m_i L$ for any $i \in \{2, \dots, N_1\}$ and degree of each $p_j <$ degree of $\hat{m}L$ for any $j \in \{1, \dots, N_2\}$, the numerator of the final expression is a nonzero polynomial in $\mathbb{F}[Y, Z, \bar{\xi}]$. ◀

The above proof shows that the matrix $f(N_1 M_1 N_1, \dots, N_n M_n N_n)$ is nonzero with rational entries in $\mathbb{F}[Y, Z, \bar{\xi}]$. Each entry is a linear combination of terms of the form m_1/m_2 , where m_1 and m_2 are monomials in $Y \cup Z \cup \{\xi_1, \dots, \xi_{k'+1}\}$ of degree bounded by D . Note that, the matrix dimension is $k = c \log s$ for some constant c . This completes the proof of Theorem 7. ◀

To get an identity testing algorithm, we can do random substitutions. The matrix dimension is $\log s$ and the overall running time of the algorithm is $\text{poly}(n, \log s, \log D)$. This also proves Corollary 8. ◀

► Remark 15. For algorithmic purposes, we note that Theorem 4 is sometimes preferable to Theorem 7. For instance, the encoding used in Theorem 7 does not preserve the sparsity of the polynomial as required in the sparse reconstruction result (see Theorem 6).

4 Adaptation for Fields of Positive Characteristic

Let \mathbb{F} be any finite field of characteristic p . We will ensure that for each word m in the free group algebra, the scalar α_m (see Equation 1) produced by the automaton described in Section 2 is not zero in \mathbb{F} . Recall that, reading $w_i^{b_i} w_j^{b_j}$ for two consecutive positions, the automaton produces a scalar $(b_i \cdot i + b_j \cdot j)$ where $b_i, b_j \in \{-1, +1\}$. Moreover, this is the only way the automaton produces a scalar and for each m , α_m is a product of such terms. Hence, it suffices to ensure that for each pair $i, j \in [n]$, $(b_i \cdot i + b_j \cdot j) \neq 0$. Similarly, it ensures that the scalar produced by the automaton described in Section 3 is nonzero.

We note that, if p is more than $2n$ then each term $(b_i \cdot i + b_j \cdot j) \neq 0 \pmod{p}$ where $b_i, b_j \in \{-1, +1\}$ and $i, j \in [n]$. This results in a dependence on the characteristic of the base field for the analogous statements of Theorems 4, 7 for finite field. Additionally, for Theorem 4, the $(1, 2d)^{th}$ entry of the output matrix is a polynomial of degree d , and for Theorem 7, the degrees of the numerator polynomials in the rational expression of the output matrix is bounded by some scalar multiple of $nD \log s$. This lower bounds the size of the fields in the application. We summarize the above discussion in the following.

► **Observation 16.** *We can obtain results analogous to Theorem 4 and Theorem 7 for finite fields of characteristic more than $2n$ and sizes at least $d + 1$ and $\Omega(nD \log s)$ respectively.*

However, the algorithms presented in Theorem 6 and Corollaries 5, 8 can be modified to work for finite fields of any characteristic. To this end, we first notice the following simple fact.

► **Proposition 17.** *Let \mathbb{F} be a finite field of characteristic $p \leq 2n$. In We can find elements $\alpha_1, \alpha_2, \dots, \alpha_n$ from a suitable (deterministically constructed) small extension field \mathbb{F}' of \mathbb{F} in deterministic $\text{poly}(n)$ time, such that for any $b_i \in \{-1, 1\}$, $1 \leq i \leq n$ we have*

$$\text{For each } 1 \leq i < j \leq n, b_i \alpha_i + b_j \alpha_j \neq 0.$$

Let $\alpha_1, \alpha_2, \dots, \alpha_n \in \mathbb{F}'$ as given by the above proposition. We modify the matrix N'_i in the proof of Theorem 6 and Corollary 5 as

$$N'_i = \begin{bmatrix} 1 & \alpha_i \\ 0 & 1 \end{bmatrix},$$

and in Corollary 8 we modify N'_i as

$$N'_i = \begin{bmatrix} 1 & \alpha_i & 0 & \alpha_i \\ 0 & 1 & 0 & 0 \\ 0 & \alpha_i & 1 & \alpha_i \\ 0 & 0 & 0 & 1 \end{bmatrix}.$$

For each pair $i, j \in [n]$, $(b_i \cdot \alpha_i + b_j \cdot \alpha_j) \neq 0$ by Proposition 17. Thus, for each word m , the scalar α_m produced by the automata are nonzero in the extension field \mathbb{F}' as well. Furthermore, the test set of [14] works for all fields. Hence Theorem 6 holds for all finite fields too. To obtain Corollaries 5 and 8, we will do random substitutions from a suitable small degree extension field and use Schwartz-Zippel-Demillo-Lipton Theorem [19, 21, 7]. In summary, our algorithms in the paper can be adapted to work for all fields.

Proof of Proposition 17. Define polynomial $g \in \mathbb{F}[x_1, x_2, \dots, x_n]$ as

$$g(x_1, x_2, \dots, x_n) = \prod_{1 \leq i < j \leq n} (x_i + x_j) \cdot (x_i - x_j).$$

We substitute y^i for x_i , $1 \leq i \leq n$. Then $g(y, y^2, \dots, y^n) = G(y) \in \mathbb{F}[y]$ is a univariate polynomial of degree at most $2n^3$. Using standard techniques, in deterministic polynomial time we can construct an extension field \mathbb{F}' of \mathbb{F} such that $|\mathbb{F}'|$ is of $\text{poly}(n) \geq 2n^3 + 1$ size. We can find an element $\alpha \in \mathbb{F}'$ such that $G(\alpha) \neq 0$ and set $\alpha_i = \alpha^i$, $1 \leq i \leq n$. ◀

Abstract

In the Maximum Label Propagation Algorithm (**Max-LPA**), each vertex draws a distinct random label. In each subsequent round, each vertex updates its label to the label that is most frequent among its neighbours (including its own label), breaking ties towards the larger label. It is known that this algorithm can detect communities in random graphs with planted communities if the graphs are very dense, by converging to a different consensus for each community. In [17] it was also conjectured that the same result still holds for sparse graphs if the degrees are at least $C \log n$. We disprove this conjecture by showing that even for degrees n^ε , for some $\varepsilon > 0$, the algorithm converges without reaching consensus. In fact, we show that the algorithm does not even reach almost consensus, but converges prematurely resulting in orders of magnitude more communities.

1 Introduction

In the last years, opinion exchange dynamics on graphs and networks has received much attention, see [19] for an excellent survey. Apart from the desire to improve our understanding of social processes, opinion exchange dynamics have also found applications in the fields of distributed computing and network analysis. For example, opinion exchange dynamics like the 3-majority protocol or the 2-choice dynamics have been proposed as simple distributed solutions to the basic problems of consensus forming, majority detection, and plurality consensus in distributed networks [2, 3, 5, 7, 10, 12, 13].

Label propagation algorithms (LPA) are a certain kind of opinion exchange dynamics which have been used for community detection in networks [4, 14, 15, 21, 23]. Despite their great practical importance (see the surveys [4, 15, 23]), and although obtaining theoretical bounds on success and speed of LPAs was proposed as an important research question [1, 8, 18], rigorous theoretical analyses of LPAs have only appeared recently. The first such study by Kothapalli, Pemmaraju and Sardeshmukh [17] investigated an algorithm called **Max-LPA**. In this algorithm, each vertex starts with a random label in the interval $[0, 1]$. In each round, every vertex switches its label to the majority label in its neighbourhood (including its own label), breaking ties towards larger labels. In [17] **Max-LPA** was studied on an Erdős-Rényi model with planted communities.¹ In this model, the vertex set is partitioned as $V = V_1 \dot{\cup} \dots \dot{\cup} V_k$, where all sets V_k have a certain minimal size. Then every edge inside of one of the sets V_i is inserted independently with some probability p_i , and every edge between different partite sets is inserted independently with probability $p' \ll p := \min_i \{p_i\}$. The study [17] considered dense cases, e.g. for $|V_i| = \Omega(n)$ they set $p = \Omega(n^{-1/4+\epsilon})$ and $p' = O(p^2)$. For this case they show that **Max-LPA** successfully recovers the communities, i.e., it converges quickly to a state where for each i the labels within the set V_i are all identical, and any two distinct sets V_i have different labels. The authors of [17] conjectured that their conditions on p are very far from tight, and that it should suffice to require $p \geq C \log n/n$ (i.e., expected degrees of $C \log n$ instead of $\Omega(n^{3/4+\epsilon})$), if there is a sufficient gap between p and p' .

The conjecture from [17] has been considered in at least two subsequent papers [6, 9], both of whom have tried to obtain results for LPA algorithms in sparser cases, see Section 1.1 below. However, the conjecture remained unresolved, and the behaviour of **Max-LPA** and other LPAs generally remained poorly understood in the sparse case. In this paper we show that the conjecture from [17] is actually false in a strong sense. Even in the extreme case of just one rather dense community, i.e. $p' = 0$, and $p = n^{-1+\epsilon}$, **Max-LPA** fails to label the communities consistently. In fact, with high probability the algorithm gets stuck with all label classes having size $o(n)$. For this negative result, note that the case of just one community corresponds to running the **Max-LPA** process on a classical Erdős-Rényi graphs $G_{n,p}$, in which each edge is inserted independently with probability p . We thus phrase our main result for Erdős-Rényi graphs $G_{n,p}$ with expected degree $d := np \leq n^\epsilon$.

► **Theorem 1.** *There exists constants $C > 0$ and $\epsilon > 0$ such that for any $C \log n/n \leq p \leq n^{-1+\epsilon}$, the **Max-LPA** process on an Erdős-Rényi graph $G_{n,p}$ terminates with $\Omega(d^3)$ different label classes each of size at most $O(n/d^3)$, where $d := np$ denotes the expected degree of a vertex in $G_{n,p}$.*

Note that our result does not immediately extend to smaller values of p , as the property “**Max-LPA** finds consensus on G ” is not monotone.

A rigorous analysis of LPAs is challenging due to the high influence of dependencies. In [9] this was stated as: “The absence of substantial theoretical progress in the analysis of LPAs is largely due to the lack of techniques for handling the interplay between the non-linearity of the local update rules and the topology of the graph.” In order to prove our result we need to combine local analysis of the dynamics with global properties of the graph, in particular by inventing a discharging technique for showing that no set of size $O(n/d^3)$ can propagate much further without the help of (suitably defined) unstable vertices. We hope that this technique will also turn out to be useful for the analysis of other LPAs.

¹ also called *clustered Erdős-Rényi graph* or *stochastic block model*

1.1 Other related work

There is a huge body of experimental work on LPAs for community detection, and we refer the reader to surveys [4, 15, 23]. Basic properties of **Max-LPA** were analysed in [20], and in particular it was shown that the algorithm always converges to a stable configuration or to a limiting cycle of length 2. An experimental comparison of **Max-LPA** with other tie-breaking techniques was performed in [8], with the conclusion that **Max-LPA** typically converges faster than other tie-breaking rules, but that repeated runs on the same graph produces slightly less consistent outcomes than other LPAs.

As outlined above, there are only very few rigorous mathematical results on LPAs. In an attempt to improve on results from [17], Cruciani, Natale, and Scornavacca [9] studied the 2-choices dynamics as a “sampling” approximation of an LPA. In this dynamics, a vertex updates its label to the majority label among its own and the labels of two randomly drawn neighbours, breaking ties towards its own label. For this variant of an LPA, [9] studied clustered regular graphs with two clusters, i.e., graphs with fixed degree d within each of the clusters, and fixed degree $d' \ll d$ between the clusters. While both, the algorithm and the setting, differ slightly from [17], the authors compare their results with [17] and improve the (average) degree d from $d = n^{3/4+\varepsilon}$ to $d = n^{1/2}$. The proof idea relies on expansion properties of the graph, and $n^{1/2}$ is a natural barrier for this approach.

In [6], Clementi et al. analysed the Erdős-Rényi model with two planted communities, for an LPA which uses a different tie-breaking rule than **Max-LPA**: it breaks ties randomly. For this variant they claim that a repeated application of this LPA with random tie breaking can successfully recover the communities with high probability, even for densities as sparse as $p = \Theta(1/n)$. However, their result has a catch: the analysis is only done for a *dynamic* version of the random graph model, in which all edges are re-drawn in every round. This simplifies the analysis considerably, since it removes dependencies between different rounds. In particular, the state of the algorithm at any time can be completely described by the *number* of vertices of each label in each of the partite sets, whereas in the static case the structural information is essential. As we show in this paper, the behaviour of the **Max-LPA** in the sparse case reveals that it fails precisely because of the structural properties of the label classes. In other words, the behaviour in the static and the dynamic case are completely different, and an analysis of the dynamic case in general will not explain the behaviour of the static case.

1.2 Some intuition on the **Max-LPA** process

In this section we provide some intuition for Theorem 1. Recall that we assume that, by definition of the **Max-LPA** process, each $v \in V$ chooses its original label uniformly and independently from $[0, 1]$. With high probability all vertices will therefore have different labels. Throughout our paper we will thus assume without loss of generality that in the beginning of the process the labels of all vertices are pairwise different.

Consider a random graph $G_{n,p}$ and recall that we denote by $d = pn$ its average degree. Then almost all vertices will have a neighbour which holds one of the n/d highest labels (here and in the sequel of this overview we ignore polylog(d) factors). After the first round we thus expect that (almost) all but the largest n/d labels are extinct, i.e., are not present any more at any vertex.

Let us thus have a closer look at how such a high label evolves in the first few rounds of the **Max-LPA** process. Hence, consider a vertex v with a label ℓ that belongs to the n/d largest labels. We expect that v pushes ℓ to some of its neighbours. Depending on the size

of ℓ , the number of neighbours which receive ℓ in round 1 can range from very few to almost all neighbours (but this is not our concern at the moment). In order to understand what can happen in subsequent rounds, we need to distinguish two cases: (i) v receives in round 1 a new label $\ell' > \ell$ or (ii) v keeps its initial label ℓ in round 1. In case (i), whenever the label ℓ got pushed onto enough neighbours of v in round 1, vertex v will get back its initial label ℓ in round 2. In this case quite a number of different scenarios can happen in further rounds, as for example v can receive back its initial label not only in round 2, but also in other subsequent rounds if the label ℓ was pushed down far enough into the r -neighbourhood of u .

In case (ii), on the contrary, v is already in a quite stable situation, as v and many of its neighbours have the same label. More precisely, in order for v to change its label in any of the subsequent rounds, (almost) all neighbours of v which receive label ℓ in round 1 need to lose ℓ again in one of the subsequent rounds. For any such neighbour $u \in N(v)$ this can either happen if, at some point in time, say t , the initial label of u is pushed back onto u or the neighbourhood of u will contain a different label $\ell' \neq \ell$ on two or more of its vertices. Note that, for most neighbours of v , the first case is unlikely, as the vast majority of neighbours of v initially held one of the $n - n/d$ labels which are extinct after the first round. The latter case, on the other hand, can only happen if u is in a cycle of length at most $2(t + 1)$ (here we use that we assumed that in the beginning all vertices have pairwise different labels). Note that for each constant $t \in \mathbb{N}$ there exists a constant $\varepsilon = \varepsilon(t) > 0$ so that the random graph $G_{n,p}$ with $\omega(1/n) \leq p \leq n^{-1+\varepsilon}$ has the property that all but a negligible number of vertices are *not* contained in a cycle of length at most t . Hence, almost all vertices $v \in V$ which keep their label in round 1, together with their neighbours $u \in N(v)$ which receive the label of v in round 1 and initially held one of the $n - n/d$ smallest labels, are in a quite stable configuration already after the first round.

After the first round only a constant fraction of vertices are in such a stable configuration. However, by analysing the subsequent rounds of the process in a similar fashion we can show that after the first few rounds, all but n/d^4 vertices are in such a stable configuration.

Once we have shown that all but n/d^4 vertices are in stable configurations, we still have to argue that the n/d^4 non-stable vertices will not be able to break up these stable configurations. To handle this case we use a discharging argument to show that if a label class grows to size n/d^3 , then this label class induces a subgraph with density at least $3/2$. As a random graph $G_{n,p}$ with $\log(n)/n \leq p \leq n^\varepsilon$ whp does not contain such a set, we deduce that no label class gets that large. We note that this idea is similar to techniques used to study k -bootstrap percolation on Erdős-Rényi graphs [11], in which an initial set of active vertices successively activates every vertex that has at least k active neighbours. Our case can be viewed as a (hypothetical) $3/2$ -bootstrap percolation.

1.3 Notation and terminology

Our graph-theoretic notation is standard and follows that of [22]. In particular, for a graph G , we denote by V and E the set of vertices and edges, respectively. Moreover, $e(G) := |E|$ is the number of edges of G . For any subset $S \subseteq V$ we let $G[S]$ denote the subgraph of G that is induced by the vertices of S . We denote by $E(S)$ the set of edges of $G[S]$ and define $e(S) := |E(S)|$. For any two disjoint subsets $S, T \subset V$ we denote by $E(S, T)$ the set of edges with one endpoint in S and the other in T and define $e(S, T) := |E(S, T)|$. For a vertex $v \in V$, we denote by $N(v)$ the neighbourhood of v , which excludes v , and by $d(v) := |N(v)|$ its degree. For any positive integer $r \geq 2$, the r -neighbourhood of a vertex v , denoted by $N^r(v)$, is the set of vertices that can be reached from v by a path of length at most r (i.e. the r -neighbourhood of a vertex v includes v).

We consider the classical random graph model from Erdős and Rényi. For a positive integer n and $0 \leq p := p(n) \leq 1$. We denote by $G_{n,p}$ the probability space over graphs on n vertices where every possible edge is present with probability p independently of all other edges. We write $d := np$ for the expected degree of a graph $G \sim G_{n,p}$ and $\Delta(G)$ for its maximum degree. We say that an event $\mathcal{E} = \mathcal{E}(n)$ happens *with high probability*, or *whp*, if $\Pr[\mathcal{E}(n)] \rightarrow 1$ for $n \rightarrow \infty$. We use the notation $\tilde{O}(\cdot)$ to hide polylog(d) factors.

2 Some properties of random graphs

In this section, we provide some results on random graphs which are important in our analysis. First, we state a standard result from random graph theory on degree concentration (the proof follows e.g. from [16, Corollary 2.3] together with a union bound).

► **Lemma 2.** *For every $\varepsilon > 0$ there exists a positive constant C such that for $G \sim G_{n,p}$ with $p \geq \frac{C \log(n)}{n}$ with probability at least $1 - 2ne^{-\frac{\varepsilon^2 d}{3}}$, it holds for every vertex $v \in V$ that*

$$(1 - \varepsilon)d \leq d(v) \leq (1 + \varepsilon)d,$$

where $d = pn$.

The next lemma gives a lower bound on the number of vertices that do not have a neighbour in a large subset.

► **Lemma 3.** *Let $M > 0$, $\varepsilon > 0$, $\log(n)/n \leq p \leq n^{-1+\varepsilon}$ and $G = (V, E) \sim G_{n,p}$. Let $S \subset V$ be a subset of vertices of size $|S| = \Omega\left(\frac{n(\log(d))^2}{d}\right)$, where $d = pn$. Then whp all but at most nd^{-M} vertices $v \in V \setminus S$ have at least one neighbour in S .*

Proof. As each vertex $v \in V \setminus S$ has $|S|$ opportunities to have an edge into S we have that

$$\Pr[e(v, S) = 0] = (1 - p)^{|S|} \leq e^{-\Omega((\log(d))^2)} = d^{-\Omega(\log(d))}.$$

Thus, letting X be the random variable which counts the number of vertices in $V \setminus S$ with no neighbour on S and writing X as a sum of indicator random variables, we can conclude that

$$\mathbb{E}[X] \leq nd^{-\Omega(\log(d))}.$$

Setting $t = nd^{-M} - \mathbb{E}[X] = \omega(\log(n))$, the proof now follows by Chernoff bounds. ◀

In the following we argue that there are not many vertices which are in short cycles.

► **Lemma 4.** *Let k be a positive integer and let $G \sim G_{n,p}$ with $p = \omega(1/n)$. Then whp the number of cycles of length at most k is less than d^{k+1} , where $d = pn$. Therefore, at most kd^{k+1} vertices are contained in such cycles.*

Proof. For $1 \leq i \leq k$ let X_i be a random variable counting the number of cycles of length i in G . Then the expectation of X_i is given by

$$\mathbb{E}[X_i] = \binom{n}{i} \frac{(i-1)!}{2} p^i \leq d^i \leq d^k,$$

where the last inequality follows as $d \geq 1$. Thus, letting $X := \sum_{i=1}^k X_i$ be the random variable counting the number of cycle of length at most k , we can conclude by linearity of expectation that

$$\mathbb{E}[X] \leq kd^k.$$

Using Markov's inequality we get

$$\Pr [X \geq d^{k+1}] \leq \frac{k}{d} = o(1)$$

which finishes the proof, as each cycle contains at most k vertices. \blacktriangleleft

3 Notation and terminology for the Max-LPA process

Let us assume that the Max-LPA process runs on a random graph $G \sim G_{n,p}$ with $C \log(n)/n \leq p \leq n^{-1+\varepsilon}$, for some suitable constants $C > 0$ and $\varepsilon > 0$. We first introduce some notation. We define \mathcal{L} to be the set of labels used in the Max-LPA process and for any $t \geq 0$ we denote by $\ell_t(v)$ the label of a vertex $v \in V$ after the t -th round of the Max-LPA process. Recall that we assume without loss of generality that all labels $\ell_0(v)$ are distinct. For any label $\ell \in \mathcal{L}$ we denote by v_ℓ the (by our assumption unique) vertex from which label ℓ originated from, i.e. $\ell_0(v_\ell) = \ell$. Moreover, we call a label ℓ *extinct* in a round $t > 0$ if there exists no vertex $v \in V$ with $\ell_t(v) = \ell$.

During the Max-LPA process, we say that a vertex v *propagates* its label onto $u \in N(v)$ in the t -th round of the process if $\ell_{t-1}(v) = \ell_t(u)$ and $\ell_{t-1}(v) \neq \ell_{t-1}(u)$. If $\ell_i(u) \neq \ell_{t-1}(v)$ for all $i \leq t-1$ (i.e. if u never held the label $\ell_{t-1}(v)$ so far), we say that v *forward-propagates* the label $\ell_{t-1}(v)$ onto u in round t . Otherwise, we say that v *back-propagates* the label $\ell_{t-1}(v)$ onto u in round t . In abuse of notation, we will also call a label ℓ to be *forward-propagating* and *backward-propagating* from or onto a vertex v .

As we saw in the introduction, in the absence of (short) cycles, back-propagation is essentially the only way that a vertex which has a neighbour holding the same label can change its current label. Thus, in order to create stable configurations, we need to understand such back-propagation of labels properly. The following definition will help us do so.

► Definition 5. Let $v \in V$, $t \geq 0$ and assume that ℓ is a label which v holds for the first time in round t , i.e. $\ell_t(v) = \ell$ and $\ell_i(v) \neq \ell$ for all $i < t$. Then we define the ℓ -propagation set of v to be the vertex v together with all vertices w for which there exists a path $v = v_0, \dots, v_k = w$ such that for all $0 \leq i \leq k$ the vertex v_i receives label ℓ in round $t + i$ from v_{i-1} and did not hold it in any round $j < t + i$.

Recall from Section 1.2 that two vertices u and v that are connected by an edge and that hold the same label in some round t can only change their label if they are in a short cycle or if a label is back-propagated. In the following definition we only capture the latter (as we will argue in Section 4 that we do not have to consider vertices that are in short cycles).

► Definition 6. Let $t \geq 0$ and assume that the Max-LPA process has run for t rounds. For any $v \in V$ we denote by $L_v^{(t)} := \{\ell \in \mathcal{L} : \exists i \leq t \text{ such that } \ell_i(v) = \ell\}$ the set of labels v held in the first t rounds of the process. We then call an edge $\{u, v\} \in E$ *stable after round t* if

- (i) $\ell_t(v) = \ell_t(u)$,
- (ii) for all forward-propagating labels $\ell \in L_v^{(t)} \setminus \{\ell_t(v)\}$ of v we have that no vertex in the ℓ -propagation set of v holds the label ℓ after round t , and
- (iii) for all forward-propagating labels $\ell \in L_u^{(t)} \setminus \{\ell_t(u)\}$ of u we have that no vertex in the ℓ -propagation set of u holds the label ℓ after round t .

A vertex $v \in V$ is then called *stable after round t* if it belongs to a stable edge after the t -th round. All other vertices are called *unstable after round t* .

Moreover, we call an unstable vertex *vulnerable* in round $t + 1$ if the labels of all vertices in $N(v) \cup \{v\}$ are pairwise different after round t .

Note that being stable a priori does not mean that a vertex will never change its label again. However, we can show:

► **Lemma 7.** *Let t_0 and t be positive integers with $t < t_0$ and let $u, v \in V$ be adjacent vertices. If $\{u, v\}$ is a stable edge at time t and neither u nor v belong to a cycle of length $2t_0$ or less then both u and v will keep their label (and thus remain stable vertices) until round t_0 .*

Proof. Let $t \leq i < t_0$ and let us assume that $\{u, v\}$ is a stable edge in round i . We claim that then the same is true in round $i + 1$ as well. Indeed, as u and v are in a stable edge and not contained in cycles of length less than $2t_0$, we have that any label $\ell \in L_u^{(t)} \setminus \ell_t(u)$ appears at most once in the neighbourhood of u namely on the unique vertex which pushed the label ℓ onto u . As the same is true for v as well, no label ℓ can be back-propagated onto u or v .

Hence, the only way for u or v to change their label is if they see a label ℓ in their neighbourhood at least twice. As these two neighbours cannot be connected (else u or v would be in a triangle), this can only happen if there exist two different paths from u or v to the vertex v_ℓ from which the label ℓ originated from. Hence, the appearance of the label ℓ in two neighbours of u (or v) in round $t \leq i < t_0$ implies the existence of a cycle of length at most $2i + 2 \leq 2t_0$ which contains u (or v). As this is a contradiction, we have that u and v will not change their label in the i -th round. Thus $\ell_{i+1}(u) = \ell_{i+1}(v)$. As furthermore, again since u and v are not contained in cycles of length less than $2t_0$, no label $\ell \in L_u^{(t)} \setminus \ell_t(u)$ (or $\ell \in L_v^{(t)} \setminus \ell_t(v)$) can reappear in the ℓ -propagation set of u (or v) through a path from v_ℓ not through u (or v), the edge $\{u, v\}$ remains stable as desired. The statement of the lemma now follows by a simple induction. ◀

4 The first two rounds of the process

In this section we carefully analyse the first two rounds of the process and show that after two rounds there are at most $\tilde{O}(n/d)$ unstable vertices left. As explained in the introduction, we are mainly interested in the behaviour of the highest labels, hence we define the following.

► **Definition 8.** *For a label $\ell \in \mathcal{L}$, let the rank of ℓ be $\text{rk}(\ell) := |\{\ell' \in \mathcal{L} \mid \ell' \leq \ell\}|$. In particular, the smallest label has rank 1, and the largest label has rank n . Then we define*

$$\begin{aligned} L_X &= \left\{ \ell \in \mathcal{L} : \text{rk}(\ell) \geq n \left(1 - \frac{(\log(d))^2}{d^3} \right) \right\}, \\ L_Y &= \left\{ \ell \in \mathcal{L} : n \left(1 - \frac{(\log(d))^2}{d^2} - \frac{(\log(d))^2}{d^3} \right) \leq \text{rk}(\ell) < n \left(1 - \frac{(\log(d))^2}{d^3} \right) \right\}, \\ L_Z &= \left\{ \ell \in \mathcal{L} : n \left(1 - \frac{(\log(d))^2}{d} \right) \leq \text{rk}(\ell) < n \left(1 - \frac{(\log(d))^2}{d^2} - \frac{(\log(d))^2}{d^3} \right) \right\}. \end{aligned}$$

Additionally, we denote by $X^{(t)}$, $Y^{(t)}$ and $Z^{(t)}$ the sets of vertices holding labels in L_X, L_Y and L_Z after round $t \geq 0$, respectively.

We are particularly interested in vertices that propagate their label to at least one neighbour in the first round but also lose their label in this round. Those are vertices which initially engage in back-propagation. As this can cause a series of troubles, we call those vertices and their labels “bad”. More precisely, we define the following:

► **Definition 9.** *A label ℓ is called good if $\ell_1(v_\ell) = \ell$ and v_ℓ forward-propagates label ℓ in the first round to at least one of its neighbours. Otherwise, we call ℓ bad.*

As not only vertices which initially hold a bad label can cause troubles, but also all vertices which (potentially) hold such a bad label in later rounds, we also consider the 2-neighbourhood of such vertices.

► **Definition 10.** We denote by

$$X_{\text{bad}}^{(2)} := \bigcup_{\substack{\ell \in L_X \\ \ell \text{ is bad}}} N^2(v_\ell)$$

the set of all vertices that are in the 2-neighbourhood of a vertex $v \in X^{(0)}$ initially holding a bad label. Similarly, we define

$$Y_{\text{bad}}^{(2)} := \bigcup_{\substack{\ell \in L_Y \\ \ell \text{ is bad}}} N^2(v_\ell).$$

Additionally, for any bad label $\ell \in L_X$ or $\ell \in L_Y$ we call the 2-neighbourhood $N^2(v_\ell)$ an X_{bad} -set and a Y_{bad} -set, respectively.

In the later rounds the following situation can also arise. Whenever we have a vulnerable vertex, it can propagate its label and get a new label in the same round. This again results in vertices which engage in back-propagation. The following rather general definition will later allow us to capture all such situations. The definition may remain a bit mysterious at first glance, but we will show later why it makes sense (see Section 5).

► **Definition 11.** We define two sets set of vertices, called *A-nodes* and *B-nodes*, as follows:

$$A := \bigcup_{v \in X^{(0)}} \bigcup_{w \in N(v) \cap Z^{(0)}} (N(w) \setminus \{v\})$$

$$B := \bigcup_{v \in Y^{(0)}} \bigcup_{w \in N(v) \cap Z^{(0)}} (N(w) \setminus \{v\})$$

With the above definitions at hand, we can state our first main lemma, which summarises the behaviour of the algorithm in the first two rounds.

► **Lemma 12.** For every $M > 0$ there exist $C > 0$ and $\varepsilon > 0$ such that the following holds. Let $\frac{C \log n}{n} \leq p \leq n^{-1+\varepsilon}$ and assume that we run the **Max-LPA** process on a graph $G \sim G_{n,p}$. Then with high probability there exists a set $D \subseteq V$ of size at most nd^{-M} such that the following statements hold:

- (ACYC) All cycles in $G[V \setminus D]$ have length larger than 200.
- (NBZ) Every vertex in $V \setminus D$ has at least one neighbour in $Z^{(0)}$. Moreover, all vertices in $V \setminus D$ which forward-propagate in round 1 hold a label from L_X , L_Y or L_Z .
- (NBY) Every vertex in $V \setminus D$ has at least one neighbour in $Y^{(1)}$. Moreover, all vertices in $V \setminus D$ which forward-propagate in round 2 hold a label from L_X or L_Y .
- (NBX) Every vertex in $V \setminus D$ has at least one neighbour in $X^{(2)}$. Moreover, all vertices in $V \setminus D$ which forward-propagate in round 3 hold a label from L_X .
- (UNST-TYPES2) After the second round, every unstable vertex in $V \setminus N(D)$ is in $Z^{(0)}$, A , B , $X_{\text{bad}}^{(2)}$ or $Y_{\text{bad}}^{(2)}$.

- (UNST2X) There are $\tilde{O}(n/d^3)$ vertices in $X_{\text{bad}}^{(2)}$.
- (UNST2Y) There are $\tilde{O}(n/d)$ vertices in $Y_{\text{bad}}^{(2)}$.
- (UNST2Z) There are $\tilde{O}(n/d)$ vertices in $Z^{(0)}$.
- (UNST2A) There are $\tilde{O}(n/d^2)$ vertices in A .
- (UNST2B) There are $\tilde{O}(n/d)$ vertices in B .
- (UNST2) There are $\tilde{O}(n/d)$ unstable vertices after the second round.

As the proof of Lemma 12 is rather long, we only give a short overview. As a first step one can argue that the labels from L_Y and L_X propagate their labels to a linear fraction of their 1-Neighbourhood and 2-Neighbourhood, respectively. I.e. one can show that both $Y^{(1)}$ and $X^{(2)}$ are of size $\Theta(n(\log(d))^2/d)$. Thus, by Lemma 3 and Lemma 4, we can define D as the 5-Neighbourhood of all vertices which do not have a neighbour in $Z^{(0)}$ or $Y^{(1)}$ or $X^{(2)}$ and which are contained in cycles of length 200 or less, and the first four items of Lemma 12 then follow easily.

The proof of (UNST-TYPES2) is a rather involved case analysis. In a nutshell, one can show that all vertices $v \in V \setminus N(D)$ which are not contained in $Z^{(0)}$, A , B , $X_{\text{bad}}^{(2)}$ or $Y_{\text{bad}}^{(2)}$ are connected through a stable path of length at most two to a vertex v_ℓ for some good label ℓ .

To show items (UNST2X) to (UNST2B) one can calculate the number of bad labels in L_X and L_Y using standard probabilistic tools (as e.g. Chernoff bounds). The sizes of these five sets then simply follow from their definition and Lemma 2. Last, note that (UNST2) is just a summary of the other statements of Lemma 12.

5 The next rounds of the Max-LPA process

The main goal of this section is to show the following proposition.

► **Proposition 13.** *After at most 100 rounds, whp the number of unstable vertices is $\tilde{O}(n/d^4)$.*

In the remainder of the paper, we will mostly neglect vertices which are outside the 101-neighbourhood of D . Since $|N^{101}(D)| = o(n/d^4)$ (if we choose the constant M in Lemma 12 large enough) the above proposition also follows if we only show that a $1 - \tilde{O}(n/d^4)$ fraction of vertices in $V \setminus N^{101}(D)$ is stable after round 100. The main advantage of neglecting these vertices is that all vertices we consider in this section, and their complete 100-neighbourhood, are not contained in cycles of length less than 200. Thus, all structures we analyse (such as X_{bad} -sets, Y_{bad} -sets and ℓ -propagation sets, label classes) are actually trees (and in the following, we hence also refer to them as e.g. ℓ -propagation trees instead of ℓ -propagation sets). To ease notation, we henceforth denote for any set $S \subseteq V$ by $\hat{S} := S \setminus N^{101}(D)$ the set S without the 100-neighbourhood of D .

As the proof of the above proposition is quite involved, we only provide a detailed overview.

By Lemma 12, we know that after the second round a $1 - \tilde{O}(1/d)$ fraction of the vertices in \hat{V} is already stable. In order to argue that the number of unstable vertices drops even further over the next few rounds, we cover all unstable vertices in \hat{V} by the five classes \hat{X}_{bad} , \hat{Y}_{bad} , $\hat{Z}^{(0)}$, \hat{A} and \hat{B} , depending on the mechanism that keep them unstable. Note that the definitions of \hat{X}_{bad} , \hat{Y}_{bad} , $\hat{Z}^{(0)}$, \hat{A} and \hat{B} are a bit over-pessimistic: vertices may occur in

several classes, or several times in the same class, and all classes may also contain some stable vertices. However, our definitions allow us to show that the vertices in each class behave as if they were randomly distributed. In particular, for a given vertex, say, of type \hat{X}_{bad} , it is easy to count the number of neighbours in other \hat{X}_{bad} -structures, in \hat{Y}_{bad} -structures, and so on.

The weighted meta-graph in Figure 1 summarizes the situation after round 2. Each vertex in the meta-graph corresponds to one (or two) of the five classes of unstable vertices (we depict $\hat{Z}^{(0)}$ and \hat{B} as one vertex in all our figures because they evolve identically). The weights on the edges in the meta-graph are guided by the following idea. Assume that a vertex is, say, in an \hat{X}_{bad} -structure, and assume pessimistically that its label can take over arbitrary parts of this structure. Then the weights of the arrows going out from \hat{X}_{bad} are (an upper bound for) the expected number of structures of other types that the label sees (and thus, can potentially take over). If we pessimistically assume that it also takes over these new structures, then the weights of the outgoing edges in the meta-graph also gives a bound on the expected number of structures that the label can see form there, and so on. Thus if for each walk in the meta-graph we multiply the weights along a walk, and then sum these products over all walks in the meta-graph, then we obtain an a bound for the expected number of structures that the label can take over.

■ **Figure 1 Meta-graph after round 2.** The first value in a node S indicates the size of a structure S , the second value indicates number of vertices (counted with multiplicity) in structures of type S . The weight x of a meta-edge from node S to node T indicates that from a random S -structure S_0 there are in expectation at most x edges to T -structures (not counting edges within S_0 if $S = T$). The same bound is also valid if S_0 is not random among all S -structures, but rather a random neighbour of a T' -structure, for any type T' that appears in the meta-graph. All values are upper bounds and suppress any polylog(d) factors.

An important intermediate goal is to show that the graph $G' = (V', E')$ induced by unstable vertices from \hat{V} is scattered, i.e. that most vertices are in small components. To this end, we would like to have that for any walk in the meta-graph, the weights of the edges multiply up to something of size $o(1)$. Then, if we start with a random vertex in V' , all paths in G' containing this vertex are short, since its unstable structure is only connected to few other meta-vertices. Hence, the vertex has small probability to be in a large component. Unfortunately, after round 2 the meta-graph is still much too dense for our purpose.

Analysing the Max-LPA process further, we show that in the third round the number of unstable $\hat{Z}^{(0)}$ and \hat{B} structures decreases by a factor of $\tilde{O}(1/d)$. For the \hat{Y}_{bad} structures, something even more dramatic happens: most of them scatter internally by round 5, in the

sense that if we choose a random vertex in a random \hat{Y}_{bad} structure, then the expected size of the component of this vertex within the \hat{Y}_{bad} structure shrinks to $\tilde{O}(1)$. The analysis after round 2 becomes more tricky, since the structures lose their independence. For example, although the number of $\hat{Z}^{(0)}/\hat{B}$ -structures decreases, the weight of the arrow $\hat{A} \rightarrow \hat{Z}^{(0)}/\hat{B}$ does not decrease because neighbours of \hat{A} -vertices are biased towards remaining unstable. However, we can prove that some weights decrease as one would expect for random edges, namely for the edges between \hat{Y}_{bad} and $\hat{Z}^{(0)}/\hat{B}$, and the edges that go out of \hat{Y}_{bad} . The meta-graph after round 5 can be found in Figure 2.

■ **Figure 2** Meta-graph after round 5. The first value in a node S indicates, given a random vertex v in a random structure S_0 of type S , the size of the connected component of v induced by unstable vertices in S_0 . The weight of the edge from S to T indicates how many edges into T -structures there are in expectation from this connected component. Again, all bounds remain valid if we choose v as a random vertex as seen from structures of some type T' . The second value in a node S indicates the number of unstable vertices in structures of type S . All values are upper bounds and suppress any $\text{polylog}(d)$ factors. Compared to round 2, only a $\tilde{O}(1/d)$ -fraction of the nodes in \hat{Y}_{bad} and in $\hat{Z}^{(0)}/\hat{B}$ remain unstable. This decreases the weights from Y_{bad} and Z/B into \hat{Y}_{bad} and \hat{Z}/\hat{B} by a factor of $1/d$, but not the weights from \hat{X}_{bad} or \hat{A} into these sets, because the target nodes of these edges are biased towards remaining unstable. Moreover, the remaining \hat{Y}_{bad} -structures are scattered into connected components of expected size $\tilde{O}(1)$, which decreases the weights of all outgoing edges from \hat{Y}_{bad} by $1/d^2$. There are no cycles in which the weights multiply to strictly more than one, and every cycle with a product of one is a combination of the cycles $\hat{X}_{\text{bad}} \rightarrow \hat{X}_{\text{bad}}$, $\hat{X}_{\text{bad}} \leftrightarrow \hat{Y}_{\text{bad}}$ and $\hat{X}_{\text{bad}} \leftrightarrow \hat{Z}^{(0)}/\hat{B}$.

After round 5, there are still some cycles for which the weights do not multiply to $o(1)$, in particular the loop at \hat{X}_{bad} and the cycles $\hat{X}_{\text{bad}} \leftrightarrow \hat{Z}^{(0)}/\hat{B}$ and $\hat{X}_{\text{bad}} \leftrightarrow \hat{Y}_{\text{bad}}$. To deal with those, we use the fact that a typical leaf v of an \hat{X}_{bad} -structure sees neighbours in \hat{Y}_{bad} and in $\hat{Z}^{(0)}/\hat{B}$ after round 2, but these do not see further unstable neighbours in round 3 and 4 with probability $1 - \tilde{O}(1/d)$. In this case, we show that the leaf v stabilizes by round 20, and we may decrease the weights from \hat{X}_{bad} to \hat{Y}_{bad} and to $\hat{Z}^{(0)}/\hat{B}$ accordingly (Figure 3). In the remaining meta-graph, all walks accumulate decreasing factors except for the loop for \hat{X}_{bad} . However, since there are only $\tilde{O}(n/d^4)$ vertices in \hat{X}_{bad} structures, we can show that even the union of the connected components in G' of all these structures has size $\tilde{O}(n/d^4)$. For all vertices outside of this union, a long path in G' from such a vertex induces a long walk in the meta-graph, which is unlikely. Thus almost all vertices are either among the $\tilde{O}(n/d^4)$ vertices of \hat{X}_{bad} components, or are in components of diameter less than K , for a suitable constant K . For the latter one, we show that they stabilise after K further rounds if the vertices are not contained in any cycles of length at most $2K$.

■ **Figure 3** Meta-graph after round 20. Values have the same meaning as in Figure 2. Compared to Figure 2, the X_{bad} -structures have decreased by a $1/d$ factor in component size and in the number of unstable vertices, and the number of outgoing edges from \hat{X}_{bad} to \hat{Y}_{bad} and to $\hat{Z}^{(0)}/\hat{B}$ has decreased by a factor of $1/d$. The only remaining cycle in which the labels multiply to one is the loop at \hat{X}_{bad} .

6 Finishing the proof

For the last part of the proof, we fix a label, and show that this label cannot take over the complete graph. We only give the proof under the following simplifying assumption, and defer the full proof to the journal version. More precisely, we will assume that the label is ℓ_{max} , the maximum label, and after round 100 we change the labels of all unstable vertices and all vertices whose label appears in a cycle of length at most 200 to ℓ_{max} . This gives the label class of ℓ_{max} a considerable boost after round 100, but it also simplifies the setting. In particular, since every other vertex v is stable and not in a cycles of length at most 200, the definition of stable implies that all neighbours of v have either the label of v , the label ℓ_{max} , or other mutually distinct labels. Moreover, after round 100 they have at least one neighbour of the same label, so they can only change their label to ℓ_{max} . This remains true inductively, since if a vertex v loses its neighbours of the same label, then those neighbours change their label to ℓ_{max} , and thus v also changes its label to ℓ_{max} . Thus the only possible change in the remaining graph is that vertices change their label to ℓ_{max} .

Let us first estimate the number of vertices that have or receive label ℓ_{max} after round 100. There are at most $\tilde{O}(n/d^4)$ unstable vertices by Lemma 13. Moreover, at this point no label class has swallowed more than its 100-neighbourhood, which has size $O(d^{100}) = \tilde{O}(n/d^4)$ whp (Lemma 2). Consider some $\delta > 0$. By choosing $\varepsilon = \varepsilon(\delta)$ sufficiently small, it follows from Lemma 4 that the number of vertices that are contained in cycles of length at most 200 is $O(n^\delta)$. Since each label class has at most size $O(d^{100})$, the number of vertices with labels that appear in such cycles is $O(d^{100}n^\delta) = \tilde{O}(n/d^4)$, if we choose δ sufficiently small. Thus after round 100 the label class of ℓ_{max} has size $\tilde{O}(n/d^4)$. In the following, we will show that with high probability, the structure of $G_{n,p}$ is such that no set of this size can take over all the stable vertices in the graph.

First we argue that in order to take over a certain set of stable vertices S from one of the stable trees, there needs to be a certain number of edges going from S to the vertices holding label ℓ_{max} . Let $T \subseteq V$ be the set of vertices that initially (i.e., after the relabelings in round 100) have label ℓ_{max} , and denote for each $\ell \neq \ell_{\text{max}}$ by V_ℓ the set of vertices with

label ℓ at this time. Now fix some later point in time t . Let $T' \supseteq T$ be the set of vertices with label ℓ_{\max} at round t , and for each $\ell \neq \ell_{\max}$, let $S_\ell = V_\ell \cap T'$ be the set of vertices with label ℓ that have been taken over by ℓ_{\max} by round t . Then we claim that

$$e(T' \setminus T, T) + e(T' \setminus T) \geq |T' \setminus T| + \sum_{\ell \in \mathcal{L}, \ell \neq \ell_{\max}} (e(S_\ell, V_\ell \setminus S_\ell) + e(S_\ell)). \quad (1)$$

To prove (1), let us assume that v_1, v_2, \dots, v_k is the order in which the vertices of $T' \setminus T$ acquire the label ℓ_{\max} , where we break ties arbitrarily. For an index $i \leq k$, let ℓ_i be the label of v_i and let $T_i := T \cup \{v_1, \dots, v_{i-1}\}$. Note that

$$e(v_i, T') = e(v_i, T_i) + e(v_i, T' \setminus T_i).$$

Moreover, when v_i changes its label then all vertices in $V_{\ell_i} \setminus T_i$ still have label ℓ_i . Hence, v_i can only change its label if $e(v_i, T_i) \geq e(v_i, V_{\ell_i} \setminus T_i) + 1$, where the “+1” comes from the fact that the vertex v considers its own label as well when taking the majority. Hence,

$$\begin{aligned} e(v_i, T') &= e(v_i, T_i) + e(v_i, T' \setminus T_i) \\ &\geq e(v_i, V_{\ell_i} \setminus T_i) + 1 + e(v_i, T' \setminus T_i) \\ &= 1 + e(v_i, V_{\ell_i}) - e(v_i, \{v_1, \dots, v_{i-1}\} \cap V_{\ell_i}) + e(v_i, T' \setminus T_i). \end{aligned}$$

Now we sum both sides over all $1 \leq i \leq k$. Note that summing over $e(v_i, T')$ yields $e(T' \setminus T, T) + 2e(T' \setminus T)$ since edges in $T' \setminus T$ are counted twice. Likewise, summing over $e(v_i, V_{\ell_i})$ yields $\sum_{\ell \neq \ell_{\max}} (e(S_\ell, V_\ell \setminus S_\ell) + 2e(S_\ell))$, and summing over $e(v_i, \{v_1, \dots, v_{i-1}\} \cap V_{\ell_i})$ yields $\sum_{\ell \neq \ell_{\max}} e(S_\ell)$. Finally, summing over $e(v_i, T' \setminus T_i)$ yields $e(T' \setminus T)$. Thus, summing and canceling $e(T' \setminus T)$ yields

$$e(T' \setminus T, T) + e(T' \setminus T) \geq k + \sum_{\ell \in \mathcal{L}, \ell \neq \ell_{\max}} (e(S_\ell, V_\ell \setminus S_\ell) + e(S_\ell)),$$

which implies (1) as $k = |T' \setminus T|$.

Note that the term $e(T' \setminus T, T) + e(T' \setminus T)$ on the left hand side counts the number of edges by which the label class of ℓ_{\max} increases when it grows from T to T' , while the term $e(S_\ell, V_\ell \setminus S_\ell) + e(S_\ell)$ counts the number of edges within V_ℓ which have at least one endpoint in S_ℓ . So basically (1) says that in order to recruit k vertices, the label class is “charged” at least $k + \sum_{\ell \neq \ell_{\max}} (e(S_\ell, V_\ell \setminus S_\ell) + e(S_\ell))$ edges. It is easy to check that the minimal ratio of charged edges per recruited vertex is attained if $S_\ell = V_\ell$ is of size 2 for all $\ell \neq \ell_{\max}$, in which case the ratio is $3/2$ (three edges for two vertices).

Hence, in order to take over a set S of size k we need at least $3k/2$ edges in $S \cup V_{\ell_{\max}}$. However, a sparse $G_{n,p}$ does not have sets of this density of order $\Theta(n/d^3)$, as the following lemma shows.

► **Lemma 14** (Lemma 4.2 in [11]). *Consider $G_{n,p}$ with $1 \ll d = np = o(n)$. Let $\beta = \frac{3}{2} - \frac{1}{2 \log(d)}$, and set $s = \frac{n}{3d^3}$. Then with high probability no set of s vertices spans at least βs edges.*

We may thus conclude the proof by contradiction as follows. Assume that ℓ_{\max} would take over the graph. After round 100, it has size $s_0 = \tilde{O}(n/d^4)$, so at some later point the label class must have size $s = n/(2d^3)$. At this point, the number of edges in the label class is at least $\frac{3}{2}(s - s_0) = (1 - \tilde{O}(1/d)) \frac{3}{2}s \geq \beta s$, where β is as in Lemma 14. This is a contradiction to Lemma 14. Hence, the assumption must be wrong and ℓ_{\max} cannot take over the graph. In fact, the proof shows that the label class of ℓ_{\max} cannot grow to any size larger than $O(n/d^3)$.

7 Conclusion

We have shown that Max-LPA does not reach consensus on $G_{n,p}$ if $p = O(n^{-1+\varepsilon})$. Consequently it fails to identify communities in planted network models. This disproves a conjecture by Kothapalli, Pemmarajum, and Sardeshmukh. Our result is obtained by combining a careful local analysis of the process with suitable global properties of the network.

For the Max-LPA process, it is natural to assume that there is some threshold α such that for any small $\delta > 0$ we have that for $p = \Omega(n^{-\alpha+\delta})$ the Max-LPA process reaches consensus on $G_{n,p}$ with high probability, while for $p = O(n^{-\alpha-\delta})$ it does not reach consensus with high probability. Assuming such an α exists, it follows from our result that $\alpha \leq 1 - \varepsilon$; from [17] we know that $\alpha \geq 1/4$.

We conducted some experiments, which seem to suggest $\alpha = 4/5$. Our experimental data was obtained by doing a binary search where in every step we ran the algorithm on 32 independent $G_{n,p}$. If the majority of the runs converged with a unique label (modulo isolated vertices) then we decreased the value of p for the following run, otherwise we increased it. We stopped when the change in the probability was small enough. To visualize the data we plot it on a log-log-scale, with basis 2 for the log. In this setting the exponent becomes a linear factor. We computed a linear regression of the log-log-data (i.e., the line which minimizes the sum of the square-distances of the log-log data points), and obtained the line $\log_2(d) = 0.19964 \log_2(n) + 0.4652$. Since the leading constant is very close to 0.2, this suggests that the correct threshold might be $d = \Theta(n^{1/5})$ and thus $p = \Theta(n^{-4/5})$.

■ **Figure 4** Our experimental data with a linear regression. We plot an experimental evaluation of the threshold d such that the Max-LPA converges in 50% of the cases with a unique label, on a log-log scale. The experimental data is extremely well described by a line with slope ≈ 0.2 , suggesting that the threshold satisfies $d = \Theta(n^{1/5})$.

Abstract

Błasiok (SODA'18) recently introduced the notion of a subgaussian sampler, defined as an averaging sampler for approximating the mean of functions $f : \{0, 1\}^m \rightarrow \mathbb{R}$ such that $f(U_m)$ has subgaussian tails, and asked for explicit constructions. In this work, we give the first explicit constructions of subgaussian samplers (and in fact averaging samplers for the broader class of subexponential functions) that match the best known constructions of averaging samplers for $[0, 1]$ -bounded functions in the regime of parameters where the approximation error ε and failure probability δ are subconstant. Our constructions are established via an extension of the standard notion of randomness extractor (Nisan and Zuckerman, JCSS'96) where the error is measured by an arbitrary divergence rather than total variation distance, and a generalization of Zuckerman's equivalence (Random Struct. Alg.'97) between extractors and samplers. We believe that the framework we develop, and specifically the notion of an extractor for the Kullback–Leibler (KL) divergence, are of independent interest. In particular, KL-extractors are stronger than both standard extractors and subgaussian samplers, but we show that they exist with essentially the same parameters (constructively and non-constructively) as standard extractors.

1 Introduction

1.1 Averaging samplers

Averaging (or oblivious) samplers, introduced by Bellare and Rompel [6], are one of the main objects of study in pseudorandomness. Used to approximate the mean of a $[0, 1]$ -valued function with minimal randomness and queries, an averaging sampler takes a short random seed and produces a small set of correlated points such that any given $[0, 1]$ -valued function will (with high probability) take approximately the same mean on these points as on the entire space. Formally,

59:2 Samplers and Extractors for Unbounded Functions

► **Definition 1.1** ([6]). A function $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ is a (δ, ε) averaging sampler if for all $f : \{0, 1\}^m \rightarrow [0, 1]$, it holds that

$$\Pr_{x \sim U_n} \left[\left| \frac{1}{D} \sum_{i=1}^D f(\text{Samp}(x)_i) - \mathbb{E}[f(U_m)] \right| > \varepsilon \right] \leq \delta,$$

where U_n is the uniform distribution on $\{0, 1\}^n$. The number n is the randomness complexity of the sampler, and D is the sample complexity. A sampler is explicit if $\text{Samp}(x)_i$ can be computed in time $\text{poly}(n, m, \log D)$.

Traditionally, averaging samplers have been used in the context of randomness-efficient error reduction for algorithms and protocols, where the function f is the indicator of a set ($\{0, 1\}$ -valued), or more generally the acceptance probability of an algorithm or protocol ($[0, 1]$ -valued). There has been significant effort in the literature to establish optimal explicit and non-explicit constructions of samplers, which we summarize in Table 1. We recommend the survey of Goldreich [17] for more details, especially regarding non-averaging samplers¹.

■ **Table 1** Best known constructions of averaging samplers for $[0, 1]$ -valued functions.

Key Idea	Randomness complexity n	Sample complexity D	Best regime
Pairwise-independent Expander Neighbors [19]	$m + O(\log(1/\delta) + \log(1/\varepsilon))$	$O\left(\frac{1}{\delta\varepsilon^2}\right)$	$\delta = \Omega(1)$
Ramanujan Expander Neighbors ^{a)} [22, 19]	m	$O\left(\frac{1}{\delta\varepsilon^2}\right)$	$\delta = \Omega(1)$
Extractors [40, 19, 30, 20]	$m + (1 + \alpha) \cdot \log(1/\delta)$ any constant $\alpha > 0$	$\text{poly}(\log(1/\delta), 1/\varepsilon)$	$\varepsilon, \delta = o(1)$
Expander Walk Chernoff [16]	$m + O(\log(1/\delta)/\varepsilon^2)$	$O\left(\frac{\log(1/\delta)}{\varepsilon^2}\right)$	$\varepsilon = \Omega(1)$
Pairwise Independence [12]	$O(m)$	$O\left(\frac{1}{\delta\varepsilon^2}\right)$	None, but simple
Non-Explicit [40]	$m + \log(1/\delta) - \log \log(1/\delta)$ $+ O(1)$	$O\left(\frac{\log(1/\delta)}{\varepsilon^2}\right)$	All
Lower Bound [11, 40, 27]	$m + \log(1/\delta) + \log(1/\varepsilon)$ $- \log(D) - O(1)$	$\Omega\left(\frac{\log(1/\delta)}{\varepsilon^2}\right)$	N/A

a) Requires explicit constructions of Ramanujan graphs.

However, averaging samplers can also have uses beyond bounded functions: Blasiok [9], motivated by an application in streaming algorithms, introduced the notion of a *subgaussian sampler*, which he defined as an averaging sampler for functions $f : \{0, 1\}^m \rightarrow \mathbb{R}$ such that $f(U_m)$ is a subgaussian random variable. Since subgaussian random variables have strong tail bounds, subgaussian functions from $\{0, 1\}^m$ have a range contained in an interval of length $O(\sqrt{m})$, and thus one can construct a subgaussian sampler from a $[0, 1]$ -sampler by simply scaling the error ε by a factor of $O(\sqrt{m})$. Unfortunately, looking at Table 1 one sees that this

¹ A non-averaging sampler is an algorithm Samp which makes oracle queries to f and outputs an estimate of its average which is good with high probability, but need not simply output the average of f 's values on the queried points.

induces a multiplicative dependence on m in the sample complexity, and for the expander walk sampler induces a dependence of $m \log(1/\delta)$ in the randomness complexity. This loss can be avoided for some samplers, such as the sampler of Chor and Goldreich [12] based on pairwise independence (as its analysis requires only bounded variance) and (as we will show) the Ramanujan Expander Neighbor sampler of [22, 19], but Błasiok showed [8] that the expander-walk sampler does not in general act as a subgaussian sampler without reducing the error to $o(1)$. We remark briefly that the median-of-averages sampler of Bellare, Goldreich, and Goldwasser [5] still works and is optimal up to constant factors in the subgaussian setting (since the underlying pairwise independent sampler works), but it is not an averaging sampler¹, and matching its parameters with an averaging sampler remains open in general even for $[0, 1]$ -valued functions.

One of the contributions of this work is to give explicit averaging samplers for subgaussian functions (in fact even for *subexponential* functions that satisfy weaker tail bounds) matching the extractor-based samplers for $[0, 1]$ -valued functions in Table 1 (up to the hidden polynomial in the sample complexity). This achieves the best parameters currently known in the regime of parameters where ε and δ are both subconstant, and in particular has no dependence on m in the sample complexity. We also show non-constructively that subexponentially samplers exist with essentially the same parameters as $[0, 1]$ -valued samplers.

► **Theorem 1.2** (Informal version of Theorem 6.1). *For every integer $m \in \mathbb{N}$ and $1 > \delta, \varepsilon > 0$, there is an explicit subgaussian (in fact subexponential) sampler with randomness complexity $n = m + O(\log(1/\delta))$ and sample complexity $D = \text{poly}(\log(1/\delta), 1/\varepsilon)$.*

In the full version of this work [1], we show also that for every $m \in \mathbb{N}$, $1 > \delta, \varepsilon > 0$, and $\alpha > 0$, there is a function $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ that is:

- *an explicit subexponential sampler with randomness complexity $n = m + (1 + \alpha) \cdot \log(1/\delta)$ and sample complexity $D = \text{poly}(\log(1/\delta), 1/\varepsilon)$.*
- *a non-constructive subexponential sampler with randomness complexity $n = m + \log(1/\delta) - \log \log(1/\delta) + O(1)$ and sample complexity $D = O(\log(1/\delta)/\varepsilon^2)$.*

1.2 Randomness extractors

To prove Theorem 1.2, we develop a corresponding theory of generalized *randomness extractors* which we believe is of independent interest. For bounded functions, Zuckerman [40] showed that averaging samplers are essentially equivalent to randomness extractors, and in fact several of the best-known constructions of such samplers arose as extractor constructions. Formally, a randomness extractor is defined as follows:

► **Definition 1.3** (Nisan and Zuckerman [26]). *A function $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is said to be a (k, ε) extractor if for every distribution X over $\{0, 1\}^n$ satisfying $2^{-k} \geq \max_{x \in \{0, 1\}^n} \Pr[X = x]$, the distributions $\text{Ext}(X, U_d)$ and U_m are ε -close in total variation distance. Equivalently, for all $f : \{0, 1\}^m \rightarrow [0, 1]$ it holds that $\mathbb{E}[f(\text{Ext}(X, U_d))] - \mathbb{E}[f(U_m)] \leq \varepsilon$. The number d is called the seed length, and m the output length.*

The formulation of Definition 1.3 in terms of $[0, 1]$ -valued functions implies that extractors produce an output distribution that is indistinguishable from uniform by all bounded functions f . It is therefore natural to consider a variant of this definition for a different set \mathcal{F} of test functions $f : \{0, 1\}^m \rightarrow \mathbb{R}$ which need not be bounded.

► **Definition 1.4** (Special case of Definition 3.1 using Definition 2.5). *A function $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is said to be a (k, ε) extractor for a set of real-valued functions \mathcal{F} from $\{0, 1\}^m$ if for every distribution X over $\{0, 1\}^n$ satisfying $\max_{x \in \{0, 1\}^n} \Pr[X = x] \leq 2^{-k}$ and every $f \in \mathcal{F}$, it holds that $\mathbb{E}[f(\text{Ext}(X, U_d))] - \mathbb{E}[f(U_m)] \leq \varepsilon$.*

We show that much of the theory of extractors and samplers carries over to this more general setting. In particular, we generalize the connection of Zuckerman [40] to show that extractors for a class of functions of \mathcal{F} are also samplers for that class, along with the converse (though as for total variation distance, there is some loss of parameters in this direction). Thus, to construct a subgaussian sampler it suffices (and is preferable) to construct a corresponding extractor for subgaussian test functions, which is how we prove Theorem 1.2.

Unfortunately, the distance induced by subgaussian test functions is not particularly pleasant to work with: for example the point masses on 0 and 1 in $\{0, 1\}$ are $O(1)$ apart, but embedding them in the larger universe $\{0, 1\}^m$ leads to distributions which are $\Theta(\sqrt{m})$ apart. We solve this problem by constructing extractors for a stronger notion, the *Kullback–Leibler (KL) divergence*, equivalently, extractors whose output is required to have very high Shannon entropy.

► **Definition 1.5** (Special case of Definition 3.1 using KL divergence). *A function $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is said to be a (k, ε) KL-extractor if for every distribution X over $\{0, 1\}^m$ satisfying $\max_{x \in \{0, 1\}^n} \Pr[X = x] \leq 2^{-k}$ it holds that $\text{KL}(\text{Ext}(X, U_d) \parallel U_m) \leq \varepsilon$, or equivalently $H(\text{Ext}(X, U_d)) \geq m - \varepsilon$.*

A strong form of Pinsker’s inequality (e.g. [10, Lemma 4.18]) implies that a (k, ε^2) KL-extractor is also a (k, ε) extractor for subgaussian test functions. The KL divergence has the advantage that is nonincreasing under the application of functions (the famous *data-processing inequality*), and although it does not satisfy a traditional triangle inequality, it does satisfy a similar inequality when one of the segments satisfies stronger ℓ_2 bounds. These properties allow us to show in the full version of this paper that the zig-zag product for extractors of Reingold, Wigderson, and Vadhan [30] also works for KL-extractors, and therefore to construct KL-extractors with seed length depending on n and k only through the *entropy deficiency* $n - k$ of X rather than n itself, which in the sampler perspective corresponds to a sampler with sample complexity depending on the failure probability δ rather than the universe size 2^m . Hence, we prove Theorem 1.2 by constructing corresponding KL-extractors.

► **Theorem 1.6** (Informal version of Theorem 6.5). *For all integers m and $1 > \delta, \varepsilon > 0$ there is an explicit (k, ε) KL-extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with $n = m + O(\log(1/\delta))$, $k = n - \log(1/\delta)$, and $d = O(\log \log(1/\delta) + \log(1/\varepsilon))$.*

In the full version, we show that n can be as small as $m + (1 + \alpha) \cdot \log(1/\delta)$ for any constant $\alpha > 0$.

Though the above theorem is most interesting in the high min-entropy regime where $n - k = o(n)$, we also show the existence of KL-extractors matching most of the existing constructions of total variation extractors. In particular, we note that extractors for ℓ_2 are immediately KL-extractors without loss of parameters, and also that any extractor can be made a KL-extractor by taking slightly smaller error, so that the extractors of Guruswami, Umans, and Vadhan [20] can be taken to be KL-extractors with essentially the same parameters.

Furthermore, in addition to our explicit constructions, we also show non-constructively that KL-extractors (and hence subgaussian extractors) exist with very good parameters:

► **Theorem 1.7** (Formal statement and proof in full version [1]). *For any integers $k < n \in \mathbb{N}$ and $1 > \varepsilon > 0$ there is a (k, ε) KL-extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with $d = \log(n - k) + \log(1/\varepsilon) + O(1)$ and $m = k + d - \log(1/\varepsilon) - O(1)$.*

One key thing to note about the nonconstructive KL extractors of the above theorem is that they incur an entropy loss of only $1 \cdot \log(1/\varepsilon)$, whereas total variation extractors necessarily incur entropy loss $2 \cdot \log(1/\varepsilon)$ by the lower bound of Radhakrishnan and Ta-Shma [27]. In particular, by Pinsker’s inequality, (k, ε^2) KL-extractors with the above parameters are also optimal (k, ε) standard (total variation) extractors [27], so that one does not lose anything by constructing a KL-extractor rather than a total variation extractor. We also remark that the above theorem gives subgaussian samplers with better parameters than a naive argument that a random function should directly be a subgaussian sampler, as it avoids the need to take a union bound over $O(M^M) = O(2^{M \log M})$ test functions (for $M = 2^m$) which results in additional additive log log factors in the randomness complexity.

In the total variation setting, there are only a couple of methods known to explicitly achieve optimal entropy loss $2 \cdot \log(1/\varepsilon)$, the easiest of which is to use an extractor which natively has this sort of loss, of which only three are known: An extractor from random walks over Ramanujan Graphs due to Goldreich and Wigderson [19], the Leftover Hash Lemma due to Impagliazzo, Levin, and Luby [21] (see also [23, 7]), and the extractor based on almost-universal hashing of Srinivasan and Zuckerman [33]. Unfortunately, all of these are ℓ_2 extractors and so must have seed length linear in $\min(n - k, m)$ (cf. [35, Problem 6.4]), rather than logarithmic in $n - k$ as known non-constructively. The other alternative is to use the generic reduction of Raz, Reingold, and Vadhan [28] which turns any extractor Ext with entropy loss Δ into one with entropy loss $2 \cdot \log(1/\varepsilon) + O(1)$ by paying an additive $O(\Delta + \log(n/\varepsilon))$ in seed length. We show in the full version of this paper that all of these ℓ_2 extractors and the [28] transformation also work to give KL-extractors with entropy loss $1 \cdot \log(1/\varepsilon) + O(1)$, so that applications which require minimal entropy loss can also use explicit constructions of KL-extractors.

1.3 Future directions

Broadly speaking, we hope that the perspective of KL-extractors will bring new tools (perhaps from information theory) to the construction of extractors and samplers. For example, since KL-extractors can have seed length with dependence on ε of only $1 \cdot \log(1/\varepsilon)$, trying to explicitly construct a KL-extractor with seed length $1 \cdot \log(1/\varepsilon) + o(\min(n - k, k))$ may also shed light on how to achieve optimal dependence on ε in the total variation setting.

In the regime of constant $\varepsilon = \Omega(1)$, we do not have explicit constructions of subgaussian samplers matching the expander-walk sampler of Gillman [16] for $[0, 1]$ -valued functions, which achieves randomness complexity $m + O(\log(1/\delta))$ and sample complexity $O(\log(1/\delta))$, as asked for by Blasiok [9]. From the extractor point-of-view, it would suffice (by the reduction of [19, 30] that we analyze for KL-extractors) to construct explicit *linear degree* KL-extractors with parameters matching the linear degree extractor of Zuckerman [41], i.e. with seed length $d = \log(n) + O(1)$ and $m = \Omega(k)$ for $\varepsilon = \Omega(1)$. A potentially easier problem, since the Zuckerman linear degree extractor is itself based on the expander-walk sampler, could be to instead match the parameters of the near-linear degree extractors of Ta-Shma, Zuckerman, and Safra [34] based on Reed–Muller codes, thereby achieving sample complexity $O(\log(1/\delta) \cdot \text{poly} \log(1/\delta))$.

Finally, we hope that KL-extractors can also find uses beyond being subgaussian samplers and total variation extractors: for example it seems likely that there are applications (perhaps in coding or cryptography, cf. [4]) where it is more important to have high Shannon entropy in the output than small total variation distance to uniform, in which case one may be able to use (k, ε) KL-extractors with entropy loss only $1 \cdot \log(1/\varepsilon)$ directly, rather than a total variation extractor or (k, ε^2) KL-extractor with entropy loss $2 \cdot \log(1/\varepsilon)$.

2 Preliminaries

2.1 (Weak) statistical divergences and metrics

Our results in general will require very few assumptions on notions of “distance” between probability distributions, so we will give a general definition and indicate in our theorems when we need which assumptions.

► **Definition 2.1.** A weak statistical divergence (or simply weak divergence) on a finite set \mathcal{X} is a function D from pairs of probability distributions over \mathcal{X} to $\mathbb{R} \cup \{\pm\infty\}$. We write $D(P \parallel Q)$ for the value of D on distributions P and Q . Furthermore

1. If $D(P \parallel Q) \geq 0$ with equality iff $P = Q$, then D is positive-definite, and we simply call D a divergence.
2. If $D(P \parallel Q) = D(Q \parallel P)$, then D is symmetric.
3. If $D(P \parallel R) \leq D(P \parallel Q) + D(Q \parallel R)$, then D satisfies the triangle inequality.
4. If $D(\lambda P_1 + (1 - \lambda)P_2 \parallel \lambda Q_1 + (1 - \lambda)Q_2) \leq \lambda D(P_1 \parallel Q_1) + (1 - \lambda)D(P_2 \parallel Q_2)$ for all $\lambda \in [0, 1]$, then D is jointly convex. If this holds only when $Q_1 = Q_2$ then D is convex in its first argument.
5. If D is defined on all finite sets \mathcal{Y} and for all functions $f : \mathcal{X} \rightarrow \mathcal{Y}$ the divergence is nonincreasing under f , that is $D(f(P) \parallel f(Q)) \leq D(P \parallel Q)$, then D satisfies the data-processing inequality.

If D is positive-definite, symmetric, and satisfies the triangle inequality, then it is called a metric.

► **Example 2.2.** The ℓ_p distance for $p > 0$ between probability distributions over \mathcal{X} is

$$d_{\ell_p}(P, Q) \stackrel{\text{def}}{=} \left(\sum_{x \in \mathcal{X}} |P_x - Q_x|^p \right)^{1/p}$$

and is positive-definite and symmetric. Furthermore, for $p \geq 1$ it satisfies the triangle inequality (and so is a metric), and is jointly convex. The ℓ_p distance is nonincreasing in p .

► **Example 2.3.** The total variation distance is

$$d_{TV}(P, Q) \stackrel{\text{def}}{=} \frac{1}{2} d_{\ell_1}(P, Q) = \sup_{S \subseteq \mathcal{X}} |\Pr[P \in S] - \Pr[Q \in S]| = \sup_{f \in [0, 1]^{\mathcal{X}}} (\mathbb{E}[f(P)] - \mathbb{E}[f(Q)])$$

and is a jointly convex metric that satisfies the data-processing inequality.

► **Example 2.4** (Rényi Divergences [31]). For two probability distributions P and Q over a finite set \mathcal{X} , the Rényi α -divergence or Rényi divergence of order α is defined for real $0 < \alpha \neq 1$ by

$$D_\alpha(P \parallel Q) \stackrel{\text{def}}{=} \frac{1}{\alpha - 1} \log \left(\sum_{x \in \mathcal{X}} \frac{P_x^\alpha}{Q_x^{\alpha-1}} \right)$$

where the logarithm is in base 2 (as are all logarithms in this paper unless noted otherwise). The Rényi divergence is continuous in α and so is defined by taking limits for $\alpha \in \{0, 1, \infty\}$, giving for $\alpha = 0$ the divergence $D_0(P \parallel Q) \stackrel{\text{def}}{=} \log(1 / \Pr_{x \sim Q}[P_x \neq 0])$, for $\alpha = 1$ the Kullback–Leibler (or KL) divergence

$$\text{KL}(P \parallel Q) \stackrel{\text{def}}{=} D_1(P \parallel Q) = \sum_{x \in \mathcal{X}} P_x \log \frac{P_x}{Q_x},$$

and for $\alpha = \infty$ the *max-divergence* $D_\infty(P \parallel Q) \stackrel{\text{def}}{=} \max_{x \in X} \log \frac{P_x}{Q_x}$. The Rényi divergence is nondecreasing in α . Furthermore, when $\alpha \leq 1$ the Rényi divergence is jointly convex, and for all α the Rényi divergence satisfies the data-processing inequality [37].

When $Q = U_{\mathcal{X}}$ is the uniform distribution over the set \mathcal{X} , then for all α , $D_\alpha(P \parallel U_{\mathcal{X}}) = \log|\mathcal{X}| - H_\alpha(P)$ where $0 \leq H_\alpha(P) \leq \log|\mathcal{X}|$ is called the *Rényi α -entropy of P* . For $\alpha = 0$, $H_0(P) = \log|\text{Supp}(P)|$ is the *max-entropy of P* , for $\alpha = 1$, $H_1(P) = \sum_{x \in \mathcal{X}} P_x \log(1/P_x)$ is the *Shannon entropy of P* , and for $\alpha = \infty$, $H_\infty(P) = \min_{x \in \mathcal{X}} \log(1/P_x)$ is the *min-entropy of P* .

For $\alpha = 2$, the Rényi 2-entropy can be expressed in terms of the ℓ_2 -distance to uniform:

$$\log|\mathcal{X}| - H_2(P) = D_2(P \parallel U_{\mathcal{X}}) = \log(1 + |\mathcal{X}| \cdot d_{\ell_2}(P, U_{\mathcal{X}})^2)$$

2.2 Statistical weak divergences from test functions

Zuckerman's connection [40] between samplers for bounded functions and extractors for total variation distance is based on the following standard characterization of total variation distance as the maximum distinguishing advantage achieved by bounded functions,

$$d_{TV}(P, Q) = \sup_{f \in [0,1]^{\mathcal{X}}} \mathbb{E}[f(P)] - \mathbb{E}[f(Q)].$$

By considering an arbitrary class of functions in the supremum, we get the following weak divergence:

► **Definition 2.5.** Given a finite \mathcal{X} and a set of real-valued functions $\mathcal{F} \subseteq \mathbb{R}^{\mathcal{X}}$, the \mathcal{F} -distance on \mathcal{X} between probability measures on \mathcal{X} is denoted by $D^{\mathcal{F}}$ and is defined as

$$D^{\mathcal{F}}(P \parallel Q) \stackrel{\text{def}}{=} \sup_{f \in \mathcal{F}} (\mathbb{E}[f(P)] - \mathbb{E}[f(Q)]) = \sup_{f \in \mathcal{F}} D^{\{f\}}(P \parallel Q),$$

where we use a superscript to avoid confusion with the Csiszár-Morimoto-Ali-Silvey f -divergences [13, 24, 2].

We call the set of functions \mathcal{F} symmetric if for all $f \in \mathcal{F}$ there is $c \in \mathbb{R}$ and $g \in \mathcal{F}$ such that $g = c - f$, and distinguishing if for all $P \neq Q$ there exists $f \in \mathcal{F}$ with $D^{\{f\}}(P \parallel Q) > 0$.

► **Example 2.6.** If $\mathcal{F} = \{0, 1\}^{\mathcal{X}}$ or $\mathcal{F} = [0, 1]^{\mathcal{X}}$, then $D^{\mathcal{F}}$ is exactly the total variation distance.

► **Remark 2.7.** An equivalent definition of \mathcal{F} being symmetric is that for all $f \in \mathcal{F}$ there exists $g \in \mathcal{F}$ with $D^{\{g\}}(P \parallel Q) = -D^{\{f\}}(P \parallel Q) = D^{\{f\}}(Q \parallel P)$ for all distributions P and Q . Hence, one might also consider a weaker notion of symmetry that reverses quantifiers, where \mathcal{F} is “weakly-symmetric” if for all $f \in \mathcal{F}$ and distributions P and Q there exists $g \in \mathcal{F}$ such that $D^{\{g\}}(P \parallel Q) = -D^{\{f\}}(P \parallel Q) = D^{\{f\}}(Q \parallel P)$. However, such a class \mathcal{F} gives exactly the same weak divergence $D^{\mathcal{F}}$ as its “symmetrization” $\overline{\mathcal{F}} = \mathcal{F} \cup \{-f \mid f \in \mathcal{F}\}$, so we do not need to introduce this more complex notion.

► **Remark 2.8.** By identifying distributions with their probability mass function, one can realize $\mathbb{E}[f(P)] - \mathbb{E}[f(Q)]$ as an inner product $\langle P - Q, f \rangle$. Definition 2.5 can thus be written as $D^{\mathcal{F}}(P \parallel Q) = \sup_{f \in \mathcal{F}} \langle P - Q, f \rangle$, which is essentially the notion of indistinguishability considered in several prior works, (see e.g. the survey of Reingold, Trevisan, Tulsiani, and Vadhan [29]), but without requiring all f to be bounded.

► **Remark 2.9.** For simplicity, all our probabilistic distributions are given only for random variables and distributions over finite sets as this is all we need for our application. A more general version of Definition 2.5 has been studied by e.g. Zolotarev [39] and Müller [25] and is commonly used in developments of Stein's method in probability.

We now note some basic properties of $D^{\mathcal{F}}$.

► **Lemma 2.10.** *Let $\mathcal{F} \subseteq \mathbb{R}^{\mathcal{X}}$ be a set of real-valued functions over a finite set \mathcal{X} . Then $D^{\mathcal{F}}$ satisfies the triangle inequality and is jointly convex, and*

1. *if \mathcal{F} is symmetric then $D^{\mathcal{F}}$ is symmetric and*

$$D^{\mathcal{F}}(P \parallel Q) = \sup_{f \in \mathcal{F}} \left| \mathbb{E}[f(P)] - \mathbb{E}[f(Q)] \right| \geq 0,$$

2. *if \mathcal{F} is distinguishing then $D^{\mathcal{F}}$ is positive-definite, so that if \mathcal{F} is both symmetric and distinguishing then $D^{\mathcal{F}}$ is a jointly convex metric on probability distributions over \mathcal{X} , in which case we also use the notation $d_{\mathcal{F}}(P, Q) \stackrel{\text{def}}{=} D^{\mathcal{F}}(P \parallel Q)$.*

Furthermore, the notion of dual norm has an appealing interpretation in this framework via Remark 2.8, generalizing the fact that total variation distance corresponds to $[0, 1]$ -valued test functions (or equivalently that ℓ_1 distance corresponds to $[-1, 1]$ -valued functions).

► **Proposition 2.11.** *Let $1 \leq p, q \leq \infty$ be Hölder conjugates (meaning $1/p + 1/q = 1$), and let*

$$\mathcal{M}_q \stackrel{\text{def}}{=} \left\{ f : \{0, 1\}^m \rightarrow \mathbb{R} \mid \|f(U_m)\|_q \stackrel{\text{def}}{=} \mathbb{E}[|f(U_m)|^q]^{1/q} \leq 1 \right\}$$

be the set of real-valued functions from $\{0, 1\}^m$ with bounded q -th moments. Then $d_{\ell_p} = 2^{-m/q} \cdot d_{\mathcal{M}_q}$, in the sense that for all probability distributions A and B over $\{0, 1\}^m$ it holds that $d_{\ell_p}(A, B) = 2^{-m/q} \cdot d_{\mathcal{M}_q}(A, B)$. In particular, taking $p = 1$ and $q = \infty$ recovers the result for ℓ_1 (equivalently total variation) distance.

Proof Sketch. As mentioned this is just the standard fact that the ℓ_p and ℓ_q norms are dual, but for completeness we include a proof in Appendix A. ◀

3 Extractors for weak divergences and connections to samplers

3.1 Definitions

We now use this machinery to extend the notion of an extractor due to Nisan and Zuckerman [26] and the average-case variant of Dodis, Ostrovsky, Reyzin, and Smith [14].

► **Definition 3.1** (Extends Definition 1.4). *Let D be a weak divergence on the set $\{0, 1\}^m$, and $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$. Then if for all distributions X over $\{0, 1\}^n$ with $H_{\infty}(X) \geq k$ it holds that*

1. $D(\text{Ext}(X, U_d) \parallel U_m) \leq \varepsilon$, *then Ext is said to be a (k, ε) extractor for D , or a (k, ε) D-extractor.*
2. $\mathbb{E}_{s \sim U_d}[D(\text{Ext}(X, s) \parallel U_m)] \leq \varepsilon$, *then Ext is said to be a (k, ε) strong extractor for D , or a (k, ε) strong D-extractor.*

Furthermore, if for all joint distributions (Z, X) where X is distributed over $\{0, 1\}^n$ with $\tilde{H}_{\infty}(X|Z) \stackrel{\text{def}}{=} \log(1/\mathbb{E}_{z \sim Z}[2^{-H_{\infty}(X|Z=z)}]) \geq k$, it holds that

3. $\mathbb{E}_{z \sim Z}[D(\text{Ext}(X|_{Z=z}, U_d) \parallel U_m) \leq \varepsilon]$, *then Ext is said to be a (k, ε) average-case extractor for D , or a (k, ε) average-case D-extractor.*
4. $\mathbb{E}_{z \sim Z, s \sim U_d}[D(\text{Ext}(X|_{Z=z}, s) \parallel U_m)] \leq \varepsilon$, *then Ext is said to be a (k, ε) average-case strong extractor for D , or a (k, ε) average-case strong D-extractor.*

► **Remark 3.2.** By taking D to be the total variation distance we recover the standard definitions of extractor and strong extractor due to [26] and the definition of average-case extractor due to [14].

However, our definitions are phrased slightly differently for strong and average-case extractors as an expectation rather than a joint distance, that is, for strong average-case extractors we require a bound on the expectation $\mathbb{E}_{z \sim Z, s \sim U_d} [D(\text{Ext}(X|_{Z=z}, s) \parallel U_m)]$ rather than a bound on $D(Z, U_d, \text{Ext}(X, U_d) \parallel Z, U_d, U_m)$. In our setting, the weak divergence D need not be defined over the larger joint universe, but it is defined for all random variables over $\{0, 1\}^m$. In the case of d_{TV} and KL divergence, both definitions are equivalent (for KL divergence, this is an instance of the *chain rule*).

In the full version of this work [1] we include more discussion about this definition, and also generalize a result of Vadhan [35, Problem 6.8] showing that all $D^{\mathcal{F}}$ -extractors are average-case with only a constant factor loss in the error parameter.

We also give the natural definition of averaging samplers for arbitrary classes of functions \mathcal{F} extending Definition 1.1, along with the strong variant of Zuckerman [40].

► **Definition 3.3.** Given a class of functions $\mathcal{F} : \{0, 1\}^m \rightarrow \mathbb{R}$, a function $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ is said to be a (δ, ε) strong averaging sampler for \mathcal{F} or a (δ, ε) strong averaging \mathcal{F} -sampler if for all $f \in \mathcal{F}$, it holds that

$$\Pr_{x \sim U_n} \left[\mathbb{E}_{i \sim U_{[D]}} \left[f_i(\text{Samp}(x)_i) - \mathbb{E}[f_i(U_m)] \right] > \varepsilon \right] \leq \delta$$

where $[D] = \{1, \dots, D\}$. If this holds only when $f_1 = \dots = f_D$, then it is called a (non-strong) (δ, ε) averaging sampler for \mathcal{F} or (δ, ε) averaging \mathcal{F} -sampler. We say that Samp is a (δ, ε) strong absolute averaging sampler for \mathcal{F} if it also holds that

$$\Pr_{x \sim U_n} \left[\left| \mathbb{E}_{i \sim U_{[D]}} \left[f_i(\text{Samp}(x)_i) - \mathbb{E}[f_i(U_m)] \right] \right| > \varepsilon \right] \leq \delta.$$

with the analogous definition for non-strong samplers.

► **Remark 3.4.** We separated a single-sided version of the error bound in Definition 3.3 as in [35], as it makes the connection between extractors and samplers cleaner and allows us to be specific about what assumptions are needed. Note that if \mathcal{F} is symmetric then every (δ, ε) (strong) sampler for \mathcal{F} is a $(2\delta, \varepsilon)$ (strong) absolute sampler for \mathcal{F} , recovering the standard notion up to a factor of 2 in δ .

3.2 Equivalence of extractors and samplers

We now show that Zuckerman's connection [40] does indeed generalize to this broader setting as promised.

► **Theorem 3.5.** Let $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ be an $(n - \log(1/\delta), \varepsilon)$ -extractor (respectively strong extractor) for the weak divergence $D^{\mathcal{F}}$ defined by a class of test functions $\mathcal{F} : \{0, 1\}^m \rightarrow \mathbb{R}$ as in Definition 2.5. Then the function $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ for $D = 2^d$ defined by $\text{Samp}(x)_i = \text{Ext}(x, i)$ is a (δ, ε) -sampler (respectively strong sampler) for \mathcal{F} .

Proof sketch. The proof is given in Appendix A and is similar to that of Zuckerman [40]. The key idea is that for any function $f \in \mathcal{F}$, the set of seeds B_f which are bad for Samp with respect to f must be small, as otherwise $\mathbb{E}[f(\text{Ext}(U_{B_f}, U_d))] - \mathbb{E}[f(U_m)] > \varepsilon$ contradicting the extractor property, where U_{B_f} is uniform over the set B_f . ◀

► **Remark 3.6.** Hölder's inequality implies that an extractor for ℓ_p with error $\varepsilon \cdot 2^{-m(p-1)/p}$ is also an ℓ_1 extractor and thus $[-1, 1]$ -averaging sampler with error ε . Proposition 2.11 and Theorem 3.5 show that they are in fact samplers for the much larger class of functions $\mathcal{M}_{p/(p-1)}$ with bounded $p/(p-1)$ moments (rather than just ∞ moments), also with error ε .

Furthermore, if all the functions in \mathcal{F} have bounded deviation from their mean (for example, subgaussian functions from $f : \{0, 1\}^m \rightarrow \mathbb{R}$ have such a bound of $O(\sqrt{m})$ by the tail bounds from Lemma 4.3), then we also have a partial converse that recovers the standard converse in the case of total variation distance.

► **Theorem 3.7.** *Let \mathcal{F} be a class of functions $\mathcal{F} \subset \{0, 1\}^m \rightarrow \mathbb{R}$ with finite maximum deviation from the mean, meaning $\max \text{dev}(\mathcal{F}) \stackrel{\text{def}}{=} \sup_{f \in \mathcal{F}} \max_{x \in \{0, 1\}^m} (f(x) - \mathbb{E}[f(U_m)]) < \infty$. Then given a (δ, ε) \mathcal{F} -sampler (respectively (δ, ε) strong \mathcal{F} -sampler) $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$, the function $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ for $d = \log D$ defined by $\text{Ext}(x, i) = \text{Samp}(x)_i$ is a $(k, \varepsilon + \delta \cdot 2^{n-k} \cdot \max \text{dev}(\mathcal{F}))$ $D^{\mathcal{F}}$ -extractor (respectively strong $D^{\mathcal{F}}$ -extractor) for every $0 \leq k \leq n$.*

In particular, Ext is an $(n - \log(1/\delta) + \log(1/\eta), \varepsilon + \eta \cdot \max \text{dev}(\mathcal{F}))$ average-case $D^{\mathcal{F}}$ -extractor (respectively strong average-case $D^{\mathcal{F}}$ -extractor) for every $\delta \leq \eta \leq 1$.

Proof sketch. The proof is given in Appendix A and is again similar to that of Zuckerman [40]. The key idea is that for any function $f \in \mathcal{F}$, since most $x \in \{0, 1\}^n$ are good for Samp , for any source X of sufficient min-entropy, the probability over x from X that $\mathbb{E}[f(\text{Ext}(x, U_d))] - \mathbb{E}[f(U_m)] > \varepsilon$ must be at most η , and in this failure case we can fall back on the trivial bound of $\max \text{dev}(\mathcal{F})$. ◀

4 Subgaussian distance and connections to other notions

Now that we've introduced the general machinery we need, we can go back to our motivation of subgaussian samplers. We will need some standard facts about subgaussian and subexponential random variables, we recommend the book of Vershynin [38] for an introduction.

► **Definition 4.1.** *A real-valued mean-zero random variable Z is said to be subgaussian with parameter σ if for every $t \in \mathbb{R}$ the moment generating function of Z is bounded as $\ln \mathbb{E}[e^{tZ}] \leq \frac{t^2 \sigma^2}{2}$. If this is only holds for $|t| \leq b$ then Z is said to be (σ, b) -subgamma, and if Z is $(\sigma, 1/\sigma)$ -subgamma then Z is said to be subexponential with parameter σ .*

► **Remark 4.2.** There are many definitions of subgaussian (and especially subexponential) random variables in the literature, but they are all equivalent up to constant factors in σ and only affect constants already hidden in big- O 's.

► **Lemma 4.3.** *Let Z be a real-valued random variable. Then*

1. (Hoeffding's lemma) *If Z is bounded in the interval $[0, 1]$, then $Z - \mathbb{E}[Z]$ is subgaussian with parameter $1/2$.*
2. *If Z is mean-zero, then Z is subgaussian (respectively subexponential) with parameter σ if and only if cZ is subgaussian (respectively subexponential) with parameter $|c|\sigma$ for every $c \neq 0$.*

Furthermore, if Z is mean-zero and subgaussian with parameter σ , then

1. *For all $t > 0$, $\max(\Pr[Z > t], \Pr[Z < -t]) \leq e^{-t^2/2\sigma^2}$.*
2. $\|Z\|_p \stackrel{\text{def}}{=} \mathbb{E}[|Z|^p]^{1/p} \leq 2\sigma\sqrt{p}$ for all $p \geq 1$.
3. *Z is subexponential with parameter σ .*

We are now in a position to formally define the *subgaussian distance*.

► **Definition 4.4.** For every finite set \mathcal{X} , we define the set $\mathcal{G}_{\mathcal{X}}$ of subgaussian test functions on \mathcal{X} (respectively the set $\mathcal{E}_{\mathcal{X}}$ of subexponential test functions on \mathcal{X}) to be the set of functions $f : \mathcal{X} \rightarrow \mathbb{R}$ such that the random variable $f(U_{\mathcal{X}})$ is mean-zero and subgaussian (respectively subexponential) with parameter $1/2$. Then $\mathcal{G}_{\mathcal{X}}$ and $\mathcal{E}_{\mathcal{X}}$ are symmetric and distinguishing, so by Lemma 2.10 the respective distances induced by $\mathcal{G}_{\mathcal{X}}$ and $\mathcal{E}_{\mathcal{X}}$ are jointly convex metrics called the subgaussian distance and subexponential distance respectively and are denoted as $d_{\mathcal{G}}(P, Q)$ and $d_{\mathcal{E}}(P, Q)$.

► **Remark 4.5.** We choose subgaussian parameter $1/2$ in Definition 4.4 as by Hoeffding’s lemma, all functions $f : \{0, 1\}^m \rightarrow [0, 1]$ have that $f(U_m) - \mathbb{E}[f(U_m)]$ is subgaussian with parameter $1/2$, so this choice preserves the same “scale” as total variation distance. However, the choice of parameter is essentially irrelevant by linearity, as different choices of parameter simply scale the metric $d_{\mathcal{G}}$.

Note that absolute averaging samplers for $\mathcal{G}_{\{0,1\}^m}$ from Definition 3.3 are exactly subgaussian samplers as defined in the introduction. Thus, by Remark 3.4 and Theorem 3.5, to construct subgaussian samplers it is enough to construct extractors for the subgaussian distance $d_{\mathcal{G}}$.

4.1 Composition

Unfortunately, the subgaussian distance has a major disadvantage compared to total variation distance that complicates extractor construction: it does not satisfy the data-processing inequality, that is, there are probability distributions P and Q over a set A and a function $f : A \rightarrow B$ such that

$$d_{\mathcal{G}}(f(P), f(Q)) \not\leq d_{\mathcal{G}}(P, Q).$$

This happens because subgaussian distance is defined by functions which are required to be subgaussian only with respect to the *uniform distribution*. A simple explicit counterexample comes from taking $f : \{0, 1\}^1 \rightarrow \{0, 1\}^m$ defined by $x \mapsto (x, 0^{m-1})$ and taking P to be the point mass on 0 and Q the point mass on 1. Their subgaussian distance in $\{0, 1\}^1$ is obviously $O(1)$, but the subgaussian distance of $f(P)$ and $f(Q)$ in $\{0, 1\}^m$ is $\Theta(\sqrt{m})$.

The reason this matters because a standard operation (cf. Nisan and Zuckerman [26]; Goldreich and Wigderson [19]; Reingold, Vadhan, and Wigderson [30]) in the construction of samplers and extractors for bounded functions is to do the following: given extractors

$$\text{Ext}_{out} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m \quad \text{Ext}_{in} : \{0, 1\}^{n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^d,$$

define $\text{Ext} : \{0, 1\}^{n+n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^m$ by

$$\text{Ext}((x, y), s) = \text{Ext}_{out}(x, \text{Ext}_{in}(y, s)).$$

The reason this works for total variation distance is exactly the data-processing inequality: if Y has enough min-entropy given X , then $\text{Ext}_{in}(Y, U_{d'})$ will be close in total variation distance to U_d , and by the data-processing inequality for total variation distance this closeness is not lost under the application of Ext_{out} . The assumption that Y has min-entropy given X means that (X, Y) is a so-called *block-source*, and is implied by (X, Y) having enough min-entropy as a joint distribution. From the sampler perspective, this construction uses the inner sampler Ext_{in} to subsample the outer sampler. On the other hand, for subgaussian distance, the

distribution $\text{Ext}_{in}(Y, U_{d'})$ can be ε -close to uniform but still have some element with excess probability mass $\Omega(\varepsilon/\sqrt{d})$, and this element (seed) when mapped by Ext_{out} can retain² this excess mass in $\{0, 1\}^m$, which results in subgaussian distance $\Theta(\varepsilon\sqrt{m/d}) \gg \varepsilon$. Similarly, from the sampler perspective, even when the outer sampler Ext_{out} is a good subgaussian sampler for $\{0, 1\}^m$, there is no reason that a good subgaussian sampler Ext_{in} for $\{0, 1\}^d$ the seeds of Ext_{out} will preserve the larger sampler property when $m \gg d$.

Thus, since this composition operation is needed to construct high-min entropy extractors with the desired seed length even for total variation distance, to construct such extractors for subgaussian distance we need to bypass this barrier. The natural approach is to construct extractors for a better-behaved weak divergence that bounds the subgaussian distance.

4.2 Connections to other weak divergences

Therefore, to aid in extractor construction, we show how $d_{\mathcal{G}}$ relates to other statistical weak divergences (though for space reasons, we defer all proofs to Appendix A).

Most basically, the subgaussian distance over $\{0, 1\}^m$ differs from total variation distance up to a factor of $O(\sqrt{m})$.

► **Lemma 4.6.** *Let P and Q be distributions on $\{0, 1\}^m$. Then*

$$d_{TV}(P, Q) \leq d_{\mathcal{G}}(P, Q) \leq \sqrt{2 \ln 2 \cdot m} \cdot d_{TV}(P, Q)$$

While this allows constructing subgaussian extractors and samplers from total variation extractors, as discussed in the introduction the fact that the upper bound depends on m leads to suboptimal bounds. By starting with a stronger measure of error, we pay a much smaller penalty.

► **Lemma 4.7.** *Let P and Q be distributions on $\{0, 1\}^m$. Then for every $\alpha > 0$*

$$\begin{aligned} 2d_{TV}(P, Q) = d_{\ell_1}(P, Q) &\leq 2^{m\alpha/(1+\alpha)} \cdot d_{\ell_{1+\alpha}}(P, Q) \\ d_{\mathcal{G}}(P, Q) &\leq 2^{m\alpha/(1+\alpha)} \sqrt{1 + \frac{1}{\alpha}} \cdot d_{\ell_{1+\alpha}}(P, Q) \end{aligned}$$

In particular, that there is only an additional $\sqrt{1 + 1/\alpha}$ factor when moving to subgaussian distance compared to total variation, which in particular does not depend on m and is constant for constant α . We give the proof in Appendix A.

One downside of starting with bounds on $\ell_{1+\alpha}$ is that, extending a well-known linear seed length linear bound for ℓ_2 -extractors (e.g. [35, Problem 6.4]), we show in the full version of this work [1] that for every $1 > \alpha > 0$, there is a constant $c_\alpha > 0$ such any $\ell_{1+\alpha}$ extractor with error smaller than $c_\alpha \cdot 2^{-m\alpha/(1+\alpha)}$ requires seed length linear in $\alpha \cdot \min(n - k, m)$, for $n - k$ the entropy deficiency and m the output length. One might hope that sending α to 0 would eliminate this linear lower bound but still bound the subgaussian distance, but phrased this way sending α to 0 just results in a total variation extractor.

However, with a shift in perspective essentially the same approach works: by Example 2.4, $d_{\ell_2}(P, U_m) \leq \varepsilon \cdot 2^{-m/2}$ implies $D_2(P \parallel U_m) \leq \varepsilon^2/\ln 2$, and there is an analogous linear seed length lower bound on constant error $D_{1+\alpha}$ extractors for every $\alpha > 0$. In this case, however, sending α to 0 results in the *KL divergence*, which does upper bound the subgaussian distance, and in fact with the same parameters as for total variation distance.

² Given a subgaussian extractor Ext with $d \geq \log(m/\varepsilon)$, adding a single extra seed $*$ to Ext such that $\text{Ext}(x, *) = 0^m$ results in a subgaussian extractor with error at most $2^{-d} \cdot \sqrt{2m} + \varepsilon \leq 3\varepsilon$ by convexity of $d_{\mathcal{G}}$ and the fact that $\|d_{\mathcal{G}_{\{0,1\}^m}}\|_\infty < \sqrt{2m}$.

► **Lemma 4.8** (cf. [10, Lemma 4.15], [18, Fact B.1]). *Let P be a distribution on $\{0, 1\}^m$. Then*

$$d_{\mathcal{G}}(P, U_m) \leq \sqrt{\frac{\ln 2}{2} \cdot \text{KL}(P \parallel U_m)}$$

$$d_{\mathcal{E}}(P, U_m) \leq \begin{cases} \sqrt{\frac{\ln 2}{2} \cdot \text{KL}(P \parallel U_m)} & \text{if } \text{KL}(P \parallel U_m) \leq \frac{1}{2 \ln 2} \\ \frac{\ln 2}{2} \cdot \text{KL}(P \parallel U_m) + \frac{1}{4} & \text{if } \text{KL}(P \parallel U_m) > \frac{1}{2 \ln 2} \end{cases}$$

where these bounds are concave in $\text{KL}(P \parallel U_m)$. In the reverse direction, it holds that

$$\text{KL}(P \parallel U_m) \leq m \cdot d_{TV}(P, U_m) + h(d_{TV}(P, U_m))$$

where $h(x) = x \log(1/x) + (1-x) \log(1/(1-x))$ is the (concave) binary entropy function.

Due to space constraints, we defer the proof to Appendix A.

5 Extractors for KL divergence

Since by Lemma 4.8 the subgaussian distance can be bounded in terms of the KL divergence to uniform, the following easy lemma shows that to construct subgaussian extractors it suffices to construct extractors for KL divergence.

► **Lemma 5.1.** *Let V_1 and V_2 be weak divergences on the set $\{0, 1\}^m$ and $f : \mathbb{R} \rightarrow \mathbb{R}$ be a function such that $V_1(P \parallel U_M) \leq f(V_2(P \parallel U_m))$ for all distributions P on $\{0, 1\}^m$. Then if f is increasing on $(0, \varepsilon)$, every (k, ε) extractor Ext for V_1 is also a $(k, f(\varepsilon))$ -extractor for V_2 , and if f is also concave, then if Ext is strong or average-case as a V_1 -extractor, it has the same properties as a $(k, f(\varepsilon))$ extractor for V_2 .*

Importantly, the KL divergence does not have the flaws of subgaussian distance discussed in Section 4.1. For instance, the classic *data-processing inequality* says that KL divergence is non-increasing under postprocessing by (possibly randomized) functions, and the *chain rule* for KL divergence says that

$$\text{KL}(A, B \parallel X, Y) = \text{KL}(A \parallel X) + \mathbb{E}_{a \sim A} [\text{KL}(B|_{A=a} \parallel Y|_{X=a})]$$

for all distributions A, B, X , and Y , which implies for example that

$$\mathbb{E}_{s \sim U_d} [\text{KL}(\text{Ext}(X, s) \parallel U_m)] = \text{KL}(U_d, \text{Ext}(X, U_d) \parallel U_d, U_m).$$

Furthermore, KL divergence satisfies a type of triangle inequality when combined with higher Rényi divergences:

► **Lemma 5.2** (cf. [36, Lemma 6.6]). *Let P, Q , and R be distributions over a finite set \mathcal{X} . Then for all $\alpha > 0$, it holds that*

$$\text{KL}(P \parallel R) \leq \left(1 + \frac{1}{\alpha}\right) \cdot \text{KL}(P \parallel Q) + D_{1+\alpha}(Q \parallel R)$$

We give the proof in Appendix A.

5.1 Composition

These properties imply that composition does work as we want (without any loss depending on the output length m) assuming we have extractors for KL and higher divergences.

- **Theorem 5.3** (Composition for high min-entropy Rényi entropy extractors, cf. [19]). *Suppose*
1. $\text{Ext}_{out} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ is an $(n - \log(1/\delta), \varepsilon_{out})$ extractor for $D_{1+\alpha}$ with $\alpha > 0$,
 2. $\text{Ext}_{in} : \{0, 1\}^{n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^d$ is an $(n' - \log(1/\delta), \varepsilon_{in})$ average-case KL-extractor, and define $\text{Ext} : \{0, 1\}^{n+n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^m$ by $\text{Ext}((x, y), s) = \text{Ext}_{out}(x, \text{Ext}_{in}(y, s))$. Then Ext is an $(n + n' - \log(1/\delta), \varepsilon_{out} + (1 + 1/\alpha) \cdot \varepsilon_{in})$ extractor for KL.

We prove this in Appendix A.

5.2 Further theory

The reader is advised to consult the full version of this paper [1] for a more thorough development of the theory of KL-extractors, including an extension of the zig-zag product for extractors (Reingold, Vadhan, and Wigderson [30]), which allows us to avoid the $\log(1/\delta)$ entropy loss inherent in Theorem 5.3. We also give lower bounds, an optimal non-explicit construction, and interpretations of several existing extractor constructions as KL-extractors.

6 Constructions of subgaussian samplers

We can now establish a weak version of our explicit construction of subgaussian samplers with sample complexity having no dependence on m and sample complexity matching the best-known $[0, 1]$ -valued sampler when ε and δ are subconstant (up to the hidden polynomial in the sample complexity). Obtaining matching randomness complexity as well requires more technology from KL-extractors to develop, and as such we defer the proof to the full version of this paper [1].

- **Theorem 6.1.** *For all $m \in \mathbb{N}$, $1 > \varepsilon, \delta > 0$, and $\alpha > 0$ there is an explicit (δ, ε) absolute averaging sampler for subgaussian and subexponential functions $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ with sample complexity $D = \text{poly}(\log(1/\delta), 1/\varepsilon)$ and randomness complexity $n = m + O(\log(1/\delta))$.*

- **Remark 6.2.** In the full version of this paper, we show for every constant $\alpha > 0$ the existence of an explicit absolute subexponential sampler with the same sample complexity $D = \text{poly}(\log(1/\delta), 1/\varepsilon)$ and randomness complexity $n = m + (1 + \alpha) \log(1/\delta)$, and also an analogous result for strong subexponential samplers.

We will use essentially the same construction used for bounded samplers in this regime, combining the expander extractor of Goldreich and Wigderson [19] and an extractor with logarithmic seed length. However, as described in Section 4.1, this construction does not work for general subgaussian extractors, so we will instead use the analysis of Theorem 5.3. This requires a $D_{1+\alpha}$ -extractor for $\alpha > 0$, for this we note (following [35]) that the extractor of [19] is already an extractor for D_2 (see the full version of this work [1] for more details).

- **Theorem 6.3** ([19] [35, Discussion after Theorem 6.22]). *For all $k \leq n \in \mathbb{N}$ and $1/2 \geq \varepsilon > 0$ there is an explicit (k, ε) D_2 -extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with seed length $d = O(n - k + \log(1/\varepsilon))$ and output length $m = n$.*

We also need an average-case KL-extractor, which we can construct by reducing the error in the extractors of Guruswami–Umans–Vadhan [20]:

► **Theorem 6.4** (Akin to [20, Theorem 1.5]). *For every $\alpha, \varepsilon > 0$ and integers $k \leq n$, there is an explicit average-case (k, ε) -KL-extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with $d \leq \log n + O_\alpha(\log(k/\varepsilon))$ and $m \geq (1 - \alpha)k$.*

Though Theorem 6.4 has seed length depending on n the input length, this is tolerable for us since we will apply it to Ext_{in} in the composition of Theorem 5.3 with $n = O(\log(1/\delta) + \log(1/\varepsilon))$:

Proof. Let $\varepsilon' = \frac{\min(\varepsilon, 1/2)}{48(m + \log(1/\varepsilon))}$ so that $m \cdot 3\varepsilon' + h(3\varepsilon') \leq \varepsilon$, where $h(x) = x \log(1/x) + (1 - x) \log(1/(1 - x))$ is the binary entropy function. By [20, Theorem 1.5] and [35, Problem 6.8] there is an explicit $(k, 3\varepsilon')$ extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with $d \leq \log n + O_\alpha(\log(k/\varepsilon')) = \log n + O_\alpha(\log(k/\varepsilon))$ and $m \geq (1 - \alpha)k$. By Lemmas 4.8 and 5.1, we also have that Ext is a $(k, m \cdot 3\varepsilon' + h(3\varepsilon'))$ average-case KL-extractor, and thus a (k, ε) average-case KL-extractor as desired. ◀

► **Theorem 6.5.** *For all integers m and $\delta, \varepsilon > 0$ there is an explicit (k, ε) -KL-extractor $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ with $n = m + O(\log(1/\delta))$, $k = n - \log(1/\delta)$, and $d = O(\log \log(1/\delta) + \log(1/\varepsilon))$.*

Proof. Let $\text{Ext}_{out} : \{0, 1\}^m \times \{0, 1\}^{d_{out}} \rightarrow \{0, 1\}^m$ be the $(m - \log(1/\delta), \varepsilon/3)$ D_2 -extractor from Theorem 6.3 with $d_{out} = O(\log(1/\delta) + \log(1/\varepsilon))$, and let $\text{Ext}_{in} : \{0, 1\}^{n_{in}} \times \{0, 1\}^{d_{in}} \rightarrow \{0, 1\}^{d_{out}}$ be the $(n_{in} - \log(1/\delta), \varepsilon/3)$ average-case KL-extractor from Theorem 6.4 with output length d_{out} , so that $n_{in} = O(\log(1/\delta) + \log(1/\varepsilon))$ and $d_{in} = O(\log \log(1/\delta) + \log(1/\varepsilon))$.

Then instantiating Theorem 5.3 with Ext_{out} and Ext_{in} gives an $(n' - \log(1/\delta), \varepsilon)$ KL-extractor $\text{Ext}' : \{0, 1\}^{n'} \times \{0, 1\}^{d'} \rightarrow \{0, 1\}^m$ with $n' = m + n_{in}$, $d' = d_{in}$. The result follows from defining $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ by $\text{Ext}(x, (s, t)) = \text{Ext}'((x, s), t)$ for s of length $O(\log(1/\varepsilon))$. ◀

We can now prove Theorem 6.1.

Proof of Theorem 6.1. Let $\text{Ext} : \{0, 1\}^n \times \{0, 1\}^d \rightarrow \{0, 1\}^m$ be the explicit $(k, \varepsilon^2/2)$ KL-extractor of Theorem 6.5 with $n = O(m + \log(1/\delta') + \log(1/\varepsilon))$, $k = n - \log(1/\delta')$, and $d = O(\log \log(1/\delta') + \log(1/\varepsilon))$ for $\delta' = \delta/2$. Then by Lemmas 4.8 and 5.1, Ext is also a (k, ε) extractor for d_ε , so by Theorem 3.5 the function $\text{Samp} : \{0, 1\}^n \rightarrow (\{0, 1\}^m)^D$ for $D = 2^d$ defined by $\text{Samp}(x)_i = \text{Ext}(x, i)$ is a (δ', ε) subexponential sampler. Finally, by Remark 3.4, we have that Samp is a (δ, ε) absolute subexponential sampler as desired. ◀

In the full version [1] of this paper, in addition to proving the stronger version of Theorem 6.1, we also discuss explicit samplers for other ranges of parameters and non-explicit constructions.

A Missing proofs

In this section, we include some proofs that were omitted from the main text due to space constraints.

Proof of Proposition 2.11. As mentioned this is just the standard fact that the ℓ_p and ℓ_q norms are dual, but for completeness we include a proof in our language using the extremal form of Hölder’s inequality (note that since we are dealing with finite probability spaces the extremal equality holds even for $p = \infty$ and $q = 1$). Given probability distributions A and B over $\{0, 1\}^m$, we have that

$$\begin{aligned}
 d_{\ell_p}(A, B) &= \left(\sum_x |A_x - B_x|^p \right)^{1/p} \\
 &= 2^{m/p} \mathbb{E}_{x \sim U_m} [|A_x - B_x|^p]^{1/p} \\
 &= 2^{m/p} \max_{\substack{f: \{0,1\}^m \rightarrow \mathbb{R} \\ \|f(U_m)\|_q \leq 1}} \left| \mathbb{E}_{x \sim U_m} [f(x)(A_x - B_x)] \right| && \text{(Hölder’s extremal equality)} \\
 &= 2^{-m+m/p} \max_{\substack{f: \{0,1\}^m \rightarrow \mathbb{R} \\ \|f(U_m)\|_q \leq 1}} \left| \mathbb{E}[f(A)] - \mathbb{E}[f(B)] \right| \\
 &= 2^{-m/q} \cdot d_{\mathcal{M}_q}(A, B) && \text{(by symmetry of } \mathcal{M}_q)
 \end{aligned}$$

as desired. ◀

Proof of Theorem 3.5. The proof is essentially the same as that of [40].

Fix a collection of test functions $f_1, \dots, f_D \in \mathcal{F}$, where if Ext is not strong we restrict to $f_1 = \dots = f_D$, and let $B_{f_1, \dots, f_D} \subseteq \{0, 1\}^n$ be defined as

$$\begin{aligned}
 B_{f_1, \dots, f_D} &\stackrel{\text{def}}{=} \left\{ x \in \{0, 1\}^n \mid \mathbb{E}_{i \sim U_{[D]}} \left[f_i(\text{Ext}(x, i)) - \mathbb{E}[f_i(U_m)] \right] > \varepsilon \right\} \\
 &= \left\{ x \in \{0, 1\}^n \mid \mathbb{E}_{i \sim U_{[D]}} \left[D^{\{f_i\}}(U_{\{\text{Ext}(x, i)\}} \parallel U_m) \right] > \varepsilon \right\},
 \end{aligned}$$

where $U_{\{z\}}$ is the point mass on z . Then if X is uniform over B_{f_1, \dots, f_D} , we have

$$\begin{aligned}
 \varepsilon &< \mathbb{E}_{x \sim X} \left[\mathbb{E}_{i \sim U_{[D]}} \left[f_i(\text{Ext}(x, i)) - \mathbb{E}[f_i(U_m)] \right] \right] \\
 &= \mathbb{E}_{i \sim U_{[D]}} \left[D^{\{f_i\}}(\text{Ext}(X, i) \parallel U_m) \right]
 \end{aligned}$$

$$\begin{aligned} \dots &= \begin{cases} D^{\{f_1\}}(\text{Ext}(X, U_d) \parallel U_m) & \text{if } f_1 = \dots = f_D \\ \mathbb{E}_{i \sim U_{[D]}} \left[D^{\{f_i\}}(\text{Ext}(X, i) \parallel U_m) \right] & \text{always} \end{cases} \\ &\leq \begin{cases} D^{\mathcal{F}}(\text{Ext}(X, U_d) \parallel U_m) & \text{if } f_1 = \dots = f_D \\ \mathbb{E}_{i \sim U_{[D]}} \left[D^{\mathcal{F}}(\text{Ext}(X, i) \parallel U_m) \right] & \text{always} \end{cases} \end{aligned}$$

Since Ext is an $(n - \log(1/\delta), \varepsilon)$ -extractor (respectively strong extractor) for $D^{\mathcal{F}}$ we must have $H_\infty(X) < n - \log(1/\delta)$. But $H_\infty(X) = \log|B_{f_1, \dots, f_D}|$ by definition, so we have $|B_{f_1, \dots, f_D}| < \delta 2^n$. Hence, the probability that a random $x \in \{0, 1\}^n$ lands in B_{f_1, \dots, f_D} is less than δ , and since B_{f_1, \dots, f_D} is exactly the set of seeds which are bad for Samp , this concludes the proof. \blacktriangleleft

Proof of Theorem 3.7. Again the proof is analogous to the one in [40].

Fix a distribution X over $\{0, 1\}^n$ with $H_\infty(X) \geq k$ and a collection of test functions $f_1, \dots, f_D \in \mathcal{F}$, where if Samp is not strong we restrict to $f_1 = \dots = f_D$. Then since Samp is a (δ, ε) \mathcal{F} -sampler, we know that the set of seeds for which the sampler is bad must be small. Formally, the set

$$\begin{aligned} B_{f_1, \dots, f_D} &\stackrel{\text{def}}{=} \left\{ x \in \{0, 1\}^n \mid \mathbb{E}_{i \sim U_d} \left[f_i(\text{Samp}(x)_i) - \mathbb{E}[f_i(U_m)] \right] > \varepsilon \right\} \\ &= \left\{ x \in \{0, 1\}^n \mid \mathbb{E}_{i \sim U_d} \left[f_i(\text{Ext}(x, i)) - \mathbb{E}[f_i(U_m)] \right] > \varepsilon \right\} \end{aligned}$$

has size $|B_{f_1, \dots, f_D}| \leq \delta 2^n$. Thus, since X has min-entropy at least k we know that $\Pr[X \in B_{f_1, \dots, f_D}] \leq 2^{-k} \cdot \delta 2^n$, so we have

$$\begin{aligned} &\mathbb{E}_{i \sim U_d} \left[\mathbb{E} \left[f_i(\text{Ext}(X, i)) - \mathbb{E}[f_i(U_m)] \right] \right] \\ &= \mathbb{E}_X \left[\mathbb{E}_{i \sim U_d} \left[f_i(\text{Ext}(X, i)) - \mathbb{E}[f_i(U_m)] \right] \right] \\ &= \Pr[X \in B_{f_1, \dots, f_D}] \cdot \mathbb{E}_X \left[\mathbb{E}_{i \sim U_d} \left[f_i(\text{Ext}(X, i)) - \mathbb{E}[f_i(U_m)] \right] \mid X \in B_{f_1, \dots, f_D} \right] \\ &\quad + \Pr[X \notin B_{f_1, \dots, f_D}] \cdot \mathbb{E}_X \left[\mathbb{E}_{i \sim U_d} \left[f_i(\text{Ext}(X, i)) - \mathbb{E}[f_i(U_m)] \right] \mid X \notin B_{f_1, \dots, f_D} \right] \\ &\leq \Pr[X \in B_{f_1, \dots, f_D}] \cdot \max \text{dev}(\mathcal{F}) + \Pr[X \notin B_{f_1, \dots, f_D}] \cdot \varepsilon \\ &\leq 2^{-k} \cdot \delta 2^n \cdot \max \text{dev}(\mathcal{F}) + \varepsilon \end{aligned}$$

completing the proof of the main claim. The “in particular” statement follows since if (Z, X) are jointly distributed with $\tilde{H}_\infty(X|Z) \geq n - \log(1/\delta) + \log(1/\eta)$ we have

$$\begin{aligned} \mathbb{E}_{z \sim Z} \left[\varepsilon + \delta \cdot 2^{n - H_\infty(X|Z=z)} \cdot \max \text{dev}(\mathcal{F}) \right] &= \varepsilon + \delta \cdot 2^{n - \tilde{H}_\infty(X|Z)} \cdot \max \text{dev}(\mathcal{F}) \\ &\leq \varepsilon + \eta \cdot \max \text{dev}(\mathcal{F}) \end{aligned}$$

by definition of conditional min-entropy. \blacktriangleleft

Proof of Lemma 4.6. That $d_{TV} \leq d_G$ is immediate from Hoeffding’s lemma and the discussion in Remark 4.5. The reverse bound holds since any subgaussian function takes values at most $\sqrt{\ln 2/2} \cdot m$ away from the mean by the tail bounds from part 3 of Lemma 4.3, and so any subgaussian test function f has the property that $1/2 + f/\sqrt{2 \ln 2} \cdot m$ is $[0, 1]$ -valued and thus lower bounds the total variation distance. \blacktriangleleft

Proof of Lemma 4.7. By Proposition 2.11, for any function $f : \{0, 1\}^m \rightarrow \mathbb{R}$ it holds that

$$D^{\{f\}}(P \parallel Q) \leq \|f(U_m)\|_{1+\frac{1}{\alpha}} \cdot d_{\mathcal{M}_{1+\frac{1}{\alpha}}}(P, Q) = \|f(U_m)\|_{1+\frac{1}{\alpha}} \cdot 2^{m\alpha/(1+\alpha)} \cdot d_{\ell_{1+\alpha}}(P, Q).$$

The result follows since $[-1, 1]$ -valued functions f satisfy moment bounds $\|f(U_m)\|_q \leq 1$ for all $q \geq 1$, and functions f which are subgaussian satisfy moment bounds $\|f(U_m)\|_q \leq \sqrt{q}$ by Lemma 4.3. \blacktriangleleft

Proof of Lemma 4.8. The upper bound on subgaussian distance follows from a general form of Pinsker’s inequality as in [10, Lemma 4.18], but for the extension to subexponential functions we reproduce its proof here, based on the Donsker–Varadhan “variational” formulation of KL divergence [15] (cf. [10, Corollary 4.15])

$$\text{KL}(P \parallel U_m) = \frac{1}{\ln 2} \cdot \sup_{g: \{0,1\}^m \rightarrow \mathbb{R}} \left(\mathbb{E}[g(P)] - \ln \mathbb{E}[e^{g(U_m)}] \right).$$

Now if $f : \{0, 1\}^m \rightarrow \mathbb{R}$ satisfies $\mathbb{E}[f(U_m)] = 0$, then by letting $g(x) = t \cdot f(x)$, this implies

$$\mathbb{E}[f(P)] - \mathbb{E}[f(U_m)] = \frac{1}{t} \cdot \mathbb{E}[g(P)] \leq \frac{\ln 2 \cdot \text{KL}(P \parallel U_m) + \ln \mathbb{E}[e^{t \cdot f(U_m)}]}{t}$$

for all $t > 0$. Thus, when $\ln \mathbb{E}[e^{t \cdot f(U_m)}] \leq t^2/8$, we have $\mathbb{E}[f(P)] - \mathbb{E}[f(U_m)] \leq \ln 2 \cdot \text{KL}(P \parallel U_m)/t + t/8$.

Then since subgaussian random variables satisfy such a bound for all t , we can make the optimal choice $t = \sqrt{8 \ln 2 \cdot \text{KL}(P \parallel U_m)}$ to get the claimed bound on $d_{\mathcal{G}}$. For subexponential random variables, which satisfy such a bound only for $|t| \leq 2$, we choose $t = \min(\sqrt{8 \ln 2 \cdot \text{KL}(P \parallel U_m)}, 2)$, which gives

$$d_{\mathcal{E}}(P, U_m) \leq \begin{cases} \sqrt{\frac{\ln 2}{2} \cdot \text{KL}(P \parallel U_m)} & \text{if } \text{KL}(P \parallel U_m) \leq \frac{1}{2 \ln 2} \\ \frac{\ln 2}{2} \cdot \text{KL}(P \parallel U_m) + \frac{1}{4} & \text{if } \text{KL}(P \parallel U_m) > \frac{1}{2 \ln 2} \end{cases}$$

as desired. The concavity of this bound follows by noting that it has a continuous and nonincreasing derivative.

For the reverse inequality, we use a bound on the difference in entropy between distributions P and Q on a set of size S which states

$$|H(P) - H(Q)| \leq \lg(S - 1) \cdot d_{TV}(P, Q) + h(d_{TV}(P, Q)).$$

This inequality is a simple consequence of Fano’s inequality as noted by Goldreich and Vadhan [18, Fact B.1], and implies the desired result by taking $Q = U_m$ as $\text{KL}(P \parallel U_m) = H(U_m) - H(P)$ and $|\{0, 1\}^m| = 2^m$. \blacktriangleleft

► **Remark A.1.** There are sharper upper bounds on the KL divergence than given in Lemma 4.8, such as the bound of Audenaert and Eisert [3, Theorem 6], but the bound we use has the advantage of being defined for the entire range of the total variation distance and being everywhere concave.

Proof of Lemma 5.2. This follows from a characterization of Rényi divergence due to van Erven and Harremoës [36, Lemma 6.6] [37, Theorem 30] and Shayevitz [32, Theorem 1], who prove that for every positive real $\beta \neq 1$ and distributions X and Y that

$$(1 - \beta) D_{\beta}(X \parallel Y) = \inf_Z \{ \beta \text{KL}(Z \parallel X) + (1 - \beta) \text{KL}(Z \parallel Y) \}.$$

In particular, choosing $\beta = 1 + \alpha$, $X = Q$, and $Y = R$ and upper bounding the infimum by the particular choice of $Z = P$ gives the claim. \blacktriangleleft

Proof of Theorem 5.3. Let (X, Y) be jointly distributed random variables with X distributed over $\{0, 1\}^n$ and Y over $\{0, 1\}^{n'}$ such that $\tilde{H}_\infty(X, Y|Z) \geq n + n' - \log(1/\delta)$. Then by Lemma 5.2 and the data-processing inequality for KL divergence we have that

$$\begin{aligned}
& \text{KL}(\text{Ext}((X, Y), U_d) \parallel U_m) \\
&= \text{KL}(\text{Ext}_{out}(X, \text{Ext}_{in}(Y, U_d)) \parallel U_m) \\
&\leq (1 + 1/\alpha) \cdot \text{KL}(\text{Ext}_{out}(X, \text{Ext}_{in}(Y, U_d)) \parallel \text{Ext}_{out}(X, U_d)) \\
&\quad + D_{1+\alpha}(\text{Ext}_{out}(X, U_d) \parallel U_m) \\
&\leq (1 + 1/\alpha) \cdot \text{KL}(X, \text{Ext}_{in}(Y, U_d) \parallel X, U_d) + D_{1+\alpha}(\text{Ext}_{out}(X, U_d) \parallel U_m) \\
&= (1 + 1/\alpha) \cdot \mathbb{E}_{x \sim X}[\text{KL}(\text{Ext}_{in}(Y|_{X=x}, U_d) \parallel U_d)] + D_{1+\alpha}(\text{Ext}_{out}(X, U_d) \parallel U_m)
\end{aligned}$$

where the last equality follows from the chain rule for KL divergence. Now by standard properties of conditional min-entropy (see for example [14, Lemma 2.2]), we know that $H_\infty(X) \geq H_\infty(X, Y) - \log|\text{Supp}(Y)| \geq n - \log(1/\delta)$ and $\tilde{H}_\infty(Y|X) \geq H_\infty(X, Y) - \log|\text{Supp}(X)| \geq n' - \log(1/\delta)$. Thus, since by assumption Ext_{in} is an average-case $(n' - \log(1/\delta), \varepsilon_{in})$ KL-extractor the first term is bounded by $(1 + 1/\alpha) \cdot \varepsilon_{in}$, and similarly since Ext_{out} is an $(n - \log(1/\delta), \varepsilon_{out})$ $D_{1+\alpha}$ -extractor we have that the second term is bounded by ε_{out} as desired. \blacktriangleleft

Successive Minimum Spanning Trees

Abstract

In a complete graph K_n with edge weights drawn independently from a uniform distribution $U(0, 1)$ (or alternatively an exponential distribution $\text{Exp}(1)$), let T_1 be the MST (the spanning tree of minimum weight) and let T_k be the MST after deletion of the edges of all previous trees T_i , $i < k$. We show that each tree's weight $w(T_k)$ converges in probability to a constant γ_k with $2k - 2\sqrt{k} < \gamma_k < 2k + 2\sqrt{k}$, and we conjecture that $\gamma_k = 2k - 1 + o(1)$. The problem is distinct from that of Frieze and Johansson [6], finding k MSTs of combined minimum weight, and the combined cost for two trees in their problem is, asymptotically, strictly smaller than our $\gamma_1 + \gamma_2$.

Our results also hold (and mostly are derived) in a multigraph model where edge weights for each vertex pair follow a Poisson process; here we additionally have $\mathbb{E}(w(T_k)) \rightarrow \gamma_k$. Thinking of an edge of weight w as arriving at time $t = nw$, Kruskal's algorithm defines forests $F_k(t)$, each initially empty and eventually equal to T_k , with each arriving edge added to the first $F_k(t)$ where it does not create a cycle. Using tools of inhomogeneous random graphs we obtain structural results including that $C_1(F_k(t))/n$, the fraction of vertices in the largest component of $F_k(t)$, converges in probability to a function $\rho_k(t)$, uniformly for all t , and that a giant component appears in $F_k(t)$ at a time $t = \sigma_k$. We conjecture that the functions ρ_k tend to time translations of a single function, $\rho_k(2k + x) \rightarrow \rho_\infty(x)$ as $k \rightarrow \infty$, uniformly in $x \in \mathbb{R}$.

Simulations and numerical computations give estimated values of γ_k for small k , and support the conjectures stated above.

1 Introduction

1.1 Problem definition and main results

Consider the complete graph K_n with edge costs that are i.i.d. random variables, with a uniform distribution $U(0, 1)$ or, alternatively, an exponential distribution $\text{Exp}(1)$. A well-known problem is to find the minimum (cost) spanning tree T_1 , and its cost or “weight” $w(T_1)$. A famous result by Frieze [7] shows that as $n \rightarrow \infty$, $w(T_1)$ converges in probability to $\zeta(3)$, in both the uniform and exponential cases.

Suppose now that we want a second spanning tree T_2 , edge-disjoint from the first, and that we do this in a greedy fashion by first finding the minimum spanning tree T_1 , and then the minimum spanning tree T_2 using only the remaining edges. (I.e., T_2 is the minimum spanning tree in $K_n \setminus T_1$, meaning the graph with edge set $E(K_n) \setminus E(T_1)$.) We then continue and define T_3 as the minimum spanning tree in $K_n \setminus (T_1 \cup T_2)$, and so on. The main purpose of the present paper is to show that the costs $w(T_2)$, $w(T_3)$, \dots also converge in probability to some constants.

► **Theorem 1.** *For each $k \geq 1$, there exists a constant γ_k such that, as $n \rightarrow \infty$, $w(T_k) \xrightarrow{P} \gamma_k$ (for both uniform and exponential cost distributions).*

The result extends easily to other distributions of the edge costs (see full version for details), but we consider in this paper only the uniform and exponential cases.

A minor technical problem is that T_2 and subsequent trees do not always exist; it may happen that T_1 is a star and then $K_n \setminus T_1$ is disconnected. This happens only with a small probability, and w.h.p. (with high probability, i.e., with probability $1 - o(1)$ as $n \rightarrow \infty$) T_k is defined for every fixed k ; see the full version for details. However, in the main part of the paper we avoid this problem completely by modifying the model: we assume that we have a multigraph, which we denote by K_n^∞ , with an infinite number of copies of each edge in K_n , and that each edge’s copies’ costs are given by the points in a Poisson process with intensity 1 on $[0, \infty)$. (The Poisson processes for different edges are, of course, independent.) Note that when finding T_1 , we only care about the cheapest copy of each edge, and its cost has an $\text{Exp}(1)$ distribution, so the problem for T_1 is the same as the original one. However, on K_n^∞ we never run out of edges and we can define T_k for all integers $k = 1, 2, 3, \dots$. Asymptotically, the three models are equivalent (see full version for details), and Theorem 1 holds for any of the models. In particular:

► **Theorem 2.** *For each $k \geq 1$, as $n \rightarrow \infty$, $w(T_k) \xrightarrow{P} \gamma_k$ also for the multigraph model with Poisson process costs.*

Frieze [7] also proved that the expectation $\mathbb{E} w(T_1)$ converges to $\zeta(3)$. For the multigraph model just described, this too extends.

► **Theorem 3.** *For the Poisson multigraph model, $\mathbb{E} w(T_k) \rightarrow \gamma_k$ for each $k \geq 1$ as $n \rightarrow \infty$.*

1.2 Motivations

Frieze and Johansson [6] recently considered a related problem, where instead of choosing spanning trees T_1, T_2, \dots greedily one by one, they choose k edge-disjoint spanning trees with minimum total cost. It is easy to see, by small examples, that selecting k spanning trees greedily one by one does not always give a set of k edge-disjoint spanning trees with minimum cost, so the problems are different.

We show in Theorem 19 that, at least for $k = 2$, the two problems also asymptotically have different answers, in the sense that the limiting values of the minimum cost – which exist for both problems – are different. (Also, as discussed in Section 3.1, we improve on the upper bound from [6, Section 3] on the cost of the net cheapest k trees, since our upper bound (3.1) on the cost of the first k trees is smaller.)

Both our question and that of Frieze and Johansson [6] are natural, both seem generally relevant to questions of robust network design, and both have mathematically interesting answers.

Another reason for interest in T_2 comes from the field of algorithmic mechanism design. Imagine that each edge of $G = K_n$ is owned by a different “agent”; the agent owning edge e values it at $w(e)$, an amount known only to them. We, an “auctioneer”, want to buy a spanning tree, at low cost. One “mechanism” for doing so is a sealed-bid auction where each agent posts a price $w'(e)$ for their edge, and we buy the tree that is cheapest according to these prices. Here, agents will naturally inflate their prices, posting prices $w'(e) > w(e)$.

One alternative is a VCG (Vickrey–Clarke–Groves) auction, a generalization of a single-item second-price auction. Here, we again buy the tree that is cheapest according to the posted prices w' , but for each edge e purchased, we pay an amount that is a function of w'_{-e} , i.e., of all posted prices *except* that of e ; for details see for example [16, Chapter 9]. This means that varying $w'(e)$ affects only whether edge e is purchased, not how much is paid for it if it is, and results in the mechanism being *truthful*: it is in each agent’s selfish interest to set $w'(e) = w(e)$. Thus, the tree purchased is simply T_1 , the tree cheapest according to the values w . However, the amount paid for it is more than $w(T_1)$, as the mechanism ensures the amount paid for each edge e purchased is at least $w(e)$ and typically more. A central question is the extent of this overpayment, measured by the “frugality ratio” of the VCG cost V (or that of any mechanism) to some benchmark.

The question applies of course to problems other than MSTs, including the purchase of a cheapest path between two given points in a graph, or of a basis in a bridgeless matroid. In any of these contexts, let us continue to use T_1 for the cheapest structure and T_2 for the cheapest structure disjoint from T_1 . The cost $w(T_1)$ is not a useful benchmark because $V/w(T_1)$ is unbounded in even the simplest examples (such as buying one of two identical items).

Instead, Talwar [17] and Archer and Tardos [1] propose $w(T_2)$ as the benchmark. (An often-equivalent benchmark, based on a Nash equilibrium, is given by [14] and [16, Chapter 13].) [17] shows that for any bridgeless matroid, $V/w(T_2) \leq 1$, and, focusing on the worst case over all weights w , this bound is achieved by some weights (namely weights 0 on T_1 , 1 on T_2 , and infinity elsewhere). By contrast, for paths the ratio is unbounded. The interpretation, based on worst-case weights, is that this frugality ratio is 1 for amenable problems like MSTs and other matroids, and larger for other problems.

In our setting of an MST in K_n with random weights, though, the frugality ratio is naturally less than its maximum of 1. Specifically, [4] and [11] show that the VCG cost is typically $2w(T_1)$, which by [7] is $2\zeta(3) \doteq 2.4041$. We show here that $w(T_2)$ is typically γ_2 , which by Remark 21 is at least 2.9683, making the frugality typically at most 0.8099. (We estimate non-rigorously that γ_2 is about 3.09 – see Table 1 – in which case the frugality ratio is typically about 0.78.) Specifically, this holds w.h.p. for n large, and also holds for the ratio between the expected VCG cost and the expected cost $w(T_2)$.

1.3 Further results, structural properties, and conjectures

It is well known that the minimum spanning tree (with any given costs, obtained randomly or deterministically) can be found by *Kruskal's algorithm* [15], which processes the edges in order of increasing cost and keeps those that join two different components in the forest obtained so far. (I.e., it keeps each edge that does not form a cycle together with previously chosen edges.) As in many other previous papers on the random minimum spanning tree problem, from [7] on, our proofs are based on analyzing the behavior of this algorithm.

Rescale weight as time, thinking of an edge of weight w as arriving at time $t = nw$. Kruskal's algorithm allows us to construct all trees T_k simultaneously by growing forests $F_k(t)$, with $F_k(0)$ empty and $F_k(\infty) = T_k$: taking the edges of K_n (or K_n^∞) in order of time arrival (increasing cost), an edge is added to the first forest F_k where it does not create a cycle. We will also consider a sequence of graphs $G_k(t) \supseteq F_k(t)$, where when we add an edge to F_k we also add it to all the graphs G_1, \dots, G_k ; see Section 2.2 for details.

The proof of Theorem 1 is based on a detailed structural characterization of the graphs $G_k(t)$, given by Theorem 9 (too detailed to set forth in full here in the introduction), relying heavily on the theory of inhomogeneous random graphs from [3] and related works. Where $C_1(G_k(t))$ denotes the number of vertices in the largest component of $G_k(t)$ (or equivalently of $F_k(t)$, as by construction they have the same components), Theorem 9 shows that $C_1(G_k(t))/n$ converges in probability to some function $\rho_k(t)$, uniformly for all times t . Moreover, each G_k has its own giant-component threshold: $\rho_k(t)$ is 0 until some time σ_k , and strictly positive thereafter.

The functions $\rho_k(t)$ are of central interest. For one thing, an edge is rejected from F_k , making it a candidate for F_{k+1} , precisely if its two endpoints are within the same component of F_k , and we show that this is essentially equivalent to the two endpoints both being within the largest component. This line of reasoning yields the constants γ_k explicitly, albeit not in a form that is easily evaluated. We are able, at least, to re-prove that $\gamma_1 = \zeta(3)$, as first shown in [7].

The functions ρ_k also appear to have a beautiful structure, tending to time-translated copies of a single universal function:

► **Conjecture 4.** *There exists a continuous increasing function $\rho_\infty(x) : (-\infty, \infty) \rightarrow [0, 1]$ such that $\rho_k(2k + x) \rightarrow \rho_\infty(x)$ as $k \rightarrow \infty$, uniformly in $x \in \mathbb{R}$.*

This suggests, though does not immediately imply, another conjecture.

► **Conjecture 5.** *For some δ , as $k \rightarrow \infty$, $\gamma_k = 2k + \delta + o(1)$.*

If this conjecture holds, then necessarily $\delta \in [-1, 0]$, see Remark 17.

A variety of computational results are given in Section 5. They are supportive of Conjecture 4 and a stronger version of Conjecture 5 where we take $\delta = -1$:

► **Conjecture 6.** *As $k \rightarrow \infty$, $\gamma_k = 2k - 1 + o(1)$.*

Although we cannot prove these conjectures, some bounds on γ_k are obtained in Section 3 by a more elementary analysis of the sequence of forests F_k . In particular, Theorem 12 and Corollary 13 lead to the following, implying that $\gamma_k \sim 2k$ as $k \rightarrow \infty$.

► **Corollary 7.** *For every $k \geq 1$,*

$$2k - 2k^{1/2} < \gamma_k < 2k + 2k^{1/2}. \quad (1.1)$$

► Remark 8. For the minimum spanning tree T_1 , various further results are known, including refined estimates for the expectation of the cost $w(T_1)$ [5], a normal limit law [9], and asymptotics for the variance [9, 13, 18]. It seems challenging to show corresponding results for T_2 or later trees. ◀

1.4 Notes on this extended abstract

A full version of this work can be found as [12]. The present extended abstract omits most proofs as well as many further results. However, Sections 2 and 3 here are reasonably complete. We will say a few words in Section 2.5 on the approach to proving Theorem 9, but the technicalities are substantial.

2 Model and main structural results

2.1 Some notation

We use $:=$ as defining its left-hand side, and $\stackrel{\text{def}}{=}$ as a reminder that equality of the two sides is by definition. We write \doteq for numerical approximate equality, and \approx for approximate equality in an asymptotic sense (details given where used).

If x and y are real numbers, then $x \vee y := \max(x, y)$ and $x \wedge y := \min(x, y)$. Furthermore, $x_+ := x \vee 0$. These operators bind most strongly, e.g., $t - \tau(i) \vee \tau(j)$ means $t - (\tau(i) \vee \tau(j))$.

We use “increasing” and “decreasing” in their weak senses; for example, a function f is increasing if $f(x) \leq f(y)$ whenever $x \leq y$.

Unspecified limits are as $n \rightarrow \infty$. As said above, w.h.p. means with probability $1 - o(1)$. Convergence in probability is denoted $\xrightarrow{\text{P}}$. Furthermore, if X_n are random variables and a_n are positive constants, $X_n = o_p(a_n)$ means, as usual, $X_n/a_n \xrightarrow{\text{P}} 0$; this is also equivalent to: for every $\varepsilon > 0$, w.h.p. $|X_n| < \varepsilon a_n$.

Graph means, in general, multigraph. (It is usually clear from the context whether we consider a multigraph or simple graph.) If G is a multigraph, then \dot{G} denotes the simple graph obtained by merging parallel edges and deleting loops. (Loops do not appear in the present paper.) The number of vertices in a graph G is denoted by $|G|$, and the number of edges by $e(G)$.

For a graph G , let $\mathcal{C}_1(G), \mathcal{C}_2(G), \dots$ be the largest component, the second largest component, and so on, using any rule to break ties. (If there are less than k components, we define $\mathcal{C}_k(G) = \emptyset$.) Furthermore, let $C_i(G) := |\mathcal{C}_i(G)|$; thus $C_1(G)$ is the the number of vertices in the largest component, and so on. We generally regard components of a graph G as sets of vertices.

2.2 Model

We elaborate the multigraph model in the introduction.

We consider (random) (multi)graphs on the vertex set $[n] := \{1, \dots, n\}$; we usually omit n from the notation. The graphs will depend on time, and are denoted by $G_k(t)$ and $F_k(t)$, where $k = 1, 2, 3, \dots$ and $t \in [0, \infty]$; they all start as empty at time $t = 0$ and grow as time increases. We will have $G_k(t) \supseteq G_{k+1}(t)$ and $F_k(t) \subseteq G_k(t)$ for all k and t . Furthermore, $F_k(t)$ will be a forest. As $t \rightarrow \infty$, $F_k(t)$ will eventually become a spanning tree, $F_k(\infty)$, which is the k th spanning tree T_k produced by the greedy algorithm in the introduction, operating on the multigraph $G_1(\infty)$.

Since the vertex set is fixed, we may when convenient identify the multigraphs with sets of edges. We begin by defining $G_1(t)$ by letting edges arrive as independent Poisson processes with rate $1/n$ for each pair $\{i, j\}$ of vertices; $G_1(t)$ consists of all edges that have arrived at

or before time t . (This scaling of time turns out to be natural and useful. In essence this is because what is relevant is the cheapest edges on each vertex, and these have expected cost $\Theta(1/n)$ and thus appear at expected time $\Theta(1)$.) We define the cost of an edge arriving at time t to be t/n , and note that in $G_1(\infty)$, the costs of the edges joining two vertices form a Poisson process with rate 1. Hence, $G_1(\infty)$ is the multigraph model defined in Section 1.

Thus, for any fixed $t \geq 0$, $G_1(t)$ is a multigraph where the number of edges between any two fixed vertices is $\text{Po}(t/n)$, and these numbers are independent for different pairs of vertices. This is a natural multigraph version of the Erdős–Rényi graph $G(n, t)$. (The process $G_1(t)$, $t \geq 0$, is a continuous-time version of the multigraph process in e.g. [2] and [10, Section 1], ignoring loops.) Note that $\dot{G}_1(t)$, i.e., $G_1(t)$ with multiple edges merged, is simply the random graph $G(n, p)$ with $p = 1 - e^{-t/n}$.

Next, we let $F_1(t)$ be the subgraph of $G_1(t)$ consisting of every edge that has arrived at some time $s \leq t$ and at that time joined two different components of $G_1(s)$. Thus, this is a subforest of $G_1(t)$, as stated above, and it is precisely the forest constructed by Kruskal's algorithm (recalled in the introduction) operating on $G_1(\infty)$, at the time all edges with cost $\leq t/n$ have been considered. Hence, $F_1(\infty)$ is the minimum spanning tree T_1 of $G_1(\infty)$.

Let $G_2(t) := G_1(t) \setminus F_1(t)$, i.e., the subgraph of $G_1(t)$ consisting of all edges rejected from $F_1(t)$; in other words $G_2(t)$ consists of the edges that, when they arrive to $G_1(t)$, have their endpoints in the same component.

We continue recursively. $F_k(t)$ is the subforest of $G_k(t)$ consisting of all edges in $G_k(t)$ that, when they arrived at some time $s \leq t$, joined two different components in $G_k(s)$. And $G_{k+1}(t) := G_k(t) \setminus F_k(t)$, consisting of the edges rejected from $F_k(t)$.

Hence, the k th spanning tree T_k produced by Kruskal's algorithm equals $F_k(\infty)$, as asserted above.

Note that $F_k(t)$ is a spanning subforest of $G_k(t)$, in other words, the components of $F_k(t)$ (regarded as vertex sets) are the same as the components of $G_k(t)$; this will be used frequently below. Moreover, each edge in $G_{k+1}(t)$ has endpoints in the same component of $G_k(t)$; hence, each component of $G_{k+1}(t)$ is a subset of a component of $G_k(t)$. It follows that an edge arriving to $G_1(t)$ will be passed through $G_2(t), \dots, G_k(t)$ and to $G_{k+1}(t)$ (and possibly further) if and only if its endpoints belong to the same component of $G_k(t)$, and thus if and only if its endpoints belong to the same component of $F_k(t)$.

2.3 More notation

We say that a component \mathcal{C} of a graph G is the *unique giant* of G if $|\mathcal{C}| > |\mathcal{C}'|$ for every other component \mathcal{C}' ; if there is no such component (i.e., if the maximum size is tied), then we define the unique giant to be \emptyset .

We say that a component \mathcal{C} of $F_k(t)$ is the *permanent giant* of $F_k(t)$ (or of $G_k(t)$) if it is the unique giant of $F_k(t)$ and, furthermore, it is a subset of the unique giant of $F_k(u)$ for every $u > t$; if there is no such component then the permanent giant is defined to be \emptyset .

Let $\mathfrak{C}_k(t)$ denote the permanent giant of $F_k(t)$. Note that the permanent giant either is empty or the largest component; thus $|\mathfrak{C}_k(t)|$ is either 0 or $C_1(F_k(t)) = C_1(G_k(t))$. Note also that the permanent giant $\mathfrak{C}_k(t)$ is an increasing function of t : $\mathfrak{C}_k(t) \subseteq \mathfrak{C}_k(u)$ if $t \leq u$. Furthermore, for sufficiently large t (viz. t such that $G_k(t)$ is connected, and thus $F_k(t)$ is the spanning tree T_k), $\mathfrak{C}_k(t) = \mathfrak{C}_k(\infty) = [n]$.

2.4 A structure theorem

The basis of our proof of Theorems 1 and 2 is the following theorem on the structure of the components of $G_k(t)$. Recall that $F_k(t)$ has the same components as $G_k(t)$, so the theorem applies as well to $F_k(t)$.

For $k = 1$, the theorem collects various known results for $G(n, p)$. Our proof includes this case too, making the proof more self-contained.

► **Theorem 9.** *With the definitions above, the following hold for every fixed $k \geq 1$ as $n \rightarrow \infty$.*

(i) *There exists a continuous increasing function $\rho_k : [0, \infty) \rightarrow [0, 1)$ such that*

$$C_1(G_k(t))/n \xrightarrow{P} \rho_k(t), \tag{2.1}$$

uniformly in $t \in [0, \infty)$; in other words, for any $\varepsilon > 0$, w.h.p., for all $t \geq 0$,

$$\rho_k(t) - \varepsilon \leq C_1(G_k(t))/n \leq \rho_k(t) + \varepsilon. \tag{2.2}$$

(ii) $\sup_{t \geq 0} C_2(G_k(t))/n \xrightarrow{P} 0$.

(iii) *There exists a threshold $\sigma_k > 0$ such that $\rho_k(t) = 0$ for $t \leq \sigma_k$, but $\rho_k(t) > 0$ for $t > \sigma_k$. Furthermore, ρ_k is strictly increasing on $[\sigma_k, \infty)$.*

(iv) *There exist constants $b_k, B_k > 0$ such that*

$$\rho_k(t) \geq 1 - B_k e^{-b_k t}, \quad t \geq 0. \tag{2.3}$$

In particular, $\rho_k(t) \rightarrow 1$ as $t \rightarrow \infty$.

(v) *If $t > \sigma_k$, then w.h.p. $G_k(t)$ has a non-empty permanent giant. Hence, for every $t \geq 0$,*

$$|\mathfrak{C}_k(t)|/n \xrightarrow{P} \rho_k(t). \tag{2.4}$$

We note also a formula for the number of edges in $G_k(t)$, and two simple inequalities relating different k .

► **Theorem 10.** *For each fixed $k \geq 1$ and uniformly for t in any finite interval $[0, T]$,*

$$e(G_k(t))/n \xrightarrow{P} \frac{1}{2} \int_0^t \rho_{k-1}(s)^2 ds. \tag{2.5}$$

► **Theorem 11.** $\rho_k(t) \leq \rho_{k-1}(t)$ for every $t \geq 0$, with strict inequality when $\rho_{k-1}(t) > 0$ (equivalently, when $t > \sigma_{k-1}$). Furthermore,

$$\sigma_k \geq \sigma_{k-1} + 1. \tag{2.6}$$

Inequality (2.6) is weak in that we conjecture that as $k \rightarrow \infty$, $\sigma_k = \sigma_{k-1} + 2 + o(1)$.

2.5 The proof approach

Proofs of the results in this section are by induction on k , relying heavily on the theory of inhomogeneous random graphs by Bollobás, Janson and Riordan in [3]. When an edge is passed on by G_k this is almost always because it is contained in $\mathcal{C}_1(G_k)$; it is only rarely because it is contained in some other component, and this case is treatable as a perturbation within the theory. Thus, vertices “appear” in $G_{k+1}(t)$ as governed by $\rho_k(t)$; this is formalized as a “vertex space” in the theory. Once two vertices u and v are both present in $G_{k+1}(t)$, edges between them arrive at rate $1/n$. So, if they arrive at times τ_u and τ_v , the probability they are connected at time t is asymptotically $\frac{1}{n}(t - (\tau_u \vee \tau_v))_+ =: \frac{1}{n}\kappa_t(\tau_u, \tau_v)$; κ_t is the “kernel” in the inhomogeneous random graph framework. The framework then shows that $C_1(G_{k+1}(t))/n$ converges in probability to a certain $\rho(\kappa_t)$, the survival probability of a related inhomogeneous branching process, and this $\rho(\kappa_t)$ is precisely the desired next function $\rho_{k+1}(t)$.

3 Bounds on the expected cost

3.1 Total cost of the first k trees

The following theorem gives lower and upper bounds on the total cost of the first k spanning trees.

► **Theorem 12.** *Letting $W_k = \sum_{i=1}^k w(T_i)$ be the total cost of the first k spanning trees, for every $k \geq 1$,*

$$k^2 \frac{n-1}{n} \leq \mathbb{E} W_k \leq k(k+1) \frac{n-1}{n} < k^2 + k. \quad (3.1)$$

Comparing with Frieze and Johansson [6, Section 3], our upper bound is smaller than their $k^2 + 3k^{5/3}$ despite the fact that they considered a more relaxed minimization problem (see Section 4); as such ours is a strict improvement. In both cases the lower bound is simply the expected total cost of the cheapest $k(n-1)$ edges in G , with (3.2) matching [6, (3.1)].

Proof. The minimum possible cost of the k spanning trees is the cost of the cheapest $k(n-1)$ edges. Since each edge's costs (plural, in our model) are given by a Poisson process of rate 1, the set of all edge costs is given by a Poisson process of rate $\binom{n}{2}$. Recall that in a Poisson process of rate λ , the interarrival times are independent exponential random variables with mean $1/\lambda$, so that the i th arrival, at time Z_i , has $\mathbb{E} Z_i = i/\lambda$. It follows in this case that $W_k \geq \sum_{i=1}^{k(n-1)} Z_i$ and

$$\mathbb{E} W_k \geq \sum_{i=1}^{k(n-1)} \frac{i}{\binom{n}{2}} = \frac{(k(n-1))(k(n-1)+1)}{n(n-1)} \geq k^2 \frac{n-1}{n}. \quad (3.2)$$

We now prove the upper bound. An arriving edge is rejected from F_i iff both endpoints lie within its “forbidden” set B_i of edges, namely those edges with both endpoints in one component. The nesting property of the components means that $B_1 \supseteq B_2 \supseteq \dots$. An arriving edge e joins F_k if it is rejected from all previous forests, i.e., $e \in B_{k-1}$ (in which case by the nesting property, e also belongs to all earlier B s) but can be accepted into F_k , i.e., $e \notin B_k$. The idea of the proof is to show that the first k forests fill reasonably quickly with $n-1$ edges each, and we will do this by coupling the forest-creation process (Kruskal's algorithm) to a simpler, easily analyzable random process.

Let $\mathbf{s}(\tau) = \{s_k(\tau)\}_{k=0}^\infty$ denote the vector of the sizes (number of edges) of each forest after arrival of the τ 'th edge; we may drop the argument τ when convenient. Let $p_k = |B_k|/\binom{n}{2}$, the rejection probability for F_k . For any τ , by the nesting property of the components and in turn of the B_k ,

$$s_1 \geq s_2 \geq \dots \quad \text{and} \quad p_1 \geq p_2 \geq \dots. \quad (3.3)$$

The MST process can be simulated by using a sequence of i.i.d. random variables $\alpha(\tau) \sim U(0, 1)$, incrementing $s_k(\tau)$ if both $\alpha(\tau) \leq p_{k-1}(\tau)$ (so that e is rejected from F_{k-1} and thus from all previous forests too) and $\alpha(\tau) > p_k(\tau)$ (so that e is accepted into F_k). We take the convention that $p_0(\tau) = 1$ for all τ . For intuition, note that when $s_k = 0$ an edge is never rejected from F_k ($p_k = 0$, so $\alpha \sim U(0, 1)$ is never smaller); when $s_k = 1$ it is rejected with probability $p_k = 1/\binom{n}{2}$; and when $s_k = n-1$ it is always rejected ($|B_k|$ must be $\binom{n}{2}$, so $p_k = 1$).

Given the size $s_k = \sum_{i=1}^{\infty} (C_i(F_k) - 1)$ of the k th forest, $|B_k| = \sum_{i=1}^{\infty} \binom{C_i(F_k)}{2}$ is maximized (thus so is p_k) when all the edges are in one component, i.e.,

$$p_k \leq \binom{s_k + 1}{2} / \binom{n}{2} \tag{3.4}$$

$$\leq \frac{s_k}{n - 1} =: \bar{p}_k. \tag{3.5}$$

The size vector $\mathbf{s}(\tau)$ thus determines the values $\bar{p}_k(\tau)$ for all k .

Let $\mathbf{r}(\tau)$ denote a vector analogous to $\mathbf{s}(\tau)$, but with $r_k(\tau)$ incremented if $\hat{p}_k(\tau) < \alpha(\tau) \leq \hat{p}_{k-1}(\tau)$, with

$$\hat{p}_k := \frac{r_k}{n - 1}. \tag{3.6}$$

By construction,

$$r_1 \geq r_2 \geq \dots \quad \text{and} \quad \hat{p}_1 \geq \hat{p}_2 \geq \dots. \tag{3.7}$$

For intuition, here note that when $r_k = 0$ an arrival is never rejected from r_k ($\bar{p}_k = 0$); when $s_k = 1$ it is rejected with probability $\bar{p}_k = 1/(n - 1) > p_k = 1/\binom{n}{2}$; and when $s_k = n - 1$ it is always rejected ($\bar{p}_k = 1$).

Taking each $F_i(0)$ to be an empty forest (n isolated vertices, no edges) and accordingly $\mathbf{s}(0)$ to be an infinite-dimensional 0 vector, and taking $\mathbf{r}(0)$ to be the same 0 vector, we claim that for all τ , $\mathbf{s}(\tau)$ majorizes $\mathbf{r}(\tau)$, which we will write as $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$. That is, the prefix sums of \mathbf{s} dominate those of \mathbf{r} : for all τ and k , $\sum_{i=1}^k s_i(\tau) \geq \sum_{i=1}^k r_i(\tau)$.

We first prove this; then use it to argue that edge arrivals to the first k forests, i.e., to \mathbf{s} , can only precede arrivals to the first k elements of \mathbf{r} ; and finally analyze the arrival times of all $k(n - 1)$ elements to the latter to arrive at an upper bound on the total cost of the first k trees.

We prove $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$ by induction on τ , the base case with $\tau = 0$ being trivial. Figure 1 may be helpful in illustrating the structure of this inductive proof. Suppose the claim holds for τ . The probabilities $p_k(\tau)$ are used to determine the forests $F_k(\tau + 1)$ and in turn the size vector $\mathbf{s}(\tau + 1)$. Consider an intermediate object $\mathbf{s}'(\tau + 1)$, the size vector that would be given by incrementing $\mathbf{s}(\tau)$ using the upper-bound values $\bar{p}_k(\tau)$ taken from $\mathbf{s}(\tau)$ by (3.5). Then, $s_i(\tau + 1)$ receives the increment if $p_{i-1} \geq \alpha > p_i$, and $s'_j(\tau + 1)$ receives the increment if $\bar{p}_{j-1} \geq \alpha > \bar{p}_j$; hence, from $\bar{p}_{i-1} \geq p_{i-1} \geq \alpha$ it is immediate that $i \leq j$ and thus $\mathbf{s}(\tau + 1) \succeq \mathbf{s}'(\tau + 1)$.

It suffices then to show that $\mathbf{s}'(\tau + 1) \succeq \mathbf{r}(\tau + 1)$. These two vectors are obtained respectively from $\mathbf{s}(\tau)$ and $\mathbf{r}(\tau)$, with $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$ by the inductive hypothesis, using probability thresholds $\bar{p}_k(\tau) = f(s_k(\tau))$ and $\hat{p}_k(\tau) = f(r_k(\tau))$ respectively, applied to the common random variable α , where $f(s) = s/(n - 1)$ (but all that is important is that f is a monotone function of s). Suppose that

$$f(s_{i-1}) \geq \alpha > f(s_i) \quad \text{and} \quad f(r_{j-1}) \geq \alpha > f(r_j), \tag{3.8}$$

so that elements i in \mathbf{s} and j in \mathbf{r} are incremented. If $i \leq j$, we are done. (Prefix sums of $\mathbf{s}(\tau)$ dominated those of $\mathbf{r}(\tau)$, and an earlier element is incremented in $\mathbf{s}'(\tau + 1)$ than $\mathbf{r}(\tau + 1)$, thus prefix sums of $\mathbf{s}'(\tau + 1)$ dominate those of $\mathbf{r}(\tau + 1)$.) Consider then the case that $i > j$.

60:10 Successive Minimum Spanning Trees

■ **Figure 1** Coupling of the forests' sizes $\mathbf{s}(\tau)$ to a simply analyzable random process $\mathbf{r}(\tau)$, showing the structure of the inductive proof (on τ) that $\mathbf{s}(\tau)$ majorizes $\mathbf{r}(\tau)$.

In both processes the increment falls between indices j and i , so the k -prefix sum inequality continues to hold for $k < j$ and $k \geq i$. Thus, for $j \leq k < i$,

$$\begin{aligned} \sum_{\ell=1}^k s'_\ell(\tau+1) &= \sum_{\ell=1}^{j-1} s_\ell(\tau) + \sum_{\ell=j}^k s_\ell(\tau) \\ \sum_{\ell=1}^k r_\ell(\tau+1) &= \sum_{\ell=1}^{j-1} r_\ell(\tau) + 1 + \sum_{\ell=j}^k r_\ell(\tau). \end{aligned} \tag{3.9}$$

From $j < i$, (3.8), and (3.3) and (3.7) we have that when $j \leq \ell \leq i-1$,

$$s_\ell \geq s_{i-1} \geq f^{-1}(\alpha) > r_j \geq r_\ell,$$

implying

$$s_\ell \geq r_\ell + 1. \tag{3.10}$$

In (3.9), we have $\sum_{\ell=1}^{i-1} s_\ell(\tau) \geq \sum_{\ell=1}^{i-1} r_\ell(\tau)$ from the inductive hypothesis that $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$, while using (3.10) gives

$$\sum_{\ell=j}^k s_\ell(\tau) \geq \sum_{\ell=j}^k (1 + r_\ell(\tau)) \geq 1 + \sum_{\ell=j}^k r_\ell(\tau),$$

from which it follows that $\mathbf{s}'(\tau+1) \succeq \mathbf{r}(\tau+1)$, completing the inductive proof that $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$.

Having shown that the vector $\mathbf{s}(\tau)$ of component sizes majorizes $\mathbf{r}(\tau)$, it suffices to analyze the latter. Until this point we could have used (3.4) rather than (3.5) to define \bar{p}_k, \hat{p}_k , and the function f , but now we take advantage of the particularly simple nature of the process governing $\mathbf{r}(\tau)$. Recall that a new edge increments r_i for the first i for which the $U(0, 1)$ “coin toss” $\alpha(\tau)$ has $\alpha(\tau) > \hat{p}_i \stackrel{\text{def}}{=} r_i/(n-1)$. Equivalently, consider an array of cells $n-1$ rows high and infinitely many columns wide, generate an “arrival” at a random row or “height” $X(\tau)$ uniform on $1, \dots, n-1$, and let this arrival occupy the first unoccupied cell i at this height, thus incrementing the occupancy r_i of column i . This is equivalent because if r_i of the $n-1$ cells in column i are occupied, the chance that i is rejected – that $X(\tau)$ falls into this set and thus the arrival moves along to test the next column $i+1$ – is $r_i/(n-1)$, matching (3.6).

Recalling that the cost of an edge arriving at time t is t/n in the original graph problem, the combined cost W_k of the first k spanning trees is $1/n$ times the sum of the arrival times of their $k(n-1)$ edges. The majorization $\sum_{i=1}^k s_i(\tau) \geq \sum_{i=1}^k r_i(\tau)$ means that the ℓ 'th arrival

to the first k forests comes no later than the ℓ 'th arrival to the first k columns of the cell array. Thus, the cost W_k of the first k trees is at most $1/n$ times the sum of the times of the $k(n-1)$ arrivals to the array's first k columns.

The continuous-time edge arrivals are a Poisson process with intensity $1/n$ on each of the $\binom{n}{2}$ edges, thus intensity $(n-1)/2$ in all; it is at the Poisson arrival times that the discrete time τ is incremented and $X(\tau)$ is generated. Subdivide the “ X ” process into the $n-1$ possible values that X may take on, so that arrivals at each value (row in the cell array) are a Poisson process of intensity $\lambda = \frac{1}{2}$. The sum of the first k arrival times in a row is the sum of the first k arrival times in its Poisson process. The i th such arrival time is the sum of i exponential random variables, and has expectation i/λ . The expected sum of k arrival times of a line is thus $\binom{k+1}{2}/\lambda = k(k+1)$, and (remembering that cost is time divided by n), the expected total cost of all $n-1$ lines is

$$\frac{n-1}{n}k(k+1),$$

yielding the upper bound in (3.1) and completing the proof of the theorem. ◀

► **Corollary 13.** *Let $\Gamma_k := \sum_{i=1}^k \gamma_i$. Then, for every $k \geq 1$,*

$$k^2 \leq \Gamma_k = \sum_{i=1}^k \gamma_i \leq k^2 + k. \tag{3.11}$$

Proof. Immediate from Theorems 12 and 3. ◀

► **Example 14.** In particular, Corollary 13 gives $1 \leq \gamma_1 \leq 2$ and $4 \leq \gamma_1 + \gamma_2 \leq 6$. In fact, we know that $\gamma_1 = \zeta(3) \doteq 1.2021$ [7] and $\gamma_1 + \gamma_2 > 4.1704$ by [6] and Section 4, see Corollary 20. Numerical estimates suggest $\gamma_1 + \gamma_2 \doteq 4.30$; see Section 5, including Table 1, for various estimates of γ_2 . ◀

3.2 Corollaries and conjectures for the k th tree

Turning to individual γ_k instead of their sum Γ_k , we obtain Corollary 7, namely that $2k - 2k^{1/2} < \gamma_k < 2k + 2k^{1/2}$.

Proof of Corollary 7. For the upper bound, we note that obviously $\gamma_1 \leq \gamma_2 \leq \dots$, and thus, for any $\ell \geq 1$, using both the upper and lower bound in (3.11),

$$\begin{aligned} \ell \gamma_k &\leq \sum_{i=k}^{k+\ell-1} \gamma_i = \Gamma_{k+\ell-1} - \Gamma_{k-1} \leq (k+\ell-1)(k+\ell) - (k-1)^2 \\ &= \ell^2 + \ell(2k-1) + k-1 \end{aligned} \tag{3.12}$$

and hence

$$\gamma_k \leq 2k - 1 + \ell + \frac{k-1}{\ell}. \tag{3.13}$$

Choosing $\ell = \lceil \sqrt{k} \rceil$ gives the upper bound in (1.1).

For the lower bound we similarly have, for $1 \leq \ell \leq k$,

$$\ell \gamma_k \geq \Gamma_k - \Gamma_{k-\ell} \geq k^2 - (k-\ell)(k-\ell+1) = -\ell^2 - (2k+1)\ell - k \tag{3.14}$$

and hence

$$\gamma_k \geq 2k + 1 - \ell - \frac{k}{\ell}. \tag{3.15}$$

Choosing, again, $\ell = \lceil \sqrt{k} \rceil$ gives the lower bound in (1.1). ◀

60:12 Successive Minimum Spanning Trees

► **Remark 15.** For a specific k , we can improve (1.1) somewhat by instead using (3.13) and (3.15) with $\ell = \lfloor \sqrt{k} \rfloor$ or $\ell = \lceil \sqrt{k} \rceil$. For example, for $k = 2$, taking $\ell = 1$ yields $2 \leq \gamma_2 \leq 5$. For $k = 3$, taking $\ell = 2$ yields $3.5 \leq \gamma_3 \leq 8$. ◀

Besides these rigorous results, taking increments of the left and right-hand sides of (3.11) also suggests the following conjecture.

► **Conjecture 16.** For $k \geq 1$, $2k - 1 \leq \gamma_k \leq 2k$.

► **Remark 17.** Moreover, if $\gamma_k = 2k + \delta + o(1)$ holds, as conjectured in Conjecture 5, then $\Gamma_k = k^2 + k(\delta + 1) + o(k)$, and thus necessarily $\delta \in [-1, 0]$ as a consequence of Corollary 13. In fact, the numerical estimates described in Section 5, suggest that $\delta = -1$; see Conjecture 6. ◀

3.3 Improved upper bounds

The upper bounds in Theorem 12 and Corollary 13 were proved using the bound (3.5). A stronger, but less explicit, bound can be proved by using instead the sharper (3.4). That is, we consider the random vectors $\mathbf{r}(\tau)$ defined as above but with (3.6) replaced by

$$\hat{p}_k := \binom{r_k + 1}{2} / \binom{n}{2}. \quad (3.16)$$

As remarked before (3.4), this approximation comes from imagining all edges in each F_k to be in a single component; this overestimates the probability that an arriving edge is rejected from F_k and, as developed in the previous subsection, gives $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$ just as when \hat{p}_k was defined by (3.5).

Using for consistency our usual time scaling in which edges arrive at rate $(n - 1)/2$, by a standard martingale argument one can show that, for each $k \geq 1$,

$$\frac{1}{n} r_k(\lfloor \frac{1}{2} nt \rfloor) \xrightarrow{\text{P}} g_k(t), \quad \text{uniformly for } t \geq 0, \quad (3.17)$$

for some continuously differentiable functions $g_k(t)$ satisfying the differential equations, with $g_0(t) := 1$,

$$g'_k(t) = \frac{1}{2} (g_{k-1}(t)^2 - g_k(t)^2), \quad g_k(0) = 0, \quad k \geq 1. \quad (3.18)$$

Moreover, using $\mathbf{s}(\tau) \succeq \mathbf{r}(\tau)$ and taking limits, it can be shown that

$$\Gamma_k := \sum_{i=1}^k \gamma_i \leq \frac{1}{2} \int_0^\infty t(1 - g_k(t)^2) dt. \quad (3.19)$$

We omit the details, but roughly, in time dt , $\frac{1}{2}n dt$ edges arrive, all costing about t/n , and a $g_k(t)^2$ fraction of them pass beyond the first k graphs (to the degree that we are now modeling graphs).

For $k = 1$, (3.18) has the solution $g_1(t) = \tanh(t/2)$, and (3.19) yields the bound $\Gamma_1 = \gamma_1 \leq 2 \ln 2 \doteq 1.3863$. This is better than the bound 2 given by (3.11), but still far from precise since $\gamma_1 = \zeta(3) \doteq 1.2021$.

For $k \geq 2$ we do not know any exact solution to (3.18), but numerical solution of (3.18) and calculation of (3.19) (see Section 5) suggests that $\Gamma_k < k^2 + 1$. We leave the proof of this as an open problem. If proved, this would be a marked improvement on $\Gamma_k \leq k^2 + k$, which was the exact expectation of the random process given by (3.5) (that part of the analysis was tight). In particular, it would establish that $2k - 2 \leq \gamma_k \leq 2k$.

For $k = 2$, the numerical calculations in Section 5 give $\gamma_1 + \gamma_2 \leq 4.5542\dots$ and thus $\gamma_2 \leq 3.3521\dots$. The same value was also obtained using Maple's numerical differential equation solver, with Maple giving greater precision but the two methods agreeing in the digits shown here.

4 A related problem by Frieze and Johansson

As said in the introduction, Frieze and Johansson [6] recently considered the problem of finding the minimum total cost of k edge-disjoint spanning trees in K_n , for a fixed integer $k \geq 2$. (They used random costs with the uniform model; we may consider all three models described in Section 1.1.) We denote this minimum cost by mst_k , following [6]. Trivially,

$$\text{mst}_k \leq \sum_{i=1}^k w(T_i), \quad (4.1)$$

and as said in the introduction, it is easy to see that strict inequality may hold when $k \geq 2$, i.e., that our greedy procedure of choosing T_1, T_2, \dots successively does not yield the minimum cost set of k disjoint spanning trees.

We assume in this section that $n \geq 2k$; then k edge-disjoint spanning trees exist and thus $\text{mst}_k < \infty$.

► **Remark 18.** As observed by Frieze and Johansson [6], the problem is equivalent to finding the minimum cost of a basis in the matroid \mathcal{M}_k , defined as the union matroid of k copies of the cycle matroid of K_n . This means that the elements of \mathcal{M}_k are the edges in K_n , and a set of edges is independent in \mathcal{M}_k if and only if it can be written as the union of k forests, see e.g. [20, Chapter 8.3]. (Hence, the bases, i.e., the maximal independent sets, are precisely the unions of k edge-disjoint spanning trees. For the multigraph version in the Poisson model, of course we use instead the union matroid of k copies of the cycle matroid of K_n^∞ ; we use the same notation \mathcal{M}_k .) We write r_k for rank in this matroid. ◀

For $k = 2$, Frieze and Johansson [6] show that

$$\mathbb{E} \text{mst}_2 \rightarrow \mu_2 \doteq 4.1704. \quad (4.2)$$

This is strictly smaller than our numerical estimates from Table 1 for the total cost of two edge-disjoint spanning trees chosen successively, $\gamma_1 + \gamma_2 \doteq 1.20 + 3.09 > 4.29$; we show this calculation to only two digits as we are confident of this level of precision. This would show that choosing minimum spanning trees one by one is not optimal, even asymptotically, except that our estimates are not rigorous. The following theorem is less precise but establishes rigorously that the values are indeed different. (We rely only on $\sigma_2 < \mu_2$, coming from the estimate of μ_2 above, and our estimate $\sigma_2 \doteq 2.69521$, obtained as the numerical solution to a differential equation; see the full version for details.)

► **Theorem 19.** *There exists $\delta > 0$ such that, for any of the three models, w.h.p. $w(T_1) + w(T_2) \geq \text{mst}_2 + \delta$.*

This can be restated in the following equivalent form.

► **Corollary 20.** $\gamma_1 + \gamma_2 > \mu_2$.

Proof. The equivalence of the statements in Theorem 19 and Corollary 20 is immediate since $w(T_1) \xrightarrow{\text{P}} \gamma_1$ and $w(T_2) \xrightarrow{\text{P}} \gamma_2$ by Theorem 1 or 2 (depending on the choice of model), and $\text{mst}_2 \xrightarrow{\text{P}} \mu_2$ by [6] and justification that this holds in all three models (see the full version). ◀

► Remark 21. Numerically, $\gamma_2 > 2.9683$. This is immediate from Corollary 20, the value of μ_2 given by [6], and (by [7]) $\gamma_1 = \zeta(3)$. ◀

The proof of Theorem 19 is based on the fact that many edges are rejected from T_1 and T_2 after time σ_2 , but none is rejected from the union matroid until a later time c_3 , namely the threshold for appearance of a 3-core in a random graph.

5 Computational results

A variety of computations were performed, all of which will be mentioned here but only one presented in any detail; for the rest see [12].

1. We performed naive simulations, generating edge-weighted random graphs and finding the successive trees.
2. We performed a similar simulation, but instead of introducing edges in order of increasing weight, we simply generate random edges. The details are below.
3. We solved the differential equations (3.18) numerically up to $k = 50$, to get upper bounds on Γ_k as in (3.19). The results suggest that $\Gamma_k < k^2 + 1$ (perhaps $\Gamma_k < k^2 + 0.743$). If proved, this would be a marked improvement on $\Gamma_k \leq k^2 + k$, which was the exact expectation of the random process given by (3.5) (that part of the analysis was tight). In particular, it would establish that $2k - 2 \leq \gamma_k \leq 2k$.
4. Finally, the functions $\rho_k(t)$ can be obtained, recursively on k , through the solution to certain functional fixed-point equations. We solved these numerically, getting results consistent with those in the set of simulations listed as (2) above.

We now detail the set of simulations listed as (2) above, done with reference to the Poisson multigraph model introduced in Section 2.2 and used throughout. We begin with k empty graphs of order n . At each step we introduce a random edge e and, in the first graph G_i for which e does not lie within a component, we merge the two components given by its endpoints. (If this does not occur within the k graphs under consideration, we do nothing, just move on to the next edge.) For each graph we simulate only the components (i.e., the sets of vertices comprised by each component); there is no need for any more detailed structure. The edge arrivals should be regarded as occurring as a Poisson process of intensity $(n - 1)/2$ but instead we simply treat them as arriving at times $2/n, 4/n$, etc.

Figure 2 depicts the result of a single such simulation with $n = 1\,000\,000$, showing for each k from 1 to 5 the size of the largest component of G_k (as a fraction of n) against time. Similar experiments with multiple simulations and larger values of n support Conjecture 6 that $\gamma_k = 2k - 1 + o(1)$. The largest experiment's results are shown in part in Table 1; its support for the conjecture continues through $k = 29$, the last value for which it gives good data.

■ **Table 1** Estimates of $\gamma_1, \dots, \gamma_9$ from 10 simulations each with $n = 10\,000\,000$, through time $t = 40$.

10 simulations each with $n = 10\,000\,000$

6 Open questions

We would be delighted to confirm the various conjectures above, in particular Conjectures 4–6, and to get a better understanding of (and ideally a closed form for) ρ_∞ (provided it exists).

It is also of natural interest to ask this k th-minimum question for structures other than spanning trees. Subsequent to this work, the length X_k of the k th shortest s – t path in a complete graph with random edge weights has been studied by Mezei, Gerke and Sorkin [8]. They show that $X_k/(2k/n + \ln n/n) \xrightarrow{P} 1$ for all k from 1 to $n - 1$. In particular, the first few paths all cost nearly identical amounts, quite different from the situation for successive MSTs.

The “random assignment problem” is to determine the cost of a minimum-cost perfect matching in a complete bipartite graph with random edge weights. A great deal is known about it, by a variety of methods; for one relatively recent work, with references to others, see Wästlund [19]. It would be interesting to understand the k th cheapest matching.

It could also be interesting to consider other variants of all these questions. Frieze and Johansson [6] considered the k disjoint structures which together have the smallest possible total cost, where we consider disjoint structures generated successively. In either case, instead of asking for disjoint structures, we could require structures which are merely distinct, or perhaps which differ in some adversarially specified elements.

Simple Analysis of Sparse, Sign-Consistent JL

Meena Jagadeesan

Harvard University, Cambridge, Massachusetts, USA
mjagadeesan@college.harvard.edu

Abstract

Allen-Zhu, Gelashvili, Micali, and Shavit construct a sparse, sign-consistent Johnson-Lindenstrauss distribution, and prove that this distribution yields an essentially optimal dimension for the correct choice of sparsity. However, their analysis of the upper bound on the dimension and sparsity requires a complicated combinatorial graph-based argument similar to Kane and Nelson’s analysis of sparse JL. We present a simple, combinatorics-free analysis of sparse, sign-consistent JL that yields the same dimension and sparsity upper bounds as the original analysis. Our analysis also yields dimension/sparsity tradeoffs, which were not previously known.

As with previous proofs in this area, our analysis is based on applying Markov’s inequality to the p th moment of an error term that can be expressed as a quadratic form of Rademacher variables. Interestingly, we show that, unlike in previous work in the area, the traditionally used Hanson-Wright bound is *not* strong enough to yield our desired result. Indeed, although the Hanson-Wright bound is known to be optimal for gaussian degree-2 chaos, it was already shown to be suboptimal for Rademachers. Surprisingly, we are able to show a simple moment bound for quadratic forms of Rademachers that is sufficiently tight to achieve our desired result, which given the ubiquity of moment and tail bounds in theoretical computer science, is likely to be of broader interest.

1 Introduction

In many modern algorithms that process high dimensional data, it is beneficial to preprocess the data through a dimensionality reduction scheme that preserves the geometry of the data. Dimensionality reduction schemes have been applied in streaming algorithms [22] as well as algorithms for numerical linear algebra [29], feature hashing [27], graph sparsification [25], and many other areas. The geometry-preserving objective can be expressed mathematically as follows. The goal is to construct a probability distribution \mathcal{A} over $m \times n$ real matrices that satisfies the following condition for any $x \in \mathbb{R}^n$:

$$\mathbb{P}_{A \in \mathcal{A}}[(1 - \epsilon)\|x\|_2 \leq \|Ax\|_2 \leq (1 + \epsilon)\|x\|_2] > 1 - \delta. \quad (1)$$

An upper bound on the dimension m achievable by a probability distribution \mathcal{A} that satisfies (1) is given in the following lemma, which is a central result in the area of dimensionality reduction:

► **Lemma 1** (Johnson-Lindenstrauss [15]). *For any positive integer n and parameters $0 < \epsilon, \delta < 1$, there exists a probability distribution \mathcal{A} over $m \times n$ real matrices with $m = \Theta(\epsilon^{-2} \log(1/\delta))$ that satisfies (1).*

The optimality of the dimension m achieved by Lemma 1 was recently proven in [16, 14].

For many applications of dimensionality reduction schemes, it can be useful to consider probability distributions over sparse matrices in order to speed up the projection time. Here, sparsity refers to the constraint that there are a small number of nonzero entries in each column. In this context, Kane and Nelson [18] constructed a sparse JL distribution, improving the work of Achlioptas [1] and Dasgupta et al. [6], and proved the following:

► **Theorem 2** (Sparse JL [18]). *For any positive integer n and $0 < \epsilon, \delta < 1$, there exists a probability distribution \mathcal{A} over $m \times n$ real matrices with $m = \Theta(\epsilon^{-2} \log(1/\delta))$ and sparsity $s = \Theta(\epsilon^{-1} \log(1/\delta))$ that satisfies (1).*

Notice that this probability distribution, even with its sparsity guarantee, achieves the same dimension as Lemma 1. The proof of Theorem 2 presented in [18] involved complicated combinatorics; however, Cohen, Jayram, and Nelson [4] recently constructed two simple, combinatorics-free proofs of this result. The first approach, which is most relevant to the approach taken in this paper, used the Hanson-Wright bound on moments of quadratic forms. An analysis similar to the second approach can be recovered by specializing the analysis of Cohen [3] for sparse oblivious subspace embeddings to the case of “1-dimensional subspaces.” In fact, though this recovered analysis is more complex, it has the advantage of yielding dimension-sparsity tradeoffs that were not produced through any of the previous approaches: for $B \geq e$, the sparsity s can be set to $\Theta(\epsilon^{-1} \log_B(1/\delta))$ if m is set to $\Theta(B\epsilon^{-2} \log(1/\delta))$, enabling a $\log B$ factor reduction in sparsity at the expense of a B factor gain in dimension.

JL with sign-consistency constraints

Neuroscience-based constraints give rise to the additional condition of sign-consistency on the matrices in the probability distribution. Sign-consistency refers to the constraint that the nonzero entries of each column are either all positive or all negative. The relevance of dimensionality reduction schemes in neuroscience is described in a survey by Ganguli and Sompolinsky [9]. In convergent pathways in the brain, information stored in a massive number of neurons is compressed into a small number of neurons, and nonetheless the ability to perform the relevant computations is preserved. Modeling this information compression scheme requires a hypothesis regarding what properties of the original information must be accurately transmitted to the receiving neurons. A plausible minimum requirement is that convergent pathways preserve the similarity structure of neuronal representations at the source area.¹

It remains to select the appropriate mathematical measure of similarity. The candidate similarity measure considered in [9] is vector inner product, which conveniently gives rise to a model based on the JL distribution.² Suppose there are n “input” neurons at a source area and m “output” neurons at a target area. In this framework, the information at the

¹ This requirement is based on the experimental evidence that semantically similar objects in higher perceptual or association areas in the brain elicit similar neural activity patterns [19] and on the hypothesis that the similarity structure of the neural code is the basis of our ability to categorize objects and generalize responses to new objects [24].

² It is not difficult to see that for vectors x and y in the ℓ_2 unit ball, a $(1 + \epsilon)$ -approximation of $\|x\|_2$, $\|y\|_2$, and $\|x - y\|_2$ implies an additive error $\Theta(\epsilon)$ approximation of the inner product $\langle x, y \rangle$.

input neurons is represented as a vector in \mathbb{R}^n , the synaptic connections to output neurons are represented as a $m \times n$ matrix (with (i, j) th entry corresponding to the strength of the connection between input neuron j and output neuron i), and the information received by the output neurons is represented as a vector in \mathbb{R}^m . The similarity measure between two vectors v, w of neural information being taken to be $\langle v, w \rangle$ motivates modeling a synaptic connectivity matrix as a random $m \times n$ matrix drawn from a probability distribution that satisfies (1). Certain constraints on synaptic connectivity matrices arise from the biological limitations of neurons: the matrices must be *sparse* since a neuron is only connected to a small number (e.g. a few thousand) of postsynaptic neurons and *sign-consistent* since a neuron is usually purely excitatory or purely inhibitory.

This biological setting motivates the mathematical question: what is the optimal dimension and sparsity that can be achieved by a probability distribution over sparse, sign-consistent matrices that satisfies (1)? Allen-Zhu, Gelashvili, Micali, and Shavit [2] constructed a sparse, sign-consistent JL distribution³ and proved the following:

► **Theorem 3** (Sparse, sign-consistent JL [2]). *For every $\varepsilon > 0$, and $0 < \delta < 1/e$, there exists a probability distribution \mathcal{A} over $m \times n$ real, sign-consistent matrices with $m = \Theta(\varepsilon^{-2} \log^2(1/\delta))$ and sparsity $s = \Theta(\varepsilon^{-1} \log(1/\delta))$ that satisfies (1).*

In [2], it was also proven that the additional $\log(1/\delta)$ factor on m is essentially necessary: namely, any distribution over sign-consistent matrices satisfying (1) requires $m = \tilde{\Omega}(\varepsilon^{-2} \log(1/\delta) \min(\log(1/\delta), \log n))$. Thus, the dimension in Theorem 3 is essentially optimal. However, in order to achieve this upper bound on m , the proof presented in [2] involved complicated combinatorics even more delicate than in the analysis of sparse JL in [18].

We present a simpler, combinatorics-free proof of Theorem 3. Our analysis also yields dimension/sparsity tradeoffs, which were not previously known.⁴ We prove the following:

► **Theorem 4.** *For every $\varepsilon > 0$, $0 < \delta < 1$, and $e \leq B \leq \frac{1}{\delta}$, there exists a probability distribution \mathcal{A} over $m \times n$ real, sign-consistent matrices with $m = \Theta(B\varepsilon^{-2} \log_B^2(1/\delta))$ and sparsity $s = \Theta(\varepsilon^{-1} \log_B(1/\delta))$ that satisfies (1).*

Notice Theorem 3 is recovered if $B = e$. For larger B values, Theorem 4 enables a $\log B$ factor reduction in sparsity at the cost of a $B/\log^2 B$ factor gain in dimension.

To contextualize our tradeoff in Theorem 4, recall that the upper bounds on sparse (non-sign-consistent) JL dimension-sparsity tradeoffs by Cohen [3] take a similar form, allowing a $\log B$ factor reduction in s for a B factor gain in m . Moreover, in a recent follow-up work [13], we show lower bounds that indicate that the standard choice of sparse JL construction requires an exponential factor gain in dimension for a given reduction in sparsity, demonstrating that Cohen’s dimension-sparsity tradeoffs are essentially tight.⁵ Due to the structural similarity between sparse JL and sparse, sign-consistent JL, we believe this provides indication that our tradeoffs in Theorem 4 could be tight for this construction in many regimes.⁶

³ Related mathematical work includes, in addition to sparse JL [18], a construction of a dense, sign-consistent JL distribution [23, 10].

⁴ In Appendix A, we point out the limiting lemma in the combinatorial analysis in [2], which prevents dimension-sparsity tradeoffs from being attainable through this approach, due to an assumption that is implicitly used in the analysis. For sparse JL, it is similarly not known how to obtain these tradeoffs via the combinatorial approach of [18].

⁵ More specifically, it follows from [3] and [13] that m is exactly $\min(\text{poly}(B)\varepsilon^{-2} \log(1/\delta), 2\varepsilon^{-2}/\delta)$ for the standard choice of sparse JL construction (uniformly choosing s nonzero entries per column).

⁶ An interesting direction for future work could be to build upon the ideas in the follow-up work [13] to show lower bounds on the dimension-sparsity tradeoffs for this sparse, sign-consistent JL construction.

Proof Techniques

As in [2, 18, 4], our analysis is based on applying Markov’s inequality to the p th moment of an error term. Like in the first combinatorics-free analysis of sparse JL in [4], we express this error term as a quadratic form of Rademachers (uniform ± 1 random variables), and our analysis then boils down to analyzing the moments of this quadratic form. While the analysis in [4] achieves the optimal dimension for sparse JL using an upper bound on the moments of quadratic forms of subgaussians due to Hanson and Wright [11], we give a counterexample in Section 3.2 that shows that the Hanson-Wright bound is too loose in the sign-consistent setting to result in the optimal dimension. Since the Hanson-Wright bound is tight for quadratic forms of gaussians, we thus require a separate treatment of quadratic forms of Rademachers.

We construct a simple bound on moments of quadratic forms of Rademachers that, unlike the Hanson-Wright bound, is sufficiently tight in our setting to prove Theorem 4. Our bound borrows some of the ideas from Latafá’s tight bound on the moments of quadratic forms of Rademachers [21]. Although our bound is much weaker than the bound in [21] in the general case, it has the advantage of providing a greater degree of simplicity by consisting of easier-to-analyze terms; this simplicity is critical since our quadratic form coefficients are themselves random variables. The crux is that while the bound in [21] is focused on obtaining tight estimates for quadratic forms with scalar coefficients, our bound is much more tractable for quadratic forms with random variable coefficients. As a result, our bound enables a simple proof of Theorem 4, while retaining the necessary precision to recover the optimal dimension.

We build upon these ideas in our recent follow-up work [13], where the Hanson-Wright bound also turns out to be too loose. The work studies sparse JL performance in feature hashing and considers the restricted set of vectors with small ℓ_∞ -to- ℓ_2 norm ratio, continuing a line of work [27, 6, 17, 5, 18, 7]. The main result is a tight tradeoff between ℓ_∞ -to- ℓ_2 norm ratio and ϵ , δ , s , and m , and the lower bounds on dimension-sparsity tradeoffs mentioned before are shown as a corollary. Similar to this work, the proof boils down to a tight bound on p th moment of an error term, and it also turns out that the Hanson-Wright bound is too loose here. The work solves this issue by building upon ideas from this work, utilizing a separate treatment of Rademachers that is tractable for random variable coefficients. While the analysis in [13] does not use the exact quadratic form bound presented here, it uses intuition and generalizations of the moment bounding techniques presented in this work.

1.1 Notation

The main building blocks for our expressions are the following two types of random variables: Rademacher variables, which are uniform ± 1 random variables, and Bernoulli random variables, which have support $\{0, 1\}$. For any random variable X and value $p \geq 1$, we use the notation $\|X\|_p$ to denote the p -norm $(\mathbb{E}[|X|^p])^{1/p}$, where \mathbb{E} denotes the expectation. Similarly, for any random variable X and value $p \geq 1$ and any event E , we use the notation $\|X | E\|_p$ to denote the conditional p -norm $(\mathbb{E}[|X|^p | E])^{1/p}$, which is equivalent to the p -norm of the random variable $(X | E)$. We use the following notation to discuss certain asymptotics: given two scalar quantities Q_1 and Q_2 that are functions of some parameters, we use the notation $Q_1 \simeq Q_2$ to denote that there exist positive universal constants $C_1 \leq C_2$ such that $C_1 Q_2 \leq Q_1 \leq C_2 Q_2$, and we use the notation $Q_1 \lesssim Q_2$ to denote that there exists a positive universal constant C such that $Q_1 \leq C Q_2$.

1.2 A digression on Rademachers versus gaussians

The concept that drives our moment bound can be illustrated in the linear form setting. Suppose $\sigma_1, \sigma_2, \dots, \sigma_n$ are i.i.d Rademachers, $x = [x_1, \dots, x_n]$ is a vector in \mathbb{R}^n such that $|x_1| \geq |x_2| \geq \dots \geq |x_n|$, and $2 \leq p \leq n$. The Khintchine inequality, which is tight for linear forms of gaussians, yields the ℓ_2 -norm bound $\|\sum_{i=1}^n \sigma_i x_i\|_p \lesssim \sqrt{p} \|x\|_2$. However, this bound *cannot* be a tight bound on $\|\sum_{i=1}^n \sigma_i x_i\|_p$ for the following reason: As $p \rightarrow \infty$, the quantity $\sqrt{p} \|x\|_2$ goes to infinity, while for any $p \geq 1$, the quantity $\|\sum_{i=1}^n \sigma_i x_i\|_p$ is bounded by $\|x\|_1$. Surprisingly, a result due to Hitczenko [12] indicates that the tight bound is actually the following combination of the ℓ_2 and ℓ_1 norm bounds:

$$\left\| \sum_{i=1}^n \sigma_i x_i \right\|_p \simeq \sum_{i=1}^p |x_i| + \sqrt{p} \sqrt{\sum_{i>p} x_i^2}.$$

In this bound, the “big” terms (i.e. terms involving x_1, x_2, \dots, x_p) are handled with an ℓ_1 -norm bound, while the remaining terms are approximated as gaussians and bounded with an ℓ_2 -norm bound.

A similar complication arises when the Hanson-Wright bound on quadratic forms of subgaussians is applied to Rademachers. Let σ be a d -dimensional vector of independent Rademachers, and let $A = (a_{k,l})$ be a symmetric $d \times d$ matrix with zero diagonal. The Hanson-Wright bound [11], which is tight for gaussians, states for any $p \geq 1$,

$$\|\sigma^T A \sigma\|_p \lesssim \sqrt{p} \sqrt{\sum_{k=1}^d \sum_{l=1}^d a_{k,l}^2} + p \left(\sup_{\|y\|_2=1} |y^T A y| \right).$$

Similar to the linear form setting, this bound *can't* be a tight bound on $\|\sigma^T A \sigma\|_p$ for the following reason: As $p \rightarrow \infty$, the quantity $\sqrt{p} \sqrt{\sum_{k=1}^d \sum_{l=1}^d a_{k,l}^2}$ goes to ∞ , while for any $p \geq 1$, the quantity $\|\sigma^T A \sigma\|_p$ is bounded by the entrywise ℓ_1 -norm $\sum_{k=1}^d \sum_{l=1}^d |a_{k,l}|$.

Our quadratic form bound is based on a degree-2 analog of Hitczenko’s observation. We analogously handle the “big” terms with an ℓ_1 -norm bound and bound the remaining terms by approximating some of the Rademachers by gaussians. From this, we obtain a combination of ℓ_2 and ℓ_1 norm bounds, similar to the linear form setting. Our simple bound has the surprising feature that it yields tighter guarantees than the Hanson-Wright bound yields for our error term. While our bound is weaker than Latała’s tight bound [21] on the moments of quadratic forms of Rademachers in the general case, it provides a greater degree of simplicity: our bound avoids an operator-norm-like term in Latała’s bound that is especially difficult to analyze when A is a random matrix, as is the case in this setting. Moreover, our bound still retains the necessary precision to recover the optimal dimension for sparse, sign-consistent JL.

Although our final analysis follows a style that this is perhaps less well-known within the TCS community, in the end, it is quite simple, relying only on our quadratic form bound coupled with a few standard tricks such as repeated use of triangle inequalities on $\|\cdot\|_p$ norms and standard moment bounds involving the binomial distribution. For this reason, we believe that it is likely to be of interest in other theoretical computer science settings involving moments or tail bounds of Rademacher forms.

1.3 Outline for the rest of the paper

In Section 2, we describe the construction and analysis of [2] for sparse, sign-consistent JL. In Section 3, we present the combinatorics-free approach in [4] for sparse JL that uses the Hanson-Wright bound, and we discuss why this approach does not yield the optimal dimension in the sign-consistent setting. In Section 4, we derive our bound on the moments of quadratic forms of Rademachers and use this bound to construct a combinatorics-free proof of Theorem 4.

2 Existing Analysis for Sparse, Sign-Consistent JL

In Section 2.1, we describe how to construct the probability distribution of sparse, sign-consistent matrices analyzed in Theorem 3. In Section 2.2, we briefly describe the combinatorial proof of Theorem 3 presented in [2].

2.1 Construction of Sparse, Sign-Consistent JL

The entries of a matrix $A \in \mathcal{A}$ are generated as follows.⁷ Let $A_{i,j} = \eta_{i,j}\sigma_j/\sqrt{s}$ where $\{\sigma_i\}_{i \in [n]}$ and $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ are defined as follows:

- The families $\{\sigma_i\}_{i \in [n]}$ and $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ are independent from each other.
- The variables $\{\sigma_i\}_{i \in [n]}$ are i.i.d Rademachers.
- The variables $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ are identically distributed Bernoulli random variables with expectation s/m .
- The $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ are independent across columns but not independent within each column. For every column $1 \leq i \leq n$, it holds that $\sum_{r=1}^m \eta_{r,i} = s$. For every subset $S \subseteq [m]$ and every column $1 \leq i \leq n$, it holds that $\mathbb{E}[\prod_{r \in S} \eta_{r,i}] \leq \prod_{r \in S} \mathbb{E}[\eta_{r,i}]$. (One common definition of $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ that satisfies these conditions is the distribution defined by uniformly choosing exactly s of these variables per column to be a 1.)

For every $x \in \mathbb{R}^n$ such that $\|x\|_2 = 1$, we need to analyze an error term, which for this construction is the following random variable:

$$Z := \|Ax\|_2^2 - 1 = \frac{1}{s} \sum_{i \neq j} \sum_{r=1}^m \eta_{r,i} \eta_{r,j} \sigma_i \sigma_j x_i x_j.$$

Proving that \mathcal{A} satisfies (1) boils down to proving that $\mathbb{P}_{\eta, \sigma}[|Z| > \epsilon] < \delta$. The main technique to prove this tail bound is the moment method. Bounding a large moment of Z is useful since it follows from Markov's inequality that

$$\mathbb{P}_{\eta, \sigma}[|Z| > \epsilon] = \mathbb{P}_{\eta, \sigma}[|Z|^p > \epsilon^p] < \frac{\mathbb{E}[|Z|^p]}{\epsilon^p}.$$

The usual approach, used in the analyses in [2, 18, 4] as well as in our analysis, is to take $p = \Theta(\log(1/\delta))$ to be an even integer and analyze the p -norm $\|Z\|_p$ of the error term.

2.2 Discussion of the combinatorial analysis of [2]

In the analysis in [2], a complicated combinatorial argument was used to prove the following lemma, from which Theorem 3 follows:

► **Lemma 5** ([2]). *If $s^2 \leq m$ and $p < s$, then $\|Z\|_p \lesssim \frac{p}{s}$.*

⁷ See the appendix of the full version of the paper for a formal construction of the probability space.

The argument in [2] to prove Lemma 5 was based on expanding $\mathbb{E}[Z^p]$ into a polynomial with $\approx n^{2p}$ terms, establishing a correspondence between the monomials and the multigraphs, and then doing combinatorics to analyze the resulting sum. The approach of mapping monomials to graphs is commonly used in analyzing the eigenvalue spectrum of random matrices [28, 8] and was also used in [18] to analyze sparse JL. The analysis in [2] borrowed some methods from the analysis in [18]; however, the additional correlations between the Rademachers imposed by sign-consistency forced the analysis in [2] to require more delicate manipulations at several stages of the computation.

The expression to be analyzed was $s^p \mathbb{E}[Z^p]$, which was written as:

$$\sum_{i_1, \dots, i_p, j_1, \dots, j_p \in [n], i_1 \neq j_1, \dots, i_p \neq j_p} \left(\prod_{u=1}^p x_{i_u} x_{j_u} \right) \left(\mathbb{E}_\sigma \prod_{u=1}^p \sigma_{i_u} \sigma_{j_u} \right) \left(\mathbb{E}_\eta \prod_{u=1}^t \sum_{r=1}^m \eta_{r, i_u} \eta_{r, j_u} \right).$$

After layers of computation, it was shown that

$$s^p \mathbb{E}[Z^p] \leq e^p \sum_{v=2}^p \sum_{G \in \mathcal{G}_{v,p}} \left((1/p^p) \prod_{q=1}^v \sqrt{d_q}^{d_q} \right) \sum_{r_1, \dots, r_p \in [m]} \prod_{i=1}^w (s/m)^{v_i}$$

where $\mathcal{G}_{v,p}$ is a set of directed multigraphs with v labeled vertices and t labeled edges, where d_q is the total degree of vertex $q \in [v]$ in a graph $\mathcal{G}_{v,p}$, and where w and v_1, \dots, v_w are defined by G and the edge colorings r_1, \dots, r_t . The problem then boiled down to carefully enumerating the graphs in $\mathcal{G}_{v,p}$ in six stages and analyzing the resulting expression.

3 Discussion of Combinatorics-Free Approaches

The main ingredient of the first combinatorics-free approach for sparse JL presented in [4] is the Hanson-Wright bound on the moments of quadratic forms of subgaussians. In Section 3.1, we discuss the approach in [4]. In Section 3.2, we discuss why this approach, if applied to sparse, sign-consistent JL, fails to yield the optimal dimension.

3.1 Hanson-Wright approach for sparse JL in [4]

The relevant random variable for sparse JL is

$$Z' = \|Ax\|^2 - 1 = \frac{1}{s} \sum_{r=1}^m \sum_{i \neq j} \eta_{r,i} \eta_{r,j} \sigma_{r,i} \sigma_{r,j} x_i x_j$$

where the n independent Rademachers $\{\sigma_i\}_{i \in [n]}$ from the sign-consistent case are replaced by the mn independent Rademachers $\{\sigma_{r,i}\}_{i \in [n], r \in [m]}$. The main idea in [4] was to view Z' as a quadratic form $\frac{1}{s} \sigma^T A \sigma$. Here, σ is a mn -dimensional vector of independent Rademachers and $A = (A_{k,l})$ is a symmetric, zero diagonal, block diagonal $mn \times mn$ matrix with m blocks of size $n \times n$, where the (i, j) th entry (for $i \neq j$) of the r th block is $\eta_{r,i} \eta_{r,j} x_i x_j$. The quantity $\|\sigma^T A \sigma\|_p$ was analyzed using the Hanson-Wright bound. In order to bound $\|\sigma^T A \sigma\|_p$, since A is a random matrix whose entries depend on the η values, an expectation had to be taken over η in the expression given by the Hanson-Wright bound. This resulted in the following:

$$\|\sigma^T A \sigma\|_p \lesssim \left\| \sqrt{p} \sqrt{\sum_{k=1}^{mn} \sum_{l=1}^{mn} A_{k,l}^2} + p \sup_{\|y\|_2=1} |y^T A y| \right\|_p. \tag{2}$$

The remainder of the analysis boiled down to bounding the RHS of (2), and it successfully recovered Theorem 2.

3.2 Failure of the Hanson-Wright approach for sparse, sign-consistent JL

The Hanson-Wright-based approach for sparse JL in [4] cannot be applied to the sign-consistent case to obtain a tight bound on $\|Z\|_p$. The loss arises from the fact that while the Hanson-Wright bound is tight for quadratic forms of Gaussians, it is not guaranteed to be tight for quadratic forms of Rademachers. As discussed in Section 1.2, when $p \rightarrow \infty$, the Hanson-Wright bound goes to ∞ , while $\|\sigma^T A \sigma\|_p$ can be bounded by the entrywise ℓ_1 norm of the matrix A . Although approximating the error term Rademachers by Gaussians happened to be sufficiently tight for sparse JL, this loss results in a suboptimal dimension for sparse, sign-consistent JL.⁸ We give a counterexample, i.e. a vector x , that shows that the Hanson-Wright bound is too loose to give the optimal dimension (when $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ are defined by uniformly choosing exactly s of the variables per column to be a 1). We present the details in Appendix E.

4 Simple Proof of Theorem 4

The main ingredient in our proof of Theorem 4 is the following bound on $\|Z\|_p$:

► **Lemma 6.** *Let $B = m/s^2$. If $p \geq 2$, then*

$$\|Z\|_p \lesssim \begin{cases} \frac{p}{s \log B}, & \text{if } B \geq e \\ \frac{p}{sB} & \text{if } B < e. \end{cases}$$

We will later show that Theorem 4 follows from Lemma 6 via Markov's inequality.

In order to analyze $\|Z\|_p$, we view Z as a quadratic form $\frac{1}{s} \sigma^T A \sigma$, where the vector σ is an n -dimensional vector of independent Rademachers, and $A = (a_{i,j})$ is a symmetric, zero-diagonal $n \times n$ matrix where the (i, j) th entry (for $i \neq j$) is $x_i x_j \sum_{r=1}^m \eta_{r,i} \eta_{r,j}$. Since Z is symmetric in x_1, \dots, x_n , we can assume WLOG that $|x_1| \geq |x_2| \geq \dots \geq |x_n|$. For convenience, we define, like in [4],

$$Q_{i,j} := \sum_{r=1}^m \eta_{r,i} \eta_{r,j} \tag{3}$$

to be the number of collisions between the nonzero entries of the i th column and the nonzero entries of the j th column. Now, the (i, j) th entry of A (for $i \neq j$) can be written as $Q_{i,j} x_i x_j$.

As discussed in Section 3.2, we cannot apply the Hanson-Wright bound to tightly analyze $\|Z\|_p$ and thus require a separate treatment of Rademachers. We derive the following moment bound on quadratic forms of Rademachers⁹ that yields tighter guarantees than the Hanson-Wright bound yields for $\|Z\|_p$:

⁸ The difference results from the correlations between the signs resulting in more “tightly packed” coefficients in the error term quadratic form in the sign-consistent case.

⁹ As mentioned before, Latała [21] provides a tight bound on the moments of $\sigma^T A \sigma$ (and on the moments of more general quadratic forms). However, his bound consists of terms that are difficult to analyze when the quadratic form coefficients are random variables. Moreover, his proof is quite complicated, though the bound can be used in a black box to generate a much messier solution (by unravelling some of his proof to avoid the operator-norm-like term).

► **Lemma 7.** *If $A = (a_{i,j})$ is a symmetric square $n \times n$ matrix with zero diagonal, $\{\sigma_i\}_{i \in [n]}$ is a set of independent Rademachers, and $q \geq 1$, then*

$$\left\| \sum_{i=1}^n \sum_{j=1}^n a_{i,j} \sigma_i \sigma_j \right\|_q \lesssim \left(\sum_{i=1}^{\min(q,n)} \sum_{j=1}^{\min(q,n)} |a_{i,j}| \right) + \sqrt{q} \sqrt{\sum_{i=1}^n \left\| \sum_{j>q} a_{i,j} \sigma_j \right\|_q^2}.$$

Observe that our bound avoids the weakness of the Hanson-Wright bound in the limit as $q \rightarrow \infty$. As discussed in Section 1.2, $\left\| \sum_{i=1}^n \sum_{j=1}^n a_{i,j} \sigma_i \sigma_j \right\|_q$ can be bounded by the entrywise ℓ_1 -norm bound $\sum_{i=1}^n \sum_{j=1}^n |a_{i,j}|$ for any $q \geq 1$. While the Hanson-Wright bound goes to ∞ as $q \rightarrow \infty$, the bound in Lemma 7 approaches the entrywise ℓ_1 bound in the limit: for $q > n$, the second term in Lemma 7 vanishes since the summand $\sum_{j>q}$ is empty. As a result, the bound becomes the first-term, which becomes $\sum_{i=1}^n \sum_{j=1}^n |a_{i,j}|$ as desired. For $1 \leq q < n$, our bound becomes an interpolation of ℓ_1 and ℓ_2 norm bounds that bears resemblance to Hitzchenko’s Rademacher linear form bound in [12] discussed in Section 1.2.

Although our bound is weaker than Latała’s bound in [21] in the general case, it is much simpler to analyze, especially when A is a random matrix. While the bound in [21] is focused on obtaining tight estimates for quadratic forms where A is a scalar matrix, our bound is much more tractable when A is a random matrix. The main complication in the bound in [21] arises from the operator-norm-like term $\sup_{\|y\|_2=1, \|y\|_\infty \leq \frac{1}{\sqrt{q}}} |y^T A y|$. Due to the asymmetrical geometry of the ℓ_2 ball truncated by ℓ_∞ planes, this term becomes especially messy in our setting when A is a random matrix. Observe that our bound in Lemma 7 manages to avoid this term altogether. Moreover, our ℓ_1 norm term is straightforward to calculate, and our ℓ_2 norm term can be handled cleanly through a bound (Lemma 15) from [20] on the q -norm $\left\| \sum_{j>q} a_{i,j} \sigma_j \right\|_q$ that is tractable even when the $a_{i,j}$ are themselves random variables.

We defer our proof of Lemma 7 to Section 4.1. We now use Lemma 7 and the triangle inequality to obtain the following bound on $\|Z\|_p$:

$$\begin{aligned} \|Z\|_p &= \frac{1}{s} \left(\mathbb{E}_\eta \mathbb{E}_\sigma \left[\sum_{i=1}^n \sum_{j \leq n, j \neq i} Q_{i,j} x_i x_j \sigma_i \sigma_j \right]^p \right)^{1/p} \\ &\lesssim \frac{1}{s} \left(\mathbb{E}_\eta \left[\sum_{i=1}^p \sum_{\substack{j \leq p \\ j \neq i}} |Q_{i,j} x_i x_j| + \sqrt{p} \sqrt{\sum_{i=1}^n \left(\mathbb{E}_\sigma \left[\sum_{\substack{j>p \\ j \neq i}} Q_{i,j} x_i x_j \sigma_j \right]^p \right)^{2/p}} \right]^p \right)^{1/p} \\ &\leq \frac{1}{s} \left(\underbrace{\left\| \sum_{i=1}^p \sum_{\substack{j \leq p \\ j \neq i}} |Q_{i,j} x_i x_j| \right\|_p}_{(*)} + \sqrt{p} \underbrace{\sqrt{\sum_{i=1}^n \left\| \sum_{\substack{j>p \\ j \neq i}} Q_{i,j} x_i x_j \sigma_j \right\|_p^2}}_{(**)} \right). \end{aligned}$$

We first discuss some intuition for why using this bound to analyze $\|Z\|_p$ avoids the loss incurred by the Hanson-Wright bound here. In the Hanson-Wright bound, all of the Rademachers are essentially approximated by gaussians. In our bound, we make use of Rademachers in the appropriate places to avoid loss. For $1 \leq i \leq p$ and $1 \leq j \leq p$ (the upper left $p \times p$ minor where the $|x_i|$ and $|x_j|$ values are the largest), our approach utilizes

an ℓ_1 -norm bound rather than \sqrt{p} times an ℓ_2 bound, which turns out to allow us to save a factor of \sqrt{p} in the resulting bound on $\|Z\|_p$. Now, since the original matrix is symmetric, it only remains to consider $1 \leq i \leq n$ and $p+1 \leq j \leq n$. In this range, we approximate the σ_i Rademachers by gaussians and use an ℓ_2 -norm bound. It turns out that approximating the σ_j Rademachers by gaussians as well would yield too loose of a bound for our application, so we preserve the σ_j Rademachers. For the remaining Rademacher linear forms, the interaction between the x_j values (all of which are upper bounded in magnitude by $\frac{1}{\sqrt{p}}$) and the σ_j Rademachers yields the desired bound.

In order to prove Lemma 6, it remains to prove Lemma 7 as well as to bound (*) and (**). In Section 4.1, we prove Lemma 7. In Section 4.2 and Section 4.3, we bound (*) and (**). Since the building blocks of (*) and (**) are weighted sums of the $Q_{i,j}$ random variables, we first bound moments of these random variables separately. In Section 4.2, we use the binomial-like properties of the $Q_{i,j}$ s coupled with standard moment bounds involving the binomial distribution to analyze the moments. In Section 4.3, we use these moment bounds to bound (*) and (**), and then finish our proof of Lemma 6. In Section 4.4, we show how Lemma 6 implies Theorem 4.

4.1 Proof of Lemma 7

We use the following standard lemmas in our proof of Lemma 7.

The first lemma allows us to decouple the two sets of Rademachers in our quadratic form so that we can reduce analyzing the moments of the quadratic form to analyzing the moments of a linear form.

► **Lemma 8** (Decoupling, Theorem 6.1.1 of [26]). *If $A = (a_{i,j})$ is a symmetric, zero-diagonal $n \times n$ matrix and $\{\sigma_i\}_{i \in [n]} \cup \{\sigma'_i\}_{i \in [n]}$ are independent Rademachers, then*

$$\left\| \sum_{i=1}^n \sum_{j=1}^n a_{i,j} \sigma_i \sigma_j \right\|_q \lesssim \left\| \sum_{i=1}^n \sum_{j=1}^n a_{i,j} \sigma'_i \sigma_j \right\|_q.$$

The next lemma is due to Khintchine and gives an ℓ_2 -norm bound on linear forms of Rademachers. Since the Khintchine bound is derived from approximating $\sigma_1, \dots, \sigma_n$ by i.i.d gaussians, we only use this bound outside of the upper left $p \times p$ minor of our matrix A .

► **Lemma 9** (Khintchine). *If $\sigma_1, \sigma_2, \dots, \sigma_n$ are independent Rademachers, then for all $q \geq 1$ and $a \in \mathbb{R}^n$,*

$$\left\| \sum_{i=1}^n \sigma_i a_i \right\|_q \lesssim \sqrt{q} \|a\|_2.$$

Now, we are ready to prove Lemma 7.

Proof of Lemma 7. By Lemma 8 and the triangle inequality, we know

$$\left\| \sum_{i=1}^n \sum_{j=1}^n a_{i,j} \sigma_i \sigma_j \right\|_q \lesssim \underbrace{\left\| \sum_{i=1}^{\min(q,n)} \sum_{j=1}^{\min(q,n)} a_{i,j} \sigma'_i \sigma_j \right\|_q}_{\alpha} + \underbrace{\left\| \sum_{i=1}^n \sum_{j>q} a_{i,j} \sigma'_i \sigma_j \right\|_q}_{\beta} + \underbrace{\left\| \sum_{i>q} \sum_{j=1}^q a_{i,j} \sigma'_i \sigma_j \right\|_q}_{\gamma}.$$

We first bound α . Since a Rademacher σ satisfies $|\sigma| = 1$, it follows that α can be upper bounded by the entrywise ℓ_1 -norm bound $\sum_{i=1}^{\min(q,n)} \sum_{j=1}^{\min(q,n)} |a_{i,j}|$ as desired. Using Lemma 9, we know that β can be upper bounded by:

$$\sqrt{q} \left\| \sqrt{\sum_{i=1}^n \left(\sum_{j>q} a_{i,j} \sigma_j \right)^2} \right\|_q = \sqrt{q} \left\| \sqrt{\sum_{i=1}^n \left(\sum_{j>q} a_{i,j} \sigma_j \right)^2} \right\|_{q/2} \leq \sqrt{q} \sqrt{\sum_{i=1}^n \left\| \sum_{j>q} a_{i,j} \sigma_j \right\|_q^2}.$$

We now bound γ . An analogous argument shows $\gamma \leq \sqrt{q} \sqrt{\sum_{j=1}^q \left\| \sum_{i>q} a_{i,j} \sigma_i \right\|_q^2}$. Thus:

$$\gamma \leq \sqrt{q} \sqrt{\sum_{j=1}^q \left\| \sum_{i>q} a_{i,j} \sigma_i \right\|_q^2} \leq \sqrt{q} \sqrt{\sum_{j=1}^n \left\| \sum_{i>q} a_{i,j} \sigma_i \right\|_q^2} = \sqrt{q} \sqrt{\sum_{i=1}^n \left\| \sum_{j>q} a_{i,j} \sigma_j \right\|_q^2}. \quad \blacktriangleleft$$

4.2 Moments of Weighted Sums of $Q_{i,j}$ Random Variables

Recall that for $1 \leq i \neq j \leq n$, the $Q_{i,j}$ random variables count the number of collisions between the nonzero entries in the i th column and j th column. We first prove that these sets of random variables satisfy (conditional) independence properties, when conditioned on any choice of nonzero entries in the i th column. We also show that the moments of the random variables obtained through this conditioning are bounded by binomial moments.

► **Proposition 10.** *Let X be a random variable distributed as $\text{Bin}(s, s/m)$. For any $1 \leq i \leq n$, given any choice of s nonzero rows $r_1 \neq r_2 \neq \dots \neq r_s$ in the i th column, the set of $n-1$ random variables¹⁰ $\{(Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1)\}_{1 \leq j \leq n, j \neq i}$ are independent. Moreover, for any $q \geq 1$ and any $j \neq i$:*

$$\|Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1\|_q \leq \|X\|_q.$$

The independence properties use that the nonzero entries in different columns are independent. Moreover, the binomial bound on the moments of $Q_{i,j}$ follows from the decomposition of $Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1$ into a sum of Bernoulli random variables.

Proof of Proposition 10. Let A be a matrix drawn from \mathcal{A} , and pick any $1 \leq i \leq n$. We condition on the event that the s nonzero entries in column i of A occur at rows r_1, \dots, r_s . For $1 \leq j \leq n, j \neq i$ and $1 \leq k \leq s$, let $Y_{k,j} = \eta_{r_k,j}$, so that $(Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i}) = \sum_{k=1}^s Y_{k,j}$. Notice that the sets $\{Y_{k,j}\}_{k \in [s]}$ for $1 \leq j \leq n, j \neq i$ are independent from each other, which means random variables in the set $\{Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1\}_{1 \leq j \leq n, j \neq i}$ are independent. For $1 \leq j \leq n, j \neq i$, and $1 \leq k \leq s$, let $Z_{k,j}$ be distributed as i.i.d Bernoulli random variables with expectation s/m . Notice that for a fixed j , each $Y_{k,j}$ is distributed as $Z_{k,j}$ and the random variables $\{Y_{k,j}\}_{1 \leq k \leq s}$ are negatively correlated (and nonnegative), which means

$$\|Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1\|_q = \left\| \sum_{k=1}^s Y_{k,j} \right\|_q \leq \left\| \sum_{k=1}^s Z_{k,j} \right\|_q = \|X\|_q. \quad \blacktriangleleft$$

¹⁰ See the appendix in the full version of the paper for a formal discussion of viewing these quantities as random variables over a different probability space.

61:12 Simple Analysis of Sparse, Sign-Consistent JL

Now, we need to analyze the moments of weighted sums of $Q_{i,j}$ random variables. Using the independence properties and the fact that the moments of the $Q_{i,j}$ are upper bounded by binomial moments as given in Proposition 10, this boils down to studying the moments of weighted sums of binomial random variables. The main tools that we use in analyzing these moments are bounds on moments of sums of nonnegative random variables and sums of symmetric random variables due to Latała [20] that we state in Appendix B.¹¹

Our first estimate is an upper bound on the moments of binomial random variables, which also gives bounds on moments of the $Q_{i,j}$ by Proposition 10. We defer the proof to Appendix D.

► **Proposition 11.** *Suppose that X is a random variable distributed as $\text{Bin}(N, \alpha)$ for any $\alpha \in (0, 1)$ and any integer $N \geq 1$. If $q \geq 1$ and $B = \frac{q}{\alpha \max(N, q)}$, then*

$$\|X\|_q \lesssim \begin{cases} \frac{q}{\log B} & \text{if } B \geq e \\ \frac{q}{B} & \text{if } B < e \end{cases}.$$

Our next estimate is essentially an upper bound on the moments of sums of binomial random variables weighted by Rademachers. We defer the proof to Appendix C.

► **Proposition 12.** *Suppose that $q \geq 2$ is even and $y = [y_1, \dots, y_M]$ is a vector that satisfies $\|y\|_2 \leq 1$ and $\|y\|_\infty \leq \frac{1}{\sqrt{q}}$. Let X be a random variable distributed as $\text{Bin}(N, \alpha)$ for some $\alpha \in (0, 1)$ and some integer $N \geq 1$. Suppose that Y_1, \dots, Y_M are independent random variables that satisfy $\|Y_k\|_l \leq \|X\|_l$ for $1 \leq k \leq M$ and for $l \geq 1$. Suppose that $\sigma_1, \dots, \sigma_M$ are independent Rademachers, also independent of $\{Y_k\}_{k \in [M]}$. If $B = \frac{q}{\alpha \max(N, q)}$, then*

$$\left\| \sum_{k=1}^M Y_k y_k \sigma_k \right\|_q \lesssim \begin{cases} \frac{\sqrt{q}}{\log B} & \text{if } B \geq e \\ \frac{\sqrt{q}}{B} & \text{if } B < e \end{cases}.$$

4.3 Bounding (*) and (**) to prove Lemma 6

We bound the quantities (*) and (**) in the following sublemmas, which assume the notation used throughout the paper:

► **Lemma 13.** *If $m/s^2 = B$, then*

$$\left\| \sum_{i=1}^p \sum_{j \leq p, j \neq i} |Q_{i,j} x_j x_i| \right\|_p \lesssim \begin{cases} \frac{p}{\log B} & \text{if } B \geq e \\ \frac{p}{B} & \text{if } B < e \end{cases}.$$

► **Lemma 14.** *If $m/s^2 = B$, then*

$$\sqrt{p} \sqrt{\sum_{i=1}^n \left\| \sum_{j > p, j \neq i} Q_{i,j} x_i x_j \sigma_j \right\|_p^2} \lesssim \begin{cases} \frac{p}{\log B} & \text{if } B \geq e \\ \frac{p}{B} & \text{if } B < e \end{cases}.$$

We now use Proposition 10 as well as the moment bound on binomial random variables from Proposition 11 to prove Lemma 13 and thus bound (*).

¹¹The proofs of these bounds given in [20] are not complicated; for the sake of being self-contained, we give sketches of these proofs in the appendix of the full version of the paper.

Proof of Lemma 13. We carefully use the triangle inequality to see¹²:

$$\left\| \sum_{i=1}^p \sum_{\substack{j \leq p \\ j \neq i}} |Q_{i,j} x_j x_i| \right\|_p \leq 2 \left\| \sum_{i=1}^p \sum_{\substack{j \leq p \\ j > i}} Q_{i,j} |x_j| |x_i| \right\|_p \lesssim \left\| \sum_{i=1}^p x_i^2 \sum_{\substack{j \leq p \\ j > i}} Q_{i,j} \right\|_p \lesssim \sum_{i=1}^p x_i^2 \left\| \sum_{\substack{j \leq p \\ j > i}} Q_{i,j} \right\|_p.$$

Let $X \sim \text{Bin}(s, s/m)$ and $Y \sim \text{Bin}(sp, s/m)$. By Proposition 10, for any i and any $r_1 \neq r_2 \neq \dots \neq r_s$, the random variables $\{Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\}_{j \neq i}$ are independent and $\|Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\|_p \leq \|X\|_p$. It follows from taking p th powers of both sides that

$$\left\| \left(\sum_{\substack{j \leq p \\ j > i}} Q_{i,j} \right) \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1 \right\|_p = \left\| \sum_{\substack{j \leq p \\ j > i}} (Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1) \right\|_p \leq \|Y\|_p.$$

Now, Proposition 11 gives us a bound on $\|Y\|_p$, and the result follows from the law of total expectation.¹³ ◀

We now use Proposition 10 as well as the moment bound on weighted sums of binomial random variables from Proposition 12 to prove Lemma 14 and thus bound (**).

Proof of Lemma 14. Observe that

$$\sqrt{p} \sqrt{\sum_{i=1}^n \left\| \sum_{\substack{j > p \\ j \neq i}} Q_{i,j} x_i x_j \sigma_j \right\|_p^2} = \sqrt{p} \sqrt{\sum_{i=1}^n x_i^2 \left\| \sum_{\substack{j > p \\ j \neq i}} Q_{i,j} x_j \sigma_j \right\|_p^2} \leq \sqrt{p} \max_{1 \leq i \leq n} \left\| \sum_{\substack{j > p \\ j \neq i}} Q_{i,j} x_j \sigma_j \right\|_p.$$

Let $X \sim \text{Bin}(s, s/m)$ and $Y \sim \text{Bin}(sp, s/m)$. By Proposition 10, for any i and any $r_1 \neq r_2 \neq \dots \neq r_s$, the random variables $\{Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\}_{j \neq i}$ are independent and $\|Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\|_p \leq \|X\|_p \leq \|Y\|_p$. Moreover, $|x_j| \leq \frac{1}{\sqrt{p}}$ for $j > p$. Now, we consider $\left\| \sum_{j > p, j \neq i} Q_{i,j} x_j \sigma_j \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1 \right\|_p$ which is equal to $\left\| \sum_{j > p, j \neq i} (Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1) (\sigma_j \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1) x_j \right\|_p$. Since each $(\sigma_j \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1)$ is distributed as a Rademacher and since the set of $n - 1$ random variables $\{\sigma_j \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\}_{j \neq i}$ are independent and also independent of $\{Q_{i,j} \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1\}_{j \neq i}$, we can apply Proposition 12 to this expression and thus get a bound¹⁴ on the conditional p -norm $\left\| \sum_{j > p, j \neq i} Q_{i,j} x_j \sigma_j \mid \eta_{r_1,i} = \dots = \eta_{r_s,i} = 1 \right\|_p$. Now, the result follows from the law of total expectation. ◀

We now show the bound on $\|Z\|_p$ follows from the bounds on (*) and (**) in Lemmas 13, 14.

¹²Naively applying the triangle inequality yields a suboptimal bound, so we require this more careful treatment.

¹³See the appendix in the full version of the paper for a formal discussion of why a uniform bound on the conditional p -norm implies a bound on the p -norm here.

¹⁴Approximating the σ_j by gaussians yields a suboptimal bound, so we require the bound given in Proposition 12.

61:14 Simple Analysis of Sparse, Sign-Consistent JL

Proof of Lemma 6. Applying Lemmas 13,14 after the following simplification proves the lemma:

$$\|Z\|_p \lesssim \frac{1}{s} \left\| \sum_{i=1}^p \sum_{j \leq p, j \neq i} |Q_{i,j} x_i x_j| \right\|_p + \frac{\sqrt{p}}{s} \sqrt{\sum_{i=1}^n \left\| \sum_{j > p, j \neq i} Q_{i,j} x_i x_j \sigma_j \right\|_p^2}. \quad \blacktriangleleft$$

4.4 Proof of Theorem 4

We show Lemma 6 implies Theorem 4, completing the proof.

Proof of Theorem 4. It suffices to show $\mathbb{P}_{\eta, \sigma}[|Z| > \epsilon] < \delta$. By Markov's inequality, we know

$$\mathbb{P}_{\eta, \sigma}[|Z| > \epsilon] = \mathbb{P}_{\eta, \sigma}[|Z|^p > \epsilon^p] < \epsilon^{-p} \mathbb{E}[|Z|^p] = \left(\frac{\|Z\|_p}{\epsilon} \right)^p.$$

Suppose that $B \geq e$. Then by Lemma 6, we know

$$\left(\frac{\|Z\|_p}{\epsilon} \right)^p \leq \left(\frac{Cp}{(\log B)s\epsilon} \right)^p.$$

Thus, to upper bound this quantity by δ , we can set $s = \Theta(\epsilon^{-1}p/\log B) = \Theta(\epsilon^{-1} \log_B(1/\delta))$ and $m = \Theta(Bs^2)$. We impose the additional constraint that $B \leq \frac{1}{\delta}$ to guarantee that $s \geq 1$. This proves the desired result.¹⁵ \blacktriangleleft

¹⁵If we set $B < e$, if we use Lemma 6, we know that in order to obtain an upper bound of δ , we would have to set $s = \Theta(\epsilon^{-1}p/B) = \Theta(\epsilon^{-1} \log(1/\delta)/B)$ and $m = \Theta(\epsilon^{-1} \log^2(1/\delta)/B)$. This yields no better s or m values than those achieved when $B = e$.

A Limitations of the Combinatorial Approach

At first glance, it appears that the bound of $\mathbb{P}[|Z| > \epsilon] \leq \left(\frac{Cts}{\epsilon m}\right)^t$ of [2] in the proof of the main theorem (p. 9 of the arXiv version) implies the desired dimension-sparsity tradeoffs by setting $s = \epsilon^{-1}t$, $m = \frac{B\epsilon^{-1}ts}{2C}$, and $t = \log_B(1/\delta)$ (this t value is equivalent to the p value in this paper). However, this does not actually follow from the analysis in [2]: there is an assumption made in one of the lemmas, which is not stated explicitly in the statement of the lemma, that does not allow the parameters to be set in this way. The limiting factor is the lemma that states that

$$s^t \mathbb{E}[Z^t] \leq 2^{O(t)} t^t \left(\frac{s^2}{m}\right)^t.$$

This is Lemma 3 in the conference version of [2], and Lemma 4.3 in the arXiv version of [2]. Here, Z is defined analogously as in section 2.1 of this paper.

The proof of this lemma, given in Appendix A.3 in [2], implicitly relies on the fact that $\frac{s^2}{m} \geq 1$, although this condition is not explicitly stated in the lemma statement. This assumption arises from the last line of the proof, where the sum $\sum_{w=1}^t \left(\frac{s^2}{m}\right)^w$ is upper bounded by $t \left(\frac{s^2}{m}\right)^t$. Following the end of the proof of Theorem 1 (the top of p. 9 of the arXiv version), this yields $\mathbb{P}[|Z| > \epsilon] \leq \left(\frac{Cts}{\epsilon m}\right)^t$. Now, suppose we instead set $m = Bs^2$ (where $B \leq 1$ as required by the assumption). Then we obtain $\left(\frac{Cts}{\epsilon m}\right)^t = \left(\frac{Ct}{\epsilon Bs}\right)^t$. Thus, we can set s to be $C\epsilon^{-1}B^{-1} \log(1/\delta)$ and m to be $C^2\epsilon^{-2} \log^2(1/\delta)B^{-1}$. Since $B \leq 1$, this is no better than the original theorem statement and thus yields no dimension-sparsity tradeoff.

Now, suppose we instead let $\frac{s^2}{m} \leq 1$. Then we can modify the proof of Lemma 4.3 to obtain the weaker upper bound of $\sum_{w=1}^t \left(\frac{s^2}{m}\right)^w$ by $t \frac{s^2}{m}$. Let $B = m/s^2$ where $B \geq 1$. In order to ensure that m is polynomial in $\log(1/\delta)$, we assume that $B \leq \delta$. In this case, mimicking the calculation at the end of the proof of Theorem 1, we obtain $\mathbb{P}[|Z| > \epsilon] \leq \frac{1}{B} \left(\frac{Ct}{\epsilon s}\right)^t = \left(\frac{Ct}{\epsilon s B^{1/t}}\right)^t$. Thus, we can set $s = C \log(1/\delta) \epsilon^{-1} e^{-\log B/t}$. Observe that $0 \leq \log B \leq t$, so $1 \geq e^{-\log B/t} \geq e^{-1}$. Thus, $s = \Theta(\log(1/\delta) \epsilon^{-1})$ and $m = \Theta(Bs^2)$, which does not yield a dimension-sparsity tradeoff.

Thus, it is not clear how to directly obtain the dimension-sparsity tradeoff from the combinatorial approach of [2]. Some intuition for this limitation is that the moment bounds on Z obtained by the combinatorial approach are not sufficiently tight for varying values of B due to the fact that the bounding techniques are implicitly tailored to the case of $B = \Theta(1)$. The combinatorics-free approach in this paper avoids this issue through making use of a more structured method to bound the moments of Z .

B Latała's Moment Bounds

The following bounds on sums of independent random variables are due to Latała [20]. These proofs are not complicated: for sake of being self-contained, in the appendix of the full version of the paper, we sketch proofs of these bounds. Full proofs of these lemmas can be found in [20].

► **Lemma 15** ([20]). *If $q \geq 2$ and X, X_1, \dots, X_n are independent symmetric random variables, then*

$$\left\| \sum_{i=1}^n X_i \right\|_q \simeq \inf \left\{ T > 0 \text{ such that } \sum_{i=1}^n \log \left(\mathbb{E} \left[\left(1 + \frac{X_i}{T} \right)^q \right] \right) \leq q \right\}.$$

► **Lemma 16** ([20]¹⁶). If $1 \leq q \leq n$ and X, X_1, \dots, X_n are i.i.d nonnegative random variables, then

$$\left\| \sum_{i=1}^n X_i \right\|_q \simeq \sup_{1 \leq t \leq q} \frac{q}{t} \left(\frac{n}{q} \right)^{1/t} \|X\|_t.$$

C Proof of Proposition 12

The main ingredient in this proof is Lemma 15 (Latała's bound on moments of sums of symmetric random variables).

Proof of Proposition 12. Since the Y_i are independent random variables, we can apply Lemma 15 to obtain:

$$\left\| \sum_{k=1}^M Y_k y_k \sigma_k \right\|_q \lesssim \inf \left\{ T > 0 \mid \sum_{k=1}^M \log \left(\mathbb{E} \left[\left| 1 + \frac{Y_k \sigma_k y_k}{T} \right|^q \right] \right) \leq q \right\}.$$

Thus, it suffices to show

$$T \simeq \begin{cases} \frac{\sqrt{q}}{\log B} & \text{if } B \geq e \\ \frac{\sqrt{q}}{B} & \text{if } B < e \end{cases}$$

satisfies $\sum_{k=1}^M \log \left(\mathbb{E} \left[\left(1 + \frac{Y_k \sigma_k y_k}{T} \right)^q \right] \right) \leq q$. We see

$$\begin{aligned} \sum_{k=1}^M \log \left(\mathbb{E} \left[\left(1 + \frac{Y_k \sigma_k y_k}{T} \right)^q \right] \right) &= \sum_{k=1}^M \log \left(1 + \sum_{l=1}^q \binom{q}{l} \frac{(\mathbb{E}[(Y_k \sigma_k)^l]) y_k^l}{T^l} \right) \\ &= \sum_{k=1}^M \log \left(1 + \sum_{l=1}^{q/2} \binom{q}{2l} \frac{\|Y_k\|_{2l}^{2l} y_k^{2l}}{T^{2l}} \right) \\ &\leq \sum_{k=1}^M \log \left(1 + \sum_{l=1}^{q/2} \left(\frac{qe}{2l} \right)^{2l} \left(\frac{\|Y_k\|_{2l} y_k}{T} \right)^{2l} \right) \end{aligned}$$

By the bound on moments of binomial random variables in Proposition 11, we know if $B \geq e$ that there exists a universal constant C such that $\|Q_{i,j}\|_{2l} \leq \frac{2lC}{\log B}$. Thus, we obtain

$$\begin{aligned} \sum_{k=1}^M \log \left(\mathbb{E} \left[\left(1 + \frac{Y_k \sigma_k y_k}{T} \right)^q \right] \right) &\leq \sum_{k=1}^M \log \left(1 + \sum_{l=1}^{q/2} \left(\frac{qe}{2l} \right)^{2l} \left(\frac{2lC y_k}{T \log B} \right)^{2l} \right) \\ &\leq \sum_{k=1}^M \log \left(1 + \sum_{l=1}^{q/2} \left(\frac{qeC y_k}{T \log B} \right)^{2l} \right). \end{aligned}$$

¹⁶This result was actually first due to S.J. Montgomery-Smith through a private communication with Latała. Nonetheless, it is also a corollary of a result in [20].

61:18 Simple Analysis of Sparse, Sign-Consistent JL

Since $|y_k| \leq \frac{1}{\sqrt{q}}$, if we set $T = \frac{2eC\sqrt{q}}{\log B}$, then we obtain

$$\sum_{k=1}^M \log \left(1 + \sum_{l=1}^{q/2} \left(\frac{\sqrt{q}y_k}{2} \right)^{2l} \right) \leq \sum_{k=1}^M \log \left(1 + (\sqrt{q}y_k)^2 \sum_{l=1}^{q/2} \left(\frac{1}{2} \right)^{2l} \right).$$

This can be bounded by

$$\sum_{k=1}^M \log \left(1 + (\sqrt{q}y_k)^2 \right) = \sum_{k=1}^M \log (1 + qy_k^2) \leq \sum_{i=1}^n qy_i^2 \leq q$$

as desired. An analogous argument shows that if $B < e$, we can set $T = \frac{2eC\sqrt{q}}{B}$. \blacktriangleleft

D Proof of Proposition 11

The main tool that we use in this proof is Lemma 16 (Latała's bound on moments of sums of i.i.d nonnegative random variables).

Proof of Proposition 11. Notice that it suffices to obtain an upper bound on $\|X\|_q$ for all $N \geq q$. (Since $\|X\|_q$ is an increasing function of N , an upper bound on $\|X\|_q$ at $N = q$ is also an upper bound on $\|X\|_q$ for all $N < q$). For the rest of the proof, we assume $N \geq q$.

Notice X has the same distribution as $\sum_{j=1}^N Z_j$ where Z, Z_1, \dots, Z_N are i.i.d Bernoulli random variables with expectation α . Since $\|Z\|_t = \alpha^{1/t}$, we know by Lemma 16,

$$\begin{aligned} \|X\|_q &\simeq \sup_{1 \leq t \leq q} \frac{q}{t} \left(\frac{N}{q} \right)^{1/t} \alpha^{1/t} \\ &= \sup_{1 \leq t \leq q} \frac{q}{t} \left(\frac{1}{B} \right)^{1/t} \end{aligned}$$

At $t = 1$, this quantity is equal to $\frac{q}{B}$, and at $t = q$, this quantity is equal to $\left(\frac{1}{B}\right)^{1/q} = e^{\log(1/B)/q}$. The only $t \in \mathbb{R}$ for which this quantity has derivative 0 is $t = \log B$. Notice that $1 \leq \log B \leq q$ if and only if $e \leq B \leq e^q$. Thus

$$\|X\|_q \simeq \begin{cases} \max\left(\frac{q}{B}, \frac{q}{\log B}, e^{\log(1/B)/q}\right) & \text{if } e \leq B \leq e^q \\ \max\left(\frac{q}{B}, e^{\log(1/B)/q}\right) & \text{if } B < e \text{ or if } B > e^q. \end{cases}$$

For $B \geq e$, we want to show $\|X\|_q \lesssim q/\log B$. Since $\log B > 0$, we see $e^{\log(1/B)/q} = e^{-\log B/q} \leq q/\log B$ and $q/B \leq q/\log B$.

For $B < e$, we want to show $\|X\|_q \lesssim q/B$. Since $\frac{1}{B} > \frac{1}{e}$, we see $e^{\log(1/B)/q} = \left(\frac{1}{B}\right)^{1/q} \leq \frac{e}{B} \lesssim \frac{q}{B}$. \blacktriangleleft

E Weakness of bound on $\|Z\|_p$ from Equation (4)

Like in Section 4, we view the random variable Z as a quadratic form $\frac{1}{s}\sigma^T A \sigma$, where σ an n -dimensional vector of independent Rademachers and A is a symmetric, zero-diagonal $n \times n$ matrix where the (i, j) th entry (for $i \neq j$) is $x_i x_j \sum_{r=1}^m \eta_{r,i} \eta_{r,j} = Q_{i,j} x_i x_j$. Applying the Hanson-Wright bound followed by an expectation over the η values yields

$$\|\sigma^T A \sigma\|_p \lesssim \left\| \sqrt{p} \sqrt{\sum_{i=1}^n \sum_{j \leq n, j \neq i} Q_{i,j}^2 x_i^2 x_j^2} + p \sup_{\|y\|_2=1} \left| \sum_{i=1}^n \sum_{j \leq n, j \neq i} Q_{i,j} x_i x_j y_i y_j \right| \right\|_p =: U_p. \quad (4)$$

We show that the vector $x = [\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0, \dots, 0] \in \mathbb{R}^n$ forces U_p to be too large to yield the optimal m value, thus proving that the Hanson-Wright bound does not provide a sufficiently tight bound on $\|Z\|_p$ to achieve Theorem 3. The main ingredient in our proof is the following lemma, which we prove in subsection C.1:

► **Lemma 17.** *For every column $1 \leq i \leq n$, suppose that the random variables $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ have the distribution defined by uniformly choosing exactly s of the variables per column. If $x = [\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0, \dots, 0]$, $p < s$ and $B = m/s^2 \leq \frac{e^p}{p}$, then*

$$U_p \simeq \begin{cases} \frac{p^2}{\log Bp} & \text{if } B \geq \frac{e}{p} \\ \frac{p}{B} & \text{if } B < \frac{e}{p}. \end{cases}$$

We can obtain bounds on s and m from Lemma 17 via Markov’s inequality. We disregard the case where $B \geq \frac{e^p}{p}$, since this case would yield a value for m that is not polynomial in $\log(1/\delta)$. If $B < e/p$, then it follows that $s = \Theta(\varepsilon^{-1}B^{-1} \log(1/\delta)) = \Omega(\varepsilon^{-1} \log^2(1/\delta))$ and $m = \Theta(\varepsilon^{-2}B^{-1} \log^2(1/\delta)) = \Omega(\varepsilon^{-2} \log^3(1/\delta))$. If $B \geq e/p$, then it follows that $s = \Theta(\varepsilon^{-1}p^2/\log(Bp)) = \Omega(\varepsilon^{-1} \log(1/\delta))$ and $m = \Theta(\varepsilon^{-2}p^4B/\log^2(Bp)) = \Omega(\varepsilon^{-2} \log^3(1/\delta))$. These bounds on m incur an extra $\log(1/\delta)$ factor, and thus the Hanson-Wright bound is too weak for this setting. Now, it suffices to prove Lemma 17, which we do in the next section.

E.1 Proof of Lemma 17

In this section, we assume that $x = [\frac{1}{\sqrt{2}}, \frac{1}{\sqrt{2}}, 0, \dots, 0]$ and that the random variables $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ have the distribution defined by uniformly choosing exactly s of the variables per column. We first show the following computation of $\|Q_{i,j}\|_p$.

► **Proposition 18.** *Assume that the random variables $\{\eta_{r,i}\}_{r \in [m], i \in [n]}$ have the distribution defined by uniformly choosing exactly s of the variables per column. Then, if $p < s$ and $X \sim \text{Bin}(s, s/m)$, we have that $\|Q_{i,j}\|_p \simeq \|X\|_p$.*

Proof. We condition on the even that the nonzero locations in column i are at r_1, r_2, \dots, r_s . Notice that the random variable $(Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1)$ is distributed as $Z_{r_1} + Z_{r_2} + \dots + Z_{r_s}$ where Z_{r_k} is an indicator for the k th entry in the j th column being nonzero. Let Z'_{r_k} for $1 \leq k \leq s$ be i.i.d random variables distributed as $\text{Bern}(s/m)$. Now, observe that

$$\mathbb{E}[(Z_{r_1} + Z_{r_2} + \dots + Z_{r_s})^p] = \sum_{\substack{0 \leq t_1, t_2, \dots, t_s \leq p \\ t_1 + t_2 + \dots + t_s = p}} \mathbb{E}[\prod_{i=1}^s Z_{r_i}^{t_i}] = \sum_{\substack{0 \leq t_1, t_2, \dots, t_s \leq p \\ t_1 + t_2 + \dots + t_s = p}} \mathbb{E}[\prod_{i|t_i > 0} Z_{r_i}].$$

Notice that $\mathbb{E}[(Z'_{r_1} + Z'_{r_2} + \dots + Z'_{r_s})^p] = \sum_{0 \leq t_1, t_2, \dots, t_s \leq p, t_1 + t_2 + \dots + t_s = p} \mathbb{E}[\prod_{i|t_i > 0} Z'_{r_i}]$. Thus, it suffices to compare $\mathbb{E}[\prod_{i|t_i > 0} Z_{r_i}]$ and $\mathbb{E}[\prod_{i|t_i > 0} Z'_{r_i}]$. We see that $\mathbb{E}[\prod_{i|t_i > 0} Z'_{r_i}] = (\frac{s}{m})^{|\{i|t_i > 0\}|}$. Since $p < s$, we see that $\mathbb{E}[\prod_{i|t_i > 0} Z_{r_i}] = \prod_{j=0}^{|\{i|t_i > 0\}|-1} \frac{s-j}{m-j}$. It is not difficult to verify that this ratio is bounded by $2^{O(p)}$ as desired, so

$$\frac{\mathbb{E}[(Q_{i,j} \mid \eta_{r_1,i} = \eta_{r_2,i} = \dots = \eta_{r_s,i} = 1)^p]}{\mathbb{E}[X^p]} = \frac{\mathbb{E}[(Z_{r_1} + Z_{r_2} + \dots + Z_{r_s})^p]}{\mathbb{E}[X^p]} \geq 2^{-O(p)}.$$

Now, by the law of total expectation, we know that

$$\frac{\mathbb{E}[Q_{i,j}^p]}{\mathbb{E}[X^p]} \geq 2^{-O(p)}$$

as desired. ◀

61:20 Simple Analysis of Sparse, Sign-Consistent JL

We now prove the following relation between U_p and $\|Q_{1,2}\|_p$:

► **Lemma 19.** *Assume the notation and restrictions above. Then $U_p \simeq p \|Q_{1,2}\|_p$.*

Proof of Lemma 19. For ease of notation, we define

$$S_1 := p \sup_{\|y\|_2=1} \left| \sum_{i=1}^n \sum_{j \leq n, j \neq i} Q_{i,j} x_i x_j y_i y_j \right|$$

$$S_2 := \sqrt{p} \sqrt{\sum_{i=1}^n \sum_{j=1}^n Q_{i,j}^2 x_i^2 x_j^2}.$$

Our goal is to calculate $U_p = \|S_1 + S_2\|_p$. We make use of the following upper and lower bounds on $\|S_1 + S_2\|_p$:

$$\left| \|S_1\|_p - \|S_2\|_p \right| \leq \|S_1 - S_2\|_p \leq \|S_1 + S_2\|_p \leq \|S_1\|_p + \|S_2\|_p. \quad (5)$$

In order to compute $\left| \|S_1\|_p - \|S_2\|_p \right|$ and $\|S_1\|_p + \|S_2\|_p$, we first compute $\|S_1\|_p$ and $\|S_2\|_p$. For our choice of x , notice

$$\|S_1\|_p \simeq p \left\| \sup_{\|y\|_2=1} |Q_{1,2} y_1 y_2| \right\|_p \simeq p \|Q_{1,2}\|_p$$

$$\|S_2\|_p \simeq \sqrt{p} \left\| \sqrt{Q_{1,2}^2} \right\|_p = \sqrt{p} \|Q_{1,2}\|_p.$$

From these bounds, coupled with (5), it follows that $\|U\|_p \simeq p \|Q_{1,2}\|_p$ as desired. ◀

We now show Lemma 17 follows from Lemma 19 and Proposition 18.

Proof of Lemma 17. After applying Lemma 19, it suffices to calculate $\|Q_{1,2}\|_p$. It follows from Proposition 18 that $\|Q_{1,2}\|_p \simeq \|X\|_p$ where X is distributed as $\text{Bin}(s, s/m)$. Now, the following calculation $\|X\|_p$ for $p < s$ and $B = m/s^2 \leq \frac{e^p}{p}$ follows from the lower and upper bounds of Lemma 16 (Latała's bound on moments of sums of i.i.d nonnegative random variables):

$$\|X\|_p \simeq \begin{cases} \frac{p}{\log Bp} & \text{if } B \geq \frac{e}{p} \\ \frac{1}{B} & \text{if } B < \frac{e}{p} \end{cases}.$$

From this, Lemma 17 follows. ◀

Streaming Coreset Constructions for M-Estimators

Abstract

We introduce a new method of maintaining a (k, ϵ) -coreset for clustering M -estimators over insertion-only streams. Let (P, w) be a weighted set (where $w : P \rightarrow [0, \infty)$ is the weight function) of points in a ρ -metric space (meaning a set \mathcal{X} equipped with a positive-semidefinite symmetric function D such that $D(x, z) \leq \rho(D(x, y) + D(y, z))$ for all $x, y, z \in \mathcal{X}$). For any set of points C , we define $\text{COST}(P, w, C) = \sum_{p \in P} w(p) \min_{c \in C} D(p, c)$. A (k, ϵ) -coreset for (P, w) is a weighted set (Q, v) such that for every set C of k points, $(1 - \epsilon)\text{COST}(P, w, C) \leq \text{COST}(Q, v, C) \leq (1 + \epsilon)\text{COST}(P, w, C)$. Essentially, the coreset (Q, v) can be used in place of (P, w) for all operations concerning the COST function. Coresets, as a method of data reduction, are used to solve fundamental problems in machine learning of streaming and distributed data.

M -estimators are functions $D(x, y)$ that can be written as $\psi(d(x, y))$ where (\mathcal{X}, d) is a true metric (i.e. 1-metric) space. Special cases of M -estimators include the well-known k -median ($\psi(x) = x$) and k -means ($\psi(x) = x^2$) functions. Our technique takes an existing offline construction for an M -estimator coreset and converts it into the streaming setting, where n data points arrive sequentially. To our knowledge, this is the first streaming construction for any M -estimator that does not rely on the merge-and-reduce tree. For example, our coreset for streaming metric k -means uses $O(\epsilon^{-2} k \log k \log n)$ points of storage. The previous state-of-the-art required storing at least $O(\epsilon^{-2} k \log k \log^4 n)$ points.

1 Introduction

In the streaming model of computation, the input arrives sequentially. This differs from the random-access memory model (i.e. the offline setting) where the algorithm may freely and repeatedly access the entire input. The goal of a streaming algorithm is to perform the computation using a sublinear amount of memory.

A stream consists of n elements p_1, \dots, p_n . Sometimes the algorithm will be allowed to pass over the stream multiple times, resulting in another parameter called the number of passes. Our algorithm uses $O(\log n)$ memory and requires only a single pass over the input stream.

Prior to the current work, the merge-and-reduce technique due to Har-Peled and Mazumdar [19] and Bentley and Sax [5] was used to maintain coresets on streams using an offline coreset construction as a blackbox. For a brief review of this technique, see Section 4.1. Suppose the offline construction’s space depends on ϵ as ϵ^{-a} . In this paper we introduce an alternative technique that reduces the multiplicative overhead from $O(\log^{a+1} n)$ to $O(1)$ when moving to the streaming setting. For example, the state-of-the-art k -median offline coreset [6] has size $O(\epsilon^{-2}k \log k \log n)$. The current paper improves the space requirement from $O(\epsilon^{-2}k \log k \log^4 n)$ to $O(\epsilon^{-2}k \log k \log n)$ to maintain the coreset on a stream. While our method is not as general as merge-and-reduce (it requires a function to satisfy more than just the “merge” and “reduce” properties, defined in Section 4.1), it is general enough to apply to all M -estimators.

2 Definitions

We begin by defining a ρ -metric space. Let \mathcal{X} be a set. If $D : \mathcal{X} \times \mathcal{X} \rightarrow [0, \infty)$ is a symmetric positive-semidefinite function such that for every $x, y, z \in \mathcal{X}$ we have that $D(x, z) \leq \rho(D(x, y) + D(y, z))$ then we call (\mathcal{X}, D) a ρ -metric space. Note that this is a weakening of the triangle inequality, and at $\rho = 1$ we recover the definition of a metric space. Clustering M -estimators in a metric space can be re-cast as k -median in a ρ -metric space. For example, metric k -means in the space (\mathcal{X}, d) is reducible to 2-metric k -median in the space (\mathcal{X}, D) using $D(\cdot, \cdot) = d(\cdot, \cdot)^2$. See Table 1 for more examples. We work in this slightly abstract language since it allows a single proof to naturally generalize our results to any M -estimator.

A weighted set (P, w) is a set $P \subset \mathcal{X}$ along with a weight function $w : P \rightarrow [0, \infty)$. As usual, we define the distance between a point and a set $D(p, Z) = \min_{z \in Z} D(p, z)$. Let

$$\text{COST}(P, w, Z) = \sum_{p \in P} w(p)D(p, Z)$$

The ρ -metric k -median problem is, given input (P, w) and an integer $k \geq 1$, to find a set C of k points in \mathcal{X} that minimizes $\text{COST}(P, w, C)$. We use $\text{OPT}_k(P)$ to denote the minimal value. Other works have shown that for small enough ϵ , it is NP-Hard to even compute a $(1 + \epsilon)$ approximation for k -means or k -median when k is part of the input (see the Related Work section of [4] for a survey of hardness results). Therefore weaker definitions of approximation have been introduced. The notion of a bicriterion approximation is well-known; we state a slightly more verbose definition that suits our needs. The difference is that usually the map f is implicit, simply mapping a point to a nearest center.

► **Definition 1** ((α, β) -approximation). For $\alpha, \beta \geq 1$, an (α, β) -approximation for the k -median clustering of a weighted set (P, w) is a weighted set (B, v) along with a map $f : P \rightarrow B$ such that:

1. $\sum_{p \in P} w(p)D(p, f(p)) \leq \alpha \text{OPT}_k(P)$
2. $|B| \leq \beta k$
3. $v(b) = \sum_{p \in f^{-1}(b)} w(p)$ for every $b \in B$

Observe that a $(1, 1)$ -approximation is an optimal solution. We now define a coreset, the datastructure that we compute in this paper.

► **Definition 2** ((k, ϵ) -coreset). For $k \in \mathbb{N}$ and $\epsilon \in (0, 1)$, a (k, ϵ) -coreset for a weighted set (P, w) is a weighted set (Q, v) such that for every $Z \in \mathcal{X}^k$ we have $(1 - \epsilon) \text{COST}(P, w, Z) \leq \text{COST}(Q, v, Z) \leq (1 + \epsilon) \text{COST}(P, w, Z)$.

Coresets with possibly negative weight functions have been considered [13]. However, computing approximate solutions on these coresets in polynomial-time remains an open problem, so we restrict our definition to non-negative weight functions to ensure that an approximate solution can be quickly produced [16, 8]. This implies a PTAS for Euclidean space and a polynomial-time $2\tau(1 + \epsilon)$ -approximation for general metric spaces (where τ is the best polynomial-time approximation factor for the problem in the offline setting). This factor of $2\tau(1 + \epsilon)$ is well-known in the literature, see [9, 7, 16] for details.

3 Our Techniques

In this work, we provide an alternative technique for constructing a ρ -metric k -median coreset in the streaming setting. Instead of using the merge-and-reduce tree (see Section 4.1) where each node of the tree uses the offline construction, we perform a single offline construction in the streaming setting. This reduces $O(\log^{a+1} n)$ multiplicative overhead¹ of merge-and-reduce to $O(1)$ overhead.

The offline coreset construction of [6] has the following structure: first, a bicriterion approximation (see Definition 1) is computed over the entire input set P . The bicriterion is used to estimate for each point p its “sensitivity” $s_P(p)$ which, intuitively speaking, measures how important p is relative to the entire set P . Then, $m = m(n, k, \epsilon)$ points are sampled i.i.d. according to the distribution of sensitivities. This suggests a two-pass streaming algorithm with no overhead: in the first pass, construct a bicriterion using an algorithm such as [7]. In the second pass, sample according to sensitivity distribution, computed using the bicriterion found in the first pass. Our contribution is showing how these two passes can be combined into a single-pass.

How do we accomplish both these tasks in parallel? If the sensitivities stayed constant, we could use weighted reservoir sampling to maintain an i.i.d. sample. However, we cannot do this for a changing distribution. The sensitivities may decrease because when a new point is added, all existing points may become less important to the overall stream.

Inductively assume that we have a coreset. Upon receiving the next point, we generate a new bicriterion which we use to update the sensitivities of the points seen so far. The first idea is that instead of sampling m points from a distribution such that point p is sampled with probability $s_P(p)$, we built a set which contains point p with probability $s_P(p)$ as follows: let $u(p)$ be a uniform random number in $[0, 1)$, and store p as long as $u(p) < m s_P(p)$ (recall

¹ Recall that a is the exponent in the offline construction’s dependence on ϵ^{-1} , and n is the length of the stream.

that $s_P(p)$ decreases as more points are added to P . With high probability, we return a set of $\Theta(m)$ points. The problem is that this set is not an i.i.d. sample. To see this, consider the fact that unlike an i.i.d. sample, this set cannot have repeated points.

To solve this problem, we repeat the above process independently in parallel m times, where each process should sample *exactly* 1 point. The first issue is that the total probability $t = \sum_{p \in P} s_P(p)$, which must be scaled to 1, is only known up to a factor of k . Even after solving this, and assuming we have at least m trials that return exactly one point, they do not follow the original distribution. Indeed, the probability of a trial returning only one point p is the probability of drawing point p multiplied the probabilities of not drawing all other points. The rough idea to overcome this is that we distort the probabilities by computing the inverse to this transformation such that the final probabilities follow the desired distribution.

We prove our result for ρ -metric k -median. As stated before, it is well-known that most M -estimators can be recast as a ρ -metric k -median problem for a low value of ρ [14]. See Table 1 for a list of several common M -estimators along with the ρ -metric they satisfy. For many M -estimators, ours is the first coreset result over data streams besides merge-and-reduce.

■ **Table 1** List of several examples to which our result applies. An M -estimator with ψ -function $\psi(x)$ induces a clustering problem with cost $\psi(d(p, c))$ for a point p with nearest center c . The ρ -value is calculated from the ψ -function, making the column redundant but non-trivial to compute.

Estimator	ψ -function	ρ
k -median	x	1
k -means	x^2	2
Huber	$\psi(x) = \begin{cases} \frac{x^2}{2} & \text{if } x < 1 \\ x - \frac{1}{2} & \text{if } x \geq 1 \end{cases}$	2
Cauchy	$\psi(x) = \log(1 + x^2)$	2
Tukey	$\psi(x) = \begin{cases} \frac{1}{6}(1 - (1 - x^2)^3) & \text{if } x < 1 \\ \frac{1}{6} & \text{if } x \geq 1 \end{cases}$	3

4 Related Work

Table 2 summarizes previous work along with our current results. By far, the most widely-studied problems in this class have been the k -median and k -means functions. In general, the extension to arbitrary M -estimators is non-trivial; the first such result was [14]. Our approach naturally lends itself to this extension. M -estimators are highly important for noisy data or data with outliers. As one example, Huber’s estimator is widely used in the statistics community [17, 20]. It was written that “this estimator is so satisfactory that it has been recommended for almost all situations” [22]. Our results work not only for Huber’s estimator but for all M -estimators, such as the Cauchy and Tukey biweight functions which are also widely-used functions.

Note that in the below table, \tilde{O} notation is used to write in terms of d , ϵ , k , and $\log n$ (therefore hiding factors of $\log \log n$ but not $\log n$).

k -means

In the k -means problem we wish to compute a set k of centers (points) in some metric space, such that the sum of squared distances to the input points is minimized, where each input point is assigned to its nearest center. The corresponding coreset is a positively weighted subset of points that approximates this cost to every given set of k centers. Deterministic

■ **Table 2** Summary of Related Work. Note that Metric M -estimators are the most general, and these results apply to all other categories.

coresets of size exponential in d were first suggested by Har-Peled and Mazumdar in [19]. The first coreset construction of size polynomial in d was suggested by Ke-Chen in [10] using several sets of uniform sampling. Other high-dimensional results (e.g. [2]) are also known in the streaming setting.

Streaming

The metric results of [10, 13] and Euclidean results of [10, 19, 18, 13] that rely on merge-and-reduce appear in Table 2. In Euclidean space, a more diverse set of stronger results is known. In particular, coreset constructions are known that do not begin with a bicriterion solution, and whose streaming variant does not rely on merge-and-reduce [1]. Sketches have been given in [12] for M -estimators in Euclidean space. With the additional assumption that points lie on a discrete Euclidean grid $\{1, \dots, \Delta\}^d$, alternative techniques are known for k -means and other problems, even when the stream allows the deletion of points [15].

4.1 Merge and Reduce Tree

We briefly summarize the previous technique for maintaining coresets in the streaming setting due to Har-Peled and Mazumdar [19] and Bentley and Sax [5]. In this method, a merge-and-reduce tree is built by using an offline coreset construction as a blackbox. Previously, this was the only known technique for building a streaming coreset for many metric problems. It relies solely on the following two properties which can be easily verified:

1. Merge: The union of (k, ϵ) -coresets is a (k, ϵ) -coreset.
2. Reduce: A (k, ϵ) -coreset of a (k, ϵ') -coreset is a $(k, \epsilon + \epsilon' + \epsilon\epsilon')$ -coreset.

The merge-and-reduce tree works as follows. There are buckets T_i for $i \geq 0$. In each step, the bucket T_0 takes in a segment of $O(1)$ points from the stream. Then the tree works like counting in binary: whenever buckets T_0 to T_{i-1} are full, these i buckets are merged and then reduced by taking a $(k, \frac{\epsilon}{\log n})$ -coreset of their union and storing the result in T_i .

Let s be the space of offline construction, which depends on ϵ as ϵ^{-a} . At the end of the stream, $O(\log n)$ buckets have been used and each bucket uses $O(s \log^a n)$ space; this incurs a multiplicative overhead of $\Theta(\log^{a+1} n)$ in the storage requirement. The second factor comes from using the accuracy parameter $\frac{\epsilon}{\log n}$, which is necessary by Property 2 since the construction will be compounded $O(\log n)$ times. Due to this compounding, the runtime is multiplied by a factor of $O(\log n)$.

5 Streaming Algorithm

We present a streaming algorithm to construct a coreset for ρ -metric k -median. Our method combines a streaming bicriterion algorithm [7, 21] and a batch coreset construction [13] to create a streaming coreset algorithm. The space requirements are combined additively, therefore ensuring no overhead.

We now state our main theorem. The probability of success $1 - \delta$ typically has one of two meanings: that the construction succeeds at the end of the stream (a weaker result), or that the construction succeeds at every intermediate point of the stream (a stronger result). Our theorem gives the stronger result, maintaining a valid coreset at every point of the stream. Our space and time bounds follow the convention that a point can be stored in $O(1)$ space.

► **Theorem 3 (Main Theorem).** *Let $\epsilon, \delta \in (0, 1)$. Given the problem of k -median clustering in a ρ -metric space for $\rho = O(1)$, there exists an insertion-only streaming algorithm that maintains a (k, ϵ) -coreset on a stream of n points while requiring $O(\epsilon^{-2} k (\log k \log n + \log \frac{1}{\delta}))$ space and worst-case update time, and succeeds at every point of the stream with probability at least $1 - \delta$.*

In Section 5.1 we introduce the streaming bicriterion algorithm. Then in Section 5.2 we review the offline coreset construction we will be adapting to the streaming setting. We prove in Section 5.3 how to use the bicriterion to bound the importance of points. Finally we present the streaming algorithm in Section 5.4.

5.1 Streaming Bicriterion Algorithm

Let P_i denote the prefix of the stream $\{p_1, \dots, p_i\}$. The entire stream P is then P_n . Recall that in the streaming setting, we receive each point sequentially in the order (p_1, p_2, \dots) . We use the function $\mathbb{1} : P \rightarrow \{1\}$ to map every point to unit weight. For ease of exposition we assume the input set is weighted as $(P, \mathbb{1})$ and that all points of P are distinct. Consider the moment when the first i points have arrived, meaning that the prefix P_i is the current set of arrived points. The algorithm \mathcal{A} of [7] provides an $(O(1), O(\log n))$ -approximation of P_i . We now restate their general result, adding several details (such as the outputs L_i and π_i) that were merely internal details for them but will be crucial for us.

► **Theorem 4 ([7], restated).** *Let $\alpha, \gamma > 1$ be absolute constants. Define $B_0 = \emptyset$. Let (p_1, \dots, p_n) be a stream of at most n points in a ρ -metric space for $\rho = O(1)$. Let $n, k \geq 1$, $\delta \in (0, 1)$ be input parameters. Upon receiving point p_i , algorithm $\mathcal{A}(k, n, \delta)$ returns a weighted set (B_i, w_i) , a value $L_i > 0$, and a map $\pi_i : B_{i-1} \cup \{p_i\} \rightarrow B_i$. Define $f_i(p_j) = \pi_i(\pi_{i-1}(\dots \pi_j(p_j) \dots))$. For any integer $i \in [n]$ we have with probability at least $1 - \delta$ that the following three statements hold.*

1. $L_i \leq OPT_k(P_i)$
2. $\sum_{p \in P_i} D(p, f_i(p)) \leq \alpha L_i$
3. (B_i, w_i) along with the map $f_i : P_i \rightarrow B_i$ is an $(\alpha, \gamma(\log n + \log \frac{1}{\delta}))$ -approximation for $(P, \mathbb{1})$.

The algorithm requires $O(\gamma(\log n + \log \frac{1}{\delta}))$ space and update time.

Algorithm \mathcal{A} reduces the number of distinct points by combining nearby points into a single point of higher weight.

5.2 Offline Coreset Construction

In the offline coreset construction of [6], the sensitivity of a point $p \in P$ in a ρ -metric space (\mathcal{X}, D) is defined as:

$$s_P(p) = \max_{Z \in \mathcal{X}^k} \frac{D(p, Z)}{\sum_{q \in P} D(q, Z)}$$

Notice that $0 \leq s_P(p) \leq 1$ for every point $p \in P$, and that the sensitivity of a point p is relative to the set P it belongs to. When context is clear, we omit the subscript and write $s(p)$. Computing $s(p)$ may be difficult, but we can give an upper bound $s'(p) \in [s(p), 1]$. Define the total sensitivity $t' = \sum_{p \in P} s'(p)$. We will apply the following theorem:

► **Theorem 5** (proven in [6]). *Let P be a set of n points, and define $s' : P \rightarrow [0, 1]$ and t' as above. Let $\delta, \epsilon \in (0, 1)$ be input parameters. Consider a distribution \mathcal{S} supported on P where p has weight $s'(p)/t'$. Define $m' = \lceil 3t'\epsilon^{-2}(\log n \log t' + \log(1/\delta)) \rceil$. Let Q be an i.i.d. sample of at least m' points from \mathcal{S} . Define a weight function $v : Q \rightarrow [0, \infty)$ as $v(q) = (|Q|s'(q))^{-1}$. With probability at least $1 - \delta$, (Q, v) is a (k, ϵ) -coreset for P .*

One may be skeptical why only an upper bound is necessary, wondering why not simply set $s'(p) = 1$. This does indeed work, but has the undesirable effect of setting $t' = n$ and therefore results in a coreset of $\Omega(n)$ points. More generally, the coreset is useless if t' is large since the size of Q may be comparable to the size of P . In the next subsection, we show how to bound $t' = O(\rho^2 k)$. Observe that neither k nor ρ appear explicitly in the sample size, but they both appear implicitly through the value of t' .

5.3 Bounding the Sensitivity

Let the map $p \mapsto p'$ be an (σ, λ) -approximation of P for some constants σ and λ . Define $P(p) = \{q \in P : q' = p'\}$ to be the cluster containing p .

► **Lemma 6.** *Let the map $p \mapsto p'$ define an (σ, λ) -approximation for the k -median clustering of P . For every point $p \in P$:*

$$s(p) \leq \frac{\rho \sigma D(p, p')}{\sum_{q \in P} D(q, q')} + \frac{\rho^2 (\sigma + 1)}{|P(p)|}$$

Proof. For an arbitrary $Z \in \mathcal{X}^k$ we need to provide a uniform bound for

$$\begin{aligned} \frac{D(p, Z)}{\sum_{q \in P} D(q, Z)} &\leq \frac{\rho D(p, p')}{\sum_{q \in P} D(q, Z)} + \frac{\rho D(p', Z)}{\sum_{q \in P} D(q, Z)} \\ &\leq \frac{\sigma \rho D(p, p')}{\sum_{q \in P} D(q, q')} + \frac{\rho D(p', Z)}{\sum_{q \in P} D(q, Z)} \end{aligned} \quad (1)$$

where the second inequality holds because $\sum_{q \in P} D(q, q') \leq \sigma \text{OPT}(P) \leq \sigma \sum_{q \in P} D(q, Z)$. To

bound the last term, recall that $q' = p'$ for all $q \in P(p)$ so:

$$\begin{aligned}
D(p', Z)|P(p)| &= \sum_{q \in P(p)} D(p', Z) = \sum_{q \in P(p)} D(q', Z) \\
&\leq \rho \sum_{q \in P(p)} (D(q', q) + D(q, Z)) \\
&\leq \rho \sum_{q \in P} D(q', q) + \rho \sum_{q \in P(p)} D(q, Z) \\
&\leq \rho \sigma \sum_{q \in P} D(q, Z) + \rho \sum_{q \in P(p)} D(q, Z) \\
&\leq \rho(\sigma + 1) \sum_{q \in P} D(q, Z)
\end{aligned}$$

Dividing by $|P(p)| \sum_{q \in P} D(q, Z)$ gives

$$\frac{D(p', Z)}{\sum_{q \in P} D(q, Z)} \leq \frac{\rho(\sigma + 1)}{|P(p)|}$$

Substituting this in (1) yields the desired result. \blacktriangleleft

We will use Lemma 6 to define our upper bound $s'(p)$. An immediate but extremely important consequence of Lemma 6 is that $t' = \sum_{p \in P} s'(p) = \rho\sigma + \rho^2(\sigma + 1)\lambda k$. This can be seen by directly summing the formula given by the lemma.

5.4 Streaming Algorithm

Consider the prefix P_i which is the input after the first i points have arrived. For ease of notation, we write $s'_i(p)$ to refer to $s'_{P_i}(p)$, an upper bound on the sensitivity of p with respect to the first i points. After processing first i points of the stream, Algorithm 1 constructs a set (Q_i, v_i) . With probability at least $1 - \delta$, (Q_i, v_i) is a (k, ϵ) -coreset for P_i for every $i \in [n]$. This algorithm will satisfy the claims of Theorem 3.

5.4.1 Overview of the algorithm

The algorithm initializes on Lines 1-9. The main loop of Lines 10-38 processes the stream, accepting one point per iteration. For each iteration, the first step is to process the point with algorithm \mathcal{A} (Line 11) then compute a $(O(1), O(1))$ -bicriterion approximation on its output (Line 18). On Line 23 we use this to maintain an upper bound $s'_i(p)$ on the sensitivity of a point p with respect to P_i . In the analysis, let $t'_i = \sum_{\ell=1}^i s'_i(p_\ell)$ be the upper bound on the total sensitivity of P_i . We now define \mathcal{S}_i , the distribution from which we will draw our sample. Note that \mathcal{S}_i is non-deterministic, since the values of $s'_i(p)$ (and therefore t'_i) depend on the randomness of Algorithm \mathcal{A} as well as any possible randomness used in the bicriterion approximation.

► Definition 7. *The probability distribution \mathcal{S}_i is supported on P_i and assigns probability $s'_i(p)/t'_i$ to point p .*

By Theorem 5, it suffices to sample $m'_i = \lceil 3t'_i \epsilon^{-2} (\log n \log t'_i + \log(n/\delta)) \rceil$ points i.i.d. from \mathcal{S}_i to construct a coreset for $(P_i, \mathbb{1})$ with probability at least $1 - \delta/n$. On Line 2 we define t_\circ to upper bound the maximal value of t'_i over any set of points in \mathcal{X} . Likewise on Line 3 we set $m_\circ = \lceil 3t_\circ \epsilon^{-2} (\log n \log t_\circ + \log(n/\delta)) \rceil$ which is an upper bound on the required sample size.

We maintain $\Theta(k(\log n \log k + \log \frac{n}{\delta}))$ sets M_y , each containing a sample of the stream. We hope that many of these samples contain only a single point, because if so then by Lemma 6 the point follows the distribution \mathcal{S}_i . With high probability, at least m'_i sets will be singletons, and so we take their union to construct the coreset (Q_i, v_i) .

Memory considerations

Due to memory constraints, we only store the maps g_i, f_i, u_y, z_i , and s'_i for points in $\cup_{y \in Y} M_y$. In the analysis only, we use f_i, z_i , and $s'_i(p)$ for points that have been deleted. This refers to the value that would have been set if we continued executing Lines 21-23 for p .

5.4.2 Proof of correctness

Using Algorithm \mathcal{A} we obtain an $(\alpha, \gamma(\log n + \log \frac{n}{\delta}))$ -approximation (B_i, w_i) with the map $\pi_i : B_{i-1} \cup \{p_i\} \rightarrow B_i$ which we use to obtain the map $f_i : P_i \rightarrow B_i$. Line 23 runs an offline (γ, λ) -approximation algorithm on B_i , and we obtain weighted set (C_i, v_i) . The following lemma shows that (C_i, v_i) is a (σ, λ) -approximation for P_i , where $\sigma = \rho\alpha + 2\rho^2\gamma(\alpha + 1)$ as defined on Line 1. The clustering map will be $g_i \circ f_i : P_i \rightarrow B_i \rightarrow C_i$.

► **Lemma 8.** *Assume that algorithm \mathcal{A} has not failed. Then (C_i, w_i^C) with $g_i \circ f_i : P_i \rightarrow C_i$ is a (σ, λ) -approximation of P_i .*

Proof. As the context is clear, we drop the subscript i . By Theorem 4, (B, w^B) with $f : P \rightarrow B$ is an (α, β) -approximation of P where $\beta = \gamma(\log n + \log \frac{n}{\delta})$. Also, (C, w^c) with $g : B \rightarrow C$ is the (γ, λ) -approximation of B . In the following, all sums will be taken over all $p \in P$. The hypotheses state that $\sum D(p, f(p)) \leq \alpha \text{OPT}_k(P)$ and $\sum D(f(p), g(f(p))) \leq \gamma \text{OPT}_k(B)$. Let P^* be an optimal clustering of P , that is $\sum D(p, P^*) = \text{OPT}_k(P)$. Then $\frac{1}{2} \text{OPT}_k(B) \leq \sum D(f(p), P^*) \leq \rho \sum (D(f(p), p) + D(p, P^*)) \leq \rho(\alpha + 1) \text{OPT}(P)$. The factor of $\frac{1}{2}$ comes from the fact that $\text{OPT}(B)$ is defined using centers restricted to B (see [16] for details). We now write $\sum D(p, g(f(p))) \leq \rho \sum (D(p, f(p)) + D(f(p), g(f(p)))) \leq (\rho\alpha + 2\rho^2\gamma(\alpha + 1)) \text{OPT}_k(P)$ as desired. ◀

To use Lemma 6 to determine $s'_i(p)$, we will compute the cluster sizes $|P_i(p)|$ and estimate the clustering cost $\sum_{q \in P} D(q, q')$ by L_i . We must bound the clustering cost from below because we require $s'_i(p)$ to be an upper-bound of $s_i(p)$.

► **Lemma 9.** *Assume that algorithm \mathcal{A} has not failed and that (Q_{i-1}, v_{i-1}) is a (k, ϵ) -coreset for P_{i-1} . Then $z_i(p) \geq s_i(p)$ for every $p \in P_i$.*

Proof. For the first claim, consider Lemma 6 applied with the clustering map $g_i \circ f_i : P_i \rightarrow C_i$. We write $p' = g_i \circ f_i(p)$. By Lemma 8, this map is a (σ, λ) -approximation of P_i . Observe that $|P_i(p)|$ (from Lemma 6) is precisely $w_i^C(g_i \circ f_i(p))$ since the weight of a point c is determined by how many points in P_i were clustered to c . By Theorem 4, $L_i \leq \text{OPT}_k(P_i) \leq \text{COST}(P_i, \mathbb{1}, C_i)$. We may then write:

$$\begin{aligned} z_i(r) &= \frac{\rho\sigma D(r, g_i \circ f_i(r))}{L_i} + \frac{\rho^2(\sigma + 1)}{w_i^C(g_i \circ f_i(r))} \\ &\geq \frac{\rho\sigma D(r, r')}{\sum_{p \in P_i} D(p, p')} + \frac{\rho^2(\sigma + 1)}{|P_i(r)|} \\ &\geq s_i(r) \end{aligned}$$

where the last inequality follows by Lemma 6. ◀

62:10 Streaming Coreset Constructions for M-Estimators

■ **Algorithm 1** Input: parameters $\epsilon, \delta \in (0, 1)$ and $n, k \in \mathbb{N}$. A stream of n points in a ρ -metric space. Notes: $\mathcal{A}(\cdot, \cdot, \cdot)$ denotes the blackbox algorithm from Theorem 4 along with its universal constants α and γ . Line 18 uses any RAM-model $(O(1), O(1))$ -approximation such as [3].

```

1:  $\sigma \leftarrow \rho\alpha + 2\rho^2\gamma(\alpha + 1)$ 
2:  $t_\circ \leftarrow \rho\sigma\alpha + \rho^2(\sigma + 1)\lambda k$ 
3:  $m_\circ \leftarrow \lceil 3t_\circ\epsilon^{-2}(\log n \log t_\circ + \log(n/\delta)) \rceil$ 
4:  $Q_0 \leftarrow \emptyset$ 
5: Initialize  $\mathcal{A}(k, n, \delta/n)$ 
6:  $Y \leftarrow \{1, \dots, 8m_\circ\}$ 
7: for each  $y \in Y$  do
8:    $M_y \leftarrow \emptyset$ 
9: end for
10: for the next point  $p_i$  from the stream do
11:    $(B_i, w_i^B, \pi_i, L_i) \leftarrow$  update  $\mathcal{A}$  with point  $p_i$ 
12:   for each  $y \in Y$  do
13:      $u_y(p_i) \leftarrow$  uniform random number from  $[0, 1)$ 
14:      $M_y \leftarrow M_y \cup \{p_i\}$ 
15:   end for
16:    $f_{i-1}(p_i) \leftarrow p_i$ 
17:    $s'_{i-1}(p_i) \leftarrow 1$ 
18:    $(C_i, w_i^C, g_i) \leftarrow (\gamma, \lambda)$ -approximation of  $(B_i, w_i^B)$ 
19:    $R \leftarrow \cup_y M_y$ 
20:   for each  $r \in R$  do
21:      $f_i(r) \leftarrow \pi_i \circ f_{i-1}(r)$ 
22:      $z_i(r) \leftarrow \frac{\rho\sigma D(r, g_i \circ f_i(r))}{L_i} + \frac{\rho^2(\sigma+1)}{w_i^C(g_i \circ f_i(r))}$ 
23:      $s'_i(r) \leftarrow \min(s'_{i-1}(r), z_i(r))$ 
24:   end for
25:   for each  $y \in Y$  do
26:     for each  $q \in M_y$  do
27:       if  $u_y(q) > \frac{s'_i(q)}{s'_i(q) + t_\circ}$  then
28:         Delete  $q$  from  $M_y$ 
29:       end if
30:     end for
31:   end for
32:    $\Gamma_i \leftarrow \{y \in Y : |M_y| = 1\}$ 
33:    $Q_i \leftarrow \cup_{y \in \Gamma_i} M_y$ 
34:   for each  $q \in Q_i$  do
35:      $v_i(q) \leftarrow (|\Gamma_i| s'_i(q))^{-1}$ 
36:   end for
37:   return  $(Q_i, v_i)$ 
38: end for

```

The implication is that our upper bound on sensitivity is valid, as we now prove formally:

► **Lemma 10.** *Assume that algorithm \mathcal{A} has not failed and that (Q_{i-1}, v_{i-1}) is a (k, ϵ) -coreset for P_{i-1} . Then $s'_i(p) \geq s_i(p)$ for every $p \in P_i$.*

Proof. Fix a point $p \in P_i$. We see from Line 23 that $s'_i(p) = z_j(p)$ for some $j \leq i$. Lemma 11 shows that $z_j(p) \geq s_j(p)$. Observe directly from the definition of sensitivity that $s_i(p) \leq s_j(p)$ for any $j \leq i$. Combining these shows that $s'_i(p) = z_j(p) \geq s_j(p) \geq s_i(p)$. We conclude that $s'_i(p) \geq s_i(p)$ for all $p \in P_i$. ◀

For each point p , the value of $s'_i(p)$ is non-increasing in i . This is because $s'_i(p)$ is defined as the minimum of itself and a new value on Line 23. It follows from the monotonicity of $f(x) = \frac{x}{x+1}$ that $\frac{s'_i(r)}{s'_i(r)+t_o}$ is also non-increasing in i . Therefore once the deletion condition on Line 27 becomes satisfied, it remains satisfied forever. This is essential because after deleting a point from memory, it can never be retrieved again. We can characterize $M_y^{(i)}$ without reference to the streaming setting: $M_y^{(i)} = \{p \in P_i : u_y(p) \leq \frac{s'_i(p)}{s'_i(p)+t_o}\}$. This has the important implication that $Pr(p \in M_y^{(i)}) = \frac{s'_i(p)}{s'_i(p)+t_o}$.

► **Lemma 11.** *Assume that algorithm \mathcal{A} has not failed and that (Q_{i-1}, v_{i-1}) is a (k, ϵ) -coreset for P_{i-1} . Then $\sum_{p \in P_i} z_i(p) < t_o$.*

Proof. The value of t_o is defined on Line 2 as $\rho\sigma\alpha + \rho^2(\sigma + 1)\lambda k$.

$$\begin{aligned} \sum_{p \in P_i} z_i(p) &= \sum_{p \in P_i} \frac{\rho\sigma D(p, g_i \circ f_i(p))}{L_i} + \frac{\rho^2(\sigma + 1)}{w_i^C(g_i \circ f_i(p))} \\ &\leq \frac{\rho\sigma\alpha L_i}{L_i} + \rho^2(\sigma + 1)\lambda k \\ &\leq \rho\sigma\alpha + \rho^2(\sigma + 1)\lambda k \\ &= t_o \end{aligned}$$

where the first inequality comes from Lemma 8 and Theorem 4. Note that we have summed the second term using the fact that a center $c \in C_i$ with weight $w_i^C(c)$ has exactly $w_i^C(c)$ points of P_i clustered to it. Therefore we may re-write the sum:

$$\sum_{p \in P_i} \frac{1}{w_i^C(g_i \circ f_i(p))} = \sum_{c \in C_i} 1 = \lambda k \quad \blacktriangleleft$$

To construct a coreset by sampling from \mathcal{S}_i , the algorithm take the union of those M_y for $y \in Y$ that are singletons. Any set M_y that is either empty or contains more than one point will be ignored, but still kept track of since it may later become a singleton. We now show that if a sample M_y contains a single point, then it follows the distribution \mathcal{S}_i . Let $M_y^{(i)}$ denote the state of M_y after the prefix P_i has been processed, and let $Pr(A : B)$ denote the probability of event A conditioned on event B .

► **Lemma 12.** *For any $p \in P_i$, $Pr(M_y^{(i)} = \{p\} : |M_y^{(i)}| = 1) = s'_i(p) / \sum_{\ell=1}^i s'_i(p_\ell)$.*

Proof. Define $\alpha_\ell = \frac{s'_i(p_\ell)}{s'_i(p_\ell)+t_o}$ and $\Psi = \prod_{\ell=1}^i (1 - \alpha_\ell)$. For $z \in [i]$ let E_z denote the event that $M_y^{(i)} = \{p_z\}$. The probability that the sampler contains only p_z means that it failed to sample all p_ℓ for $\ell \neq z$, meaning that $Pr(E_z) = \alpha_z \Psi / (1 - \alpha_z) = s'_i(p_z) \Psi / t_o$. The result is obtained since:

$$\begin{aligned}
Pr(E_z : |M_y^{(i)}| = 1) &= Pr(E_z)/Pr(|M_y^{(i)}| = 1) \\
&= Pr(E_z)/Pr(\cup_{\ell=1}^i E_\ell) \\
&= Pr(E_z)/\sum_{\ell=1}^i Pr(E_\ell) \\
&= s'_i(p_z)/\sum_{\ell=1}^i s'_i(p_\ell) \quad \blacktriangleleft
\end{aligned}$$

The significance of Lemma 12 is tantamount. If a sample M_y contains a singleton, then it is equivalent to a random draw from \mathcal{S}_i . Therefore if at least m'_i samplers contain a singleton, taking their union gives us an i.i.d. sample of at least m'_i points from \mathcal{S}_i . This is precisely what we need to construct a coreset using Theorem 5. However, it remains to show that we will have enough singleton samplers with high probability. The next lemma begins to establish this fact.

► **Lemma 13.** *Fix any $y \in Y$ and $i \in [n]$. Then $P(|M_y^{(i)}| = 1) \geq \frac{t'}{4t_o}$.*

Proof. Let p_i be the most recently arrived point, and define $\alpha_\ell = \frac{s'_i(p_\ell)}{s'_i(p_\ell) + t_o}$. Observe that $s'_i(p_\ell) \geq 0$ implies $\alpha_\ell \leq s'_i(p_\ell)/t_o$. It follows from Line 27 that $Pr(p_\ell \in M_y) = \alpha_\ell \leq s'_i(p_\ell)/t_o$. The expected value of $|M_y|$ is therefore at most $\sum_{\ell=1}^i \frac{1}{t_o} s'_i(p_\ell) = \frac{t'}{t_o}$. Markov's inequality yields $Pr(|M_y| \geq 2) = Pr(|M_y| \geq \frac{2t_o}{t'} \frac{t'}{t_o}) \leq \frac{t'}{2t_o} \leq \frac{1}{2}$.

$$\begin{aligned}
P(|M_y| = 1) &= \sum_{\ell=1}^i P(|M_y| = \{p_\ell\}) \\
&= \sum_{\ell=1}^i \alpha_\ell \prod_{z \neq \ell} (1 - \alpha_z) \\
&= \sum_{\ell=1}^i \frac{\alpha_\ell}{1 - \alpha_\ell} \prod_{z=1}^i (1 - \alpha_z) \\
&= \frac{1}{t_o} \left(\sum_{\ell=1}^i s'_i(p_\ell) \right) \left(\prod_{z=1}^i (1 - \alpha_z) \right) \\
&= \frac{t'}{t_o} Pr(|M_y| = 0)
\end{aligned}$$

We know that $Pr(|M_y| = 0) + Pr(|M_y| = 1) + Pr(|M_y| \geq 2) = 1$, so substitution gives $(\frac{t_o}{t'} + 1)Pr(|M_y| = 1) + \frac{1}{2} \geq 1$. Rearranging this, we obtain $Pr(|M_y| = 1) \geq \frac{1}{2} \frac{1}{t_o/t' + 1} \geq \frac{t'}{4t_o}$ as desired. \blacktriangleleft

Now that we have provided a lower bound on the probability of any sample M_y being a singleton, we move on to lower bound the probability of at least m'_i of the samples $\{M_y\}_{y \in Y}$ being singletons. Observe that the $\{M_y\}$ are entirely independent. We use a Chernoff bound to lower bound the size of Γ_i , defined on Line 32, which is the set of all singleton samples.

► **Lemma 14.** *$|\Gamma_i| \geq m'_i$ with probability at least $1 - \delta/n$.*

Proof. We see directly from Line 32 that $|\Gamma_i|$ is a sum of $|Y|$ independent Bernoulli trials, each which succeeds with probability at least $\frac{t'}{4t_o}$ by Lemma 13. By a Chernoff bound, $Pr(|S| \leq \frac{1}{2}|Y|\frac{t'}{4t_o}) \leq e^{-|Y|t'/32t_o}$. We note that $|Y|t'/32t_o = 8m_o t'/32t_o \geq \ln(n/\delta)$. Plugging this into the Chernoff bound yields that $|S| \geq m_o t'/t_o$ with probability at least $1 - \delta/n$. We conclude by noting that $m_o t'/t_o = 3t'(\log n \log t_o + \log \frac{\delta}{n}) \geq m'$. \blacktriangleleft

We now have all the tools to proceed with the proof of Theorem 1. We begin with the space requirement, then prove correctness.

► **Lemma 15.** *After processing P_i , Algorithm 1 stores $O(\epsilon^{-2}k(\log k \log n + \log \frac{n}{\delta}))$ points with probability at least $1 - \delta/n$.*

Proof. First note that $O(\log n + \log \frac{n}{\delta}) = O(\log n + \log \frac{1}{\delta})$. By Theorem 4 we know that \mathcal{A} stores $O(k(\log n + \log \frac{n}{\delta}))$ points deterministically. In addition to the blackbox \mathcal{A} , the algorithm stores the sets M_y along with a constant amount of satellite data per point.

We showed that $E[|M_y|] \leq t'/t_o$ in the proof of Lemma 13. Directly from Lemma 13, we lower bound $E[|M_y|] \geq \Pr(|M_y| = 1) \geq t'/4t_o$. Combining these upper and lower bounds permits us to write $2m_o t'/t_o \leq E[\sum_{y \in Y} |M_y|] \leq 8m_o t'/t_o$.

A Chernoff bound can be applied for a high-probability guarantee. The random variable $X = \sum_{y \in Y} |M_y|$ is a sum of $|Y|$ independent Bernoulli trials, each event being $p_\ell \in M_y$ for some $1 \leq \ell \leq i$ and $y \in Y$. We have the Chernoff bound that $\text{Prob}[X \geq (1 + \eta)\mu] \leq e^{-\eta^2 \mu / (2 + \eta)}$ for any $\eta \geq 1$ where $\mu = E[X]$. Using $\eta = 1$, this yields that $X < 16m_o$ with probability at least $1 - e^{-2m_o t' / 3t_o} < e^{-2m' / 3} < \delta/n$. ◀

We now prove correctness, using the following lemma as a tool for our final claim.

► **Lemma 16.** *Assume that algorithm \mathcal{A} has not failed and that (Q_{i-1}, v_{i-1}) is a (k, ϵ) -coreset for P_{i-1} . Then (Q_i, v_i) is a (k, ϵ) coreset of $(P_i, \mathbb{1})$ with probability at least $1 - 3\delta/n$.*

Proof. Lemma 10 shows that \mathcal{S}_i meets the criteria of Theorem 5 with probability at least $1 - \delta/n$. Lemmas 12 and 14 show that Q_i is an i.i.d. sample of at least m'_i points from \mathcal{S}_i with probability at least $1 - \delta/n$. By Theorem 5, conditioning on the success of the previous two statements, (Q_i, v_i) is a (k, ϵ) -coreset for $(P_i, \mathbb{1})$ with probability at least $1 - \delta/n$. We arrive at the desired result by applying the union bound. ◀

We complete the proof of Theorem 3 by induction over each prefix P_i on the following events: (1) the success of \mathcal{A} ; (2) that (Q_i, v_i) is a (k, ϵ) coreset of $(P_i, \mathbb{1})$; and (3) the storage requirement holding from Lemma 15. The base cases hold trivially.

By Theorem 4, Algorithm $\mathcal{A}(n, k, \delta/n)$ will succeed on P_i with probability at least $1 - \delta/n$. By Lemma 15, the space requirement is maintained with probability at least $1 - \delta/n$. By Lemma 16, (Q_i, v_i) is a (k, ϵ) coreset of $(P_i, \mathbb{1})$ with probability at least $1 - 3\delta/n$. Combining these pieces, we succeed inductively after processing a single point with probability at least $1 - 5\delta/n$. Therefore we succeed at every step of the entire stream with probability at least $1 - 5\delta$. Theorem 3 follows by scaling δ appropriately.

Pairwise Independent Random Walks Can Be Slightly Unbounded

Shyam Narayanan

Massachusetts Institute of Technology, Cambridge, Massachusetts, USA
shyam.s.narayanan@gmail.com

Abstract

A family of problems that have been studied in the context of various streaming algorithms are generalizations of the fact that the expected maximum distance of a 4-wise independent random walk on a line over n steps is $O(\sqrt{n})$. For small values of k , there exist k -wise independent random walks that can be stored in much less space than storing n random bits, so these properties are often useful for lowering space bounds. In this paper, we show that for all of these examples, 4-wise independence is required by demonstrating a pairwise independent random walk with steps uniform in ± 1 and expected maximum distance $\Omega(\sqrt{n} \lg n)$ from the origin. We also show that this bound is tight for the first and second moment, i.e. the expected maximum square distance of a 2-wise independent random walk is always $O(n \lg^2 n)$. Also, for any even $k \geq 4$, we show that the k th moment of the maximum distance of any k -wise independent random walk is $O(n^{k/2})$. The previous two results generalize to random walks tracking insertion-only streams, and provide higher moment bounds than currently known. We also prove a generalization of Kolmogorov's maximal inequality by showing an asymptotically equivalent statement that requires only 4-wise independent random variables with bounded second moments, which also generalizes a result of Błasiok.

1 Introduction

Random walks are well-studied stochastic processes with numerous applications in physics [14], math [17], computer science [2], economics [13], and biology [4]. A commonly studied random walk on \mathbb{Z} is a process that starts at 0 and at each step independently moves either $+1$ or -1 with equal probability. In this paper, we do not study this random walk but instead study k -wise independent random walks, meaning that steps are not totally independent but that any k steps are completely independent. In many low-space randomized algorithms, information is tracked with processes similar to random walks, but simulating a totally random walk of n steps is known to require $O(n)$ bits while there exist k -wise independent families which can be simulated with $O(k \lg n)$ bits [10]. As a result, understanding properties of k -wise independent random walks have applications to streaming algorithms, such as heavy-hitters [8, 9], distinct elements [5], and ℓ_p tracking [6].

For any k -wise independent random walk, where $k \geq 2$, it is well-known that after n steps, the expected squared distance from the origin is exactly n , since $\mathbb{E}_{h \in \mathcal{H}}(h(1) + \dots + h(n))^2 = n$ for any 2-wise independent hash family \mathcal{H} . One can see this by expanding and applying linearity of expectation. This property provides good bounds for the distribution of the final position of a 2-wise independent random walk. However, we study the problem of bounding the position throughout the random walk, by providing comparable moment bounds for $\sup_{1 \leq i \leq n} |h(1) + \dots + h(i)|$ rather than just for $|h(1) + \dots + h(n)|$ and determining an example of a 2-wise independent random walk where the expected bounds do not hold, even though very strong bounds for even 4-wise independent random walks can be established.

Two more general questions that have been studied in the context of certain streaming algorithms are random walks corresponding to insertion-only streams, and random walks with step sizes corresponding to random variables. These are useful generalizations as the first proves useful in certain algorithms with insertion stream inputs, and the second allows for a setup similar to Kolmogorov's inequality [16], which we will generalize to 4-wise independent random variables. To understand these two generalizations, consider a k -wise independent family of random variables X_1, \dots, X_n and an insertion stream $p_1, \dots, p_m \in [n]$, where now seeing p_j means that our random walk moves by X_{p_j} on the j th step. The insertion stream can be thought of as keeping track of a vector z in \mathbb{R}^n where seeing p_j increments the p_j th component of z by 1, and \vec{X} can be thought of as a vector in \mathbb{R}^n with i th component X_i . Then, one goal is to bound for appropriate values of k'

$$\mathbb{E}_{h \in \mathcal{H}} \left[\sup_{1 \leq t \leq m} \left| \langle \vec{X}, z^{(t)} \rangle \right|^{k'} \right],$$

where $z^{(t)}$ is the vector z after seeing only the first t elements of the insertion stream. Notice that bounding the k' th moment of the furthest distance from the origin in a k -wise independent random walk is the special case of $m = n$, $p_j = j$ for all $1 \leq j \leq n$, and the X_i 's are uniform random signs.

1.1 Main Results

Intuitively, even in a pairwise independent random walk, since the positions at various times have strong correlations with each other, the expectation of the furthest we ever get from the origin should not be much more than the expectation of than our distance from the origin after n steps. But surprisingly, we show in Section 2 that there is a pairwise independent family \mathcal{H} such that

$$\mathbb{E}_{h \in \mathcal{H}} \left[\sup_{1 \leq t \leq n} |h_1 + \dots + h_t| \right] = \Omega(\sqrt{n} \lg n), \quad (1)$$

meaning there is a uniform pairwise independent ± 1 -valued random walk which is not continuously bounded in expectation by $O(\sqrt{n})$. Furthermore, this bound of $\sqrt{n} \lg n$ is tight up to the first and second moments, because in Section 3 we prove that for any pairwise independent family \mathcal{H} from $[n]$ to $\{-1, 1\}$ with $\mathbb{E}[h_i] = 0$ for all i ,

$$\mathbb{E}_{h \in \mathcal{H}} \left[\sup_{1 \leq t \leq n} (h_1 + \dots + h_t)^2 \right] = O(n \lg^2 n). \quad (2)$$

In Section 4, we uniformly bound random walks corresponding to insertion-only streams and random walks with step sizes not necessarily uniform ± 1 variables. We first generalize Kolmogorov's inequality [16] by proving that for any 4-wise independent random variables X_1, \dots, X_n with mean 0 and finite variance,

$$\mathbb{P} \left(\sup_{1 \leq i \leq n} |X_1 + \dots + X_i| \geq \lambda \right) \leq \frac{\sum \mathbb{E}[X_i^2]}{\lambda^2} \quad (3)$$

for all $\lambda > 0$. In Appendix A, we generalize Equation (2) by proving for any family X_1, \dots, X_n of pairwise independent variables such that $\mathbb{E}[X_i] = 0, \mathbb{E}[X_i^2] \leq 1$, and for any insertion stream $p_1, \dots, p_m \in [n]$,

$$\mathbb{E} \left[\sup_{1 \leq t \leq m} \left| \langle \vec{X}, z^{(t)} \rangle \right|^2 \right] = O(\|z\|_2^2 \lg^2 m) \quad (4)$$

where $z = z^{(m)}$ is the final position of the vector. Finally, we show that for any even $k \geq 4$, any k -wise independent family X_1, \dots, X_n such that $\mathbb{E}[X_i] = 0, \mathbb{E}[X_i^k] \leq 1$, and any insertion stream $p_1, \dots, p_m \in [n]$,

$$\mathbb{E} \left[\sup_{1 \leq t \leq m} \left| \langle \vec{X}, z^{(t)} \rangle \right|^k \right] = O(\|z\|_2^k). \quad (5)$$

Equations (3), (4), and (5) are interesting together as they provide various bounds on the supremum of generalized random walks under differing moment bounds and degrees of independence.

Finally, we note that to prove Equation (1), we create a complicated pairwise independent hash function, which suggests that standard pairwise independent hash functions do not have this property. Indeed, for many such families, such as some types of codes constructed from Hadamard matrices or random linear functions from $\mathbb{Z}/p\mathbb{Z} \rightarrow \mathbb{Z}/p\mathbb{Z}$, we have $\mathbb{E} \sup_i |h_1 + \dots + h_i| = o(n \lg n)$. (See the appendices in the arXiv version of this paper.) However, we note that for some standard pairwise independent hash functions, it is difficult to provide either an upper or lower bound for $\mathbb{E} \sup_i |h_1 + \dots + h_i|$. Therefore, even if some simpler pairwise independent hash function satisfies Equation 1, our hash family has the advantage that the analysis is simpler, even if the construction of the family is not.

1.2 Motivation and Relation to Previous Work

The primary motivation of this paper comes from certain theorems that provide strong bounds for certain variants of 4-wise independent random walks, which raised the question of whether any of these bounds can be extended to 2-wise independence. For example, Theorem 1 in [8] proves for any family \mathcal{H} of $h \in \{-1, 1\}^n$ with 4-wise independent coordinates, $\mathbb{E}_{h \in \mathcal{H}} (\sup_t \langle h, z^{(t)} \rangle) = O(\|z\|_2)$. This result generalizes a result from [9] which proves the same but only if h is uniformly chosen from $\{-1, 1\}^n$. [8] provides an algorithm that successfully finds all ℓ_2 ε -heavy hitters in an insertion-only stream in $O(\varepsilon^{-2} \log \varepsilon^{-1})$ space, in which the above result was crucial for analysis of a subroutine which attempts to find bit-by-bit the index of a single “super-heavy” heavy hitter if one exists. Theorem 1 in [8] also proved valuable for an algorithm for continuous monitoring of ℓ_p norms in insertion-only data streams [6]. Lemma 18 in [5] shows that even without bounded fourth moments, given 4-wise independent random variables X_1, \dots, X_n , each with mean 0 and finite variance,

$$\mathbb{P} \left(\max_{1 \leq i \leq n} |X_1 + \dots + X_i| \geq \lambda \right) = O \left(\frac{n \cdot \max_i \mathbb{E}[X_i^2]}{\lambda^2} \right).$$

This theorem was crucial in analyzing an algorithm tracking distinct elements that provides a $(1 + \varepsilon)$ -approximation with failure probability δ in $O(\varepsilon^{-2} \lg \delta^{-1} + \lg n)$ bits of space. Notice that our Equation (3) is stronger than the above equation and is asymptotically equivalent to Kolmogorov’s inequality, though under much weaker assumptions.

A natural follow-up question to the above theorems is whether 4-wise independence is necessary, or whether lesser levels of independence such as 2-wise or 3-wise are required. Equation (1) shows that 2-wise independence does not suffice for any of the above results,

because the random walk on a line case is strictly weaker than all of the above results, though the case of 3-wise independence is still unknown. As a result, we know that the tracking sketches in [8, 6, 5] cannot be extended to 2-wise independent sketches.

However, the results given still have interesting extensions, such as to higher moments. Equation (5) shows a stronger result than the one established in [8], since it not only bounds the first moment of $\sup_t \langle h, z^{(t)} \rangle$ for a 4-wise independent family of uniform ± 1 variables but also bounds the 4th moment equally (as they have mean 0 and k th moment 1). The main methods used for proving most of our upper bounds are based on chaining methods, specifically Dudley chaining, with slight modifications, although the bounds in Section 3 are proved differently from standard chaining methods but are still motivated by similar ideas. Dudley chaining was introduced in [11], and Dudley chaining and other chaining techniques, along with applications, are summarized in [18].

k -wise independence for hash functions was first introduced in [10]. Bounding the amount of independence required for analysis of algorithms has been studied in various contexts, often since k -wise independent hash families can be stored in low space but may provide equally adequate bounds as totally independent families. As further examples, the well-known AMS sketch [1] is a streaming algorithm to estimate the ℓ_2 norm of a vector z to a factor of $1 \pm \varepsilon$ with high probability by multiplying the vector by a sketch matrix $\Pi \in \mathbb{R}^{n \times (1/\varepsilon^2)}$ of 4-wise independent random signs and using $\|\Pi z\|_2$ as an estimate for $\|z\|_2$. It is known from [20, 22] that the accuracy of the AMS sketch can be much worse if 3-wise independent random signs are used instead of 4-wise independent random signs. If z is given as an insertion stream, it is known that the AMS sketch with 8-wise independent random signs can provide weak tracking [8], meaning that $\mathbb{E} \sup_t \left| \|\Pi z^{(t)}\|_2^2 - \|z^{(t)}\|_2^2 \right| \leq \varepsilon \|z\|_2^2$. This implies that the approximation of the ℓ_2 norm with the 8-wise independent AMS sketch is quite accurate at all times t . While one cannot perform weak tracking with 3-wise independence of the AMS sketch, it is unknown for 4-wise independence through 7-wise independence whether the AMS sketch provides weak tracking. Finally, linear probing, a well-known implementation of hash tables, was shown to take $O(1)$ expected update time with any 5-wise independent hash function [19] but was shown to take $\Theta(\lg n)$ expected update time for certain 4-wise independent hash functions and $\Theta(\sqrt{n})$ expected update time for certain 2-wise independent hash functions [20].

Bounding the maximum distance traveled of a random walk has also been studied in probability theory independent of computer science applications, both when the steps are totally independent or k -wise independent. For example, Kolmogorov's inequality [16] provides bounds for $\sup_t (X_1 + \dots + X_t)$ for independent random variables X_1, \dots, X_t even if only the second moments of X_1, \dots, X_t are finite. [3] constructed an infinite sequence $\{X_1, X_2, \dots\}$ of pairwise independent random variables taking on the values ± 1 such that $\sup_t (X_1 + \dots + X_t)$ is bounded almost surely, though the paper also proved that this phenomenon can never occur for 4-wise independent variables taking on the values ± 1 . Finally, the supremum of a random walk with i.i.d. bounded random variable steps was studied in [12], which provided comparisons with the supremum of a Brownian motion random walk regardless of the random variable chosen for step size.

1.3 Notation

We define $[n] := \{1, \dots, n\}$, and treat $p_1, \dots, p_m \in [n]$ as an insertion-only stream that keeps track of a vector z that starts at the origin and increments its p_j th component by 1 after we see p_j .

A k -wise independent family from $[n]$ to $\{-1, 1\}$ is a family \mathcal{H} of functions $h : [n] \rightarrow \{-1, 1\}$ such that for any k distinct indices, their values are independent *Rademachers*, where Rademachers are random variables uniformly selected from $\{-1, 1\}$. A k -wise independent random walk is a random walk where one's position after t steps is $h(1) + \dots + h(t)$, with h chosen from \mathcal{H} . We may also denote a k -wise independent random walk as a random walk where the i th step is a random variable X_i , assuming X_1, \dots, X_n are random variables such that any k distinct X_i 's are totally independent.

In this paper, we think of a hash function $h : [n] \rightarrow \{-1, 1\}$ as a vector in \mathbb{R}^n , where $h_i = h(i)$, for the purpose of denoting inner products. Similarly, treat \vec{X} as the vector (X_1, \dots, X_n) .

Finally, in Section 2, we assume that n is a power of 4, in Section 3, we assume n is a power of 2 and is at least 4, and in Section 4, we assume m is a sufficiently large power of 2. We note that these assumptions can be removed by replacing n with the largest power of 4 less than n or the smallest power of 2 greater than n or m , respectively.

1.4 Overview of Proof Ideas

Here, we briefly outline some of the main ideas behind the proofs of Equations (1) through (5).

The main goal in Section 2 is to establish Equation (1), i.e. construct a pairwise independent \mathcal{H} such that $\mathbb{E}[h_i h_j] = 0$ for all $i \neq j$. In other words, we wish for the covariance matrix $\mathcal{M} = \mathbb{E}[h^T h]$ to be the identity matrix I_n . We also want $\sup_{1 \leq i \leq n} |h_1 + \dots + h_i|$ to be $\Omega(\sqrt{n} \lg n)$ in expectation. The construction has two major steps.

1. Create a hash function such that $\mathbb{E} \sup_{1 \leq i \leq n} |h_1 + \dots + h_i| = \Omega(\sqrt{n} \lg n)$ but rather than have $\mathbb{E}[h_i h_j] = 0$ for all $i \neq j$, have $\sum_{i \neq j} |\mathbb{E}[h_i h_j]| = O(n)$, i.e. the cross terms in total aren't very large in absolute value (this hash function will be \mathcal{H}_2 in our proof). To do this, we first created \mathcal{H}_1 , which certain properties, most notably that $\mathbb{E}[h_1 + \dots + h_n] = 0$ but $\mathbb{E}[h_1 + \dots + h_{n/2}] = \Theta(\sqrt{n} \lg n)$, and rotated the hash family by a uniform index. The rotation allows many of the cross terms to average out, reducing the sum of their absolute values.
2. Remove the cross terms. To do this, we make \mathcal{H} a hash family where with some constant probability, we choose from \mathcal{H}_2 and with some probability, we choose some set of indices and pick a hash function such that $\mathbb{E}[h_i h_j]$ will be the opposite sign of $\mathbb{E}_{h \in \mathcal{H}_2}[h_i h_j]$ for certain indices i, j , so that overall, $\mathbb{E}[h_i h_j]$ will be 0. Certain symmetry properties and most importantly the fact that $\sum_{i \neq j} |\mathbb{E}_{h \in \mathcal{H}_2}[h_i h_j]| = O(n)$ will allow for us to choose from \mathcal{H}_2 with constant probability, which means even for our final hash function, $\mathbb{E} \sup_{1 \leq i \leq n} |h_1 + \dots + h_i| = \Omega(\sqrt{n} \lg n)$.

The goal of Section 3 is to establish Equation (2), i.e. to show that if $\mathcal{M} = \mathbb{E}[h^T h] = I_n$, which is true for any pairwise independent hash function, then $\sup_{1 \leq i \leq n} |h_1 + \dots + h_i|^2 = O(n \lg^2 n)$. To do this, we apply probabilistic method ideas. We notice that for any matrix A , $\mathbb{E}[h^T A h] = \text{Tr}(A)$, and thus, if we can find a matrix such that the trace of the matrix is small, but $h^T A h$ is reasonably large in comparison to $\sup_{1 \leq i \leq n} |h_1 + \dots + h_i|^2$, then $\mathbb{E}[h^T A h]$ is small but is large in comparison to $\mathbb{E}[\sup_{1 \leq i \leq n} |h_1 + \dots + h_i|^2]$. If we assume that n is a power of 2, then the matrix that corresponds to the quadratic form

$$h^T A h = \sum_{r=0}^{\lg n - 1} \sum_{i=0}^{(n/2^r)-1} (h_{i \cdot 2^r + 1} + \dots + h_{(i+1) \cdot 2^r})^2,$$

i.e. $h^T A h = h_1^2 + \dots + h_n^2 + (h_1 + h_2)^2 + \dots + (h_{n-1} + h_n)^2 + \dots + (h_1 + \dots + h_n)^2$ can be shown to satisfy $\text{Tr}(A) = n \lg n$ and for any vector x , $x^T A x \geq \frac{1}{\lg n} \cdot (x_1 + \dots + x_i)^2$ for all $1 \leq i \leq n$, not just in expectation. These conditions will happen to be sufficient for our goals.

This method, in combination with Equation (1), will also allow us to prove an interesting matrix inequality, proven at the end of Section 3. The method above actually generalizes to looking at k th moments of k -wise independent hash functions, as well as random walks corresponding to tracking insertion-only streams, and will allow us to prove Equations (4) and (5). However, these generalizations will also need the construction of ε -nets, which are explained in Appendix A, or in [18].

We finally explain the ideas behind Equation (3), the generalization of Kolmogorov's inequality and Lemma 18 of [5]. We use ideas of chaining, such as in [18], and an idea of [5] that allows us to bound the minimum of $X_{i+1} + \dots + X_j$ and $X_{j+1} + \dots + X_k$ where $i < j < k$, given 4-wise independent functions X_1, \dots, X_n with only bounded second moments. We combine these with another idea, that we can consider distances between i and j for $1 \leq i < j \leq n$ as $\mathbb{E}[X_{i+1}^2 + \dots + X_j^2]$ and that for any $i < j < k$, either $\mathbb{E}[X_{i+1}^2 + \dots + X_j^2]$ is very small and we can bound $X_{i+1} + \dots + X_j$, $\mathbb{E}[X_{j+1}^2 + \dots + X_k^2]$ is very small and we can bound $X_{j+1} + \dots + X_k$, or we can bound $\min(|X_{i+1} + \dots + X_j|, |X_{j+1} + \dots + X_k|)$ with the idea of [5]. These ideas allow for our chaining method to be quite effective, even if the X_i 's do not have bounded 4th moments or if the X_i 's wildly differ in variance.

2 Lower Bounds for Pairwise Independence

In this section, we construct a 2-wise independent family \mathcal{H} such that the furthest distance traveled by the random walk is $\Omega(\sqrt{n} \lg n)$ in expected value. In other words, we prove the following:

► **Theorem 1.** *There exists a 2-wise independent hash family \mathcal{H} from $[n] \rightarrow \{-1, 1\}$ such that*

$$\mathbb{E}_{h \in \mathcal{H}} \left[\sup_{1 \leq t \leq n} \left| \sum_{1 \leq j \leq t} h_j \right| \right] = \Omega(\sqrt{n} \lg n).$$

To actually construct this counterexample, we proceed by a series of families and tweak each family accordingly to get to the next one, until we get the desired \mathcal{H} .

We start by creating \mathcal{H}_1 . First, split $[n]$ into blocks of size \sqrt{n} so that $\{(c-1)\sqrt{n} + 1, \dots, c\sqrt{n}\}$ form the c th block for each $1 \leq c \leq \sqrt{n}$. Also, define $\ell = \frac{\sqrt{n}}{2}$. Now, to pick a function h from \mathcal{H}_1 , choose the value of h_i for each $1 \leq i \leq n$ independently, but if i is in the c th block for some $1 \leq c \leq \ell$, make $\mathbb{P}[h_i = 1] = \frac{1}{2} + \frac{1}{2(\ell+1-c)}$ and if i is in the c th block for some $\ell+1 \leq c \leq \sqrt{n}$, make $\mathbb{P}[h_i = 1] = \frac{1}{2} - \frac{1}{2(c-\ell)}$. This way, $\mathbb{E}[h_i] = \frac{1}{\ell+1-c}$ if i is in the c th block for $c \leq \ell$ and $\mathbb{E}[h_i] = -\frac{1}{c-\ell}$ if i is in the c th block for $c > \ell$.

From now on, assume that h_i is periodic modulo n , i.e. $h_{i+n} = h_i$ for all integers i . We first prove the following about \mathcal{H}_1 :

► **Lemma 2.** *Suppose that $1 \leq i < j \leq n$. Suppose that i is in block c_1 and j is in block c_2 , where c_1 and c_2 are not necessarily distinct. Define $r = \min(c_2 - c_1, \sqrt{n} - (c_2 - c_1))$. Then,*

$$\sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1} (h_{i+d\sqrt{n}} h_{j+d\sqrt{n}}) = O\left(\frac{\lg(r+2)}{(r+1)^2}\right).$$

Proof. For $1 \leq c \leq \sqrt{n}$, define f_c to equal $\frac{1}{\ell+1-c}$ if $1 \leq c \leq \ell$ and to equal $-\frac{1}{c-\ell}$ if $\ell+1 \leq c \leq \sqrt{n}$. In other words, $f_c = \mathbb{E}[h_i]$ if i is in the c th block. Furthermore, assume that f is periodic modulo \sqrt{n} , i.e. $f_c = f_{c+\sqrt{n}}$ for all integers c . Then,

$$\begin{aligned} \sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}} h_{j+d\sqrt{n}}) &= \sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}}) \mathbb{E}_{h \in \mathcal{H}_1}(h_{j+d\sqrt{n}}) \\ &= \sum_{d=0}^{\sqrt{n}-1} f_{c_1+d} f_{c_2+d} = \sum_{d=1}^{\sqrt{n}} f_d f_{r+d}. \end{aligned}$$

Now, since $r \leq \ell$, if we assume $r \geq 1$, this sum can be explicitly written as

$$\begin{aligned} &2 \cdot \sum_{d=1}^{\ell-r} \frac{1}{d(d+r)} - \sum_{d=1}^r \frac{1}{d(r+1-d)} - \sum_{d=1}^r \frac{1}{(n+1-d)(n+1-(r+1-d))} \\ &\leq 2 \sum_{d=1}^{\infty} \frac{1}{d(d+r)} - \sum_{d=1}^r \frac{1}{d(r+1-d)} \\ &= \frac{2}{r} \sum_{d=1}^{\infty} \left(\frac{1}{d} - \frac{1}{d+r} \right) - \frac{1}{r+1} \sum_{d=1}^r \left(\frac{1}{d} + \frac{1}{r+1-d} \right) \\ &= \frac{2}{r} \left(\sum_{d=1}^r \frac{1}{d} \right) - \frac{2}{r+1} \left(\sum_{d=1}^r \frac{1}{d} \right) \\ &= \frac{2}{r(r+1)} \left(\sum_{d=1}^r \frac{1}{d} \right) \leq \frac{C_1 \lg(r+2)}{(r+1)^2} \end{aligned}$$

for some constant C_1 . If we assume $r = 0$, then this sum can be explicitly written as

$$2 \cdot \sum_{d=1}^{\ell} \frac{1}{d^2} \leq C_2 = \frac{(C_2) \cdot \lg(0+2)}{(0+1)^2}$$

for some constant C_2 . Therefore, setting $C_3 = \max(C_1, C_2)$ as our constant, we are done. \blacktriangleleft

To construct \mathcal{H}_2 , first choose $h \in \mathcal{H}_1$ at random, and then choose an index d between 0 and $\sqrt{n}-1$ uniformly at random. Our chosen function h' will then be the function that satisfies $h'_i = h_{i+d\sqrt{n}}$ for all i . We show the following about \mathcal{H}_2 :

► Lemma 3. *The following three statements are true:*

- For all $i, j \in \mathbb{Z}$, $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = \mathbb{E}_{h \in \mathcal{H}_2}(h_{i+\sqrt{n}} h_{j+\sqrt{n}})$.
- Suppose that $1 \leq i, i', j, j' \leq n$, where i, i' are in blocks c_1 , j, j' are in blocks c_2 , and $i \neq j, i' \neq j'$. Then, $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = \mathbb{E}_{h \in \mathcal{H}_2}(h_{i'} h_{j'})$.
- $\sum_{i \neq j} |\mathbb{E}_{h \in \mathcal{H}_2} h_i h_j| = O(n)$.

Proof. Part a) is quite straightforward, since

$$\begin{aligned} \mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) &= \frac{1}{\sqrt{n}} \sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}} h_{j+d\sqrt{n}}) \\ &= \frac{1}{\sqrt{n}} \sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+(d+1)\sqrt{n}} h_{j+(d+1)\sqrt{n}}) = \mathbb{E}_{h \in \mathcal{H}_2}(h_{i+\sqrt{n}} h_{j+\sqrt{n}}) \end{aligned}$$

by periodicity of h modulo n .

63:8 Pairwise Independent Random Walks Can Be Slightly Unbounded

For part b), for all $d \in \mathbb{Z}$, note that $i + d\sqrt{n}$ and $i' + d\sqrt{n}$ are in the same blocks, $j + d\sqrt{n}$ and $j' + d\sqrt{n}$ are in the same blocks, $i + d\sqrt{n} \neq j + d\sqrt{n}$ and thus $h_{i+d\sqrt{n}}, h_{j+d\sqrt{n}}$ are independent, and $i' + d\sqrt{n} \neq j' + d\sqrt{n}$ and thus $h_{i'+d\sqrt{n}}, h_{j'+d\sqrt{n}}$ are independent. Therefore, $\mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}}h_{j+d\sqrt{n}}) = \mathbb{E}_{h \in \mathcal{H}_1}(h_{i'+d\sqrt{n}}h_{j'+d\sqrt{n}})$ for all d . Because of the way we constructed \mathcal{H}_2 , part b) is immediate from these observations.

We use Lemma 2 to prove part c). First note that for all $i \neq j$,

$$\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = \frac{1}{\sqrt{n}} \sum_{d=0}^{\sqrt{n}-1} \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}} h_{j+d\sqrt{n}}) \leq \frac{C_3 \lg(r+2)}{\sqrt{n} \cdot (r+1)^2},$$

where i is in block c_1 , j is in block c_2 , and $r = \min(|c_1 - c_2|, \sqrt{n} - |c_1 - c_2|)$. Now, there are exactly $n(\sqrt{n} - 1)$ pairs (i, j) where $1 \leq i, j \leq n$, $i \neq j$, and $r = 0$. This is because we can choose from \sqrt{n} blocks for the value of $c_1 = c_2$, and then choose from $\sqrt{n}(\sqrt{n} - 1)$ possible pairs (i, j) in each block. For a fixed $0 < r < \ell$, there are exactly $2n^{3/2}$ pairs (i, j) , since there are $2\sqrt{n}$ choices for blocks c_1 and c_2 and \sqrt{n} choices for each of i and j after that, for $r = \ell$, there are exactly $n^{3/2}$ such pairs, since there are $2\sqrt{n}$ choices for blocks c_1 and c_2 and \sqrt{n} choices for each of i and j after that, and finally we cannot have $r > \ell$. Therefore,

$$\sum_{i \neq j} \max(0, \mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j)) \leq 2n^{3/2} \cdot \sum_{r=0}^{\ell} \frac{C_3 \lg(r+2)}{\sqrt{n}(r+1)^2} \leq C_4 n$$

for some constant C_4 , since $\sum \frac{\lg(r+2)}{(r+1)^2}$ is a convergent series.

To finish, note that $|x| = 2 \cdot \max(0, x) - x$, so

$$\sum_{i \neq j} |\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j)| \leq 2 \cdot C_4 n - \sum_{i \neq j} \mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) \leq (2C_4 + 1)n,$$

since

$$\sum_{i \neq j} \mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = \sum_{i, j} \mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) - \sum_i \mathbb{E}_{h \in \mathcal{H}_2} h_i^2 = \mathbb{E}_{h \in \mathcal{H}_2}(h_1 + \dots + h_n)^2 - n \geq -n.$$

Thus, setting $C_5 = 2C_4 + 1$ gets us our desired result. ◀

Next, we tweak \mathcal{H}_2 to create a new family \mathcal{H}_3 . First, notice that we can define $g_{c_1 c_2}$ for $1 \leq c_1, c_2 \leq \sqrt{n}$ to equal $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j)$ for some i in the c_1 th block and j in the c_2 th block such that $i \neq j$. This is well defined by Lemma 3 b), and as $1 \leq c_1, c_2 \leq \sqrt{n}$, there always exist $i \neq j$ with i in the c_1 th block and j in the c_2 th block, as long as $n \geq 4$. Now, to create \mathcal{H}_3 , define $g = 1 + \sum_{c_1 < c_2} |g_{c_1 c_2}|$. Then, with probability $\frac{1}{g}$, we choose a hash function from \mathcal{H}_2 . With probability $\frac{|g_{c_1 c_2}|}{g}$ for each $1 \leq c_1 < c_2 \leq \sqrt{n}$, we choose $h_i = 1$ for all i in the c_1 th bucket, if $g_{c_1 c_2} \geq 0$, we make $h_i = -1$ for all i in the c_2 th bucket and if $g_{c_1 c_2} < 0$, we make $h_i = 1$ for all i in the c_2 th bucket, and if i is not in either the c_1 th or the c_2 th bucket, we let h_i be an independent Rademacher. We prove the following about \mathcal{H}_3 :

► **Lemma 4.** *If i and j are in different buckets, then $\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j) = 0$. If i, j are in the same bucket but $i \neq j$, then there is some constant $0 \leq C_6 \leq C_5$ such that $\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j) = \frac{C_6}{\sqrt{n}}$.*

Proof. Assume WLOG that $i < j$. If i, j are in different buckets, then we compute $\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j)$ as follows. With probability $\frac{1}{g}$, we are choosing h from \mathcal{H}_2 , and if i is in the c_1 th bucket and j is in the c_2 th bucket, then $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = g_{c_1 c_2}$. With probability $\frac{|g_{c_1 c_2}|}{g}$ we have $h_i h_j = 1$ with probability 1 if $g_{c_1 c_2} < 0$ and $h_i h_j = -1$ with probability 1 if

$g_{c_1 c_2} \geq 0$. In all other scenarios, either h_i or h_j is a Rademacher completely independent of all other elements, which means that $\mathbb{E}[h_i h_j] = 0$. Therefore, the overall expected value of $h_i h_j$ equals $g_{c_1 c_2} \cdot \frac{1}{g} + \frac{|g_{c_1 c_2}|}{g} \cdot \pm 1$ where the ± 1 is positive if and only if $g_{c_1 c_2} \leq 0$, so the expected value is 0.

If i, j are in the same bucket, then we can compute $\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j)$ as follows. With probability $\frac{1}{g}$, we are choosing h from \mathcal{H}_2 , and if i, j are in the c th bucket, then $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = g_{cc}$. For all $c' \neq c$, there is a $\frac{|g_{cc'}|}{g}$ probability of everything in the c th block having the same sign and everything in the c' th block having the same sign. For the other cases, i, j are independent Rademachers. Therefore,

$$\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j) = \frac{g_{cc}}{g} + \sum_{c' \neq c} \frac{|g_{cc'}|}{g} = \frac{1}{g} \left(g_{cc} + \sum_{c' \neq c} |g_{cc'}| \right).$$

However, note that $g_{cc} \geq 0$ since $\mathbb{E}_{h \in \mathcal{H}_2}(h_i h_j) = \frac{1}{\sqrt{n}} \sum_d \mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}} h_{j+d\sqrt{n}})$ and for all d , we have $\mathbb{E}_{h \in \mathcal{H}_1}(h_{i+d\sqrt{n}} h_{j+d\sqrt{n}}) \geq 0$ since $i + d\sqrt{n}, j + d\sqrt{n}$ are in the same block for all d . Furthermore, for all indices c_1, c_2 , $g_{c_1 c_2} = g_{(c_1+1)(c_2+1)}$, where indices are taken modulo \sqrt{n} , by Lemma 3 a). Combining these gives

$$\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j) = \frac{1}{\sqrt{n}} \cdot \left(\frac{1}{g} \cdot \left(\sum_{c_1, c_2} |g_{c_1 c_2}| \right) \right).$$

However, we know that $g \geq 1$ and $\sum_{c_1, c_2} |g_{c_1 c_2}| \leq C_5$ by the arguments of Lemma 3 c), so the lemma follows. \blacktriangleleft

Now, we are almost done. To create \mathcal{H} , with probability $p = \frac{1}{1+C_6(\sqrt{n}-1)/\sqrt{n}} \geq \frac{1}{1+C_6}$, choose h from \mathcal{H}_3 , and assuming we chose from \mathcal{H}_3 , with probability $\frac{1}{2}$ negate h_1, \dots, h_n . With probability $1-p$, for each block of \sqrt{n} elements, choose uniformly at random a subset of size ℓ from the block, and make the corresponding elements 1 and the remaining elements -1 . It is easy to see that now, $\mathbb{E}_{h \in \mathcal{H}}(h_i) = 0$ because of the possibility of negating. Moreover, $\mathbb{E}_{h \in \mathcal{H}}(h_i h_j) = 0$ for all $i \neq j$. To see why, if i and j are in different blocks then $\mathbb{E}_{h \in \mathcal{H}_3}(h_i h_j) = 0$ and if we do not choose h from \mathcal{H}_3 , then h_i and h_j are independent. If i, j are in the same block, then if we condition on choosing from \mathcal{H}_3 , $\mathbb{E}(h_i h_j) = \frac{C_6}{\sqrt{n}}$. If we condition on not choosing from \mathcal{H}_3 , the probability of i, j being the same sign is $\frac{(\sqrt{n}/2)-1}{\sqrt{n}-1} = \frac{\ell-1}{2\ell-1}$, meaning $\mathbb{E}(h_i h_j) = -\frac{1}{\sqrt{n}-1}$. Therefore, $\mathbb{E}_{h \in \mathcal{H}}(h_i h_j) = p \cdot \frac{C_6}{\sqrt{n}} - (1-p) \cdot \frac{1}{\sqrt{n}-1} = 0$.

To finish, it suffices to show that

$$\mathbb{E}_{h \in \mathcal{H}} \left[\sup_{1 \leq t \leq n} |h_1 + \dots + h_t| \right] = \Omega(\sqrt{n} \lg n).$$

To check this, note that with probability at least $\frac{1}{1+C_6}$ we are picking something from \mathcal{H}_3 , so we need to just verify that

$$\mathbb{E}_{h \in \mathcal{H}_3} \left[\sup_{1 \leq t \leq n} |h_1 + \dots + h_t| \right] = \Omega(\sqrt{n} \lg n).$$

But for \mathcal{H}_3 , we are choosing something from \mathcal{H}_2 with probability $\frac{1}{g}$ but $g \leq 1 + C_5$ by the arguments of Lemma 3 c), so it suffices to verify that

$$\mathbb{E}_{h \in \mathcal{H}_2} \left[\sup_{1 \leq t \leq n} |h_1 + \dots + h_t| \right] = \Omega(\sqrt{n} \lg n).$$

63:10 Pairwise Independent Random Walks Can Be Slightly Unbounded

But for \mathcal{H}_2 , if we condition on the shifting index d , we know that

$$\mathbb{E}[h_{1+d\sqrt{n}} + h_{2+d\sqrt{n}} + \cdots + h_{(d+\ell)\sqrt{n}}] \geq \sqrt{n} \left(1 + \cdots + \frac{1}{\ell}\right) \geq C_7 \sqrt{n} \lg n$$

for some C_7 , and likewise

$$\mathbb{E}[h_{1+(d+\ell)\sqrt{n}} + h_{2+(d+\ell)\sqrt{n}} + \cdots + h_{(d+2\ell)\sqrt{n}}] \leq \sqrt{n} \left(-1 - \cdots - \frac{1}{\ell}\right) \leq -C_7 \sqrt{n} \lg n,$$

which means that regardless of whether $d \leq \ell$ or $d > \ell$,

$$\mathbb{E}_{h \in \mathcal{H}_2} \left[\max(|h_1 + \cdots + h_{d\sqrt{n}}|, |h_1 + \cdots + h_{(d+\ell)\sqrt{n}}|) \right] \geq \frac{C_7}{2} \sqrt{n} \lg n$$

by the triangle inequality. But for any $h \in \mathcal{H}_2$,

$$\max(|h_1 + \cdots + h_{d\sqrt{n}}|, |h_1 + \cdots + h_{(d+\ell)\sqrt{n}}|) \leq \sup_{1 \leq t \leq n} (h_1 + \cdots + h_t),$$

so the result follows by taking the expected value of both sides, which proves our upper bound is tight in the case of a random walk. Thus, we have proven Theorem 1.

3 Moment Bounds for Pairwise Independence

We show that the bound established in Section 2 and the induced bound on the second moment are tight for the 2-wise independent random walk case by proving Equation (2) in Section 1.1:

► **Theorem 5.** For all 2-wise families \mathcal{H} from $[n]$ to $\{-1, 1\}$,

$$\mathbb{E}_{h \in \mathcal{H}} \left(\sup_{1 \leq i \leq n} (h_1 + \cdots + h_i)^2 \right) = O(n \lg^2 n).$$

We provide a generalization of this theorem in Section 4, with a slightly different method. To prove this, we first establish the following lemma:

► **Lemma 6.** Suppose that there exists a positive definite matrix $A \in \mathbb{R}^{n \times n}$ such that $\text{Tr}(A) = d_1$ for some $d_1 > 0$ and there exists some function f such that for all vectors $x \in \mathbb{R}^n$ and integers $1 \leq i \leq n$, if $x_1 + \cdots + x_i = 1$, then $x^T A x \geq \frac{1}{d_2}$ for some $d_2 > 0$. Then, for all 2-wise families \mathcal{H} ,

$$\mathbb{E}_{h \in \mathcal{H}} \left(\sup_{1 \leq i \leq n} (h_1 + \cdots + h_i)^2 \right) \leq d_1 d_2.$$

Proof. Note that $\mathbb{E}_{h \in \mathcal{H}} h_i^2 = 1$ for all i and $\mathbb{E}_{h \in \mathcal{H}} (h_i h_j) = 0$ for all $i \neq j$. Therefore,

$$\begin{aligned} \mathbb{E}_{h \in \mathcal{H}} (h^T A h) &= \sum_{1 \leq i, j \leq n} \mathbb{E}_{h \in \mathcal{H}} (h_i h_j A_{ij}) = \sum_{1 \leq i, j \leq n} A_{ij} (\mathbb{E}_{h \in \mathcal{H}} (h_i h_j)) \\ &= \sum_{1 \leq i \leq n} A_{ii} = \text{Tr}(A) = d_1. \end{aligned}$$

However, for any $1 \leq i \leq n$, for any $h \in \mathcal{H}$, if $h_1 + \cdots + h_i \neq 0$, then

$$h^T A h \geq (h_1 + \cdots + h_i)^2 \cdot \frac{1}{d_2},$$

since the vector $\frac{1}{h_1 + \dots + h_i} \cdot h$ has its first i components sum to 1, so we can let this vector equal x to get $x^T A x \geq \frac{1}{f(n)}$. If $h_1 + \dots + h_i = 0$, then the above inequality is still true as A is positive definite.

Therefore,

$$h^T A h \geq \frac{1}{d_2} \cdot \sup_{1 \leq i \leq n} (h_1 + \dots + h_i)^2,$$

which means that

$$d_1 = \mathbb{E}_{h \in \mathcal{H}}(h^T A h) \geq \frac{1}{d_2} \cdot \mathbb{E}_{h \in \mathcal{H}} \left(\sup_{1 \leq i \leq n} (h_1 + \dots + h_i)^2 \right),$$

so we are done. ◀

► **Lemma 7.** *There exists a positive definite matrix $A \in \mathbb{R}^{n \times n}$ such that $\text{Tr}(A) = n \lg n$ and for all $x \in \mathbb{R}^n$ and $1 \leq i \leq n$, if $x_1 + \dots + x_i = 1$, then $x^T A x \geq \frac{1}{\lg n}$. This clearly implies Theorem 5.*

Proof. Consider the matrix A such that for all $1 \leq i, j \leq n$, $A_{ij} = \lg n - k$ if k is the smallest nonnegative integer such that $\lfloor \frac{i-1}{2^k} \rfloor = \lfloor \frac{j-1}{2^k} \rfloor$. Alternatively, we can think of A as the sum of all matrices B^{ij} , where B^{ij} is a matrix such that $B_{kl}^{ij} = 1$ if $i \leq k, l \leq j$ and 0 otherwise. However, we sum this not over all $1 \leq i, j \leq n$ but for $i = 2^r \cdot (s-1) + 1, j = 2^r \cdot s$ for $0 \leq r \leq \lg n - 1$ and $1 \leq s \leq 2^{\lg n - r}$. As an illustrative example, for $n = 8$, A equals

$$\begin{pmatrix} 3 & 2 & 1 & 1 & 0 & 0 & 0 & 0 \\ 2 & 3 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 3 & 2 & 0 & 0 & 0 & 0 \\ 1 & 1 & 2 & 3 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3 & 2 & 1 & 1 \\ 0 & 0 & 0 & 0 & 2 & 3 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 3 & 2 \\ 0 & 0 & 0 & 0 & 1 & 1 & 2 & 3 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \end{pmatrix} + \begin{pmatrix} 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \\ 0 & 0 & 0 & 0 & 0 & 0 & 1 & 1 \end{pmatrix} + \begin{pmatrix} 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 1 & 1 & 1 & 1 & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \\ 0 & 0 & 0 & 0 & 1 & 1 & 1 & 1 \end{pmatrix}.$$

It is easy to see that $\text{Tr}(A) = n \lg n$, since $A_{ii} = \lg n$ for all i . For any $1 \leq i < n$, define $i_0 = 0$ and for any $1 \leq r \leq \lg n$, define $i_r = 2^{\lg n - r} \cdot \lfloor \frac{i}{2^{\lg n - r}} \rfloor$. Then, for any $1 \leq i < n$, one can see that $i_{\lg n} = i$ and for any $1 \leq i \leq n$, $A = B^{1i_1} + B^{(i_1+1)i_2} + \dots + B^{(i_{\lg n-1}+1)i_{\lg n}} + C$, where C is some positive semidefinite matrix and we assume B^{ij} is the 0 matrix if $i = j + 1$, because B^{1i_1} and $B^{(i_{r-1}+1)i_r}$ for all $1 \leq r \leq \lg n$ are verifiable as matrices in the summation of A . Therefore, if $x_1 + \dots + x_i = 1$,

$$\begin{aligned} x^T A x &\geq \sum_{i=1}^r x^T B^{(i_{r-1}+1)i_r} x \\ &= (x_1 + \dots + x_{i_1})^2 + (x_{i_1+1} + \dots + x_{i_2})^2 + \dots + (x_{i_{\lg n-1}+1} + \dots + x_{i_{\lg n}})^2 \\ &\geq \frac{1}{\lg n}, \end{aligned}$$

since $(x_1 + \dots + x_{i_1}) + (x_{i_1+1} + \dots + x_{i_2}) + \dots + (x_{i_{\lg n-1}+1} + \dots + x_{i_{\lg n}}) = 1$ and by Cauchy-Schwarz.

63:12 Pairwise Independent Random Walks Can Be Slightly Unbounded

Finally, if $i = n$, then $A = B^{1(n/2)} + B^{(n/2+1)n} + C$, where C is some positive semidefinite matrix. Therefore, if $x_1 + \dots + x_n = 1$,

$$\begin{aligned} x^T A x &\geq x^T B^{1(n/2)} x + x^T B^{(n/2+1)n} x \\ &= (x_1 + \dots + x_{n/2})^2 + (x_{n/2+1} + \dots + x_n)^2 \geq \frac{1}{2} \geq \frac{1}{\lg n}. \end{aligned} \quad \blacktriangleleft$$

As a final note, for any positive definite matrix A and vector v , the minimum value of $w^T A w$ over all w such that $w^T v = 1$ is known to equal $(v^T A^{-1} v)^{-1}$. This can be checked with Lagrange Multipliers, since the Lagrangian $f(w, \lambda)$ of $f(w) = w^T A w$ subject to $w^T v = 1$ equals $w^T A w - \lambda(w^T v - 1)$, which is a convex function in w and has its derivatives vanish on the hyperplane $w^T v = 1$ when $\lambda = 2(v^T A^{-1} v)^{-1}$, $w = \frac{\lambda}{2}(A^{-1} v)$ (See for example [7], Chapter 5, for more details of Lagrange Multipliers). By Lemma 6 and Theorem 1, we have the following corollary:

► **Corollary 8.** *For all positive definite A , if we define v^i as the vector with first i components 1 and last $n - i$ components 0,*

$$\text{Tr}(A) \cdot \max_{1 \leq i \leq n} (v^i A^{-1} v^i) = \Omega(n \lg^2 n)$$

and this bound is tight for the matrix of Lemma 7.

Proof. If the first part were not true, then there would be matrices A_n such that $\text{Tr}(A) = d_1$, $w^T A w = \frac{1}{d_2}$ where $w^T v^i = 0$ for some i , and $d_1 d_2 = o(n \lg^2 n)$. However, this would mean by Lemma 6 that for all pairwise independent \mathcal{H} ,

$$\mathbb{E}_{h \in \mathcal{H}} \left(\sup_{1 \leq i \leq n} (h_1 + \dots + h_i)^2 \right) \leq d_1 d_2 = o(n \lg^2 n),$$

contradicting Theorem 1. The second part is immediate by the analysis of Lemma 7. ◀

4 Generalized Upper Bounds

In this section, our goal is to prove Equation (3) of Section 1.1.

4.1 Proof of Equation 3

In this subsection, we prove a generalization of Kolmogorov's inequality [16] by proving an identical result even if we only know that our random variables X_1, \dots, X_n are 4-wise independent.

► **Theorem 9.** *Suppose that X_1, \dots, X_n are 4-wise independent random variables satisfying $\mathbb{E}[X_i] = 0$ and $\text{Var}(X_i) < \infty$ for all i . Then, for all $\lambda > 0$,*

$$\mathbb{P} \left(\sup_{1 \leq i \leq n} (X_1 + \dots + X_i) \geq \lambda \right) \leq \frac{\sum \mathbb{E}[X_i^2]}{\lambda^2}.$$

Proof. Assume WLOG that $\lambda \geq 1$, $\sum \mathbb{E}[X_i^2] = 1$, and $\mathbb{E}[X_i^2] > 0$ for all i , i.e. none of the variables are almost surely 0. Also, define $S_i = X_1 + \dots + X_i$ and $T_i = \mathbb{E}[X_1^2 + \dots + X_i^2]$ for $0 \leq i \leq n$. Note that $T_0 = 0$ and $T_n = 1$.

We proceed by constructing a series of nested intervals $[a_{r,s}, b_{r,s}]$ and our analysis will be similar to that of Lemma 18 in [5]. We construct $a_{r,s}$ and $b_{r,s}$ for $0 \leq r \leq d = \Theta(\max_i \lg(\mathbb{E}[X_i^2]^{-1}))$ and $1 \leq s \leq 2^r$, as integers between 0 and n , inclusive. First define $a_{0,1} = 0$ and $b_{0,1} = n$. Next, we inductively define $a_{r,s}, b_{r,s}$. Define $a_{r+1,2s-1} := a_{r,s}$ and $b_{r+1,2s} := b_{r,s}$. Then, if there exists any index $a_{r,s} \leq t \leq b_{r,s}$ such that

$$0.45 \cdot |T_{b_{r,s}} - T_{a_{r,s}}| \leq |T_t - T_{a_{r,s}}| \leq 0.55 \cdot |T_{b_{r,s}} - T_{a_{r,s}}|,$$

let $a_{r+1,2s} = b_{r+1,2s-1} = t$ (if there are multiple such indices t , choose any one). Else, define $b_{r+1,2s-1}$ to be the largest index $t \geq a_{r,s}$ such that

$$|T_t - T_{a_{r,s}}| \leq 0.45 \cdot |T_{b_{r,s}} - T_{a_{r,s}}|$$

and similarly define $a_{r+1,2s}$ to be the smallest index $t \leq b_{r,s}$ such that

$$|T_t - T_{a_{r,s}}| \geq 0.55 \cdot |T_{b_{r,s}} - T_{a_{r,s}}|.$$

Note that in this case, $a_{r,2s} = b_{r,2s-1} + 1$.

It is clear that intervals are all nested in each other and for every r , all integers between 0 and n are in an interval $[a_{r,s}, b_{r,s}]$ for some s (possibly at an endpoint). Also, we always have $a_{r,0} \leq b_{r,0} \leq a_{r,1} \leq \dots \leq b_{r,2^r}$, and any interval $[a_{r,s}, b_{r,s}]$ satisfies $T_{b_{r,s}} - T_{a_{r,s}} \leq 0.55^r$. The previous point implies that since $d = \Theta(\max_i(\lg \mathbb{E}[X_i^2]^{-1}))$, every integer equals $a_{d,s} = b_{d,s}$ for some s .

We now call an interval $[a_{r,s}, b_{r,s}]$ *bad* if either s is odd and $b_{r,s} \neq a_{r,s+1}$ or s is even and $a_{r,s} \neq b_{r,s-1}$. Define the *rank* $q_{r,s}$ of a bad interval as the number of distinct $r' \leq r$ such that $[a_{r,s}, b_{r,s}] \subseteq [a_{r',s'}, b_{r',s'}]$ for some bad interval $[a_{r',s'}, b_{r',s'}]$, which may equal $[a_{r,s}, b_{r,s}]$. Define the *relative rank* of a bad interval with respect to some interval $[a, b]$ as the number of distinct $r' \leq r$ such that $[a_{r,s}, b_{r,s}] \subseteq [a_{r',s'}, b_{r',s'}] \subsetneq [a, b]$ for some bad interval $[a_{r',s'}, b_{r',s'}]$. Note that $[a_{r,2s-1}, b_{r,2s-1}]$ and $[a_{r,2s}, b_{r,2s}]$ are either both bad or both *good*, i.e. not bad. We now show the following:

► **Lemma 10.** *Given distinct bad intervals $[a_{r_i,s_i}, b_{r_i,s_i}]$ for $1 \leq i \leq \ell$ all contained in some interval $[a_{r,s}, b_{r,s}]$, where each interval has relative rank exactly q with respect to $[a_{r,s}, b_{r,s}]$,*

$$\sum_{i=1}^{\ell} (T_{b_{r_i,s_i}} - T_{a_{r_i,s_i}}) \leq 0.9^q \cdot (T_{a_{r,s}} - T_{b_{r,s}}).$$

As an immediate consequence, given distinct bad intervals $[a_{r_i,s_i}, b_{r_i,s_i}]$ with absolute rank q ,

$$\sum_{i=1}^{\ell} (T_{b_{r_i,s_i}} - T_{a_{r_i,s_i}}) \leq 0.9^q.$$

Proof. First, note that the bad intervals cannot overlap, except at endpoints, as the only way for such intervals to overlap is for one to be contained in another, which would mean they have different ranks. Now, we prove this by induction on $b_{r,s} - a_{r,s}$. If $b_{r,s} - a_{r,s} = 1$, then for any value of q , this is quite straightforward, since there cannot exist bad intervals of nonzero length with positive relative rank. Now, given $b_{r,s} - a_{r,s} > 1$, then $a_{r,s} = a_{r+1,2s-1} \leq b_{r+1,2s-1} \leq a_{r+1,2s} \leq b_{r+1,2s} = b_{r,s}$, and at least one of the two outer inequalities must be strict. If $b_{r+1,2s-1} = a_{r+1,2s}$, then neither $[a_{r+1,2s-1}, b_{r+1,2s-1}]$ nor $[a_{r+1,2s}, b_{r+1,2s}]$ are bad intervals. We can separately look at intervals which are subintervals of $[a_{r+1,2s-1}, b_{r+1,2s-1}]$ or $[a_{r+1,2s}, b_{r+1,2s}]$ to see which ones have rank q . By induction on $b_{r,s} - a_{r,s}$, the total length of the subintervals of relative rank q is at most

$$0.9^q \cdot (T_{b_{r+1,2s-1}} - T_{a_{r+1,2s-1}}) + 0.9^q \cdot (T_{b_{r+1,2s}} - T_{a_{r+1,2s}}) = 0.9^q \cdot (T_{b_{r,s}} - T_{a_{r,s}}).$$

63:14 Pairwise Independent Random Walks Can Be Slightly Unbounded

If $b_{r+1,2s-1} \neq a_{r+1,2s}$, then if $q = 1$, we can only choose the subintervals $[a_{r+1,2s-1}, b_{r+1,2s-1}]$ and $[a_{r+1,2s}, b_{r+1,2s}]$, and clearly

$$(T_{b_{r+1,2s-1}} - T_{a_{r+1,2s-1}}) + (T_{b_{r+1,2s}} - T_{a_{r+1,2s}}) \leq (0.45 + 0.45) \cdot (T_{b_{r,s}} - T_{a_{r,s}}) = 0.9 \cdot (T_{b_{r,s}} - T_{a_{r,s}}).$$

If $q > 1$, we can separately look at intervals which are subintervals of $[a_{r+1,2s-1}, b_{r+1,2s-1}]$ and $[a_{r+1,2s}, b_{r+1,2s}]$ to see which ones have relative rank $q - 1$, where we have to subtract one from the rank since $[a_{r+1,2s-1}, b_{r+1,2s-1}]$ and $[a_{r+1,2s}, b_{r+1,2s}]$ are both bad. Then, the total length of the subintervals of relative rank q is at most

$$\begin{aligned} & 0.9^{q-1} \cdot (T_{b_{r+1,2s-1}} - T_{a_{r+1,2s-1}}) + 0.9^{q-1} \cdot (T_{b_{r+1,2s}} - T_{a_{r+1,2s}}) \\ & \leq 0.9^{q-1} \cdot (0.45 + 0.45) \cdot (T_{b_{r,s}} - T_{a_{r,s}}) = 0.9^q (T_{b_{r,s}} - T_{a_{r,s}}). \quad \blacktriangleleft \end{aligned}$$

Next, for any λ , we bound the probability that there exists either a bad interval $[a_{r,s}, b_{r,s}]$ with rank q such that $|S_{b_{r,s}} - S_{a_{r,s}}| \geq 0.99^q \cdot \lambda$ or good intervals $[a_{r,2s-1}, b_{r,2s-1}]$, $[a_{r,2s}, b_{r,2s}]$ such that $\min(|S_{b_{r,2s-1}} - S_{a_{r,2s-1}}|, |S_{b_{r,2s}} - S_{a_{r,2s}}|) \geq 0.99^r \cdot \lambda$. Note that by the Chebyshev inequality,

$$\mathbb{P}(|S_{b_{r,s}} - S_{a_{r,s}}| \geq 0.99^q \cdot \lambda) \leq \frac{T_{b_{r,s}} - T_{a_{r,s}}}{0.99^{2q} \cdot \lambda^2},$$

since $\mathbb{E}[(S_{b_{r,s}} - S_{a_{r,s}})^2] = T_{b_{r,s}} - T_{a_{r,s}}$ by pairwise independence. Therefore, the probability of us having this for any bad interval is at most

$$\sum_{q=1}^{\infty} \sum_{\substack{\text{bad interval} \\ \text{rank } q}} \frac{T_{b_{r,s}} - T_{a_{r,s}}}{0.99^{2q} \cdot \lambda^2} \leq \sum_{q=1}^{\infty} \frac{0.9^q}{0.99^{2q} \cdot \lambda^2} = O(\lambda^{-2}).$$

Next, note that for any good intervals $[a_{r,2s-1}, b_{r,2s-1}]$ and $[a_{r,2s}, b_{r,2s}]$, we have that

$$\begin{aligned} & \mathbb{P}(\min(|S_{b_{r,2s-1}} - S_{a_{r,2s-1}}|, |S_{b_{r,2s}} - S_{a_{r,2s}}|) \geq \lambda \cdot 0.99^r) \\ & \leq \mathbb{P}((S_{b_{r,2s-1}} - S_{a_{r,2s-1}})^2 (S_{b_{r,2s}} - S_{a_{r,2s}})^2 \geq \lambda^4 \cdot 0.99^{4r}) \\ & \leq \frac{\mathbb{E}[(S_{b_{r,2s-1}} - S_{a_{r,2s-1}})^2 (S_{b_{r,2s}} - S_{a_{r,2s}})^2]}{\lambda^4 \cdot 0.99^{4r}} \\ & \leq \frac{(T_{b_{r,2s-1}} - T_{a_{r,2s-1}})(T_{b_{r,2s}} - T_{a_{r,2s}})}{\lambda^4 \cdot 0.99^{4r}} \leq \frac{0.55^{2r}}{\lambda^4 \cdot 0.99^{4r}} \end{aligned}$$

using 4-wise independence of X_1, \dots, X_n . Since there are at most 2^r such pairs of good intervals for any r , the probability of $|S_{b_{r,2s-1}} - S_{a_{r,2s-1}}|, |S_{b_{r,2s}} - S_{a_{r,2s}}|$ both being greater than $\lambda \cdot 0.99^r$ for any pair of good intervals, is at most

$$\sum_{r=1}^{\infty} 2^r \cdot \frac{0.55^{2r}}{\lambda^4 \cdot 0.99^{4r}} = O(\lambda^{-4}).$$

Finally, the probability of $|S_n - S_0| = |S_{b_{0,1}} - S_{a_{0,1}}| > \lambda$ is at most $\frac{\mathbb{E}[S_n^2]}{\lambda^2} = O(\lambda^{-2})$.

These imply the following result:

► **Lemma 11.** *The probability of there existing a bad interval $[a_{r,s}, b_{r,s}]$ with rank q such that $|S_{b_{r,s}} - S_{a_{r,s}}| \geq 0.99^q \cdot \lambda$, or good intervals $[a_{r,2s-1}, b_{r,2s-1}]$ and $[a_{r,2s}, b_{r,2s}]$ such that $|S_{b_{r,2s-1}} - S_{a_{r,2s-1}}|, |S_{b_{r,2s}} - S_{a_{r,2s}}|$ are both greater than $\lambda \cdot 0.99^r$, or of $|S_n - S_0| \geq \lambda$ is $O(\lambda^{-2})$.*

Next, we prove the following:

► **Lemma 12.** For any $0 \leq i \leq n$, there exists a sequence $0 \leq i_0, i_1, i_2, \dots, i_d \leq n$ with $i_0 = 0, i_d = i$, and a sequence of nested intervals $[a_{0,s_0}, b_{0,s_0}] \supset \dots \supset [a_{d,s_d}, b_{d,s_d}]$ such that for any $1 \leq j \leq d-1$, i_j is an endpoint of the interval $[a_{j,s_j}, b_{j,s_j}]$ and of the interval $[a_{j-1,s_{j-1}}, b_{j-1,s_{j-1}}]$. Furthermore, for any $1 \leq j \leq d$, either $i_{j-1} = i_j$, or $[a_{j,s_j}, b_{j,s_j}]$ is a bad interval, or i_j equals $a_{j,2s} = b_{j,2s-1}$ and i_{j-1} is either $a_{j,2s-1}$ or $b_{j,2s}$ such that $|S_{i_j} - S_{i_{j-1}}| = \min(|S_{b_{j,2s}} - S_{a_{j,2s}}|, |S_{a_{j,2s-1}} - S_{b_{j,2s-1}}|)$. The intervals and values i_0, \dots, i_d may depend on the actual values of X_1, \dots, X_n .

Proof. We know that $i = i_d$ equals $a_{d,s_d} = b_{d,s_d}$ for some s_d , and thus must also equal either $a_{d-1,s_{d-1}}$ or $b_{d-1,s_{d-1}}$ for some s_{d-1} . If we are given i_{j+1} for some $1 \leq j < d$, if i_{j+1} equals $a_{j,2s-1}$ or $b_{j,2s}$ for some s , then let $i_j = i_{j+1}$ which equals $a_{j-1,s}$ or $b_{j-1,s}$, respectively. If i_j equals $a_{j,2s}$ or $b_{j,2s-1}$ for some s , then if $a_{j,2s} = b_{j,2s-1}$, we can choose i_{j-1} accordingly as either $a_{j,2s-1} = a_{j-1,s}$ or $b_{j,2s} = b_{j-1,s}$ based on whether $|S_{b_{j,2s-1}} - S_{a_{j,2s-1}}|$ or $|S_{b_{j,2s}} - S_{a_{j,2s}}|$ is smaller. If $a_{j,2s} \neq b_{j,2s-1}$, then if $i_j = a_{j,2s}$ we choose $i_{j-1} = a_{j-1,s}$ and if $i_j = b_{j,2s-1}$ then we choose $i_{j-1} = b_{j-1,s}$. ◀

As a result, we have that if the conditions of Lemma 11 do not hold, which happens with probability $1 - O(\lambda^{-2})$, then for any i , then every $|S_i|$ satisfies

$$|S_i| \leq \sum_{j=1}^d |S_{i_j} - S_{i_{j-1}}| \leq \lambda + \sum_{q=1}^{\infty} 0.99^q \cdot \lambda + \sum_{r=1}^{\infty} 0.99^r \cdot \lambda = O(\lambda),$$

where I am using the fact that the intervals $[a_{j,s_j}, b_{j,s_j}]$ are nested in each other, so no two bad intervals can have the same rank.

In summary, we have with probability at least $1 - O(\lambda^{-2})$, the supremum of $|S_i| = |X_1 + \dots + X_i|$ over all i doesn't exceed $O(\lambda)$, so we have proven Theorem 9. ◀

5 Open Problems

We note a few further directions that could be taken after this work. The first main open problem is whether 3-wise independent random walks on n steps have supremum distance bounded by $O(\sqrt{n})$ in expectation. As all 3-wise independent random walks are also 2-wise independent, we know that the supremum distance is bounded by $O(\sqrt{n} \log n)$ in expectation and the supremum square distance is bounded by $O(n \log^2 n)$ in expectation. However, we do not know if better bounds are true for 3-wise independent random walks. Likewise, for odd $k \geq 5$, we could ask if the k th moment of the supremum distance is bounded by $O(n^{k/2})$ in expectation, as we only know that the $(k-1)$ th moment of the supremum distance is bounded by $O(n^{(k-1)/2})$ in expectation by Equation (5), since $k-1$ is even and at least 4.

Finally, we could ask how the constants increase as k grows. By our proof of Equation (5) and the constants in Khintchine's inequality [15], we know that the k th moment of the supremum distance of a random walk is $O(k)^{3k/2} \cdot n^{k/2}$. Therefore, we could ask if the constant $O(k)^{3k/2}$ could be improved if k grows with respect to n (such as if $k = \Theta(\log n)$).

A Generalized Upper Bounds: Proof of Equations 4 and 5

Before we prove Equations (4) and (5), we construct $2^{-r/2}$ -nets for $0 \leq r \leq 2 \lg m + 1$ in a very similar way as in Theorem 1 in [8]. We define an ε -net to be a finite set of points $a_{r,0}, a_{r,1}, \dots, a_{r,d_r}$ such that for every $z^{(t)}$, $\|z^{(t)} - a_{r,s}\|_2 \leq \varepsilon \|z\|_2$ for some $0 \leq s \leq d_r$. The constructions are defined identically for both equations. Define $a_{0,0} := z^{(0)}$ as the only element of the $2^{-0/2} = 1$ -net. For $r \geq 1$, define $a_{r,0} = z^{(0)}$, and given $a_{r,s} = z^{(t_1)}$ then define $a_{r,s+1}$ as the smallest $t > t_1$ such that

$$\|z^{(t)} - z^{(t_1)}\|_2 > 2^{-r/2} \cdot \|z\|_2^2,$$

unless such a t does not exist, in which case let $s = d_r$ and do not define $a_{r,s'}$ for any $s' > s$.

We define the set $A_r = \{a_{r,s} : 0 \leq s \leq d_r\}$. The following is directly true from our construction:

► **Proposition 13.** *For any $0 \leq t \leq m$ and fixed r , if $t_1 \leq t$ is the largest t_1 such that $z^{(t_1)} = a_{r,s}$ for some s , then $\|z^{(t)} - z^{(t_1)}\|_2 \leq 2^{-r/2} \cdot \|z\|_2$. Consequently, $A_r = \{a_{r,0}, \dots, a_{r,d_r}\}$ is a $2^{-r/2}$ -net.*

The above proposition implies the following:

► **Proposition 14.** *For all $1 \leq t \leq m$, $z^{(t)} = a_{2 \lg m + 1, s}$ for some s .*

Proof. Let t_1 be the largest integer at most t such that $z^{(t_1)} = a_{2 \lg m + 1, s}$ for some s . Then, $\|z^{(t)} - a_{2 \lg m + 1, s}\|_2^2 \leq 2^{-(2 \lg m + 1)} \cdot \|z\|_2^2 < 1$, which is clearly impossible unless $z^{(t)} = a_{2 \lg m + 1, s}$. ◀

Next, to prove Equations (4) and (5), we will need the Marcinkiewicz–Zygmund inequality (see for example [21]), which is a generalization of Khintchine’s inequality (see for example [15]):

► **Theorem 15.** *For any even $k \geq 2$, there exists a constant B_k only depending on k such that for any fixed vector v and totally independent random variables $\bar{Y} = (Y_1, \dots, Y_n)$,*

$$\mathbb{E} \left[\left(\sum_{i=1}^n Y_i \right)^k \right] \leq B_k \mathbb{E} \left[\left(\sum_{i=1}^n Y_i^2 \right)^{k/2} \right].$$

This implies the following result:

► **Proposition 16.** *For any $k \geq 2$ and vector v , there exists a B_k only dependent on k such that*

$$\mathbb{E} \left[\langle v, \bar{X} \rangle^k \right] = \mathbb{E} \left[\left(\sum_{i=1}^n v_i X_i \right)^k \right] \leq B_k \|v\|_2^k.$$

Proof. Since the expected value of $(\sum v_i X_i)^k$ is only dependent on k -wise independence, we can assume that the X_i ’s are totally independent but have the same marginal distribution. This implies

$$\mathbb{E} \left[\left(\sum_{i=1}^n v_i X_i \right)^k \right] \leq B_k \mathbb{E} \left[\left(\sum_{i=1}^n v_i^2 X_i^2 \right)^{k/2} \right]$$

by Theorem 15. However, we know that $\mathbb{E}[X_i^{2d}] \leq 1$ for all i and all $1 \leq d \leq k/2$, since $\mathbb{E}[X_i^k] \leq 1$ and $\mathbb{E}[X_i^{2d}]^{k/d} \leq \mathbb{E}[X_i^k]$ by Jensen’s inequality, so simply expanding and using independence and linearity of expectation gets us the desired result. ◀

63:18 Pairwise Independent Random Walks Can Be Slightly Unbounded

We now prove equations (4) and (5).

Proof of Equation (4). For $r \geq 1$ and s , suppose $a_{r,s} = z^{(t)}$ and $t_1 \leq t$ is the largest index such that $z^{(t_1)} \in A_{r-1}$. Then, define $f(s, t)$ to be the index s' such that $z^{(t_1)} = a_{r-1,s'}$. Consider the quadratic form

$$\sum_{r=1}^{2 \lg m + 1} \sum_{s=0}^{d_r} \langle (a_{r,s} - a_{r-1,f(r,s)}), \vec{X} \rangle^2.$$

By Proposition 13, $\|a_{r,s} - a_{r-1,f(r,s)}\|_2 \leq 2^{-(r-1)/2} \cdot \|z\|_2$. Thus, by Proposition 16, we get the expected value of the quadratic form equals

$$\begin{aligned} & \sum_{r=1}^{2 \lg m + 1} \sum_{s=0}^{d_r} \mathbb{E}[\langle (a_{r,2s+1} - a_{r,2s}), \vec{X} \rangle^2] \leq B_2 \sum_{r=1}^{2 \lg m + 1} \sum_{s=0}^{d_r} \|a_{r,2s+1} - a_{r,2s}\|_2^2 \\ & \leq B_2 \sum_{r=1}^{2 \lg m + 1} \left(2^r \cdot 2^{-(r-1)} \|z\|_2^2 \right) \leq 2B_2(2 \lg m + 1)(\|z\|_2^2). \end{aligned}$$

Here, I am using the fact that an ε -net has size at most ε^{-2} , which is easy to see since $z^{(0)}, \dots, z^{(m)}$ is tracking an insertion stream (it is proven, for example, in Theorem 1 of [8]), and thus $d_r \leq 2^r$.

Now, for any $0 \leq i \leq n$, consider $z^{(i)}$ and let $z^{(i)} = a_{2 \lg m + 1, s}$. Then, define $s_r = s$ if $r = 2 \lg m + 1$ and $s_{r-1} = f(r, s_r)$ for $1 \leq r \leq 2 \lg m + 1$. Note that $s_0 = 0$ and for any $r \geq 1$, if $a_{r,s_r} \in A_{r-1}$, then $a_{r,s_r} = a_{r-1,s_{r-1}}$. Thus, each $\langle (a_{r,s_r} - a_{r-1,s_{r-1}}), \vec{X} \rangle^2$ for $1 \leq r \leq 2 \lg m + 1$ is either 0 (because $a_{r,s_r} - a_{r-1,s_{r-1}} = 0$) or is a summand in our quadratic form. Therefore,

$$\sum_{r=1}^{2 \lg m + 1} \sum_{s=0}^{d_r} \langle (a_{r,s} - a_{r,f(r,s)}), \vec{X} \rangle^2 \geq \sum_{r=1}^{2 \lg m + 1} \langle (a_{r,s_r} - a_{r-1,s_{r-1}}), \vec{X} \rangle^2 \geq \frac{1}{2 \lg m + 1} \cdot \langle z^{(i)}, \vec{X} \rangle^2,$$

with the last inequality true since $a_{2 \lg m + 1, s_{2 \lg m + 1}} = z^{(i)}$, $a_{0,s_0} = z^{(0)}$, and by the Cauchy-Schwarz inequality. As this is true for all i , taking the supremum over i and then expected values gives us

$$\begin{aligned} 2B_2(2 \lg m + 1)(\|z\|_2^2) & \geq \mathbb{E} \left[\sum_{r=1}^{2 \lg m + 1} \sum_{s=0}^{d_r} \langle (a_{r,2s+1} - a_{r,2s}), \vec{X} \rangle^2 \right] \\ & \geq \frac{1}{2 \lg m + 1} \cdot \sup_i \mathbb{E} \left[\langle z^{(i)}, \vec{X} \rangle^2 \right], \end{aligned}$$

and therefore,

$$\mathbb{E} \left[\langle z^{(i)}, \vec{X} \rangle^2 \right] = O(\|z\|_2^2 \cdot \lg^2 m). \quad \blacktriangleleft$$

Proof of Equation (5). Consider the form

$$\sum_{r=1}^{2 \lg m + 1} 2^{r/2} \sum_{s=0}^{d_r} \langle (a_{r,s} - a_{r-1,f(r,s)}), \vec{X} \rangle^k,$$

with $f(r, s)$ defined as in the proof of Equation (4). We again note that by Proposition 13, $\|a_{r,s} - a_{r-1,f(r,s)}\|_2 \leq 2^{-(r-1)/2} \cdot \|z\|_2$. Thus, by Proposition 16, we get the expected value of the form equals

$$\sum_{r=1}^{2 \lg m + 1} 2^{r/2} \sum_{s=0}^{d_r} \mathbb{E}[\langle (a_{r,s} - a_{r-1,f(r,s)}), \vec{X} \rangle^k] \leq B_k \sum_{r=1}^{2 \lg m + 1} 2^{r/2} \sum_{s=0}^{d_r} \|a_{r,s} - a_{r-1,f(r,s)}\|_2^k$$

$$\leq B_k \sum_{r=0}^{2 \lg m + 1} 2^{r/2} \cdot 2^r \cdot 2^{-(r-1)k/2} \|z\|_2^k \leq B_k \cdot 2^{k/2} \sum_{r=0}^{\infty} 2^{r(3-k)/2} \|z\|_2^k = O(2^{k/2} B_k) \|z\|_2^k,$$

since $k \geq 4$. Again, I am using the fact that $d_r \leq 2^r$ as an ε -net has size at most ε^{-2} .

Now, for any $0 \leq i \leq n$, suppose s satisfies $z^{(i)} = a_{2 \lg m + 1, s}$. Define $s_r = s$ if $r = 2 \lg m + 1$ and $s_{r-1} = f(r, s_r)$ for $1 \leq r \leq 2 \lg m + 1$. Then, similarly to in the proof of Equation (4),

$$\begin{aligned} \sum_{r=1}^{2 \lg m + 1} 2^{r/2} \sum_{s=0}^{d_r} \langle (a_{r,s} - a_{r-1, f(r,s)}), \vec{X} \rangle^k &\geq \sum_{r=1}^{2 \lg m + 1} 2^{r/2} \langle (a_{r,s_r} - a_{r-1, s_{r-1}}), \vec{X} \rangle^k \\ &\geq \Omega(k^{-1})^k \cdot \langle z^{(i)}, \vec{X} \rangle^k. \end{aligned}$$

The last inequality requires justification, specifically that if $x_1 + \dots + x_{2 \lg m + 1} = 1$, $\sum 2^{r/2} x_r^k = \Omega(k^{-1})^k$. This is sufficient since we can let $x_r = \langle (a_{r,s_r} - a_{r-1, s_{r-1}}), \vec{X} \rangle$. To prove this, define $x'_1, x'_2, \dots, x'_{2 \lg m + 1}$ such that $x'_1 + \dots + x'_{2 \lg m + 1} = 1$ and $x'_1 > \dots > x'_{2 \lg m + 1}$ are in a geometric series with common ratio $2^{-1/(2k)} = 1 - \Theta(1/k)$. Then, note that for any $x_1, \dots, x_{2 \lg m + 1}$ such that $x_1 + \dots + x_{2 \lg m + 1} = 1$, $x_i \geq x'_i$ for some i . But note that $(x'_r)^k 2^{r/2}$ are equal for all r because of our geometric series, and equals $(x'_1)^k = \Omega(k^{-1})^k$ since $x'_1 = \Omega(k^{-1})^k$ is clearly true. Thus, $\sum 2^{r/2} x_r^k \geq 2^{i/2} (x'_i)^k = \Omega(k^{-1})^k$, so we are done.

As this is true for all i , we can take the supremum over i and then take expected values to get

$$2^{k/2} B_k \cdot \|z\|_2^k \geq \mathbb{E} \left[\sum_{r=1}^{2 \lg m + 1} 2^{r/2} \sum_{s=0}^{d_r} \langle (a_{r,s} - a_{r-1, f(r,s)}), \vec{X} \rangle^k \right] \geq \Omega(k^{-1})^k \cdot \sup_i \mathbb{E} \left[\langle z^{(i)}, \vec{X} \rangle^k \right]$$

and therefore, for a fixed k ,

$$\mathbb{E} \sup_i \left[\langle z^{(i)}, \vec{X} \rangle^k \right] = O(\|z\|_2^k). \quad \blacktriangleleft$$

Optimal Convergence Rate of Hamiltonian Monte Carlo for Strongly Logconcave Distributions

Abstract

We study *Hamiltonian Monte Carlo* (HMC) for sampling from a strongly logconcave density proportional to e^{-f} where $f : \mathbb{R}^d \rightarrow \mathbb{R}$ is μ -strongly convex and L -smooth (the condition number is $\kappa = L/\mu$). We show that the relaxation time (inverse of the spectral gap) of ideal HMC is $O(\kappa)$, improving on the previous best bound of $O(\kappa^{1.5})$; we complement this with an example where the relaxation time is $\Omega(\kappa)$. When implemented using a nearly optimal ODE solver, HMC returns an ε -approximate point in 2-Wasserstein distance using $\tilde{O}((\kappa d)^{0.5} \varepsilon^{-1})$ gradient evaluations per step and $\tilde{O}((\kappa d)^{1.5} \varepsilon^{-1})$ total time.

1 Introduction

Sampling logconcave densities is a basic problem that arises in machine learning, statistics, optimization, computer science and other areas. The problem is described as follows. Let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a convex function. Our goal is to sample from the density proportional to $e^{-f(x)}$. We study *Hamiltonian Monte Carlo* (HMC), one of the most widely-used *Markov chain Monte Carlo* (MCMC) algorithms for sampling from a probability distribution. In many settings, HMC is believed to outperform other MCMC algorithms such as the Metropolis-Hastings algorithm or Langevin dynamics. In terms of theory, rapid mixing has been established for HMC in recent papers [9, 10, 13, 14, 15] under various settings. However, in spite of much progress, there is a gap between known upper and lower bounds even in the basic setting when f is strongly convex (e^{-f} is strongly logconcave) and has a Lipschitz gradient.

Many sampling algorithms such as the Metropolis-Hastings algorithm or Langevin dynamics maintain a position $x = x(t)$ that changes with time, so that the distribution of x will eventually converge to the desired distribution, i.e., proportional to $e^{-f(x)}$. In HMC, besides the position $x = x(t)$, we also maintain a velocity $v = v(t)$. In the simplest Euclidean setting, the Hamiltonian $H(x, v)$ is defined as

$$H(x, v) = f(x) + \frac{1}{2} \|v\|^2.$$

64:2 Optimal Convergence Rate of HMC for Strongly Logconcave Distributions

Then in every step the pair (x, v) is updated using the following system of differential equations for a fixed time interval T :

$$\begin{cases} \frac{dx(t)}{dt} = \frac{\partial H(x, v)}{\partial v} = v(t), \\ \frac{dv(t)}{dt} = -\frac{\partial H(x, v)}{\partial x} = -\nabla f(x(t)). \end{cases} \quad (1)$$

The initial position $x(0) = x_0$ is the position from the last step, and the initial velocity $v(0) = v_0$ is chosen randomly from the standard Gaussian distribution $N(0, I)$. The updated position is $x(T)$ where T can be thought of as the step-size. It is well-known that the stationary distribution of HMC is the density proportional to e^{-f} . Observe that

$$\frac{dH(x, v)}{dt} = \frac{\partial H(x, v)}{\partial x} x'(t) + \frac{\partial H(x, v)}{\partial v} v'(t) = 0,$$

so the Hamiltonian $H(x, v)$ does not change with t . We can also write (1) as the following ordinary differential equation (ODE):

$$x''(t) = -\nabla f(x(t)), \quad x(0) = x_0, \quad x'(0) = v_0. \quad (2)$$

We state HMC explicitly as the following algorithm.

■ **Algorithm 1** Hamiltonian Monte Carlo algorithm.

Input: $f : \mathbb{R}^d \rightarrow \mathbb{R}$ that is μ -strongly convex and L -smooth, ε the error parameter.

1. Set starting point $x^{(0)}$, step-size T , number of steps N , and ODE error tolerance δ .
2. For $k = 1, \dots, N$:
 - a. Let $v \sim N(0, I)$;
 - b. Denote by $x(t)$ the solution to (1) with initial position $x(0) = x^{(k-1)}$ and initial velocity $v(0) = v$. Use the ODE solver to find a point $x^{(k)}$ such that

$$\|x^{(k)} - x(T)\| \leq \delta.$$

3. Output $x^{(N)}$.
-

In our analysis, we first consider *ideal* HMC where in every step we have the exact solution to the ODE (1) and neglect the numerical error from solving the ODEs or integration ($\delta = 0$).

1.1 Preliminaries

We recall standard definitions here. Let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a continuously differentiable function. We say f is μ -strongly convex if for all $x, y \in \mathbb{R}^d$,

$$f(y) \geq f(x) + \langle \nabla f(x), y - x \rangle + \frac{\mu}{2} \|y - x\|^2.$$

We say f is L -smooth if ∇f is L -Lipschitz; i.e., for all $x, y \in \mathbb{R}^d$,

$$\|\nabla f(x) - \nabla f(y)\| \leq L \|x - y\|.$$

If f is μ -strongly convex and L -smooth, then the condition number of f is $\kappa = L/\mu$.

Consider a discrete-time *reversible* Markov chain \mathcal{M} on \mathbb{R}^d with stationary distribution π . Let

$$L_2(\pi) = \left\{ f : \mathbb{R}^d \rightarrow \mathbb{R} \mid \int_{\mathbb{R}^d} f(x)^2 \pi(dx) < \infty \right\}$$

be the Hilbert space with inner product

$$\langle f, g \rangle = \int_{\mathbb{R}^d} f(x)g(x)\pi(dx)$$

for $f, g \in L_2(\pi)$. Denote by P the transition kernel of \mathcal{M} . We can view P as a self-adjoint operator from $L_2(\pi)$ to itself: for $f \in L_2(\pi)$,

$$(Pf)(x) = \int_{\mathbb{R}^d} f(y)P(x, dy).$$

Let $L_2^0(\pi) = \{f \in L_2(\pi) : \int_{\mathbb{R}^d} f(x)\pi(dx) = 0\}$ be a closed subspace of $L_2(\pi)$. The (absolute) *spectral gap* of P is defined to be

$$\gamma(P) = 1 - \sup_{f \in L_2^0(\pi)} \frac{\|Pf\|}{\|f\|} = 1 - \sup_{\substack{f \in L_2^0(\pi) \\ \|f\|=1}} |\langle Pf, f \rangle|.$$

The relaxation time of P is

$$\tau_{\text{rel}}(P) = \frac{1}{\gamma(P)}.$$

Let ν_1, ν_2 be two distributions on \mathbb{R}^d . The 2-Wasserstein distance between ν_1 and ν_2 is defined as

$$W_2(\nu_1, \nu_2) = \left(\inf_{(X,Y) \in \mathcal{C}(\nu_1, \nu_2)} \mathbb{E} \left[\|X - Y\|^2 \right] \right)^{1/2},$$

where $\mathcal{C}(\nu_1, \nu_2)$ is the set of all couplings of ν_1 and ν_2 .

1.2 Related work

Various versions of Langevin dynamics have been studied in many recent papers, see [5, 6, 21, 17, 7, 4, 3, 2, 8, 20, 19, 12]. The convergence rate of HMC is also studied recently in [9, 10, 13, 14, 15, 18]. The first bound for our setting was obtained by Mangoubi and Smith [13], who gave an $O(\kappa^2)$ bound on the convergence rate of ideal HMC.

► **Theorem 1** ([13, Theorem 1]). *Let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a twice differentiable function such that $\mu I \preceq \nabla^2 f(x) \preceq LI$ for all $x \in \mathbb{R}^d$. Then the relaxation time of ideal HMC for sampling from the density $\propto e^{-f}$ with step-size $T = \sqrt{\mu}/(2\sqrt{2}L)$ is $O(\kappa^2)$.*

This was improved by [9], which showed a bound of $O(\kappa^{1.5})$. They also gave a nearly optimal method for solving the ODE that arises in the implementation of HMC.

► **Theorem 2** ([9, Lemma 1.8]). *Let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a twice differentiable function such that $\mu I \preceq \nabla^2 f(x) \preceq LI$ for all $x \in \mathbb{R}^d$. Then the relaxation time of ideal HMC for sampling from the density $\propto e^{-f}$ with step-size $T = \mu^{1/4}/(2L^{3/4})$ is $O(\kappa^{1.5})$.*

Both papers suggest that the correct bound is linear in κ : [13] says linear is the best one can expect while [9] shows that there *exists* a choice of step-sizes (time for running the ODE) that might achieve a linear rate (Lemma 1.8, second part); however it was far from clear how to determine these step-sizes algorithmically.

Other papers focus on various aspects and use stronger assumptions (e.g., bounds on higher-order gradients) to get better bounds on the overall convergence time or the number of gradient evaluations in some ranges of parameters. For example, [15] shows that the dependence on dimension for the number of gradient evaluations can be as low as $d^{1/4}$ with suitable regularity assumptions (and higher dependence on the condition number). We note also that sampling logconcave functions is a polynomial-time solvable problem, without the assumptions of strong convexity or gradient Lipschitzness, and even when the function e^{-f} is given only by an oracle with no access to gradients [1, 11]. The Riemannian version of HMC provides a faster polynomial-time algorithm for uniformly sampling polytopes [10]. However, the dependence on the dimension is significantly higher for these algorithms, both for the contraction rate and the time per step.

1.3 Results

In this paper, we show that the relaxation time of ideal HMC is $\Theta(\kappa)$ for strongly logconcave functions with Lipschitz gradient.

► **Theorem 3.** *Suppose that f is μ -strongly convex and L -smooth. Then the relaxation time (inverse of spectral gap) of ideal HMC for sampling from the density $\propto e^{-f}$ with step-size $T = 1/(2\sqrt{L})$ is $O(\kappa)$, where $\kappa = L/\mu$ is the condition number.*

We remark that the only assumption we made about f is strongly convexity and smoothness (in particular, we do not require that f is twice differentiable, which is assumed in both [9] and [13]).

We also establish a matching lower bound on the relaxation time of ideal HMC, implying the tightness of Theorem 3.

► **Theorem 4.** *For any $0 < \mu \leq L$, there exists a μ -strongly convex and L -smooth function f , such that the relaxation time of ideal HMC for sampling from the density $\propto e^{-f}$ with step-size $T = O(1/\sqrt{L})$ is $\Omega(\kappa)$, where $\kappa = L/\mu$ is the condition number.*

Using the nearly optimal ODE solver from [9], we obtain the following convergence rate in 2-Wasserstein distance for the HMC algorithm. We note that since our new convergence rate allows larger steps, the ODE solver is run for a longer time step.

► **Theorem 5.** *Let $f : \mathbb{R}^d \rightarrow \mathbb{R}$ be a twice differentiable function such that $\mu I \preceq \nabla^2 f(x) \preceq LI$ for all $x \in \mathbb{R}^d$. Let $\pi \propto e^{-f}$ be the target distribution, and let π_{HMC} be the distribution of the output of HMC with starting point $x^{(0)} = \arg \min_x f(x)$, step-size $T = 1/(16000\sqrt{L})$, and ODE error tolerance $\delta = \sqrt{\mu}T^2\varepsilon/16$. For any $0 < \varepsilon < \sqrt{d}$, if we run HMC for $N = O(\kappa \log(d/\varepsilon))$ steps where $\kappa = L/\mu$, then we have*

$$W_2(\pi_{\text{HMC}}, \pi) \leq \frac{\varepsilon}{\sqrt{\mu}}.$$

Each step takes $O(\sqrt{\kappa}d^{3/2}\varepsilon^{-1} \log(\kappa d/\varepsilon))$ time and $O(\sqrt{\kappa}d\varepsilon^{-1} \log(\kappa d/\varepsilon))$ evaluations of ∇f , amortized over all steps.

The comparison of convergence rates, running times and numbers of gradient evaluations is summarized in the following table with polylog factors omitted.

2 Convergence of ideal HMC

In this section we show that the spectral gap of ideal HMC is $\Omega(1/\kappa)$, and thus prove Theorem 3. We first show a contraction bound for ideal HMC, which roughly says that the distance of two points is shrinking after one step of ideal HMC.

► **Lemma 6** (Contraction bound). *Suppose that f is μ -strongly convex and L -smooth. Let $x(t)$ and $y(t)$ be the solution to (1) with initial positions $x(0)$, $y(0)$ and initial velocities $x'(0) = y'(0)$. Then for $0 \leq t \leq 1/(2\sqrt{L})$ we have*

$$\|x(t) - y(t)\|^2 \leq \left(1 - \frac{\mu}{4}t^2\right) \|x(0) - y(0)\|^2.$$

In particular, by setting $t = T = 1/(c\sqrt{L})$ for some constant $c \geq 2$ we get

$$\|x(T) - y(T)\|^2 \leq \left(1 - \frac{1}{4c^2\kappa}\right) \|x(0) - y(0)\|^2$$

where $\kappa = L/\mu$.

Proof. Consider the two ODEs for HMC:

$$\begin{cases} x'(t) = u(t); \\ u'(t) = -\nabla f(x(t)). \end{cases} \quad \text{and} \quad \begin{cases} y'(t) = v(t); \\ v'(t) = -\nabla f(y(t)). \end{cases}$$

with initial points $x(0), y(0)$ and initial velocities $u(0) = v(0)$. For the sake of brevity, we shall write $x = x(t)$, $y = y(t)$, $u = u(t)$, $v = v(t)$ and omit the variable t , as well as letting $x_0 = x(0)$, $y_0 = y(0)$. We are going to show that

$$\|x - y\|^2 \leq \left(1 - \frac{\mu}{4}t^2\right) \|x_0 - y_0\|^2$$

for all $0 \leq t \leq 1/(2\sqrt{L})$.

Consider the derivative of $\frac{1}{2} \|x - y\|^2$:

$$\frac{d}{dt} \left(\frac{1}{2} \|x - y\|^2 \right) = \langle x' - y', x - y \rangle = \langle u - v, x - y \rangle. \tag{3}$$

Taking derivative on both sides, we get

$$\begin{aligned} \frac{d^2}{dt^2} \left(\frac{1}{2} \|x - y\|^2 \right) &= \langle u' - v', x - y \rangle + \langle u - v, x' - y' \rangle \\ &= -\langle \nabla f(x) - \nabla f(y), x - y \rangle + \|u - v\|^2 \\ &= -\rho \|x - y\|^2 + \|u - v\|^2, \end{aligned} \tag{4}$$

64:6 Optimal Convergence Rate of HMC for Strongly Logconcave Distributions

where we define

$$\rho = \rho(t) = \frac{\langle \nabla f(x) - \nabla f(y), x - y \rangle}{\|x - y\|^2}.$$

Since f is μ -strongly convex and L -smooth, we have $\mu \leq \rho \leq L$ for all $t \geq 0$.

We will upper bound the term $-\rho \|x - y\|^2 + \|u - v\|^2$, while keeping its dependency on ρ . To lower bound $\|x - y\|^2$, we use the following crude bound.

▷ **Claim 7 (Crude bound).** For all $0 \leq t \leq 1/(2\sqrt{L})$ we have

$$\frac{1}{2} \|x_0 - y_0\|^2 \leq \|x - y\|^2 \leq 2 \|x_0 - y_0\|^2. \quad (5)$$

The proof of this claim is postponed to Section 2.1.

Next we derive an upper bound on $\|u - v\|^2$. The derivative of $\|u - v\|$ is given by

$$\begin{aligned} \|u - v\| \left(\frac{d}{dt} \|u - v\| \right) &= \frac{d}{dt} \left(\frac{1}{2} \|u - v\|^2 \right) \\ &= \langle u' - v', u - v \rangle \\ &= - \langle \nabla f(x) - \nabla f(y), u - v \rangle. \end{aligned}$$

Thus, its absolute value is upper bounded by

$$\left| \frac{d}{dt} \|u - v\| \right| = \frac{|\langle \nabla f(x) - \nabla f(y), u - v \rangle|}{\|u - v\|} \leq \|\nabla f(x) - \nabla f(y)\|.$$

Since f is L -smooth and convex, we have

$$\|\nabla f(x) - \nabla f(y)\|^2 \leq L \langle \nabla f(x) - \nabla f(y), x - y \rangle = L\rho \|x - y\|^2 \leq 2L\rho \|x_0 - y_0\|^2,$$

where the last inequality follows from the crude bound (5). Then, using the fact that $u_0 = v_0$ and the Cauchy-Schwarz inequality, we can upper bound $\|u - v\|^2$ by

$$\begin{aligned} \|u - v\|^2 &\leq \left(\int_0^t \left| \frac{d}{ds} \|u - v\| \right| ds \right)^2 \\ &\leq \left(\int_0^t \sqrt{2L\rho} \|x_0 - y_0\| ds \right)^2 \\ &\leq 2Lt \left(\int_0^t \rho ds \right) \|x_0 - y_0\|^2. \end{aligned}$$

Define the function

$$P = P(t) = \int_0^t \rho ds,$$

so $P(t)$ is nonnegative and monotone increasing, with $P(0) = 0$. Also we have $\mu t \leq P(t) \leq Lt$ for all $t \geq 0$. Then,

$$\|u - v\|^2 \leq 2LtP \|x_0 - y_0\|^2. \quad (6)$$

Plugging (5) and (6) into (4), we deduce that

$$\frac{d^2}{dt^2} \left(\frac{1}{2} \|x - y\|^2 \right) \leq -\rho \left(\frac{1}{2} \|x_0 - y_0\|^2 \right) + 2LtP \|x_0 - y_0\|^2.$$

If we define

$$\alpha(t) = \frac{1}{2} \|x - y\|^2,$$

then we have

$$\alpha''(t) \leq -\alpha(0)(\rho(t) - 4LtP(t)).$$

Integrating both sides and using $\alpha'(0) = 0$, we obtain

$$\begin{aligned} \alpha'(t) &= \int_0^t \alpha''(s) ds \\ &\leq -\alpha(0) \left(\int_0^t \rho(s) ds - 4L \int_0^t sP(s) ds \right) \\ &\leq -\alpha(0) \left(P(t) - 4LP(t) \int_0^t s ds \right) \\ &= -\alpha(0)P(t) (1 - 2Lt^2), \end{aligned}$$

where the second inequality is due to the monotonicity of $P(s)$. Since for all $0 \leq t \leq 1/(2\sqrt{L})$ we have $P(t) \geq \mu t$ and $1 - 2Lt^2 \geq 1/2$, we deduce that

$$\alpha'(t) \leq -\alpha(0) \frac{\mu}{2} t.$$

Finally, one more integration yields

$$\alpha(t) = \alpha(0) + \int_0^t \alpha'(s) ds \leq \alpha(0) \left(1 - \frac{\mu}{4} t^2 \right),$$

and the theorem follows. ◀

Proof of Theorem 3. Lemma 6 implies that for any constant $c \geq 2$, the Ricci curvature of ideal HMC with step-size $T = 1/(c\sqrt{L})$ is at least $1/(8c^2\kappa)$. Then, it follows from [16, Proposition 29] that the spectral gap of ideal HMC is at least $1/(8c^2\kappa)$. Hence, the relaxation time is upper bounded by $8c^2\kappa = O(\kappa)$. ◀

2.1 Proof of Claim 7

We present the proof of Claim 7 in this section. We remark that a similar crude bound was established in [9] for general matrix ODEs. Here we prove the crude bound specifically for the Hamiltonian ODE, but without assuming that f is twice differentiable.

Proof of Claim 7. We first derive a crude upper bound on $\|u - v\|$. Since f is L -smooth, we have

$$\begin{aligned} \frac{d}{dt} \|u - v\| &= \frac{-\langle \nabla f(x) - \nabla f(y), u - v \rangle}{\|u - v\|} \\ &\leq \|\nabla f(x) - \nabla f(y)\| \leq L \|x - y\|. \end{aligned}$$

Then from $u_0 = v_0$ we get

$$\|u - v\| = \int_0^t \left(\frac{d}{ds} \|u - v\| \right) ds \leq L \int_0^t \|x - y\| ds.$$

64:8 Optimal Convergence Rate of HMC for Strongly Logconcave Distributions

To obtain the upper bound for $\|x - y\|$, we first bound its derivative by

$$\left| \frac{d}{dt} \|x - y\| \right| = \frac{|\langle u - v, x - y \rangle|}{\|x - y\|} \leq \|u - v\| \leq L \int_0^t \|x - y\| ds. \quad (7)$$

Therefore,

$$\begin{aligned} \|x - y\| &= \|x_0 - y_0\| + \int_0^t \left(\frac{d}{ds} \|x - y\| \right) ds \\ &\leq \|x_0 - y_0\| + L \int_0^t \int_0^s \|x - y\| dr ds \\ &= \|x_0 - y_0\| + L \int_0^t (t - s) \|x - y\| ds. \end{aligned}$$

We then deduce from [9, Lemma A.5] that

$$\|x - y\| \leq \|x_0 - y_0\| \cosh(\sqrt{Lt}) \leq \sqrt{2} \|x_0 - y_0\|, \quad (8)$$

where we use the fact that $\cosh(\sqrt{Lt}) \leq \cosh(1/2) \leq \sqrt{2}$.

Next, we deduce from (7) and (8) that

$$\begin{aligned} \frac{d}{dt} \|x - y\| &\geq -L \int_0^t \|x - y\| ds \\ &\geq -L \|x_0 - y_0\| \int_0^t \cosh(\sqrt{L}s) ds \\ &= -\sqrt{L} \|x_0 - y_0\| \sinh(\sqrt{L}t). \end{aligned}$$

Thus, we obtain

$$\begin{aligned} \|x - y\| &= \|x_0 - y_0\| + \int_0^t \left(\frac{d}{ds} \|x - y\| \right) ds \\ &\geq \|x_0 - y_0\| - \sqrt{L} \|x_0 - y_0\| \int_0^t \sinh(\sqrt{L}s) ds \\ &= \|x_0 - y_0\| \left(2 - \cosh(\sqrt{L}t) \right) \geq \frac{1}{\sqrt{2}} \|x_0 - y_0\|, \end{aligned}$$

where we use $2 - \cosh(\sqrt{L}t) \geq 2 - \cosh(1/2) \geq 1/\sqrt{2}$. ◁

3 Lower bound for ideal HMC

In this section, we show that the relaxation time of ideal HMC can achieve $\Theta(\kappa)$ for some μ -strongly convex and L -smooth function, and thus prove Theorem 4.

Consider a two-dimensional quadratic function:

$$f(x_1, x_2) = \frac{x_1^2}{2\sigma_1^2} + \frac{x_2^2}{2\sigma_2^2},$$

where $\sigma_1 = 1/\sqrt{\mu}$ and $\sigma_2 = 1/\sqrt{L}$. Thus, f is μ -strongly convex and L -smooth. The probability density ν proportional to e^{-f} is essentially the bivariate Gaussian distribution: for $(x_1, x_2) \in \mathbb{R}^2$,

$$\nu(x_1, x_2) = \frac{1}{2\pi\sigma_1\sigma_2} \exp\left(-\frac{x_1^2}{2\sigma_1^2} - \frac{x_2^2}{2\sigma_2^2}\right).$$

The following lemma shows that ideal HMC for the bivariate Gaussian distribution ν has relaxation time $\Omega(\kappa)$, and then Theorem 4 follows immediately.

► **Lemma 8.** *For any constant $c > 0$, the relaxation time of ideal HMC for sampling from ν with step-size $T = 1/(c\sqrt{L})$ is at least $2c^2\kappa$.*

Proof. The Hamiltonian curve for f is given by the ODE

$$(x_1'', x_2'') = -\nabla f(x_1, x_2) = \left(-\frac{x_1}{\sigma_1^2}, -\frac{x_2}{\sigma_2^2} \right)$$

with initial position $(x_1(0), x_2(0))$ and initial velocity $(x_1'(0), x_2'(0))$ from the bivariate standard Gaussian $N(0, I)$. Observe that $\nu = \nu_1 \otimes \nu_2$ is a product distribution of the two coordinates and HMC for f is a product chain. Thus, we can consider the dynamics for each coordinate separately. The Hamiltonian ODE for one coordinate becomes

$$x_i'' = -\frac{x_i}{\sigma_i^2}, \quad x_i(0), \quad x_i'(0) = v_i(0) \sim N(0, 1)$$

where $i = 1, 2$. Solving the ODE above and plugging in the step-size $t = T$, we get

$$x_i(T) = x_i(0) \cos(T/\sigma_i) + v_i(0)\sigma_i \sin(T/\sigma_i).$$

Let P_i be the transition kernel of ideal HMC for the i th coordinate (considered as a Markov chain on \mathbb{R}). Then for $x, y \in \mathbb{R}$ we have

$$P_i(x, y) = \frac{1}{\sqrt{2\pi}\sigma_i \sin(T/\sigma_i)} \exp\left(-\frac{(y - x \cos(T/\sigma_i))^2}{2\sigma_i^2 \sin^2(T/\sigma_i)}\right).$$

Namely, given the current position x , the next position y is from a normal distribution with mean $x \cos(T/\sigma_i)$ and variance $\sigma_i^2 \sin^2(T/\sigma_i)$. Denote the spectral gap of P_i by γ_i for $i = 1, 2$ and that of ideal HMC by γ . Let $h(x) = x$ and note that $h \in L_2^0(\nu_i)$. Using the properties of product chains and spectral gaps, we deduce that

$$\gamma \leq \min\{\gamma_1, \gamma_2\} \leq \gamma_1 = 1 - \sup_{f \in L_2^0(\nu_1)} \frac{|\langle P_1 f, f \rangle|}{\|f\|^2} \leq 1 - \frac{|\langle P_1 h, h \rangle|}{\|h\|^2}.$$

Since we have

$$\|h\|^2 = \int_{-\infty}^{\infty} \nu_1(x) h(x)^2 dx = \sigma_1^2$$

and

$$\langle P_1 h, h \rangle = \int_{-\infty}^{\infty} \nu_1(x) P_1(x, y) h(x) h(y) dx dy = \sigma_1^2 \cos(T/\sigma_1),$$

it follows that $\gamma \leq 1 - |\cos(T/\sigma_1)|$. Suppose that $T = 1/(c\sqrt{L})$ for some $c > 0$. Then we get

$$\gamma \leq \frac{T^2}{2\sigma_1^2} = \frac{1}{2c^2} \frac{\mu}{L},$$

and consequently $\tau_{\text{rel}} = 1/\gamma \geq 2c^2\kappa$. ◀

4 Convergence rate of discretized HMC

In this section, we show how our improved contraction bound (Lemma 6) implies that HMC returns a good enough sample after $\tilde{O}((\kappa d)^{1.5})$ steps. We will use the framework from [9] to establish Theorem 5.

64:10 Optimal Convergence Rate of HMC for Strongly Logconcave Distributions

We first state the ODE solver from [9], which solves an ODE in nearly optimal time when the solution to the ODE can be approximated by a piece-wise polynomial. We state here only for the special case of second order ODEs for the Hamiltonian system. We refer to [9] for general k th order ODEs.

► **Theorem 9** ([9, Theorem 2.5]). *Let $x(t)$ be the solution to the ODE*

$$x''(t) = -\nabla f(x(t)), \quad x(0) = x_0, \quad x'(0) = v_0.$$

where $x_0, v_0 \in \mathbb{R}^d$ and $0 \leq t \leq T$. Suppose that the following conditions hold:

1. There exists a piece-wise polynomial $q(t)$ such that $q(t)$ is a polynomial of degree D on each interval $[T_{j-1}, T_j]$ where $0 = T_0 < T_1 < \dots < T_m = T$, and for all $0 \leq t \leq T$ we have

$$\|q(t) - x''(t)\| \leq \frac{\delta}{T^2};$$

2. $\{T_j\}_{j=1}^m$ and D are given as input to the ODE solver;
3. The function f has a L -Lipschitz gradient; i.e., for all $x, y \in \mathbb{R}^d$,

$$\|\nabla f(x) - \nabla f(y)\| \leq L \|x - y\|.$$

If $\sqrt{LT} \leq 1/16000$, then the ODE solver can find a piece-wise polynomial $\tilde{x}(t)$ such that for all $0 \leq t \leq T$,

$$\|\tilde{x}(t) - x(t)\| \leq O(\delta).$$

The ODE solver uses $O(m(D+1) \log(CT/\delta))$ evaluations of ∇f and $O(dm(D+1)^2 \log(CT/\delta))$ time where

$$C = O(\|v_0\| + T \|\nabla f(x_0)\|).$$

The following lemma, which combines Theorem 3.2, Lemma 4.1 and Lemma 4.2 from [9], establishes the conditions of Theorem 9 in our setting. We remark that Lemmas 4.1 and 4.2 hold for all $T \leq 1/(8\sqrt{L})$, and Theorem 3.2, though stated only for $T \leq O(\mu^{1/4}/L^{3/4})$ in [9], holds in fact for the whole region $T \leq 1/(2\sqrt{L})$ where the contraction bound (Lemma 6) is true. We omit these proofs here and refer the readers to [9] for more details.

► **Lemma 10.** *Let f be a twice differentiable function such that $\mu I \preceq \nabla^2 f(x) \preceq LI$ for all $x \in \mathbb{R}^d$. Choose the starting point $x^{(0)} = \arg \min_x f(x)$, step-size $T = 1/(16000\sqrt{L})$, and ODE error tolerance $\delta = \sqrt{\mu}T^2\varepsilon/16$ in the HMC algorithm. Let $\{x^{(k)}\}_{k=1}^N$ be the sequence of points we get from the HMC algorithm and $\{v_0^{(k)}\}_{k=1}^N$ be the sequence of random Gaussian vector we choose in each step. Let $\pi \propto e^{-f}$ be the target distribution and let π_{HMC} be the distribution of $x^{(N)}$, i.e., the output of HMC. For any $0 < \varepsilon < \sqrt{d}$, if we run HMC for*

$$N = O\left(\frac{\log(d/\varepsilon)}{\mu T^2}\right) = O(\kappa \log(d/\varepsilon))$$

steps where $\kappa = L/\mu$, then:

1. ([9, Theorem 3.2]) We have that

$$W_2(\pi_{\text{HMC}}, \pi) \leq \frac{\varepsilon}{\sqrt{\mu}};$$

2. ([9, Lemma 4.1]) For each k , let $x_k(t)$ be the solution to the ODE (2) in the k th step of HMC. Then there is a piece-wise constant function q_k of m_k pieces such that $\|q_k(t) - x_k''(t)\| \leq \delta/T^2$ for all $0 \leq t \leq T$, where

$$m_k = \frac{2LT^3}{\delta} \left(\|v_0^{(k-1)}\| + T \|\nabla f(x^{(k-1)})\| \right);$$

3. ([9, Lemma 4.2]) *We have that*

$$\frac{1}{N} \mathbb{E} \left[\sum_{k=1}^N \left\| \nabla f(x^{(k-1)}) \right\|^2 \right] \leq O(Ld).$$

Proof of Theorem 5. The convergence of HMC is guaranteed by part 1 of Lemma 10. In the k th step, the number of evaluations of ∇f is $O(m_k \log(C_k \sqrt{\kappa}/\varepsilon))$ by Theorem 9 and part 2 of Lemma 10, where

$$m_k = O\left(\frac{\sqrt{\kappa}}{\varepsilon}\right) \left(\|v_0^{(k-1)}\| + T \|\nabla f(x^{(k-1)})\|\right)$$

and

$$C_k = O\left(\|v_0^{(k-1)}\| + T \|\nabla f(x^{(k-1)})\|\right).$$

Thus, the average number of evaluations of ∇f per step is upper bounded by

$$\frac{1}{N} \mathbb{E} \left[\sum_{k=1}^N O(m_k \log(C_k \sqrt{\kappa}/\varepsilon)) \right] \leq \frac{1}{N} \mathbb{E} \left[\sum_{k=1}^N O(m_k \log m_k) \right] \leq \frac{1}{N} O(\mathbb{E}[M \log M]),$$

where $M = \sum_{k=1}^N m_k$. Since each $v_0^{(k-1)}$ is sampled from the standard Gaussian distribution, we have $\mathbb{E} \left[\|v_0^{(k-1)}\|^2 \right] = d$. Thus, by the Cauchy-Schwarz inequality and part 3 of Lemma 10, we get

$$\begin{aligned} \mathbb{E}[M^2] &\leq N \sum_{k=1}^N \mathbb{E}[m_k^2] \leq O\left(\frac{N\kappa}{\varepsilon^2}\right) \sum_{k=1}^N \mathbb{E} \left[\|v_0^{(k-1)}\|^2 \right] + T^2 \mathbb{E} \left[\|\nabla f(x^{(k-1)})\|^2 \right] \\ &\leq O\left(\frac{N^2 \kappa d}{\varepsilon^2}\right). \end{aligned}$$

We then deduce again from the Cauchy-Schwarz inequality that

$$(\mathbb{E}[M \log M])^2 \leq \mathbb{E}[M^2] \cdot \mathbb{E}[\log^2 M] \leq \mathbb{E}[M^2] \cdot \log^2(\mathbb{E}M) \leq \mathbb{E}[M^2] \cdot \log^2\left(\sqrt{\mathbb{E}[M^2]}\right),$$

where the second inequality is due to that $h(x) = \log^2(x)$ is concave when $x \geq 3$. Therefore, the number of evaluations of ∇f per step, amortized over all steps, is

$$\frac{1}{N} O\left(\sqrt{\mathbb{E}[M^2]} \log\left(\sqrt{\mathbb{E}[M^2]}\right)\right) \leq O\left(\frac{\sqrt{\kappa d}}{\varepsilon} \log\left(\frac{\kappa d}{\varepsilon}\right)\right).$$

Using a similar argument we have the bound for the expected running time per step. This completes the proof. \blacktriangleleft

Abstract

In a recent paper, Chan et al. [SODA '19] proposed a relaxation of the notion of (full) memory obliviousness, which was introduced by Goldreich and Ostrovsky [J. ACM '96] and extensively researched by cryptographers. The new notion, *differential obliviousness*, requires that any two neighboring inputs exhibit similar memory access patterns, where the similarity requirement is that of differential privacy. Chan et al. demonstrated that differential obliviousness allows achieving improved efficiency for several algorithmic tasks, including sorting, merging of sorted lists, and range query data structures.

In this work, we continue the exploration of differential obliviousness, focusing on algorithms that do not necessarily examine all their input. This choice is motivated by the fact that the existence of logarithmic overhead ORAM protocols implies that differential obliviousness can yield at most a logarithmic improvement in efficiency for computations that need to examine all their input. In particular, we explore property testing, where we show that differential obliviousness yields an almost linear improvement in overhead in the dense graph model, and at most quadratic improvement in the bounded degree model. We also explore tasks where a non-oblivious algorithm would need to explore different portions of the input, where the latter would depend on the input itself, and where we show that such a behavior can be maintained under differential obliviousness, but not under full obliviousness. Our examples suggest that there would be benefits in further exploring which class of computational tasks are amenable to differential obliviousness.

1 Introduction

A program's memory access pattern can leak significant information about the private information used by the program even if the memory content is encrypted. Such leakage can turn into a data protection problem in various settings. In particular, where data

¹ Work done while A.B. was visiting Georgetown University.

is outsourced to be stored on an external server, it has been shown that access pattern leakage can be exploited in practical attacks and lead to the compromise of the underlying data [20, 4, 29, 21, 23]. Such leakages can also be exploited when a program is executed in a secure enclave environment but needs to access memory that is external to the enclave.

Memory access pattern leakage can be avoided by employing a strategy that makes the sequence of memory accesses (computationally or statistically) independent of the content being processed. Beginning with the seminal work of Goldreich and Ostrovsky, it is well known how to transform any program running on a random access memory (RAM) machine to one with an *oblivious* memory access pattern while retaining efficiency by using an Oblivious RAM protocol (ORAM) [10, 30, 13]. Current state-of-the-art ORAM protocols achieve logarithmic overhead [2], matching a recent lowerbound by Larsen and Nielsen [24], and protocols with $O(1)$ overhead exist when the server is allowed to perform computation and large blocks are retrieved [6, 28]. To further reduce the overhead, oblivious memory access pattern protocols have been devised for specific tasks, including graph algorithms [3, 17], geometric algorithms [8] and sorting [16, 25]. The latter is motivated by sorting being a fundamental and well researched computational task as well as its ubiquity in data processing.

1.1 Differential Obliviousness

Full obliviousness is rather a strong requirement: any two possible inputs (of the same size) should exhibit identical or indistinguishable sequences of memory accesses. Achieving full obliviousness via a generic use of ORAM protocols requires a setup phase with running time (at least) linear in the memory size and then a logarithmic overhead per each memory access.

A recent work by Chan, Chung, Maggs, and Shi [5] put forward a relaxation of the obliviousness requirement where indistinguishability is replaced with differential privacy. Intuitively, this means that any two possible neighboring inputs should exhibit memory access patterns that are similar enough to satisfy differential privacy, but may still be too dissimilar to be “cryptographically” indistinguishable. It is not a priori clear whether differential obliviousness can be achieved without resorting to full obliviousness. However, the recent work Chan et al. showed that differential obliviousness does allow achieving improved efficiency for several algorithmic tasks, including sorting (over very small domains), merging of sorted lists, and range query data structures.

Also of relevance are the works by He et al. [19] and Mazloom and Gordon [27], which study protocols for secure multiparty computation in which the parties are allowed to learn information from the computation as long as this information preserves the differential privacy of the input. He et al. and Mazloom and Gordon demonstrate that this leakage is useful: He et al. construct protocols for the private record linkage problem for two databases; Mazloom and Gordon present protocols for histograms, PageRank, and matrix factorization.

Furthermore, even the use of ORAM protocols may be insufficient for preventing leakage in cases where the number of memory probes is input dependent. In fact, Kellaris et al. [21] show that such leakage can result in a complete reconstruction in the case of retrieving elements specified by range queries, as the number of records returned depends on the contents of the data structure. Full obliviousness would require that the sequence of memory accesses would be padded to a maximal one to avoid such leakage, a solution that would have a dire effect on the efficiency of many algorithms. Differential obliviousness may in some cases allow achieving meaningful privacy while maintaining efficiency. Examples of such protocols include the combination of ORAM with differentially private sanitization by Kellaris et al. [22] and the recent work of Chan et al. [5] on range query data structures, which avoids using ORAM.

1.2 This Work: Exploring Differential Obliviousness

Noting that the existence of logarithmic overhead ORAM protocols implies that differential obliviousness can yield at most a logarithmic improvement in efficiency for computations that need to examine all their input, we explore tasks where this is not the case. In particular, we focus on property testing and on tasks where the number of memory accesses can depend on the input.

Property testing. As evidence that differential obliviousness can provide a significant improvement over full obliviousness, we show in Section 3 that property testers in the dense graph model, where the input is in the adjacency matrix representation [12], can be made differentially oblivious. This result captures a large set of testable graph properties [12, 1] including, e.g., graph bipartiteness and having a large clique. Testers in this class probe a uniformly random subgraph and hence are fully oblivious without any modification, as their access pattern does not depend on the input graph. However, this is not the case if the tester reveals its output to the adversary, as this allows learning information about the specific probed subgraph. A fully oblivious tester would need to access a linear-sized subgraph, whereas we show that a differentially oblivious tester only needs to apply the original tester $O(1)$ times.²

We also consider property testing in the bounded degree model, where the input is in the incidence lists model [14]. In this model we provide negative results, demonstrating that adaptive testers cannot, generally, be made differentially oblivious without a significant loss in efficiency. In particular, in Section 4 we consider differentially oblivious property testers for connectivity in graphs of degree at most two. For non-oblivious testers, it is known that constant number of probes suffice when the tester is adaptive [14].³ It is also known that any non-adaptive tester for this task requires probing $\Omega(\sqrt{n})$ nodes [32]. We show that this lowerbound extends to differentially oblivious testers, i.e., any differentially oblivious tester for connectivity in graphs of maximal degree 2 requires $\Omega(\sqrt{n})$ probes. While this still improves over full obliviousness, the gap between full and differential obliviousness is in this case diminished.

Locating an Object Satisfying a Property. Here, our goal is to check whether a given data set of objects includes an object that satisfies a specified property. Without obliviousness requirements, a natural approach is to probe elements in a random order until an element satisfying the property is found or all elements were probed. If a p fraction of the elements satisfy the property, then the expected number of probes is $1/p$. This algorithm is in fact instance optimal when the data set is randomly permuted.⁴

A fully oblivious algorithm would require $\Omega(n)$ probes on any dataset even when $p = 1$. In contrast, we demonstrate in Section 5 that with differential obliviousness instance optimality can, to a large extent, be preserved. Our differentially oblivious algorithm always returns a correct answer and makes at most m probes with probability at least $1 - e^{-O(mp)}$.

Prefix Sum. Our last example considers a sorted dataset (possibly, the result of an earlier phase in the computation). Our goal is to compute the sum of all records in the (sorted) dataset that are less than or equal to a given value a (see Section 6 for the definition of privacy).

² We omit dependencies on privacy and accuracy parameters from this introductory description.

³ In an adaptive tester at least one choice of a node to probe should depend on information gathered from incidence lists of previously probed nodes.

⁴ Our treatment of instance optimality is rather informal. The concept was originally presented in [9].

Without obliviousness requirements, one can find the greatest record less than or equal to value a , say, using binary search, and then compute the prefix sum by a quick scan through all records appearing before this record. This algorithm is in fact nearly instance optimal, as it can be shown that any algorithm which returns the correct exact answer with non-negligible probability must probe all entries greater than a . However, fully oblivious algorithms would have to probe the entire dataset.

In Section 6, we give our nearly instance optimal differentially oblivious prefix sum algorithm. As the probes of a binary search would leak information about the memory content, we introduce a differentially oblivious “simulation” of the binary search. Our differentially oblivious binary search runs in time $O(\log^2 n)$.

We also address the scenario where there are multiple prefix sum queries to the same database. If the number of queries is bounded by some integer t , then each differentially oblivious binary search will run in time $O(t \log^2 n)$ (as we need to run the search algorithm with a smaller privacy parameter ϵ). Using ORAM, one can answer such queries with $O(n \log n)$ preprocessing time and $O(\log^2 n)$ time per query. Combining our algorithm and ORAM, we can amortize the pre-processing time over $O(\sqrt{n})$ queries, that is, without any pre-processing, the running time of answering the i -th query is $O(i \log^4 n)$ for the first $O(\sqrt{n})$ queries and $O(\log^2 n)$ for any further query.

1.3 Background Work

The papers by Chan, Chung, Maggs, and Shi [5], He, Machanavajjhala, Flynn, and Srivastava [19], and by Mazloom and Gordon [27] mentioned above are most relevant for this article. As mentioned above, Kellaris et al. [22] examined a similar concept with the goal of preventing reconstruction attacks in secure remote databases. Goldreich, Goldwasser, and Ron [12] initiated the research on graph property testing. Persiano and Yeo [31] showed that the $O(\log n)$ lowerbound for ORAM of [24] also holds when the security requirement is relaxed to differential privacy. Goldreich’s book on property testing [11] gives sufficient background for our discussion. Dwork, McSherry, Nissim, and Smith [7] defined differential privacy. For more details on ORAM and a list of relevant papers, the reader can consult [2].

2.1 Model of Computation

We consider the standard Random Access Memory (RAM) model of computation that consists of a CPU and a memory. The CPU executes a program and is allowed to perform two types of memory operations: read a value from a specified physical address, and write a value to a specified physical address. We assume that the CPU has a private cache of where it can store $O(1)$ values (and/or a polylogarithmic number of bits). As an example, in the setting of a client storing its data on the cloud, the client plays the role of the CPU and the cloud server plays the role of the memory.

We assume that a program’s sequence of read and write operations may be visible to an adversary. We will call this sequence the program’s access pattern. We will further assume that the memory content is encrypted so that no other information is leaked about the content read from and stored in memory location. The program’s access pattern may depend on the program’s input, and may hence leak information about it.

■ **Algorithm 1** Experiment $\text{Exp}_b^{A,M}$ for defining differential obliviousness.

$(\mathbf{x}_0, \mathbf{x}_1, st) \leftarrow_s A_1(\lambda, n)$
 $b' \leftarrow_s A_2^{\mathcal{M}(\mathbf{x}_b, \cdot)}(st)$
 Return b'

Oracle $\mathcal{M}(\mathbf{x}, q)$
 out $\leftarrow_s M(\mathbf{x}, q, state)$
 Return $\text{Access}^M(\mathbf{x}, q, state)$

2.2 Oblivious Algorithms

There are various works focused on oblivious algorithms [8, 15, 26] and Oblivious RAM (ORAM) constructions [13]. These works adopt “full obliviousness” as a privacy notion. Suppose that $M(\lambda, \mathbf{x})$ is an algorithm that takes in two inputs, a security parameter λ and an input dataset denoted \mathbf{x} . We denote by $\text{Access}^M(\lambda, \mathbf{x})$, the ordered sequence of memory accesses the algorithm M makes on the input λ and \mathbf{x} .

► **Definition 1** (Fully Oblivious Algorithms). *Let δ be a function in a security parameter λ . We say that algorithm M is δ -statistically oblivious, iff for all inputs \mathbf{x} and \mathbf{y} of equal length, and for all λ , it holds that $\text{Access}^M(\lambda, \mathbf{x}) \approx^{\delta(\lambda)} \text{Access}^M(\lambda, \mathbf{y})$ where $\approx^{\delta(\lambda)}$ denotes that the two distributions have at most $\delta(\lambda)$ statistical distance. We say that M is perfectly oblivious when $\delta = 0$.*

2.3 Differentially Oblivious Algorithms

Suppose that $M(\lambda, \mathbf{x}, q)$ is a (stateful) algorithm that takes in three inputs, a security parameter $\lambda > 0$, an input dataset denoted by \mathbf{x} and a value q . We slightly change the definition of differentially oblivious algorithms given in [5]:

► **Definition 2** (Neighbor-respecting). *We say that two input datasets \mathbf{x} and \mathbf{y} are neighboring iff they are of the same length and differ in exactly one entry. We say that $A = (A_1, A_2)$ is neighbor-respecting adversary iff for every λ and every n , A_1 outputs neighboring datasets $\mathbf{x}_0, \mathbf{x}_1$, with probability 1.*

► **Definition 3.** *Let ε, δ be privacy parameters. Let M be a (possibly stateful) algorithm described as above. To an adversary A we associate the experiment in Algorithm 1, for every $\lambda \in \mathbb{N}$. We say that M is (ε, δ) -adaptively differentially oblivious if for all (computationally unbounded) stateful neighbor-respecting adversary A we have*

$$\Pr[\text{Exp}_0^{A,M}(\lambda, n) = 1] \leq e^\varepsilon \cdot \Pr[\text{Exp}_1^{A,M}(\lambda, n) = 1] + \delta.$$

In Algorithm 1, $\text{Access}^M(\mathbf{x}, q, state)$ denotes the ordered sequence of memory accesses the algorithm M makes on the inputs \mathbf{x}, q and state.

► **Remark 4.** The notion of adaptivity here is different from the one defined in [5]. We require that the dataset \mathbf{x} remain the same through the experiment whereas in [5] the adaptive adversary can add or remove entries from the dataset.

As with differential privacy, we usually think about ε as a small constant and require that $\delta = o(1/n)$ where $n = |\mathbf{x}|$ [7]. Observe that if M is δ -statistically oblivious then it is also $(0, \delta)$ -differentially oblivious.

The following simple lemma will be useful to analyze our algorithms. The proof of the lemma appears in Appendix A.

► **Lemma 5.** *Let \mathcal{A} be an $(\varepsilon, 0)$ -differentially oblivious algorithm and \mathcal{B} be an algorithm such that for every dataset \mathbf{x} the statistical distance between $\mathcal{A}(\mathbf{x})$ and $\mathcal{B}(\mathbf{x})$ is at most γ (that is, $|\Pr[\mathcal{A}(\mathbf{x}) \in S] - \Pr[\mathcal{B}(\mathbf{x}) \in S]| \leq \gamma$ for every S). Then, \mathcal{B} is an $(\varepsilon, (1 + e^\varepsilon)\gamma)$ -differentially oblivious algorithm.*

3 Differentially Oblivious Property Testing of Dense Graphs Properties

In this section, we present a differentially oblivious property tester for dense graphs properties in the adjacency matrix representation model. A property tester is an algorithm that decides whether a given object has a predetermined property or is far from any object having this property by examining a small random sample of its input. The correctness requirement of property testers ignores objects that neither have the property nor are far from having the property. However, the privacy requirement is “worst case” and should hold for any two neighboring graphs. For the definition of privacy we say that two graphs G, G' of size n are neighbors if one can get G' by changing the neighbors of exactly one node of G .

Property testing of graph properties in the adjacency matrix representation was introduced in [12]. A graph $G = (V, E)$ is represented by the predicate $f_G : V \times V \rightarrow \{0, 1\}$ such that $f_G(u, v) = 1$ if and only if u and v are adjacent in G . The distance between graphs is defined to be the number of different matrix entries over $|V|^2$. This model is most suitable for dense graphs where the number of edges is $O(|V|^2)$. We define a property \mathcal{P} of graphs to be a subset of the graphs. We write $G \in \mathcal{P}$ to show that graph G has the property \mathcal{P} . For example, we can define the bipartiteness property, where \mathcal{P} is the set of all bipartite graphs.⁵ We say that an n -vertex G is γ -far from \mathcal{P} if for every n -vertex graph $G' = (V', E') \in \mathcal{P}$ it holds that the symmetric difference between E and E' is greater than γn^2 . We define the property testing in this model as follows:

► **Definition 6** ([12]). *A (β, γ) -tester for a graph property \mathcal{P} is a probabilistic algorithm that, on inputs n, β, γ , and an adjacency matrix of an n -vertex graph $G = (V, E)$:*

1. *Outputs 1 with probability at least β , if $G \in \mathcal{P}$.*
2. *Outputs 0 with probability at least β , if G is γ -far from \mathcal{P} .*

We say a tester has one-sided error, if it accepts every graph in \mathcal{P} with probability 1. We say a tester is non-adaptive if it determines all its queries to adjacency matrix only based on n, β, γ , and its randomness; otherwise, we say it is adaptive.

► **Example 7** ([12]). Consider the following $(2/3, \gamma)$ -tester for bipartiteness: Choose a random subset $A \subset V$ of size $\tilde{O}(1/\gamma^2)$ with uniform distribution and output 1 iff the graph induced by A is bipartite. Clearly, if G is bipartite, then the tester will always return 1. Goldreich et al. [12] proved that if G is γ -far from a bipartite graph, then the probability that the algorithm returns 1 is at most $1/3$.

Recall that in the graph property testing, the tester \mathcal{T} chooses a random subset of the graph with uniform distribution to test the property \mathcal{P} . Given the access pattern of the tester \mathcal{T} , an adversary will learn nothing since it is uniformly random. Thus, the access pattern by itself does not reveal any information about the input graph. However, we assume that the adversary also learns the tester’s output and can hence learn some information

⁵ Recall that an undirected graph is bipartite (or 2-colorable) if its vertices can be partitioned into two parts, V_1 and V_2 , such that each part is an independent set (i.e., $E \subseteq \{(u, v) : (u, v) \in V_1 \times V_2\}$).

■ **Algorithm 2** Differentially Oblivious Property Tester $\text{Tester}_{\mathcal{T}}$ for Dense Graphs.

Input: graph $G = (V, E)$

- 1: Let $c \leftarrow 0$ and $T \leftarrow \frac{\ln(1/2\delta)}{\varepsilon}$
- 2: **for** $i = 1$ to $4T$ **do**
- 3: **if** $\mathcal{T}(G) = 1$ **then**
- 4: $c \leftarrow c + 1$
- 5: **end if**
- 6: Let A be the subset of vertices chosen by tester \mathcal{T}
- 7: Update graph G to be the induced sub-graph on $V \setminus A$
- 8: **end for**
- 9: $\hat{T} \leftarrow 3T + \text{Lap}(\frac{1}{\varepsilon})$
- 10: **if** $c \geq \min(\hat{T}, 4T)$ **then**
- 11: output 1
- 12: **else**
- 13: output 0
- 14: **end if**

about the input graph based on the output of the tester. To protect this information, we run tester \mathcal{T} for constant number of times and output 1 iff the number of times \mathcal{T} outputs 1 exceed a (randomly chosen) threshold.

Let \mathcal{T} be a (β, γ) -tester for a graph property \mathcal{P} where $\beta \leq 1/4$. We write $c_{\beta, \gamma}$ for the number of nodes that \mathcal{T} samples. Note that $c_{\beta, \gamma}$ is constant in the graph size and a function of β and γ . For simplicity, we only consider property testers with one-sided error. In Algorithm 2, we describe a (β', γ') -tester $\text{Tester}_{\mathcal{T}}$ that outputs 1 with probability 1 if $G \in \mathcal{P}$ and outputs 0 with probability at least β' , if G is γ' -far from \mathcal{P} , where β' and γ' are defined below.

► **Theorem 8.** *Let $\varepsilon, \delta > 0$ and $\gamma' = \gamma - \frac{4 \ln(1/2\delta)c_{\beta, \gamma}}{n\varepsilon}$. Algorithm $\text{Tester}_{\mathcal{T}}$ is an $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious algorithm that outputs 1 with probability 1 if $G \in \mathcal{P}$, and output 0 with probability at least $1 - \delta - (2\delta)^{\frac{1}{3\varepsilon}}$ if G is γ' -far from \mathcal{P} .*

The proof of Theorem 8 appears in Appendix A.2.

4 Lower Bounds on Testing Connectivity in the Incidence Lists Model

We now consider differentially oblivious testing of connectivity in the incidence lists model [14]. In this model a graph has a bounded degree d and is represented as a function $f : V \times [d] \rightarrow V \cup \{0\}$, where $f(v, i)$ is the i -th neighbor of v (if no such neighbor exists, then $f(v, i) = 0$). In this model, the relative distance between graphs is normalized by dn – the maximal number of edges in the graph. Formally, for two graphs with n vertices,

$$\text{dist}_d(G_1, G_2) \triangleq \frac{|\{(v, i) : v \in V, i \in [d], f_{G_1}(v, i) \neq f_{G_2}(v, i)\}|}{dn}.$$

A (β, γ) -tester in the incidence lists model is defined as in Definition 6, where a property \mathcal{P} is a set of graphs whose maximal degree is d and the distance to a property is defined with respect to dist_d .

Goldreich and Ron [14] showed how to test if a graph is connected in the incidence list model in time $\tilde{O}(1/\gamma)$. Raskhodnikova and Smith [32] showed that a tester for connectivity (or any non-trivial property) with run-time $o(\sqrt{n})$ has to be adaptive, that is, the nodes that

the algorithm probes should depend on the neighbors of nodes the algorithm has already probed (e.g., the algorithm probes some node u , discovers that v is a neighbor and u , and probes v). We strengthen their results by showing that any tester for connectivity in graphs of maximal degree 2 and run-time $o(\sqrt{n})$ cannot be a differentially oblivious algorithm. We stress that adaptivity alone is not a reason for inefficiency with differential obliviousness. In fact, there exist differentially oblivious algorithms that are adaptive (e.g., our algorithm in Section 6).

► **Theorem 9.** *Let $\varepsilon, \delta > 0$ such that $e^{4\varepsilon}\delta < 1/16n$. Every (ε, δ) -differentially private $(3/4, 1/3)$ -tester for connectivity in graphs with maximal degree 2 runs in time $\Omega(\sqrt{n}/e^{2\varepsilon})$.*

Proof. Let TESTER be a $(3/4, 1/3)$ -tester for connectivity in graphs of degree at most 2. We somewhat relax the definition of probes and assume that once the tester probes a node, it sees all edges adjacent to this node. We prove that if TESTER probes less than $c\sqrt{n}/e^{2\varepsilon}$ nodes (for some constant c), then it is not (ε, δ) -oblivious. Assume that $n \equiv 0 \pmod{3}$. Let $G_1 = (V, E_1)$ be a cycle of length n and $G_2 = (V, E_2)$ consist of $n/3$ disjoint triangles. Clearly, G_1 is connected and G_2 is $1/3$ -far from a connected graph. For a permutation $\pi : V \rightarrow V$, define $\pi(G_i) = (V, \pi(E_i))$, where $\pi(E_i) = \{(\pi(u), \pi(v)) : (u, v) \in E_i\}$, and let $\text{perm}(G_i)$ be a random graph isomorphic to G_i , that is, $\text{perm}(G_i) = \pi(G_i)$ for a permutation π chosen with uniform distribution.⁶ On the random graph $\text{perm}(G_1)$ TESTER has to say “yes” with probability at least $3/4$ and on the random graph $\text{perm}(G_2)$ TESTER has to say “no” with probability at least $3/4$.

► **Observation 10.** *If TESTER does not probe two distinct nodes whose distance is at most two, then TESTER sees a collection of paths of length two and cannot know if the graph is $\text{perm}(G_1)$ or $\text{perm}(G_2)$.*

▷ **Claim 11.** Given the random graph $\text{perm}(G_1)$, the tester has to probe two distinct nodes whose distance is at most 2 with probability at least $1/2$.

Proof. Consider TESTER’s answer when it sees a collection of paths of length 2. Assume first that the tester returns “No” with probability at least half in this case and let p be the probability that TESTER probes two distinct nodes whose distance is at most two on the random graph $\text{perm}(G_1)$. The probability that TESTER returns “Yes” on $\text{perm}(G_1)$ is at most $p + 0.5(1 - p) = 0.5 + 0.5p$. Thus, $0.5 + 0.5p \geq 3/4$, i.e., $p \geq 0.5$.

If the tester returns “Yes” with probability at least half, then, by symmetric arguments, with probability at least $1/2$ TESTER has to probe two nodes whose distance is at most two on the random graph $\text{perm}(G_2)$. For a permutation π , if the distance between two nodes in $\pi(G_2)$ is at most 2, then the distance between these two nodes in $\pi(G_1)$ is at most 2. Thus, by Observation 10,

$$\begin{aligned} & \Pr[\text{TESTER probes 2 nodes whose distance is 1 or 2 on } \text{perm}(G_1)] \\ & \geq \Pr[\text{TESTER probes 2 nodes whose distance is 1 or 2 on } \text{perm}(G_2)] \geq 1/2. \quad \square \end{aligned}$$

⁶ When we permute a graph, we also permute its incident list representation, i.e., if $(u, v) \in \pi(E)$, then with probability half v will be the first neighbor of u and with probability half it will be the second.

■ **Figure 1** The graphs H_1 and H_2 .

Denote the nodes of G_1 by $V = \{v_0, \dots, v_{n-1}\}$ and define a distribution on pairs of graphs H_1, H_2 , obtained by the following process:

- Choose a permutation $\pi : V \rightarrow V$ with uniform distribution and let $H_1 = \pi(G_1)$.
- Denote $H_1 = (V, E_1)$ and $u_j = \pi(v_j)$ for $j \in [n]$.
- Choose with uniform distribution two indices i, j such that $j \in \{i + 4, i + 3, \dots, i - 3\}$ (where the addition is done modulo n).
- Let $H_2 = (V, E_2)$, where $E_2 = E_1 \setminus \{(u_i, u_{i+1}), (u_j, u_{j+1})\} \cup \{(u_i, u_j), (u_{i+1}, u_{j+1})\}$.

The graphs are described in Figure 1. Note that H_2 is also a random graph isomorphic to G_1 , thus, given H_2 one cannot know which pair of non-adjacent nodes u_i, u_j was used to create H_2 .

Observe that H_1 and H_2 differ on 4 nodes. Since **TESTER** is (ϵ, δ) -differentially oblivious, for every algorithm \mathcal{A} ,

$$\begin{aligned} \Pr[\mathcal{A}(H_1, H_2, \text{Access}^{\text{TESTER}}(H_1)) = 1] \\ \leq e^{4\epsilon} \cdot \Pr[\mathcal{A}(H_1, H_2, \text{Access}^{\text{TESTER}}(H_2)) = 1] + 4e^{4\epsilon}\delta. \end{aligned} \tag{1}$$

Consider the following algorithm \mathcal{A} :

If u_i and at least one of u_{i+1}, u_{i+2} is probed by **TESTER**(H) prior to seeing any other pair of nodes of distance at most 2 in H_1 or H_2 , then return 1 otherwise return 0.

▷ **Claim 12.** Let $i \in \{1, 2\}$. Suppose that **TESTER** probes at most q nodes. Pick at random with uniform distribution two nodes in V with distance at least 3 in H_i . The probability that **TESTER**(H_i) probes both u and v prior to seeing any two nodes of distance at most 2 in H_i is $O(q^2/n^2)$ (where the probability is over the random choice of u, v and the randomness of **TESTER**).

Proof. The node u is a uniformly distributed node in H_i and v is any node of distance at least 3 from u , thus there are $n(n-5)/2$ options for $\{u, v\}$. Given a collection of paths of length at most 2 in H_i all options are equally likely.

Let w_1, \dots, w_k be the nodes probed in some execution of **TESTER**. Fix some pair of indices $k_1 < k_2$. The probability that $\{u_i, u_{i+1}\} = \{w_{k_1}, w_{k_2}\}$ is at most $1/n(n-5)$. Thus, the probability that u and v are probed is at most $\frac{\binom{q}{2}}{n(n-5)/2} = O(q^2/n^2)$. ◁

65:10 Exploring Differential Obliviousness

▷ **Claim 13.** Assume that TESTER probes at most q nodes. The probability that $\mathcal{A}(H_1) = 1$ is at least $1/2n - O(q^2/n^2)$.

Proof. By Claim 11, the probability that TESTER probes at least one pair of nodes with distance at most 2 is at least $1/2$. Given that this event occurs, the probability that the random u_i (chosen with uniform distribution) has the smallest index in the first such pair in H_1 (i.e., the first pair is either (u_i, u_{i+1}) or (u_i, u_{i+2})) is at least $1/n$.

Clearly, given these events no two nodes with distance at most 2 in H_1 were probed prior to probing the pair containing u_i . Furthermore, there are $O(1)$ pairs of nodes that are of distance at most 2 in H_2 and are of distance greater than 2 in H_1 . By Claim 12, the probability that such pair is probed prior to TESTER probing a pair of distance at most 2 in H_1 is $O(q^2/n^2)$. ◁

▷ **Claim 14.** Suppose that TESTER probes at most q nodes. The probability that $\mathcal{A}(H_2) = 1$ is $O(q^2/n^2)$.

Proof. The node u_i is a uniformly distributed node in H_2 . Furthermore, the nodes u_{i+1} is a uniformly distributed node of distance at least 3 from u_i in H_2 , thus by Claim 12, the probability that TESTER probes both u_i and u_{i+1} prior to seeing any pair of distance at least 2 in H_2 is $O(q^2/n^2)$. This probability can only decrease if we require that TESTER probes both u_i and u_{i+1} prior to seeing any pair of distance at least 2 in H_1 and in H_2 .

By the same arguments, the probability that TESTER probes both u_i and u_{i+2} prior to seeing any pair of distance at least 2 in H_1 and in H_2 is $O(q^2/n^2)$. ◁

To conclude the proof of Theorem 9, we note that by (1) and Claim 13 and 14

$$\frac{1}{2n} - O(q^2/n) \leq \Pr[\mathcal{A}(H_1) = 1] \leq e^{4\epsilon} \Pr[\mathcal{A}(H_2) = 1] + e^{4\epsilon} \delta \leq e^{4\epsilon} O(q^2/n^2) + e^{4\epsilon} \delta.$$

Since $e^{4\epsilon} \delta \leq 1/4n$, it follows that $q = \Omega(\sqrt{n}/e^{2\epsilon})$. ◀

5 Differentially Oblivious Algorithm for Locating an Object

Given a dataset of objects \mathbf{x} our goal is to locate an object that satisfies a property \mathcal{P} , if one exists. E.g., given a dataset consisting of employee records, find an employee with income in the range \$35,000–\$70,000 if such an employee exists in the dataset.

Absent privacy requirements, a simple approach is to probe elements of the dataset in a random order until an element satisfying the property is found or all elements were probed. If a p fraction of the dataset entries satisfy \mathcal{P} then the expected number of elements sampled by the non-private algorithm is $1/p$. However, a perfectly oblivious algorithm would require $\Omega(n)$ probes on any dataset, in particular on a dataset where all elements satisfy \mathcal{P} , where non-privately one probe would suffice. To see why, let $\mathcal{P}(x) = 1$ if $x = 1$ and $\mathcal{P}(x) = 0$ otherwise and let \mathbf{x} include exactly one 1-entry in a uniformly random location. Observe that in expectation it requires $\Omega(n)$ memory probes to locate the 1-entry in \mathbf{x} . Perfect obliviousness would hence imply an $\Omega(n)$ probes on any input.

We give a nearly instance optimal differentially oblivious algorithm that always returns a correct answer. Except for probability $e^{-\Omega(mp)}$ the algorithm halts after m steps.

Our Algorithm. Given the access pattern of the non-private algorithm, an adversary can learn that the last probed element satisfies \mathcal{P} . To hide this information, we change the stopping condition to having probed at least a (randomly chosen) threshold of elements

■ **Algorithm 3** Differentially Oblivious Locate Algorithm $\text{Locate}_{\mathcal{P}}$.

Input: dataset $\mathbf{x} = (x_1, \dots, x_n)$

- 1: Let $c \leftarrow 0$, $\varepsilon' = \frac{\varepsilon}{2 \log(2/\delta)}$, and $T \leftarrow \frac{1}{\varepsilon'} \ln \frac{\log n}{\delta}$
- 2: **for** $i = 1$ to $n/2$ **do**
- 3: Choose $j \in [n]$ with uniform distribution
- 4: **if** $\mathcal{P}(x_j) = 1$ **then**
- 5: $c \leftarrow c + 1$
- 6: **end if**
- 7: **if** i is an integral power of 2 **then**
- 8: $\hat{T} \leftarrow T + \text{Lap}(\frac{1}{\varepsilon'})$
- 9: **if** $c > \max(\hat{T}, 0)$ **then**
- 10: output 1
- 11: **end if**
- 12: **end if**
- 13: **end for**
- 14: Scan the entire dataset, if there is an element satisfying \mathcal{P} then output 1, else output 0

satisfying \mathcal{P} . If after $n/2$ probes the number of elements satisfying \mathcal{P} is below the threshold the entire dataset is scanned. Our algorithm $\text{Locate}_{\mathcal{P}}$ is described in Algorithm 3. On a given array \mathbf{x} , algorithm $\text{Locate}_{\mathcal{P}}$ outputs 1 iff there exists an element in \mathbf{x} satisfying the property \mathcal{P} .

We remark that Algorithm $\text{Locate}_{\mathcal{P}}$ uses a mechanism similar to the the sparse vector mechanism of [18]. However, in our case instead of using a single noisy threshold across all steps, Algorithm $\text{Locate}_{\mathcal{P}}$ generates in each step a noisy threshold $\hat{T} = T + \text{Lap}(\frac{1}{\varepsilon'})$. The value of T ensures that with high probability $\hat{T} > 0$. The proof of Theorem 15 is given in Appendix A.3.

► **Theorem 15.** *Algorithm $\text{Locate}_{\mathcal{P}}$ is an $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious algorithm that outputs 1 iff there exists an element in the array that satisfies property \mathcal{P} . For $m = \Omega(T/p \log(T/p))$, with probability $1 - e^{-\Omega(mp)}$ it halts in time at most m , where $T = \frac{2 \log(2/\delta)}{\varepsilon} \ln \frac{\log n}{\delta}$.*

6 Differentially Oblivious Prefix Sum

Suppose that there is a dataset consisting of sorted sensitive user records, and one would like to compute the sum of all records in the (sorted) dataset that are less than or equal to a value a in a way that respects individual user's privacy. We call this task differentially oblivious prefix sum. For the definition of privacy we say that two datasets of size n are neighbors if they agree on $n - 1$ elements (although, as sorted arrays they can disagree on many indices). For example, $(1, 2, 3, 4)$ and $(1, 3, 4, 5)$ are neighbors and should have similar access pattern.

Without privacy one can find the greatest record less than or equal to value a , and then compute the prefix sum by a quick scan through all records appearing before such record. Any perfectly secure algorithm must read the entire dataset (since it is possible that all elements are smaller than a). Here, we give a differentially oblivious prefix sum algorithm that for many instances is much faster than any perfectly oblivious algorithm.

■ **Algorithm 4** Differentially Oblivious Search Algorithm SEARCH.

Input: a dataset $\mathbf{x} = (x_1, \dots, x_n)$ and a value a

- 1: Let $\varepsilon' \leftarrow \frac{\varepsilon}{2.5 \log n}$, $\delta' \leftarrow \frac{\delta}{2.5 \log n}$, $k \leftarrow \lceil \frac{4 \log(1/\delta')}{\varepsilon'} \rceil$, $\min \leftarrow 0$, and $\max \leftarrow n$
- 2: **while** $\max - \min > k$ **do**
- 3: $c \leftarrow \lfloor (\max - \min)/k \rfloor$
- 4: Let $\mathbf{y} = (y_1, \dots, y_k)$, where $y_i = x_{\min + i \cdot c}$ for every $i \in [k]$
- 5: Scan the entire dataset \mathbf{y} and find the maximal index I such that $y_I \leq a$; if there is no such element then $I \leftarrow 0$
- 6: $\text{noise} \leftarrow \text{Lap}(\frac{1}{\varepsilon'})$
- 7: $\min = \max\{0, \min + \lfloor (I + \text{noise} - \frac{\log 1/\delta'}{\varepsilon'}) \cdot c \rfloor\}$ and $\max = \min\{n, \min + \lfloor (I + \text{noise} + \frac{\log 1/\delta'}{\varepsilon'} + 1) \cdot c \rfloor\}$
- 8: **end while**
- 9: Scan the entire dataset \mathbf{x} between \min and \max and return the the maximal index I such that $x_I \leq a$; if there is no such element then $I \leftarrow 0$

Intuition. Absent privacy requirements, using binary search, one can find the greatest element less than or equal to a , and then compute the prefix sum by a quick scan through all records that appear before such record. However, the binary search access pattern allows the adversary to gain sensitive information about the input. Our main idea is to approximately simulate the binary search and obfuscate the memory accesses to obtain differential obliviousness. In order to do that, we first divide the input array into k chunks (where k is polynomial in $1/\varepsilon$, $\log 1/\delta$, and $\log n$). Then, we find the chunk that contains the greatest element less than or equal to a by comparing the first element (hence, the smallest element) of each chunk to a . Let I be the index of such chunk. Next, we compute a noisy interval that contains I using the Laplacian distribution. We iteratively repeat this process on the noisy interval, where in each step we eliminate more than a quarter of the elements of the interval. We continue until the size of the array is less than or equal to k . Next, we scan all elements in the remaining array and find the index of the greatest element smaller than or equal to a . Let i be the index of such element; we compute the prefix sum by scanning the array \mathbf{x} until index i .

The Search Algorithm. We present a search algorithm in Algorithm 4; on input $\mathbf{x} = (x_1, \dots, x_n)$ and a this algorithm finds the largest index I such that $x_I \leq a$. To compute the prefix sum, we compute $\hat{I} = I + \text{Lap}(1/\varepsilon) + \frac{\log 1/\delta}{\varepsilon}$ and scan the first \hat{I} elements of the dataset, summing only the first I . We show in Theorem 17 that our search algorithm is (ε, δ) -differentially oblivious.

► **Remark 16.** We prove that algorithm SEARCH is an $(\varepsilon, 0)$ -differentially private algorithm that returns a correct index with probability at least $1 - \beta$. We could change it to an (ε, δ) -differentially private algorithm that never errs. This is done by truncating the noise to $\frac{\log 1/\delta'}{\varepsilon'}$.

► **Theorem 17.** *Let $\beta < 1/n$ and $\varepsilon < \log^2 n$. Algorithm SEARCH is an $(\varepsilon, 0)$ -differentially oblivious algorithm that, for any input array with size n and $a \in \mathbb{R}$, returns a correct index with probability at least $1 - \beta$. The running time of Algorithm SEARCH is $O(\frac{1}{\varepsilon} \log^2 n \log \frac{1}{\beta})$.*

Theorem 17 is proved in Appendix A.4.

■ **Algorithm 5** Differentially Oblivious Search Algorithm MULTISEARCH for Multiple Queries.

Input: a dataset $\mathbf{x} = (x_1, \dots, x_n)$

- 1: $t \leftarrow 1$ and $M \leftarrow 0$
- 2: **for** every query a **do**
- 3: **if** the greatest element in the ORAM is greater than a or all records are in the ORAM (that is $M = n$) **then**
- 4: answer the query using the ORAM
- 5: **else**
- 6: execute algorithm SEARCH with privacy parameter $\frac{\varepsilon}{t \log n}$ and accuracy parameter β/\sqrt{n} for the database starting at record $M + 1$ and let I the largest index in this database such that $x_I \leq a$
- 7: insert the first $\max\{I, 2t\}$ elements of this database to the ORAM; for each element also insert the sum of all elements in the array up to this element
- 8: $t \leftarrow t + 1$, $M \leftarrow M + \max\{I, 2t\}$
- 9: **end if**
- 10: **end for**

6.1 Dealing with Multiple Queries

We extend our prefix sum algorithm to answer multiple queries. We can answer a bounded number of queries by running the differentially oblivious prefix sum algorithm multiple times. That is, when we want an $(\varepsilon, 0)$ -oblivious algorithm correctly answering t queries with probability at least $1 - \beta$, we execute algorithm SEARCH t times with privacy parameter ε/t and error probability β/t (each time also computing the appropriate prefix sum). Thus, the running time of the algorithm is $O(\frac{t^2}{\varepsilon} \log^2 n \log \frac{t}{\beta})$ (excluding the scan time for computing the sum).

On the other hand, we can use an ORAM to answer unbounded number of queries. That is, in a pre-processing stage we store the n records and for each record we store the sum of all records up to this record. Thereafter, answering each query will require one binary search. Using the ORAM of [2], the pre-processing will take time $O(n \log n)$ and answering each query will take time $O(\log^2 n)$. Thus, the ORAM algorithm is more efficient when $t \geq \sqrt{n}$.

We use ORAM along with our differentially oblivious prefix sum algorithm to answer unbounded number of queries while preserving privacy, combining the advantages of both of the previous algorithms.

► **Theorem 18.** *Algorithm MULTISEARCH, described in Algorithm 5, is an $(\varepsilon, 0)$ -oblivious algorithm, which executes Algorithm SEARCH at most $O(\sqrt{n})$ times, where the run time of the t -th execution is $O(\frac{t}{\varepsilon} \log^3 n \log \frac{n}{\beta})$, scans the original database at most once, and in addition each query run time is at most $O(\log^2 n)$.*

Proof. First note that we only pay for privacy in the executions of algorithm SEARCH (reading and writing to the ORAM is perfectly private). In the t -th execution of algorithm SEARCH, we insert at least $2t$ elements to the ORAM, thus after \sqrt{n} executions we inserted at least $\sum_{t=1}^{\sqrt{n}} 2t = n$ elements to the ORAM.

By simple composition, algorithm MULTISEARCH is $(\varepsilon', 0)$ -differentially private, where

$$\varepsilon' = \sum_{t=1}^{\sqrt{n}} \frac{\varepsilon}{t \log n} \leq \frac{\varepsilon}{\log n} (\ln \sqrt{n} + 1) \leq \varepsilon,$$

where the last inequality is implied by the sum of the harmonic series. ◀

A Missing Proofs

A.1 Proof of Lemma 5

Proof. Let \mathbf{x} and \mathbf{y} be two neighboring datasets and S be a sets of outputs. Then,

$$\begin{aligned}
 \Pr[\mathcal{B}(\mathbf{x}) \in S] &\leq \Pr[\mathcal{A}(\mathbf{x}) \in S] + \gamma \\
 &\leq e^\varepsilon \Pr[\mathcal{A}(\mathbf{y}) \in S] + \gamma \\
 &\leq e^\varepsilon (\Pr[\mathcal{B}(\mathbf{y}) \in S] + \gamma) + \gamma \\
 &= e^\varepsilon \Pr[\mathcal{B}(\mathbf{y}) \in S] + (1 + e^\varepsilon)\gamma. \quad \blacktriangleleft
 \end{aligned}$$

A.2 Proof of the Correctness and Privacy of Algorithm $\text{Tester}_{\mathcal{T}}$

Theorem 8 is implied by the following lemmas.

► **Lemma 19.** *Algorithm $\text{Tester}_{\mathcal{T}}$ is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious.*

Proof. We first analyze a variant of $\text{Tester}_{\mathcal{T}}$, denoted by $\text{TESTER}'_{\mathcal{T}}$, in which Step 10 is replaced by “If $c > \hat{T}$ then output 1” (that is, the algorithm does not check if $c > \min\{4T, \hat{T}\}$ before deciding in the positive).

Let $G = (V, E)$ and $G' = (V', E')$ be two neighboring graphs such that they differ on node $v \in V$. Fix the random choices of subsets A in Step 6 and observe that after the execution of for loop, the count c can differ by at most 1 between the executions on G and G' . Let \tilde{T} be the smallest integer greater than \hat{T} . Since algorithm $\text{TESTER}'_{\mathcal{T}}$ uses the Laplace mechanism $e^{-\varepsilon} \Pr[\tilde{T} < a] \leq \Pr[\tilde{T} < a - 1] \leq e^\varepsilon \Pr[\tilde{T} < a]$ for every a . Thus,

$$\begin{aligned}
 \Pr[\text{TESTER}'_{\mathcal{T}}(G) = 1] &= \sum_a \Pr[\tilde{T} = a] \Pr[c(G) > a] \\
 &\leq \sum_a \Pr[\tilde{T} = a] \Pr[c(G') > a - 1] \\
 &\leq e^\varepsilon \sum_a \Pr[\tilde{T} = a - 1] \Pr[c(G') > a - 1] \\
 &\leq e^\varepsilon \Pr[\text{TESTER}'_{\mathcal{T}}(G') = 1].
 \end{aligned}$$

Similarly, $\Pr[\text{TESTER}'_{\mathcal{T}}(G) = 1] \geq e^{-\varepsilon} \Pr[\text{TESTER}'_{\mathcal{T}}(G') = 1]$. Hence, $\text{TESTER}'_{\mathcal{T}}$ is $(\varepsilon, 0)$ -differentially oblivious.

We next prove that $\text{Tester}_{\mathcal{T}}$ is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious using Lemma 5, that is we prove that for every graph G , the statistical distance between $\text{Tester}_{\mathcal{T}}(G)$ and $\text{TESTER}'_{\mathcal{T}}(G)$ is at most δ . Let E be the event that $\hat{T} > 4T$ and observe that the probability

E occurs is at most δ .⁷ We have that $\left| \Pr[\text{Tester}_{\mathcal{T}}(G) = 1] - \Pr[\text{TESTER}'_{\mathcal{T}}(G) = 1] \right| \leq \left| \Pr[\text{Tester}_{\mathcal{T}}(G) = 1|E] - \Pr[\text{TESTER}'_{\mathcal{T}}(G) = 1|E] \right| \Pr[E] \leq \Pr[E] \leq \delta$. Thus, by Lemma 5, algorithm $\text{Tester}_{\mathcal{T}}$ is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious. \blacktriangleleft

Observe that Algorithm $\text{Tester}_{\mathcal{T}}$ never errs when $G \in \mathcal{P}$ as in that case after the for loop is executed $c = 4T$ and hence in Step 10 $\text{Tester}_{\mathcal{T}}$ outputs 1. The next lemma analyses the error probability when G is γ' -far from \mathcal{P} .

► **Lemma 20.** *Algorithm $\text{Tester}_{\mathcal{T}}$ is $(1 - \delta - (2\delta)^{\frac{1}{3\varepsilon}}, \gamma')$ -tester for the graph property \mathcal{P} .*

Proof. Observe that on Step 7 of the algorithm, we are eliminating at most $n \cdot c_{\beta, \gamma}$ edges. Thus, we are eliminating at most $4Tnc_{\beta, \gamma}$ edges in total. Then, when G is γ' -far from \mathcal{P} , it is also γ -far from \mathcal{P} after the removal of the observed nodes in each step of the for loop. We next prove that Algorithm $\text{Tester}_{\mathcal{T}}$ fails with probability at most $2\delta^{\frac{1}{3\varepsilon}}$. Observe that if Algorithm $\text{Tester}_{\mathcal{T}}$ fails on G then $c \geq 2T$ or $\text{Lap}(\frac{1}{\varepsilon}) \leq -T$. We define Z_i to be output of $\mathcal{T}(G)$ in the i -th step of the for loop. Let $Z = \sum_i Z_i$. Observe that all Z_i are independent and $\mathbb{E}[Z] \leq T$. Using the Chernoff Bounds⁸, we obtain that $\Pr[Z \geq 2T] \leq e^{-T/3} = (2\delta)^{\frac{1}{3\varepsilon}}$. We also know $\Pr[\text{Lap}(\frac{1}{\varepsilon}) \leq -\frac{\ln(1/2\delta)}{\varepsilon}] = 0.5e^{-\ln(1/2\delta)} = \delta$. Therefore, Algorithm $\text{Tester}_{\mathcal{T}}$ fails with probability $\delta + (2\delta)^{\frac{1}{3\varepsilon}}$. \blacktriangleleft

A.3 Proof of the Correctness and Privacy of Algorithm $\text{Locate}_{\mathcal{P}}$

The proof of Theorem 15 follows from the following claim and lemmas.

▷ **Claim 21.** Let $\ell \geq \log n / \log \log n$. The probability that there exists an element $j \in [n]$ such that algorithm $\text{Locate}_{\mathcal{P}}$ samples the element j in Step 3 more than 2ℓ times is less than $2^{-\ell}$.

Proof. Fix an index j . The probability that the element j is sampled more than 2ℓ times is less than $\binom{n/2}{2\ell} \frac{1}{n^{2\ell}} \leq \left(\frac{en}{4\ell}\right)^{2\ell} \frac{1}{n^{2\ell}} < \ell^{-2\ell} < 2^{-2\log n + 2} < 2^{2-\ell} / n$. The claim follows by the union bound. \blacktriangleleft

► **Lemma 22.** *Let $\delta < 1/n$. Algorithm $\text{Locate}_{\mathcal{P}}$ is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious.*

Proof. We first analyze a variant of $\text{Locate}_{\mathcal{P}}$, denoted by $\text{LOCATE}'_{\mathcal{P}}$, in which Step 9 is replaced by “If $c > \hat{T}$ then output 1” (that is, the algorithm does not check if $\hat{T} > 0$) and no element is sampled more than $2 \log(2/\delta)$ times. We analyze the privacy of $\text{LOCATE}'_{\mathcal{P}}(\mathbf{x}')$ similarly to the analysis of the sparse vector mechanism in [18].

Let \mathbf{x} and \mathbf{x}' be two neighboring datasets that such that $\mathcal{P}(x_j) = 1$ and $\mathcal{P}(x'_j) = 0$ for some j . Denote by $\tau = (\tilde{T}_1, \dots, \tilde{T}_{\log n})$ the values of the thresholds in an execution of $\text{LOCATE}'_{\mathcal{P}}$, where each threshold is rounded up to the smallest integer greater than \hat{T} . Furthermore, let $\ell_\tau \in [\log n]$ be the index such that $\text{LOCATE}'_{\mathcal{P}}$ on input \mathbf{x} outputs 1 when $i = 2^{\ell_\tau}$ (if no such i exists, then $\ell_\tau \in [\log n] + 1$). Observe that in each execution of Step 9 the count c on input \mathbf{x} is at least the count on input \mathbf{x}' and can exceed it by at most $2 \log(2/\delta)$ (since j is sampled at most $2 \log(2/\delta)$ times). Thus, $\text{LOCATE}'_{\mathcal{P}}$ on input \mathbf{x}' with thresholds $\tau' = (\tilde{T}_1, \dots, \tilde{T}_{\ell_\tau - 1}, \tilde{T}_{\ell_\tau} - 2 \log(2/\delta), \tilde{T}_{\ell_\tau + 1}, \dots, \tilde{T}_{\log n})$ outputs 1 when $i = 2^{\ell_\tau}$. Since algorithm $\text{LOCATE}'_{\mathcal{P}}$ uses the Laplace mechanism with $\varepsilon' = \varepsilon / (2 \log(1/\delta))$,

$$e^{-\varepsilon} \Pr[\tilde{T}_{\ell_\tau} = a] \leq \Pr[\tilde{T}_{\ell_\tau} = a - 2 \log(2/\delta)] \leq e^\varepsilon \Pr[\tilde{T}_{\ell_\tau} = a]$$

⁷ $\Pr[\text{Lap}(\frac{1}{\varepsilon}) \geq t/\varepsilon] = \frac{1}{2}e^{-t}$ for every $t > 0$. Thus, $\Pr[E] = \Pr[\text{Lap}(\frac{1}{\varepsilon}) \geq \frac{\ln(1/2\delta)}{\varepsilon}] = \delta$.

⁸ $\Pr[Z \geq (1 + \eta)\mu] \leq e^{-\eta^2 \mu / (2 + \eta)}$ for any $\eta > 0$ where μ is the expectation of Z .

65:18 Exploring Differential Obliviousness

for every a . Thus,

$$\begin{aligned}
& \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S] \\
&= \sum_{\tau=(\tilde{T}_1, \dots, \tilde{T}_{\log n})} \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S \mid \tilde{T}_1, \dots, \tilde{T}_{\log n}] \Pr[\tilde{T}_1, \dots, \tilde{T}_{\log n}] \\
&= \sum \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}') \in S \mid \tilde{T}_1, \dots, \tilde{T}_{\ell_\tau-1}, \tilde{T}_{\ell_\tau} - 2\log(2/\delta), \tilde{T}_{\ell_\tau+1}, \dots, \tilde{T}_{\log n}] \\
&\quad \cdot \Pr[\tilde{T}_1, \dots, \tilde{T}_{\log n}] \\
&\leq e^\varepsilon \sum \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}') \in S \mid \tilde{T}_1, \dots, \tilde{T}_{\ell_\tau-1}, \tilde{T}_{\ell_\tau} - 2\log(2/\delta), \tilde{T}_{\ell_\tau+1}, \dots, \tilde{T}_{\log n}] \\
&\quad \cdot \Pr[\tilde{T}_1, \dots, \tilde{T}_{\ell_\tau-1}, \tilde{T}_{\ell_\tau} - 2\log(2/\delta), \tilde{T}_{\ell_\tau+1}, \dots, \tilde{T}_{\log n}] \\
&= e^\varepsilon \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}') \in S].
\end{aligned}$$

Similarly,

$$\begin{aligned}
& \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S] \\
&\geq e^{-\varepsilon} \sum \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}') \in S \mid \tilde{T}_1, \dots, \tilde{T}_{\ell_\tau-1}, \tilde{T}_{\ell_\tau} - 2\log(2/\delta), \tilde{T}_{\ell_\tau+1}, \dots, \tilde{T}_{\log n}] \\
&\quad \cdot \Pr[\tilde{T}_1, \dots, \tilde{T}_{\ell_\tau-1}, \tilde{T}_{\ell_\tau} - 2\log(2/\delta), \tilde{T}_{\ell_\tau+1}, \dots, \tilde{T}_{\log n}] \\
&= e^{-\varepsilon} \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}') \in S].
\end{aligned}$$

We next prove that Locate_P is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious using Lemma 5. I.e., we prove that for every dataset \mathbf{x} , the statistical distance between $\text{Access}^{\text{Locate}_P}(\mathbf{x})$ and $\text{Access}^{\text{LOCATE}'_p}(\mathbf{x})$ is at most δ . Notice that if all the thresholds are positive and all elements are sampled at most $2\log(2/\delta)$ times then $\text{Locate}_P(\mathbf{x})$ and $\text{LOCATE}'_p(\mathbf{x})$ have the same access pattern. By Claim 21, the probability that there exists a j that is sampled more than $2\log(2/\delta)$ is at $2^{-\log(2/\delta)} = \delta/2$. We next observe that the probability that a threshold $\hat{T} = T + \text{Lap}(\frac{1}{\varepsilon'})$ is negative is at most $\delta/2$. Recall that $\Pr[\text{Lap}(\frac{1}{\varepsilon'}) \leq -t/\varepsilon'] = \frac{1}{2}e^{-t}$ for every $t > 0$. Thus, $\Pr[\hat{T} \leq 0] = \Pr[\text{Lap}(\frac{1}{\varepsilon'}) \leq -\frac{1}{\varepsilon} \ln(\frac{\log n}{\delta})] = \frac{\delta}{2\log n}$. Let A be the event that at least one of the $\log n$ thresholds \hat{T} is at most 0 or some j is sampled more than $2\log(2/\delta)$ times. By the union bound the probability of A is at most δ . Therefore, for every set of access patterns S

$$\begin{aligned}
& |\Pr[\text{Access}^{\text{Locate}_P}(\mathbf{x}) \in S] - \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S]| \\
&= \left| \Pr[\text{Access}^{\text{Locate}_P}(\mathbf{x}) \in S \mid A] \Pr[A] + \Pr[\text{Access}^{\text{Locate}_P}(\mathbf{x}) \in S \mid \bar{A}] \Pr[\bar{A}] \right. \\
&\quad \left. - \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S \mid A] \Pr[A] - \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S \mid \bar{A}] \Pr[\bar{A}] \right| \\
&= \left| \Pr[\text{Access}^{\text{Locate}_P}(\mathbf{x}) \in S \mid A] - \Pr[\text{Access}^{\text{LOCATE}'_p}(\mathbf{x}) \in S \mid A] \right| \Pr[A] \\
&\leq \Pr[A] \leq \delta.
\end{aligned}$$

Thus, by Lemma 5, algorithm Locate_P is $(\varepsilon, \delta(1 + e^\varepsilon))$ -differentially oblivious. \blacktriangleleft

We next analyze the running and probe complexity of our algorithm. Let p be the probability that a uniformly chosen element in \mathbf{x} satisfies \mathcal{P} . The non-private algorithm that samples elements until it finds an element satisfying \mathcal{P} has expected running time $1/p$ and the probability that it does not stop after m steps is $(1-p)^m = ((1-p)^{1/p})^{mp} \leq e^{-mp}$. We show that locate_P has a similar behavior.

► **Lemma 23.** *Let p be the probability that a uniformly chosen element in \mathbf{x} satisfies \mathcal{P} . Then, for every integral power of two m the probability that algorithm $\text{locate}_{\mathcal{P}}$ probes more than m memory locations is less than $\delta/\log n + e^{-(m-2T)p+2T \ln m}$. In particular, for $m = \Omega(\frac{T}{p} \log(\frac{T}{p}))$, the probability is less than $\delta/\log n + e^{-O(mp)}$.*

Proof. Let $t = 2^i$. The probability that $\hat{T} \geq 2T$ is $\Pr[\text{Lap}(\frac{1}{\epsilon'}) \geq \frac{1}{\epsilon'} \ln \frac{\log n}{\delta}] = 0.5e^{-\ln(\log n/\delta)} = \frac{\delta}{\log n}$. Assuming that $\hat{T} \geq 2T$, the probability that the algorithm does not halt after $m = 2^i$ steps is less than

$$\binom{m}{2T} (1-p)^{m-2t} \leq m^{2T} e^{-(m-2T)p} \leq e^{-(m-2T)p+2T \ln m}. \quad \blacktriangleleft$$

A.4 Proof of the Correctness and Privacy of Algorithm Search

Theorem 17 is proved in the next 3 claims. We start by analyzing the running time of the algorithm.

► **Claim 24.** Let $\beta < 1/n$ and $\epsilon < \log^2 n$. The while loop in Algorithm SEARCH is executed at most $2.5 \log n$ time. Furthermore, the total running time of the algorithm is $O(\frac{1}{\epsilon} \log^2 n \log \frac{1}{\beta})$.

Proof. Let \min_0, \max_0 and \min_1, \max_1 be the values of \min, \max before and after an execution of a step of the while loop in Algorithm SEARCH. Note that

$$\max_1 - \min_1 \leq 1 + (2 \cdot \frac{\log 1/\beta'}{\epsilon'} + 1) \cdot \frac{\max_0 - \min_0}{\frac{4 \log(1/\beta')}{\epsilon'}} \leq 3 \cdot \frac{\log 1/\beta'}{\epsilon'} \cdot \frac{\max_0 - \min_0}{\frac{4 \log(1/\beta')}{\epsilon'}} = \frac{3(\max_0 - \min_0)}{4}.$$

Therefore, algorithm SEARCH eliminates more than a quarter of the elements in each step of the while loop and the algorithm will halt after less than $2.5 \log n$ steps.

Moreover, observe that Algorithm SEARCH makes k memory accesses in each step of the while loop and additional k memory accesses after the loop. Thus, its running time is $O(\frac{1}{\epsilon} \log^2 n (\log \log n + \log \frac{1}{\beta})) = O(\frac{1}{\epsilon} \log^2 n \log \frac{1}{\beta})$ (since $\beta < 1/n$). \triangleleft

► **Claim 25.** Algorithm SEARCH returns the correct index with probability at least $1 - \beta$.

Proof. Let \bar{I} be the maximal index such that $x_{\bar{I}} \leq a$ (i.e., \bar{I} is the index that algorithm SEARCH should return). We prove by induction that if all Laplace noises in the algorithm satisfy $|\text{Lap}(\frac{1}{\epsilon'})| < \frac{\log 1/\beta'}{\epsilon'}$ then in each step of the algorithm $\min \leq \bar{I} \leq \max$, hence the algorithm will return \bar{I} in its last scan of \mathbf{x} between \min and \max .

The basis of the induction is trivial since $0 \leq \bar{I} \leq n$. For the induction step, let \min_0, \max_0 and \min_1, \max_1 be the values of \min, \max before and after an execution of a step of the while loop in Algorithm SEARCH. By the induction hypothesis, $\min_0 \leq \bar{I} \leq \max_0$. The algorithm finds an index I such that $\min_0 + Ic \leq \bar{I} \leq \min_0 + (I+1)c$. By our assumption on the Laplace noise, $\min_1 \leq \min_0 + Ic$, thus, $\min_1 \leq \bar{I}$. Similarly, $\max_1 \geq \min_0 + (I+1)c$, thus, $\max_1 \geq \bar{I}$.

Recall that $\Pr[|\text{Lap}(\frac{1}{\epsilon'})| \geq t/\epsilon'] = e^{-t}$ for every $t > 0$. Thus, by Claim 24 and the union bound, the probability that one of the Laplace noises is greater than $\frac{\log 1/\beta'}{\epsilon'}$ is at most $(2.5 \log n) \cdot \beta' = \beta$. Hence, the probability that algorithm SEARCH returns the correct index \bar{I} is at least $1 - \beta$. \triangleleft

Next, we show that algorithm SEARCH is $(\epsilon, 0)$ -differentially oblivious.

► **Claim 26.** Algorithm SEARCH is an $(\epsilon, 0)$ -differentially oblivious algorithm.

65:20 Exploring Differential Obliviousness

Proof. We show below that each step of the while loop in algorithm SEARCH is $(\varepsilon', 0)$ -differentially oblivious. Applying the basic composition theorem and Claim 24, we obtain that the SEARCH algorithm is $(\varepsilon = (2.5 \log n)\varepsilon', 0)$ -differentially oblivious.

Fix a step of the loop and view it as an algorithm that returns min and max (given these values the access pattern of the next step is fixed). Let \mathbf{x} and \mathbf{x}' be two neighboring datasets such that for some j we have $x_j > x'_j$ and $x_i = x'_i$ for all $i < j$. It holds that $x_{i-1} \leq x'_i \leq x_i$ for every i . Let $I(\mathbf{x})$ and $I(\mathbf{x}')$ be the values computed in step 5 of the algorithm on inputs \mathbf{x} and \mathbf{x}' respectively. Thus, the value $I(\mathbf{x})$ is at least the value $I(\mathbf{x}')$ and can exceed it by one. Intuitively, since algorithm SEARCH uses the Laplace mechanism, the probabilities of returning a value min on \mathbf{x} and \mathbf{x}' are at most $e^{\pm\varepsilon'}$ apart. Formally, if $\text{Lap}(1/\varepsilon') + I(\mathbf{x}) = \text{Lap}(1/\varepsilon') + I(\mathbf{x}')$ (where we consider two independent noises), then the algorithm returns the same value of min on both inputs. The lemma follows since for every set A :

$$e^{-\varepsilon'} \leq e^{-|I(\mathbf{x})-I(\mathbf{x}')|\varepsilon'} \leq \frac{\Pr[\text{Lap}(1/\varepsilon') + I(\mathbf{x}) \in A]}{\Pr[\text{Lap}(1/\varepsilon') + I(\mathbf{x}') \in A]} \leq e^{|I(\mathbf{x})-I(\mathbf{x}')|\varepsilon'} \leq e^{\varepsilon'}. \quad \triangleleft$$

Thresholds in Random Motif Graphs

Abstract

We introduce a natural generalization of the Erdős-Rényi random graph model in which random instances of a fixed motif are added independently. The *binomial random motif graph* $G(H, n, p)$ is the random (multi)graph obtained by adding an instance of a fixed graph H on each of the copies of H in the complete graph on n vertices, independently with probability p . We establish that every monotone property has a threshold in this model, and determine the thresholds for connectivity, Hamiltonicity, the existence of a perfect matching, and subgraph appearance. Moreover, in the first three cases we give the analogous hitting time results; with high probability, the first graph in the random motif graph process that has minimum degree one (or two) is connected and contains a perfect matching (or Hamiltonian respectively).

1 Introduction

In the late 1950's Gilbert [11] and Erdős and Rényi [6] introduced two of the most fundamental models for generating random graphs: the *binomial random graph* $G(n, p)$, generated by independently adding an edge between each pair of vertices in the complete graph on n vertices with probability p , and the *uniform random graph* $G(n, m)$, which is a uniformly chosen graph from all graphs on n vertices with m edges. Since, the extensive study of these simple constructions has influenced a variety of fields including combinatorics, computer science, and statistical physics (see [9, 4, 12] for surveys).

Detailed analysis of the model has led to the development of plethora of new techniques in probability for analyzing random processes, and the model has been used to verify the existence of structures with certain properties [1]. In computer science, the model has been used to analyze the performance of algorithms on an “average” case, showing that NP complete problems may be easier random instances.

The rise of data in the form of graphs (e.g. internet connections, biological networks, social networks) has further fueled the study of random graphs. In practice, the comparison of real world networks to the Erdős-Rényi model is a popular technique for highlighting the non-random aspects of a network’s structure [20, 2, 17, 14]. Moreover, the model has inspired many other models which are designed to mirror some characteristic of real-world networks (e.g. Watts-Strogatz graphs have small diameter [18], Barabási-Albert preferential attachment graph exhibit a power law degree distribution [3]).

In this paper we consider a natural generalization of the Erdős-Rényi model in which random motifs are added rather than random edges. A *motif* is a fixed small subgraph, such as a triangle. The motifs that are overrepresented in a network are correlated to the function of the network [20, 2, 17, 14]. Analyzing random graphs formed as the union of many instances of a particular motif H will give insight into the structural properties of networks with many copies of the motif H .

We define the **binomial random motif graph** $G(H, n, p)$ as the random (multi)graph obtained by adding an instance of H on each of the $\binom{n}{|V(H)|} \cdot |V(H)|! / \text{aut}(H)$ copies of H in the complete graph on n vertices K_n , independently with probability p . Here by $\text{aut}(H)$ we denote the number of automorphisms of H . Note that if H is an edge, then this is exactly $G(n, p)$. Similarly, the **uniform random motif graph** $\bar{G}(H, n, m)$ is the random (multi)graph obtained by taking the union of m uniformly chosen copies of H in K_n without replacement.

Closely related to $\bar{G}(H, n, m)$ is the *random motif graph process* $\bar{G}_0(H, n), \bar{G}_1(H, n), \dots, \bar{G}_N(H, n)$. $\bar{G}_0(H, n)$ is the empty graph on n vertices and for $0 \leq i \leq N = \binom{n}{|V(H)|} / \text{aut}(H)$ the graph $\bar{G}_{i+1}(H, n)$ is generated by adding to $\bar{G}_i(H, n)$ a copy of H , H_{i+1} , chosen uniformly at random from all the copies of H except those in $\{H_1, H_2, \dots, H_i\}$ i.e. those that have been added to $\bar{G}_0(H, n)$ so far. Clearly $\bar{G}_m(H, n)$ has the same law as $\bar{G}(H, n, m)$. In addition, by setting H to be an edge we retrieve the random graph process introduced by Erdős and Rényi [7]. By considering the random motif graph process in place of the uniform random motif graph model we can phrase results in a finer way (see for example Theorem 3).

In this work we show that every monotone graph property has a threshold in the binomial random motif graph $G(H, n, p)$. Then we determine the thresholds for connectivity, existence of a perfect matching, Hamiltonicity and subgraph appearance. In the first three cases we also show a hitting time result, according to which w.h.p.¹ the first graph in the random motif graph process that has minimum degree one (or two) is connected (or Hamiltonian respectively).

1.1 Notation

Throughout we assume the motif H has no isolated vertices. For an integer $r \geq 0$, denote by $m_r(H)$ the number of its copies in K_n which intersect the set $[r]$. For an integer $d \geq 0$ we define the quantities $\delta_d(H)$ and $p_d(H)$ by

$$\delta_d(H) := \lceil d/\delta(H) \rceil - 1 \quad \text{and} \quad p_d^\pm(H) := \frac{\ln n + \delta_d(H) \ln \ln n \pm x(n)}{m_1(H)},$$

¹ That is, with probability tending to 1 as n tends to infinity.

where $x(n)$ is any function of n satisfying $1 \ll x(n) \ll \ln \ln n$. Note that the expected number of added instances of H in $G(H, n, p_1^\pm(H))$ is $m_n(H) \cdot p_1^\pm(H)$, which only depends on n and on $|V(H)|$.

1.2 Results

A function $p^* = p^*(n)$ is a threshold for a monotone increasing property \mathcal{P} in the random graph $G(H, n, p)$ if

$$\lim_{n \rightarrow \infty} \Pr[G(H, n, p) \in \mathcal{P}] = \begin{cases} 0 & \text{if } p/p^* \rightarrow 0, \\ 1 & \text{if } p/p^* \rightarrow \infty, \end{cases}$$

as $n \rightarrow \infty$. Our first result is a generalization of a theorem by Bollobás and Thomason [5].

► **Theorem 1.** *Every non-trivial monotone graph property has a threshold.*

Given Theorem 1, a natural goal is to find the thresholds for various monotone properties. The remaining results of this paper are dedicated towards this goal; we determine the threshold for connectivity, the existence of a perfect matchings, Hamiltonicity, and subgraph appearance.

A first such result, which generalizes a result in [6], shows, in particular, that the expected number of motifs needed to make the random motif graph connected depends only on the number of (non-isolated) vertices of the motif.

► **Theorem 2.** *Let H be a fixed graph. Then*

$$\lim_{n \rightarrow \infty} \Pr[G(H, n, p) \text{ is connected}] = \begin{cases} 0 & p \leq p_1^-(H), \\ 1 & p \geq p_1^+(H). \end{cases}$$

In fact, we show a hitting time result, according to which the hitting time of connectivity equals, w.h.p., the hitting time of minimum degree one. In other words, the random motif graph process becomes connected exactly when the last isolated vertex disappears, with high probability.

Fix an integer n and a graph H . Let $\tau_c = \min\{i : \bar{G}_i(H, n) \text{ is connected}\}$, and for $d \geq 1$ denote $\tau_d = \min\{i : \delta(\bar{G}_i(H, n)) \geq d\}$.

► **Theorem 3.** *Let H be a fixed graph. Then w.h.p. $\tau_c = \tau_1$.*

We remark that if the motif H is connected, every connectivity related question depends solely on the sets of vertices on which copies of H are added, and not on the way they are put there. Thus, we may model the question as a (binomial or uniform) random k -uniform hypergraph, where $k = |V(H)|$. In this case, Theorems 2 and 3 follow immediately from known results about (loose) connectivity in random hypergraphs (see, e.g., [16]).

In the following two theorems we show that the existence of a perfect matching is also dependent on the number of non-isolated vertices of the motif.

► **Theorem 4.** *Let H be a fixed graph, and assume that n is even. Then,*

$$\lim_{n \rightarrow \infty} \Pr[G(H, n, p) \text{ has a perfect matching}] = \begin{cases} 0 & p \leq p_1^-(H), \\ 1 & p \geq p_1^+(H). \end{cases}$$

Let $\tau_M = \min\{i : \bar{G}_i(H, n) \text{ has a perfect matching}\}$. The analogue hitting time result is also true.

► **Theorem 5.** *Let H be a fixed graph, and assume that n is even. Then w.h.p. $\tau_M = \tau_1$.*

Theorem 6 establishes that the thresholds for minimum degree 2 and for Hamiltonicity are the same. Theorem 7 shows the hitting time version of that result.

► **Theorem 6.** *Let H be a fixed graph. Then*

$$\lim_{n \rightarrow \infty} \Pr[G(H, n, p) \text{ is Hamiltonian}] = \begin{cases} 0 & p \leq p_2^-(H), \\ 1 & p \geq p_2^+(H). \end{cases}$$

Let $\tau_H := \min\{i : \bar{G}_i(H, n) \text{ is Hamiltonian}\}$.

► **Theorem 7.** *Let H be a fixed graph. Then w.h.p. $\tau_H = \tau_2$.*

Next, we describe the threshold for the appearance of a subgraph S . If S appears in a random motif graph, then S is a subgraph of some configuration of b copies of H whose union contains a vertices. For such an (a, b) covering of S , we call a subset of the covering containing b' copies of H whose union contains a' vertices an (a', b') subset. The threshold for the appearance of S depends on $\bar{\gamma}$, the maximum over all covering configurations of the minimum ratio a'/b' for all subsets of the covering configuration. Definition 15 formally describes $\bar{\gamma}$.

► **Theorem 8.** *Let H be a fixed graph, let S be a fixed graph, and set $v = |V(H)|$ and $\bar{\gamma} = \bar{\gamma}(S, H)$. Then*

$$\lim_{n \rightarrow \infty} \Pr[S \subseteq \bar{G}(H, n, m)] = \begin{cases} 0 & m \ll n^{v-\bar{\gamma}} \\ 1 & m \gg n^{v-\bar{\gamma}}. \end{cases}$$

The number of excess edges of a connected graph S , or simply its *excess*, is defined to be $\text{exc}(S) = |E(S)| - |V(S)| + 1$. In particular, trees have excess 0. We say that S is *unicyclic* if its excess is 1, or *complex* if its excess is at least 2. The following theorem gives a simple description of $\bar{\gamma}$ when the motif H is a path, which allows us to deduce how the copies of H fit together to form a copy of S at the threshold when S first appears. If S is a tree, a minimal set of edge disjoint copies of H typically forms S . If S is complex, each copy of the path H typically contributes a single edge to S . If it is unicyclic, it may be formed by any edge disjoint configuration of paths H .

► **Theorem 9.** *Let H be a path of length $v - 1$ and let S be a connected graph. Let β be the minimum number of edge-disjoint copies of H whose union contains S as a subgraph. Let $\eta = \min_{X \subseteq S} \frac{|V(X)|}{|E(X)|}$. Then*

$$\bar{\gamma} = \begin{cases} v - 1 + 1/\beta & \text{exc}(S) = 0, \\ v - 1 & \text{exc}(S) = 1, \\ v - 2 + \eta & \text{exc}(S) \geq 2. \end{cases}$$

In the case where the motif is a long path, this result establishes a connection between the threshold for the appearance of subgraphs in random motif graphs and the threshold for the appearance of subgraphs in the trace of a random walk on the complete graph K_n (studied in [13]). Let S be a connected graph and β be the minimum number of paths in any edge-disjoint decomposition of S into paths. If H is longer than the maximum length path in such a minimum edge-disjoint path decomposition, then the threshold implied by Theorem 9 matches the threshold for the appearance of S in the trace of a random walk on the complete graph [13].

This should not come as a surprise; by noticing that when the motif is a long path, the random motif graph model approximates the trace model, in the following sense. One may sequentially “cut” the (lazy) simple random walk into chunks with buffers of length 1. We delete loops created by the trace of each chunk, and we enforce the condition that the remaining edges span a path of length ℓ (which is fixed but large). Hence the trace of each such chunk is an independent copy of a path of length ℓ . Thus we may couple the trace model and the random motif model such that the trace model will include the random motif model plus some loops plus a small number of buffer edges (which gets smaller as ℓ gets larger).

Viewing this analogy this way, we may use Theorems 8 and 9 to reprove the main theorems of [13] for the case where the base graph is complete.

2 Existence of thresholds for monotone properties

Proof of Theorem 1. Assume that \mathcal{P} is a monotone increasing property and let $H_1, H_2, \dots, H_{m_0(H)}$ be the copies of H that are spanned by K_n . Observe that

$$\Pr[G(H, n, p) \in \mathcal{P}] = \sum_{i=0}^{m_0(H)} \sum_{S \in \binom{m_0(H)}{i}} p^i (1-p)^{\binom{n}{|V(H)|} - i} \mathbb{I}\left(\bigcup_{j \in S} H_j \in \mathcal{P}\right)$$

is a polynomial in p . In addition, since \mathcal{P} is increasing, it is increasing. Therefore we may define $p_{1/2}$ by

$$\Pr[G(H, n, p_{1/2}) \in \mathcal{P}] = \frac{1}{2}.$$

We will show that $p_{1/2}$ is a threshold for \mathcal{P} . For two random graphs G, G' we write $G \subseteq G'$ if G, G' can be coupled such that G is a subgraph of G' .

First let $p = \omega(n)p_{1/2}$ where $\omega(n) \rightarrow \infty$ as $n \rightarrow \infty$ and let $k \in \mathbb{N}$. Let $G_i(H, n, p_{1/2})$ be distributed as a $G(H, n, p_{1/2})$ for $i \in [k]$. Then, by considering the probability of no appearance of a fixed copy of H , we have that the graph $\bigcup_{i \in [k]} G_i(H, n, p_{1/2})$ is distributed as $G(H, n, (1 - (1 - p_{1/2})^k))$. Thereafter $1 - (1 - p_{1/2})^k \leq kp_{1/2}$ implies,

$$\bigcup_{i \in [k]} G_i(H, n, p_{1/2}) = G(H, n, (1 - (1 - p_{1/2})^k)) \subseteq G(H, n, kp_{1/2}).$$

Hence,

$$\begin{aligned} \Pr[G(H, n, \omega(n)p_{1/2}) \in \mathcal{P}] &= 1 - \Pr[G(H, n, \omega(n)p_{1/2}) \notin \mathcal{P}] \\ &\geq \lim_{k \rightarrow \infty} 1 - \Pr[G(H, n, kp_{1/2}) \notin \mathcal{P}] \\ &\geq 1 - \lim_{k \rightarrow \infty} \prod_{i=1}^k \Pr[G_i(H, n, p_{1/2}) \notin \mathcal{P}] = 1. \end{aligned}$$

Now assume that $p = p_{1/2}/\omega(n)$ for some $\omega(n) \rightarrow \infty$ as $n \rightarrow \infty$ and let $k \in \mathbb{N}$. Similarly to before, if we let $G_i(H, n, p_{1/2}/\omega(n))$ to be distributed as a $G(H, n, p_{1/2}/\omega(n))$ for $i \in [k]$ then, we have that

$$\begin{aligned} \bigcup_{i \in [k]} G_i(H, n, p_{1/2}/\omega(n)) &= G(H, n, (1 - (1 - p_{1/2}/\omega(n))^k)) \\ &\subseteq G(H, n, kp_{1/2}/\omega(n)) \subseteq G(H, n, p_{1/2}). \end{aligned}$$

Hence,

$$\begin{aligned}
\frac{1}{2} &= \Pr[G(H, n, p_{1/2}) \in \mathcal{P}] = 1 - \Pr[G(H, n, p_{1/2}) \notin \mathcal{P}] \\
&\geq \lim_{k \rightarrow \infty} 1 - \Pr[G(H, n, kp_{1/2}/\omega(n)) \notin \mathcal{P}] \\
&\geq 1 - \lim_{k \rightarrow \infty} \prod_{i=1}^k \Pr[G_i(H, n, p_{1/2}/\omega(n)) \notin \mathcal{P}] \\
&= 1 - \Pr[G_i(H, n, p_{1/2}/\omega(n)) \notin \mathcal{P}]^k.
\end{aligned}$$

Rearranging the above gives,

$$\Pr[G_i(H, n, p_{1/2}/\omega(n)) \notin \mathcal{P}] \geq \lim_{k \rightarrow \infty} \left(\frac{1}{2}\right)^{1/k} = 1. \quad \blacktriangleleft$$

3 Connectivity

Proof of Theorem 2. If $p \leq p_1^-(H)$ then by Theorem 19 the minimum degree of $G(H, n, p)$ is w.h.p. 0, hence it is not connected.

Suppose $p \geq p_1^+(H)$. In fact, for the argument below, we only assume that $p = (\ln n \pm o(\ln n))/m_1(H)$ (and the conclusion will follow by monotonicity). Let k denote the number of vertices of H . For $r = 1, \dots, n/2$ denote by S_r the number of connected components of size r in $G(H, n, p)$. Note that for $r \geq k$, if a set of cardinality r is a connected component, then there exist $\lceil (r-1)/(k-1) \rceil$ copies of H inside the set which appear in $G(H, n, p)$, and there are no edges between it and its complement, so none of the $q = q_r(H)$ copies of H that intersect that set appear. By Lemma 17,

$$qp \sim r f_k(r/n) \cdot \ln n \geq (1 + o(1))k \ln n.$$

Let $\eta = k!/\text{aut}(H)$ and suppose $r \geq k$. By Lemma 18 and by the union bound there exist constants $c, c', C > 0$ depending only on H such that

$$\begin{aligned}
\Pr[S_r > 0] &\leq \binom{n}{r} \binom{\eta \binom{r}{k}}{\lceil \frac{r-1}{k-1} \rceil} p^{\lceil \frac{r-1}{k-1} \rceil} (1-p)^q \leq \left(\frac{en}{r}\right)^r \left(\frac{e\eta \binom{r}{k} p}{\lceil \frac{r-1}{k-1} \rceil}\right)^{\lceil \frac{r-1}{k-1} \rceil} e^{-qp} \\
&\leq \left[C \cdot \frac{n}{r} \cdot r \cdot p^{(r-1)/(r(k-1))} n^{-(1+o(1))k/r}\right]^r \\
&= \left[C \cdot \text{polylog } n \cdot n^{1/r - (1+o(1))k/r}\right]^r = o(1).
\end{aligned}$$

It follows that

$$\begin{aligned}
\Pr[G(H, n, p) \text{ is not connected}] &\leq \sum_{r=1}^{n/2} \Pr[S_r > 0] \\
&= \Pr[S_1 > 0] + \sum_{r=k}^{n/2} \Pr[S_r > 0] = \Pr[S_1 > 0] + o(1),
\end{aligned}$$

but according to Theorem 19 (for $p \geq p_1^+(H)$), there are no isolated vertices w.h.p., and the result follows. \blacktriangleleft

Note that a consequence of this proof is that for $p = (\ln n \pm o(\ln n))/m_1(H)$, with high probability, every connected component is of cardinality 1 or at least $n/2$. This means that w.h.p. there exists a unique “giant” component of linear size, and the rest of the vertices are isolated. The next lemma, whose proof uses a simple second moment argument, estimates the number of these isolated vertices for $p_- = (\ln n - \ln \ln n)/m_1(H)$.

► **Lemma 10.** *The number of isolated vertices in $G(H, n, p_-)$ is w.h.p. at most $2 \ln n$.*

Proof. Let D_0 be the number of isolated vertices in $G(H, n, p_-)$. First,

$$\mathbb{E}[D_0] = n(1 - p_-)^{m_1(H)} \sim ne^{-p_- \cdot m_1(H)} = ne^{-\ln n + \ln \ln n} = \ln n.$$

Moreover,

$$\mathbb{E}[D_0^2] = \mathbb{E}[D_0] + n(n-1)(1 - p_-)^{m_2(H)}.$$

Denote $L := 2m_1(H) - m_2(H)$. Thus

$$\mathbb{E}[D_0^2] \leq \mathbb{E}[D_0] + \mathbb{E}[D_0]^2(1 - p_-)^{-L},$$

and since $(1 - p_-)^{-L} - 1 \sim Lp_-$, we have that

$$\text{Var}[D_0] \leq \mathbb{E}[D_0] + \mathbb{E}[D_0]^2((1 - p_-)^{-L} - 1) \leq \mathbb{E}[D_0] + (L + 1)p_- \mathbb{E}[D_0]^2.$$

Thus, noting that $Lp_- = o(1)$,

$$\begin{aligned} \Pr[D_0 \geq 2 \ln n] &= \Pr[|D_0 - \mathbb{E}[D_0]| \geq (1 + o(1)) \mathbb{E}[D_0]] \\ &\leq (1 + o(1)) \left(\mathbb{E}[D_0]^{-1} + (L + 1)p_- \right) = o(1). \end{aligned} \quad \blacktriangleleft$$

Proof of Theorem 3. Denote $p_{\pm} = (\ln n \pm \ln \ln n)/m_1(H)$ and $m_{\pm} = p_{\pm} \cdot m_n(H)$. By asymptotic equivalence of the binomial and the uniform models (see, e.g., [12]*Section 1.4) we have that w.h.p. $G(H, n, m_-)$ has a unique giant component, and the rest of the connected components are isolated vertices, whose number is at most $2 \ln n$. Denote the set of these isolated vertices by V_0 . Together with Theorem 2 we also conclude that w.h.p.

$$m_- \leq \tau_1 \leq \tau_c \leq m_+.$$

We may thus couple $\bar{G}(H, n, m_-)$, $\bar{G}(H, n, \tau_1)$, $\bar{G}(H, n, \tau_c)$ and $\bar{G}(H, n, m_+)$ such that

$$\bar{G}(H, n, m_-) \subseteq \bar{G}(H, n, \tau_1) \subseteq \bar{G}(H, n, \tau_c) \subseteq \bar{G}(H, n, m_+),$$

by starting with $\bar{G}(H, n, m_-)$ and adding $M = m_+ - m_-$ random copies of H to create $\bar{G}(H, n, m_+)$. Note that if none of these M edges is fully contained in V_0 (and the coupling succeeds) then $\tau_1 = \tau_c$. Thus, there exist positive constants C_1, C_2 such that,

$$\Pr[\tau_1 < \tau_c] \leq o(1) + M \cdot \frac{C_1 \binom{|V_0|}{k}}{m_n(H) - m_+} \leq o(1) + C_2 \cdot \frac{m_n(H) \ln \ln n}{m_1(H)} \cdot \frac{\ln^2 n}{m_n(H)} = o(1). \quad \blacktriangleleft$$

4 Hamiltonicity and Perfect Matchings

The proof of Theorems 7 and 5 can be given in parallel, using the same techniques and tools. For clarity though, in this section we focus mainly on proving Theorem 7 and we give a sketch of the proof of Theorem 5 in the appendix.

For proving our Hamiltonicity result we use the standard technique of Posa's rotations. We define SMALL to be the vertices of significantly smaller degree than the expected one and we set LARGE to be the rest of the vertices. We first show that small to medium subsets of LARGE expand and that the vertices in SMALL are well spread. This is done in the context of Lemmas 11 and 12, 13 respectively. We use these properties of SMALL and LARGE in order to prove all the ingredients needed to apply the Posa's rotations, which we gather in Lemma 14.

Let $p_0 := (\ln n - 2 \ln \ln n)/m_1(H)$ and recall that $p_2^\pm = (\ln n + r_2 \ln \ln n \pm \omega(1))/m_1(H)$, $r_2 = \lfloor 2/\delta(H) - 1 \rfloor$. W.h.p. (see [9]) we can couple $G(H, n, p_0)$, $G(H, n, p_2^-)$, $\bar{G}(H, n, \tau_2)$ and $G(H, n, p_2^+)$ such that

- (i) $G(H, n, p_0) \subset G(H, n, p_2^-) \subset \bar{G}(H, n, \tau_2) \subset G(H, n, p_2^+)$ and
- (ii) there are $(1 + o(1))(p_2^- - p_0) \frac{r_2!}{\text{aut}(H)} \binom{n}{r} > n \ln \ln n / 2r$ copies of H in $G(H, n, p_2^-)$, hence in $\bar{G}(H, n, \tau_2)$, that are not present in $G(H, n, p_0)$.

Observe that the above coupling and Theorem 7 imply Theorem 6. In addition a similar coupling and Theorem 5 imply Theorem 4.

We now define the sets SMALL, LARGE based on the degrees of the vertices in $G(H, n, p_0)$. Let $\text{LARGE} = \{v \in V : v \text{ intersects at least } \ln \ln n \text{ copies of } H \text{ in } G(H, n, p_0)\}$ and $\text{SMALL} = V \setminus \text{LARGE}$.

► **Lemma 11.** *W.h.p. every $S \subset \text{LARGE}$ of size at most $n/30r$ satisfies $|N(S)| \geq 10|S|$.*

► **Lemma 12.** *W.h.p. for every pair $u, v \in \text{SMALL}$ there do not exist $\ell \leq 6$ copies of H in $G(H, n, p_2^+)$ that span a connected subgraph containing both u, v . Hence w.h.p. every pair $u, v \in \text{SMALL}$ is at distance at least 7 in $G(H, n, p_2^+)$.*

► **Lemma 13.** *W.h.p. for every $v \in V$ there exists at most one copy of H in $G(H, n, p_2^+)$, hence in $\bar{G}(H, n, \tau_2)$, that intersect both $\{v\}$ and $\text{SMALL} \setminus \{v\}$.*

Now we generate $\bar{G}(H, n, \tau_2)$ as follows. We first generate $G'_0 = G(H, n, p_0)$. Then we randomly permute the copies of H not appearing in G'_0 , let them be H_1, H_2, \dots . We also let $S_0 = \emptyset$. We define the sequences G'_0, G'_1, \dots and S_0, S_1, \dots in the following way. At step $i \in \mathbb{N}$ we query H_i whether it is incident to a vertex in SMALL. If it is then we set $S_i = S_{i-1}$ and $G'_i = G'_{i-1} \cup H_i$. Otherwise we set $S_i = S_{i-1} \cup \{H_i\}$ and $G'_i = G'_{i-1}$. Let $t^* = \min\{i : \delta(G'_i) = 2\}$ and $S_{t^*} = \{H_{i_1}, H_{i_2}, \dots, H_{i_w}\}$.

Given the sequence $G'_0, G'_1, \dots, G'_{t^*}$ and the set $S_{t^*} = \{H_{i_1}, H_{i_2}, \dots, H_{i_w}\}$ we define the graph sequence F_0, \dots, F_w by $F_0 = G'_{t^*}$ and $F_j = F_{j-1} \cup H_{i_j}$ for $1 \leq j \leq w$. Observe that S_{t^*} consists of all copies of H in $\{H_1, \dots, H_{t^*}\}$ that have not been added to G'_0 , equivalently the copies of H that are not incident to SMALL. Thus $F_w = G'_{t^*} \cup (\bigcup_{j=1}^w H_{i_j}) = G'_0 \cup (\bigcup_{i=1}^{t^*} H_i) = \bar{G}(H, n, \tau_2)$.

► **Lemma 14.** *W.h.p. the following hold:*

- i) $w \geq n \ln \ln n / 2r - n$,
- ii) every $S \subset V$ of size at most $n/30r$ satisfies $|N(S)| \geq 2|S|$ in F_0 ,
- iii) F_0 is connected,
- iv) for every $1 \leq j \leq w$, $\epsilon > 0$, and every set Q_j consisting of ϵn^2 edges not present in F_j there exist a constant $C_\epsilon > 0$ such that the probability that Q_j intersects $E(H_{i_{j+1}})$ is at least C_ϵ .

We are now ready to apply Posa's rotations. For that assume that F_j is not Hamiltonian and consider a longest path in F_j , P_j , $j \geq 0$. Let x, y be the end-vertices of P_j . Given uv where v is an interior vertex of P_j we can obtain a new longest path $P'_j = x..vy..w$ where w is the neighbor of v on P_j between v and y . In such a case we say that P'_j is obtained from P_j by a rotation with the end-vertex x being the fixed end-vertex.

Let $\text{END}_j(x; P_j)$ be the set of end-vertices of longest paths of F_j that can be obtained from P_j by a sequence of rotations that keep x as the fixed end-vertex. Thereafter for $z \in \text{END}_j(x; P_j)$ let $P_j(x, z)$ be a path that has end-vertices x, z and can be obtained from P_j by a sequence of rotations that keep x as the fixed end-vertex. Observe that for $z \in \text{END}_j(x; P_j)$ and $z' \in \text{END}_j(z; P_j(x, z))$ there exists a z - z' path $P_{z,z'}$ of length $|P_j|$ that can be obtained from P_j via a sequence of Posa rotations. Thus we can conclude that $\{z, z'\}$ does not belong to F_j . Indeed assume that $\{z, z'\} \in E(G_i)$. Then we can close $P_{z,z'}$ into a cycle $C_{z,z'}$ that is not Hamiltonian. Since F_j is connected there is an edge e spanned by $V(C_{z,z'}) \times V \setminus V(C_{z,z'})$. $E(C_{z,z'}) \cup \{e\}$ spans a path of length $|P_j| + 2$ contradicting the maximality of P_j . Similarly if $\{z, z'\} \in E(H_{i_{j+1}})$ then F_{j+1} is either Hamiltonian or it contains a path that is longer than P_j . At the same time it follows (see [9]*Corollary 6.7) that

$$|N(\text{END}(x, P_j))| < 2|\text{END}(x, P_j)|.$$

Moreover for every $z \in \text{END}_j(x; P_j)$

$$|N(\text{END}(z, P_j(x, z)))| < 2|\text{END}(z, P_j(x, z))|.$$

As a consequence of Lemma 11, we have that $|\text{END}(x, P_j)| \geq n/30r$ and $|\text{END}(z, P_j(x, z))| \geq n/30r$ for every $z \in \text{END}_j(x; P_j)$. Let $E_j = \{\{z, z'\} : z \in \text{END}_j(x; P_j) \text{ and } z' \in \text{END}_j(z; P_j(x, z))\}$. Then $|E_j| \geq (n/30r)^2/2$.

Now let Y_j be the indicator of the event $\{E_j \cap E(H_{i_{j+1}}) \neq \emptyset\}$ and set $Z = \sum_{j=1}^w Y_j$. From Lemma 14 iv) we have $\Pr[Y_j = 1] \geq C_\epsilon$ (here $\epsilon = 1/2(30r)^2$). In the event that G_w is not Hamiltonian, $Z \leq n$ while Y_j is a Bernoulli(C_ϵ) random variable for $1 \leq j \leq w$. Since $w \geq n \ln \ln n/2r - n$ we have $\Pr[\text{Bin}(w, C_\epsilon) \leq n] = o(1)$. Hence w.h.p. $F_w = \bar{G}(H, n, \tau_2)$ is Hamiltonian and the hitting time for Hamiltonicity equals the hitting time for minimum degree 2.

5 Subgraph appearance

In $G(n, p)$ there is only one way for a specified subgraph to appear on a fixed set of vertices: all the edges in the subgraph must be present. In the case of random motif graphs, there are multiple ways to place motifs so that a specified subgraph appears on a fixed set of vertices. For example, in a random two-path graph, a triangle may appear on $\{1, 2, 3\}$ if (i) the paths $(1, 2, 3)$ and $(3, 1, z)$ are present or (ii) the paths $(1, 2, x)$, $(2, 3, y)$ and $(3, 1, z)$ are present. In order to pin down the threshold for subgraph appearance, it is necessary to understand the various motif configurations that cause the subgraph to appear and their relative probabilities. The following definition provides the notation to describe such configurations.

► **Definition 15.** Let V be a set of vertices. Let S be a fixed graph on a subset of the vertices of V . Let H_1, H_2, \dots, H_b be copies of H also defined on subsets of vertices of V .

- (a) We say $\{H_1, H_2, \dots, H_b\}$ is an (a, b) covering of S if (i) $S \subseteq \bigcup_{j=1}^b H_j$, (ii) $|V(\bigcup_{j=1}^b H_j)| = a$, and (iii) for each $\ell \in [b]$, $S \not\subseteq \bigcup_{j=1}^b H_j \setminus H_\ell$.
- (b) Let $k(a, b)$ be the number of unique configurations of (a, b) coverings, i.e. the number of ways to place b copies of H on a vertices such that conditions (i)-(iii) of (a) hold. Enumerate the possible configurations of (a, b) coverings with values in $[k(a, b)]$. For $i \in [k(a, b)]$, an (a, b, i) covering of S is an (a, b) covering with configuration i .
- (c) We say the set $\{F_1, F_2, \dots, F_{b'}\}$ (with precisely b' elements) is an (a', b') subset of an (a, b, i) covering $\{H_1, H_2, \dots, H_b\}$ if (i) $\{F_1, F_2, \dots, F_{b'}\} \subseteq \{H_1, H_2, \dots, H_b\}$, and (ii) $|V(\bigcup_{\ell=1}^{b'} F_\ell)| = a'$.

66:10 Thresholds in Random Motif Graphs

(d) Let $\mathcal{I}(S, H) = \{(a, b, i) \mid \text{there exists an } (a, b) \text{ covering of } S \text{ by } H \text{ and } i \in [k(a, b)]\}$.

(e) For $(a, b, i) \in \mathcal{I}(S, H)$, let

$$\mathcal{D}(a, b, i) = \{(a', b') \mid \text{there exists an } (a', b') \text{ subset of the } (a, b, i) \text{ covering}\}.$$

(f) For $(a, b, i) \in \mathcal{I}(S, H)$, let $\gamma(a, b, i) = \min_{(a', b') \in \mathcal{D}(a, b, i)} \frac{a'}{b'}$ and denote

$$\bar{\gamma} = \max_{(a, b, i) \in \mathcal{I}(S, H)} \gamma(a, b, i).$$

Proof of Theorem 8. Let $G \sim \bar{G}(H, n, m)$. We say that an instance of the subgraph S in G is an (a, b, i) instance if the placed graphs H_1, \dots, H_b that contribute at least one edge to S form an (a, b, i) covering of S . Let X_i^{ab} denote the number of (a, b, i) instances of S in G . Let $Z = \sum_{(a, b, i) \in \mathcal{I}(S, H)} X_i^{ab}$ be the total number of instances of the subgraph S in G .

First we use the first moment method to show that if $m \ll n^{v-\bar{\gamma}}$, then the probability that S occurs as a subgraph is $o(1)$. It suffices to show that for all $(a, b, i) \in \mathcal{I}(S, H)$, $\mathbb{E}[X_i^{ab}] = o(1)$ since

$$\Pr[Z > 0] \leq \mathbb{E}[Z] = \sum_{(a, b, i) \in \mathcal{I}(S, H)} X_i^{ab},$$

and $|\mathcal{I}(S, H)|$ is a constant independent of n .

We now compute $\mathbb{E}[X_i^{ab}]$ for a fixed triple $(a, b, i) \in \mathcal{I}(S, H)$. Let $\{F_1, \dots, F_{b'}\}$ be an (a', b') subset of the configuration (a, b, i) with $a'/b' = \gamma(a, b, i)$. Let Y be the number of instances of $F = \bigcup_{i=1}^{b'} F_{b'}$ in G formed by the configuration $\{F_1, \dots, F_{b'}\}$. Since an (a, b, i) instance of S contains an instance of the configuration $\{F_1, \dots, F_{b'}\}$, $X_i^{ab} \leq Y$. The number of ways to select a' vertices is at most $n^{a'}$. The probability that a labeled copy of H is placed on a specified set of vertices is m/n^v . We compute

$$\mathbb{E}[X_i^{ab}] \leq \mathbb{E}[Y] \leq cn^{a'} \left(\frac{m}{n^v}\right)^{b'} = c \left(n^{\gamma(a, b, i) - v} m\right)^{b'} \leq c \left(n^{\bar{\gamma} - v} m\right)^{b'},$$

where c is a constant depending only on the number of automorphisms of S and the number of automorphisms of the configuration $\{F_1, \dots, F_{b'}\}$. It follows that for $m \ll n^{\bar{\gamma} - v}$, $\mathbb{E}[X_i^{ab}] = o(1)$, as desired.

Next we use the second moment method to show that if $m \gg n^{v-\bar{\gamma}}$ then S appears as a subgraph almost surely. It suffices to show that there exists some $(a, b, i) \in \mathcal{I}(S, H)$ such that X_i^{ab} is almost surely positive. Let (a, b, i) be such that $\bar{\gamma} = \gamma(a, b, i)$. We apply Corollary 4.3.5 of [1] to show that X_i^{ab} is almost surely positive. Let $X_i^{ab} = \sum_j A_j$ where A_j is an indicator random variable for the event that there is an (a, b, i) instance of S formed by a configuration of H_1, H_2, \dots, H_b each present on a specified set of vertices. Fix A_ℓ , and let

$$\Delta^* = \sum_{j \sim \ell} \Pr[A_j \mid A_\ell],$$

where $j \sim \ell$ indicates that A_j and A_ℓ are not independent. By 4.3.5 of [1], if $\mathbb{E}[X_i^{ab}] \rightarrow \infty$ and $\Delta^* = o(\mathbb{E}[X_i^{ab}])$, then $X_i^{ab} > 0$ almost surely.

First we show that $\mathbb{E}[X_i^{ab}] \rightarrow \infty$. We compute as above

$$\mathbb{E}[X_i^{ab}] \geq c'n^a \left(\frac{m}{n^v}\right)^b = c' \left(n^{a/b - v} m\right)^b \geq c' \left(n^{\bar{\gamma} - v} m\right)^b$$

where c' is a constant depending only on the number of automorphisms of S and the number of automorphisms of the configuration $\{H_1, \dots, H_b\}$. It follows that if $m \gg n^{v-\bar{\gamma}}$ then $\mathbb{E}[X_i^{ab}] \rightarrow \infty$.

Finally, we show $\Delta^* = o(\mathbb{E}[X_i^{ab}])$. Observe that under the assumption $m \gg n^{v-\bar{\gamma}}$,

$$\begin{aligned} \Delta^* &= \sum_{(a',b') \in \mathcal{D}(a,b,i)} cn^{a-a'} \left(\frac{m}{n^v}\right)^{b-b'} = \sum_{(a',b') \in \mathcal{D}(a,b,i)} c \mathbb{E}[X_i^{ab}] \left(n^{-a'/b'+v} m^{-1}\right)^{b'} \\ &\leq c' \mathbb{E}[X_i^{ab}] \left(n^{-\gamma(a,b,i)+v} m^{-1}\right)^b = c' \mathbb{E}[X_i^{ab}] \left(n^{v-\bar{\gamma}} m^{-1}\right)^b = o(\mathbb{E}[X_i^{ab}]). \quad \blacktriangleleft \end{aligned}$$

6 Conclusion

6.1 The value of the random motif model

The study of random motif graphs has the potential to strengthen the impact of the Erdős-Rényi construction. In the context of analyzing real-world networks with an overrepresented motif, random motif graphs may be a more insightful null hypothesis model to compare against to identify non-random structure. For instance by studying subgraphs counts of random H motif graphs one can determine if some larger motif pattern is a byproduct of having many copies of H or is itself some novel aspect of the network structure. Moreover, it is possible that a random motif graph may be used to establish the existence of a graph with some extremal property of interest. Finally, random motif graphs can be used as an alternate definition of average case for analyzing algorithms under the assumption that the input has some motif structure.

6.2 Future directions: understanding threshold behavior more broadly

We have established that random motif graphs behave similarly to traditional Erdős-Rényi random graphs with respect to thresholds and hitting times for monotone properties. Does similar behavior appear when we consider random graphs formed by randomly adding primitive subgraphs H whose size scales with n , the number of vertices of the random graph? Instead of taking H to be a fixed motif, H could be a path, cycle, matching or clique whose size depends on n , for example. Some of these cases were in fact studied in several contexts. For example, the union of $d \geq 3$ random perfect matchings is contiguous to the random d -regular graph, and is sometimes easier to analyze [19]. Moreover, we can consider the class of models where H itself is chosen from some probability distribution. In several cases, this has been studied as well. For instance, [10] and [8] consider the case when H is the uniform spanning tree, and [15] considers the case when H is an Erdős-Rényi random graph with constant density and size dependent on n . Further study of these models is a first step toward delineating a larger family of random graphs that exhibit Erdős-Rényi like threshold and hitting time behaviors.

A Estimates for useful functions

► **Lemma 16.** For $r = r(n)$, if $k = |V(H)|$ and $\alpha = r/n$ then $m_r(H) \sim rm_1(H) \cdot \frac{1 - (1 - \alpha)^k}{k\alpha}$.

Proof. Observe that for $r \geq 0$,

$$m_r(H) = \left(\binom{n}{k} - \binom{n-r}{k} \right) \cdot \frac{k!}{\text{aut}(H)},$$

thus

$$\frac{m_r(H)}{rm_1(H)} = \frac{\binom{n}{k} - \binom{n-r}{k}}{r \left(\binom{n}{k} - \binom{n-1}{k} \right)} \sim \frac{n^k - (n-r)^k}{r(n^k - (n-1)^k)} = \frac{1 - (1 - \alpha)^k}{r(1 - (1 - n^{-1})^k)} \sim \frac{1 - (1 - \alpha)^k}{k\alpha}. \blacktriangleleft$$

For $r \geq 1$, denote by $q_r(H)$ the number of copies of H that intersect $[r]$ but that are not contained in $[r]$.

► **Lemma 17.** For $r = r(n)$, if $k = |V(H)|$ and $\alpha = r/n$ then $q_r(H) \sim rm_1(H) \cdot \frac{1 - (1-\alpha)^k - \alpha^k}{k\alpha}$.

Proof. Observe that for $r \geq 0$,

$$q_r(H) = \left(\binom{n}{k} - \binom{n-r}{k} - \binom{r}{k} \right) \cdot \frac{k!}{\text{aut}(H)},$$

thus

$$\begin{aligned} \frac{q_r(H)}{rm_1(H)} &= \frac{\binom{n}{k} - \binom{n-r}{k} - \binom{r}{k}}{r \left(\binom{n}{k} - \binom{n-1}{k} \right)} \sim \frac{n^k - (n-r)^k - r^k}{r(n^k - (n-1)^k)} \\ &= \frac{1 - (1-\alpha)^k - \alpha^k}{r(1 - (1-n^{-1})^k)} \sim \frac{1 - (1-\alpha)^k - \alpha^k}{k\alpha}. \end{aligned} \quad \blacktriangleleft$$

For convenience we define for $\alpha \in [0, 1]$ and $k \geq 1$,

$$f_k(\alpha) = \frac{1 - (1-\alpha)^k - \alpha^k}{k\alpha}.$$

► **Lemma 18.** For $2 \leq k \leq r$ we have that $rf_k(r/n) \geq (1 + o(1))k$.

Proof. Write $g_k(\alpha) = f_k(\alpha) \cdot k\alpha = 1 - (1-\alpha)^k - \alpha^k$. Observe that it is strictly increasing in $(0, 1/2)$. Note also that

$$n \cdot g_k\left(\frac{k}{n}\right) = n - ne^{-k^2/n} - o(1) \sim k^2.$$

It follows that

$$\frac{kr}{n} \cdot f_k\left(\frac{r}{n}\right) = g_k\left(\frac{r}{n}\right) \geq g_k\left(\frac{k}{n}\right) \sim \frac{k^2}{n},$$

so $rf_k(r/n) \geq (1 + o(1))k$. ◀

B Minimum degree

► **Theorem 19.** With high probability

$$\delta(G(H, n, p_d^-)) < d \quad \text{and} \quad \delta(G(H, n, p_d^+)) \geq d.$$

Proof. Let $\delta = \delta(H)$. It suffices to show that with high probability for $\ell \in \mathbb{Z}_{\geq 0}$

$$\Pr[\delta(G(H, n, p_{\ell, \delta}^-)) > (\ell - 1)\delta] = o(1) \tag{1}$$

and

$$\Pr[\delta(G(H, n, p_{\ell, \delta}^+)) < \ell\delta] = o(1). \tag{2}$$

Proof of (1): Let $p = p_{\ell, \delta}^-$. For $v \in V$ let $I_v = \mathbb{I}\{d(v) = (\ell - 1)\delta\}$ and $Z = \sum_{v \in V} I_v$.

$$\begin{aligned} \mathbb{E}[Z] &\geq (1 - o(1))n \binom{n-1}{v_H-1}^{\ell-1} p^{\ell-1} (1-p)^{m_1(H)-\ell+1} \\ &\geq C_1 n (pn^{(v_H-1)})^{\ell-1} e^{-(p+4p^2)(m_1(H)-\ell+1)} \\ &\geq C_2 n (\log n)^{\ell-1} e^{-\log n - (\ell-1) \log \log n + \omega(1)} \geq e^{\omega(1)/2}. \end{aligned}$$

66:14 Thresholds in Random Motif Graphs

In addition,

$$\begin{aligned}
\mathbb{E}[Z^2] &= \sum_{u,v \in V} \Pr[I_v \wedge I_u] \\
&\leq \mathbb{E}[Z]^2 + \sum_{u \neq v \in V} \Pr[I_u \wedge I_v \wedge \{u, v \text{ lie on the same copy of } H\}] \\
&\leq \mathbb{E}[Z]^2 + \binom{n}{2} \binom{n-2}{r-2} \frac{r!}{\text{aut}(H)} p(1-p)^{(1-o(1))2m_1} \\
&= \mathbb{E}[Z]^2 + nm_1 p(1-p)^{m_1-1} C_3 (1-p_2^-)^{(1-o(1))m_1} = \mathbb{E}[Z]^2 + o(1) \mathbb{E}[Z] \\
&= (1+o(1)) \mathbb{E}[Z]^2.
\end{aligned}$$

Chebyshev's inequality give us,

$$\Pr[|Z - \mathbb{E}[Z]| \geq \mathbb{E}[Z]/2] \leq \frac{\mathbb{E}[Z^2] - \mathbb{E}[Z]^2}{0.25 \mathbb{E}[Z]^2} = o(1).$$

Hence with high probability there exist vertices of degree $(\ell-1)\delta$.

Proof of (2): Let $p = p_{\ell,\delta}^+$. Let \mathcal{E}_1 be the event that in $G(H, n, p)$ there exists a vertex of degree $d \leq \ell\delta$ that lies on more than ℓ copies of H . In the event \mathcal{E}_1 there exists a vertex v and a vertex set S of size d such that all the neighbors of v lie in S and at least $\ell+1$ copies of H intersect $S \cup \{v\}$, each in at least $\delta+1$ vertices. Therefore,

$$\begin{aligned}
\Pr[\mathcal{E}_1] &\leq n \binom{n}{d} [1-p]^{\binom{n-d-1}{v_H-1}} \left(\binom{d+1}{\delta+1} \binom{n-\delta-1}{v_H-\delta-1} \right)^{\ell+1} p^{\ell+1} \\
&\leq e^{-p \cdot \binom{n-d-1}{v_H-1}} n^{d+1-\delta(\ell+1)} [n^{v_H-1} p]^{\ell+1} \\
&\leq e^{-(1+o(1))p \cdot m_1(H)} (\log^2 n)^{\delta_a(H)+1} = o(1).
\end{aligned}$$

In the event $\neg\mathcal{E}_1$ the number of vertices of degree less than $\ell\delta$ is bounded by the number of vertices that are covered by at most $\ell-1$ copies of H . Thus

$$\begin{aligned}
\Pr[\delta(G(H, n, p_{\ell,\delta}^+)) < \ell\delta] &\leq \Pr[\mathcal{E}_1] + n \sum_{i=0}^{\ell-1} \binom{m_1(H)}{i} p^i (1-p)^{m_1(H)-i} \\
&\leq \ell n (m_1(H)p)^{\ell-1} e^{-pm_1(H)+p\ell} + o(1) \\
&\leq \ell n [2 \log n]^{\ell-1} e^{-\log n - (\ell-1) \log \log n - \omega(1)} + o(1) = o(1). \quad \blacktriangleleft
\end{aligned}$$

C Proofs of lemmas for Hamiltonicity

Proof of Lemma 11. If there exists $S \subset \text{LARGE}$ of size $n^{19/20} \leq |S| \leq n/30r$ such that $|N(S)| < 10|S|$ then there exist sets A, B of size $n^{19/20} \leq s \leq n/30r$ and $n-11s$ respectively such that no copy of H, H' satisfies $|A \cap H'| = 1$ and $|B \cap H'| = r-1$ (take $S = A$ and B to be any subset of $V \setminus (S \cup N(S))$ of size $n-11s$). The probability of such event occurring is bounded above by

$$\begin{aligned}
&\sum_{s=n^{19/20}}^{n/30r} \binom{n}{s} \binom{n-s}{10s} (1-p_0)^{\frac{r!}{\text{aut}(H)} \cdot s \binom{n-11s}{r-1}} \\
&\leq \sum_{s=n^{19/20}}^{n/30r} \left[\frac{en}{s} \cdot \left(\frac{en}{10s} \right)^{10} e^{-p_0 \frac{r!}{\text{aut}(H)} \cdot \binom{n-11s}{r-1}} \right]^s
\end{aligned}$$

$$\begin{aligned}
 \dots &\leq \sum_{s=n^{19/20}}^{n/30r} \left[\left(\frac{n}{s} \right)^{11} e^{-\frac{\ln n - 2 \ln \ln n}{(r-1)} \cdot \binom{n-11s}{r-1}} \right]^s \\
 &\leq \sum_{s=n^{19/20}}^{n/30r} \left[\left(\frac{n}{s} \right)^{11} \left(\frac{\ln^2 n}{n} \right)^{(1-\frac{11s}{n}) \dots (1-\frac{11s-r+2}{n-r+2})} \right]^s \\
 &\leq \sum_{s=n^{19/20}}^{n/30r} \left[\left(\frac{n}{s} \right)^{11} \left(\frac{\ln^2 n}{n} \right)^{1-\frac{12sr}{n}} \right]^s \leq \sum_{s=n^{19/20}}^{n/30r} \left[n^{11/20} \left(\frac{\ln^2 n}{n} \right)^{18/30} \right]^s = o(1).
 \end{aligned}$$

Now assume that there exists a set $S \subset \text{LARGE}$ of size at most $n^{19/20}$ that satisfies $|N(S)| < 10|S|$. Since every vertex in S is in at least $\ln \ln n$ copies of H and every copy of H covers r vertices we have that S intersects at least $|S| \ln \ln n / 11$ copies of H . Each of those copies is spanned by $S \cup N(S)$. Therefore there exists a set $W \supseteq S \cup N(S)$ of size $w = |W| = 11|S| \leq 11n^{19/20}$ that intersects at least $\frac{|W| \ln \ln n}{11r}$ copies of H each, in at least 2 vertices. Since every vertex in LARGE has $\ln \ln n$ neighbors $|W| \geq \ln \ln n$. The probability that such a set exists is bounded by

$$\begin{aligned}
 &\sum_{w=\ln \ln n}^{11n^{19/20}} \binom{n}{w} \binom{r! \binom{w}{2} \binom{n}{r-2}}{w \ln \ln n / 11r} p_0^{w \ln \ln n / 11r} \\
 &\leq \sum_{w=\ln \ln n}^{11n^{19/20}} n^w \left(\frac{11er^3 w n^{r-2}}{\ln \ln n} \right)^{w \ln \ln n / 11r} p_0^{w \ln \ln n / 11r} \\
 &\leq \sum_{w=\ln \ln n}^{11n^{19/20}} \left[n^{11r / \ln \ln n} \cdot \frac{11er^3 w n^{r-2}}{\ln \ln n} \cdot p_0 \right]^{w \ln \ln n / 11r} \\
 &\leq \sum_{w=\ln \ln n}^{11n^{19/20}} \left(n^{11r / \ln \ln n} \cdot \frac{w \log n}{n} \right)^{w \ln \ln n / 11r} = o(1). \quad \blacktriangleleft
 \end{aligned}$$

Proof of Lemma 12. For $u \in V$ and $Q \subset V$ let $S(u, Q)$ be the event that in $G(H, n, p_0)$ u intersects at most $\ln \ln n$ copies of H that do not intersect Q . For $0 \leq |Q| \leq 6$,

$$\Pr[S(u, Q)] \leq \Pr \left[\text{Bin} \left(\frac{r!}{\text{aut}(H)} \binom{n-7}{r-1}, p_0 \right) \leq \ln \ln n \right] \leq n^{-0.9}.$$

Let \mathcal{B} be the event that for some $u, v \in \text{SMALL}$ there exist $\ell \leq 6$ copies of H in $G(H, n, p_2^+)$ that span a connected subgraph containing both u, v . If \mathcal{B} occurs then we can find a set $Q = \{v = v_0, v_1, \dots, v_{\ell-1}, v_\ell = u\}$ such that i) the events $S(v, Q \setminus \{v\}), S(u, Q \setminus \{u\})$ occur and ii) there exist H_1, \dots, H_ℓ in $G(H, n, p_2^+)$ such that $H_i \cap Q = \{v_{i-1}, v_i\}$. Since all the aforementioned events are independent

$$\begin{aligned}
 \Pr[\mathcal{B}] &\leq \sum_{\ell=1}^6 \sum_{Q=\{v_0, v_1, \dots, v_\ell\}} \Pr[S(v_0, Q \setminus \{v_0\})] \cdot \left(\binom{n-2}{r-2} \frac{r!}{\text{aut}(H)} p_2^+ \right)^\ell \cdot \Pr[S(v_\ell, Q \setminus \{v_\ell\})] \\
 &\leq \sum_{\ell=1}^6 n^{\ell+1} \cdot n^{-0.9} \cdot \left(\frac{C_3 \ln n}{n} \right)^\ell \cdot n^{-0.9} = o(1). \quad \blacktriangleleft
 \end{aligned}$$

66:16 Thresholds in Random Motif Graphs

Proof of Lemma 13. Lemma 12 implies that w.h.p. there do not exist $v \in V$ and $u, w \in \text{SMALL}$, $u \neq w$ such that in $G(H, n, p_2^+)$ v and u are in a copy of H and v and w are in a copy of H . The probability that there exist $v \in V$, $u \in \text{SMALL} \setminus \{v\}$ that are both contained in more than one copy of H in $G(H, n, p_2^+)$ is bounded by

$$\sum_{v, u \in V} \Pr[S(u, \{v\})] \left(\binom{n-2}{r-2} \frac{r!}{\text{aut}(H)} p_2^+ \right)^2 \leq C_4 n^{-0.9} \log^2 n = o(1). \quad \blacktriangleleft$$

Proof of Lemma 14.

1. Recall that we can couple $G(H, n, p_0), \bar{G}(H, n, \tau_2)$ such that $G(H, n, p_0) \subset \bar{G}(H, n, \tau_2)$ w.h.p. and there are at least $n \ln \ln n / 2r$ copies of H in $\bar{G}(H, n, \tau_2)$ that are not present in $G(H, n, p_0)$. From Lemma 13 it follows that w.h.p. each of those copies that spans a vertex in SMALL also spans a unique vertex in $V \setminus \text{SMALL}$. Hence $w \geq n \ln \ln n / 2r - n$.
2. Let $S \subset V$, $|S| \leq n/30r$ and set $S_s = S \cap \text{SMALL}$, $S_L = S \cap \text{LARGE}$. Lemma 11 implies that $|N(S_L)| \geq 10|S_L|$. In the case $|S_L| \geq |S_s|$ we have

$$|N(S)| \geq |N(S_L) \setminus S_s| \geq 10|S_L| - |N(S_L) \cap S_s| \geq 10|S_L| - |S_s| \geq 9|S_L| \geq 2|S|.$$

Next assume $|S_L| < |S_s|$. Lemma 12 implies that no two vertices in SMALL are within distance 2 in $G(H, n, p_2^+)$, hence their neighborhoods are disjoint. Also F_0 has minimum degree 2. Therefore $|N(S_s)| \geq 2|S_s|$. Now let $S_L = S_1 \cup S_2$ where S_2 consists of all the vertices in S_L that are within distance 2 from S_s and $S_1 = S_L \setminus S_2$. If $|S_1| \geq |S_2|$ then since S_s and S_1 have disjoint neighborhoods we have that

$$|N(S)| \geq |N(S_s) \setminus S_2| + |N(S_1) \setminus S_2| \geq 2|S_s| + 10|S_1| - 2|S_2| \geq 2|S|.$$

Otherwise $|S_s| > |S_L|$ and $|S_2| > |S_1|$. For $v \in S_s$ let $N_{S_2}(v)$ be the set of vertices in S_2 that are within distance 2 from v , hence $\cup_{v \in S_s} N_{S_2}(v) = |S_2|$. Lemma 12 states that no two vertices in SMALL are within distance 6, thus for $v, u \in S_s, v \neq u$ the sets $N(N_{S_2}(v)), N(N_{S_2}(u))$ are disjoint. In addition since $N_{S_2} \subset S_L$ and $|S_L| \leq |S| \leq n/30r$, Lemma 11 implies that $|N(N_{S_2}(v))| \geq 10|N_{S_2}(v)|$ for all $v \in S_s$. Thus

$$\begin{aligned} |N(S)| &\geq \sum_{v \in S_s} |N(N_{S_2}(v) \cup \{v\})| \\ &\geq \sum_{v \in S_s} [10|N_{S_2}(v)| - |\{v\}|] \cdot \mathbb{I}_{N_{S_2}(v) \neq \emptyset} + |N(v)| \mathbb{I}_{N_{S_2}(v) = \emptyset} \\ &\geq \sum_{v \in S_s} 2 = 2|S_s| \geq |S|. \end{aligned}$$

3. Assume that there exists a set $S \subset V$ such that S is a connected component of F_0 and let $s = |S|$. F_0 has minimum degree 2 therefore $s \geq 3$. Let $S_L = S \cap \text{LARGE}$ and $S_s = S \cap \text{SMALL}$. Lemma 13 implies that every vertex in S_L can be adjacent to at most 1 vertex in SMALL hence $|S_L| \geq |S_s|$. Thereafter Lemma 11 implies that $|S| > n/30r$ since otherwise

$$|N(S)| \geq |N(S_L)| - |S_s| \geq 10|S_L| - |S_L| > 0.$$

Finally the probability that there exists a connected component of size $n/30r \leq s \leq n/2$ in $G(H, n, p_0) \subset F_0$ is bounded by

$$\sum_{s=n/30r}^{0.5n} \binom{n}{s} (1-p_0)^{\frac{r!}{\text{aut}(H)} \cdot s \binom{n-s}{r-1}} \leq \sum_{s=n/30r}^{0.5n} \left[\frac{en}{s} \cdot e^{-C_5 \ln n} \right]^s = o(1).$$

4. First we show that w.h.p. $|\text{SMALL}| \leq n^{0.1}$. Indeed by Markov's inequality,

$$\Pr[|\text{SMALL}| > n^{0.1}] \leq n^{-0.1} \cdot n \Pr\left[\text{Bin}\left(\frac{r!}{\text{aut}(H)} \binom{n-1}{r-1}, p_0\right) \leq \ln \ln n\right] = o(1).$$

Now let Q_j be a set of ϵn^2 edges not present in F_j and Q'_j be the subset of Q_j consisting of the edges that are not incident to SMALL . Then w.h.p. $|Q'_j| = (1 + o(1))\epsilon n^2$. Every edge in Q'_j belongs to $C_6 n^{r-2}$ copies of H that are not present in F_j and every copy of H may cover at most $\binom{r}{2}$ edges in Q'_j . Therefore there exists a set W_i consisting of at least $C_6 n^{r-2} \cdot (1 + o(1))\epsilon n^2 / \binom{r}{2}$ distinct copies of H that intersect Q'_j . $H_{i_{j+1}}$ is uniformly distributed among the copies of H that are not present in F_j and are not incident to a vertex in SMALL . Thus

$$\Pr[iv] = \Pr[H_i \in W_i] \geq \frac{C_6 n^{r-2} \cdot (1 + o(1))\epsilon n^2 / \binom{r}{2}}{n^r} \geq C_7 \epsilon = C_\epsilon. \quad \blacktriangleleft$$

D Proof sketch of Theorems 4 and 5

To prove Theorem 5 we first indicate the edge set Q_1 , consisting of the edges that are incident to vertices of degree 1. Then we delete these edges and the vertex set U_1 consisting of the vertices incident to them. Thereafter we use exactly the same techniques as above in order to find a Hamilton cycle in the remaining graph. We use half of the edges of that cycle and the edges in Q_1 to form a perfect matching.

Given the above, the only substantial difference is that while generating $\bar{G}(H, n, \tau_1)$ (in place of $\bar{G}(H, n, \tau_2)$) we stop at time $t^* = \min\{i : \delta(G'_i) = 1\}$. The proofs of all Lemmas with exception the proof of Lemma 14, follow in exactly the same way. For the proof of Lemma 14 we have to be slightly more cautious as we want to prove the corresponding statements for the subgraph that is spanned by $V \setminus U_1$. Thus we have to use $\text{SMALL} \setminus U_1$ and $\text{LARGE} \setminus U_1$ in place of SMALL and LARGE respectively.

E Proof of Theorem 9

Before proving Theorem 9, we derive an expression for a'/b' and establish the following upper bound on $\gamma(a, b, i)$.

► **Lemma 20.** *Consider an (a, b, i) covering of S by a path of length $v - 1$ and an (a', b') subcovering with c' connected components. Let S_j be the subgraph of S covered by j^{th} connected component of the (a', b') subcovering. Let $f_j = |E(S_j)| - |V(S_j)| + 1$ and $f' = \sum_{j=1}^{c'} f_j$. Let k be the number of duplicate edges in the (a', b') subcovering, i.e. k is the smallest integer such that removing k edges from multigraph union of b' copies of H can yield a simple graph. Then*

$$\frac{a'}{b'} = v - 1 + \frac{c' - f' - k}{b'} \tag{3}$$

and

$$\gamma(a, b, i) \leq \begin{cases} v - 1 + \frac{1-f}{b} & (a, b, i) \text{ is edge-disjoint} \\ v - 1 - \frac{f}{b} & (a, b, i) \text{ is not edge-disjoint} \end{cases} \tag{4}$$

Proof. We compute a' . Note that each of the b' copies of H contributes v vertices, however vertices may be counted multiple times. We compute

$$a' = b'v - \left(b' - \sum_{j=1}^{c'} 1 - f_j \right) - k = b'(v-1) + c' - f' - k,$$

where the first term subtracted corresponds to doubling counting vertices in each connected component and subtracting k corresponds to removing double counting for vertices adjacent to edges of S that are covered multiple times.

By definition, $\gamma(a, b, i) \leq a/b$. For the $(a', b') = (a, b)$ subcover that is the entire (a, b, i) cover, $c' = 1$, $f' = f$ and $k = 0$ if (a, b, i) is edge-disjoint and $k \geq 1$ if (a, b, i) is not edge-disjoint. Thus, Equation (4) follows directly from Equation (3). ◀

Proof of Theorem 9. We consider each case separately.

Case: $f = 0$. Consider an (a, b, i) covering. If (a, b, i) is edge-disjoint, then $b \geq \gamma$. It follows from Equation (4) that

$$\gamma(a, b, i) \leq \begin{cases} v - 1 + \frac{1}{\beta} & (a, b, i) \text{ is edge-disjoint} \\ v - 1 & (a, b, i) \text{ is not edge-disjoint.} \end{cases}$$

Thus $\bar{\gamma} = \max_{(a, b, i) \in \mathcal{I}(S, H)} \gamma(a, b, i) \leq v - 1 + 1/\beta$.

Next consider an edge-disjoint cover of S by β copies of H , (a, β, i) . By Equation (3), for any (a', b') subcover of the (a, β, i) cover,

$$\frac{a'}{b'} = v - 1 + \frac{c'}{b'}.$$

This value is minimized with $c' = 1$ and $b' = \beta$, which is achieved by the (a, β) subcover which is the whole cover. Thus $\gamma(a, \beta, i) = v - 1 + 1/\beta$, and so $\bar{\gamma} \geq v - 1 + 1/\beta$.

Case: $f = 1$. By Equation (4), $\gamma(a, b, i) \leq v - 1$ for all (a, b, i) and so it follows that $\bar{\gamma} \leq v - 1$.

Next consider an edge-disjoint cover of S , (a, b, i) . By Equation (3), for any (a', b') subcover of the (a, β, i) cover,

$$\frac{a'}{b'} = v - 1 + \frac{c' - 1}{b'}.$$

This value is minimized with $c' = 1$, which is achieved by the (a, b) subcover which is the whole cover. Thus $\gamma(a, b, i) = v - 1$, and so $\bar{\gamma} \geq v - 1$.

Case: $f \geq 2$. Consider an (a, b, i) cover. By Equation (3),

$$\gamma(a, b, i) = \min_{(a', b') \in \mathcal{D}(a, b, i)} \frac{a'}{b'} = \min_{a', b', c', k} v - 1 + \frac{c' - f' - k'}{b'}.$$

Let t' and e' be the number of edges and vertices of S covered by the subcover, so $e' = t' - c' + f' + k$. It follows

$$\gamma(a, b, i) = \min_{t', e', b'} v - 1 + \frac{t' - e'}{b'}. \quad (5)$$

To give an upper bound on $\gamma(a, b, i)$, we construct a subcover of the (a, b, i) cover as follows. Let X be a subgraph of S with t^* vertices and e^* edges such that $t^*/e^* = \eta$. Let t', e', b' correspond to the subcover that minimally covers X , and let C be the subgraph of S covered by this subcover (so X is a subgraph of C).

We claim that $t' - e' \leq t^* - e^*$. Note that $t' - t^* = |V(C) \setminus V(X)|$ and $e' - e^* = |E(C) \setminus E(X)|$. In each component of $C \setminus E(X)$, at least one vertex is included in $V(X)$. Since the number of vertices in a connected component is at least the number of edges in the connected component minus one, and at least one vertex in each connected component is not included in $V(C) \setminus V(X)$, it follows that $|V(C) \setminus V(X)| \geq |E(C) \setminus E(X)|$. Thus $t' - t^* \leq e' - e^*$ and the claim follows.

By considering this subcover with parameters t', e', b' , we obtain

$$\gamma(a, b, i) \leq v - 1 + \frac{t' - e'}{b'} \leq v - 1 + \frac{t^* - e^*}{e^*} = v - 2 + \eta$$

since $b' \leq e^*$ and $t^* - e^* \leq 0$. It follows that $\bar{\gamma} \leq v - 2 + \eta$.

Finally to lower bound $\bar{\gamma}$ we consider a cover in which there are $b = |E(S)|$ copies of H and each copy covers precisely one edge of S . In this case in all subcovers $b' = e'$. By Equation (5)

$$\gamma(a, b, i) = \min_{t', e', b'} v - 1 + \frac{t' - e'}{b'} = \min_{t', e'} v - 2 + \frac{t'}{e'} = v - 2 - \eta.$$

Thus $\bar{\gamma} \geq v - 2 + \eta$. ◀

Abstract

The random-cluster (FK) model is a key tool for the study of phase transitions and for the design of efficient Markov chain Monte Carlo (MCMC) sampling algorithms for the Ising/Potts model. It is well-known that in the high-temperature region $\beta < \beta_c(q)$ of the q -state Ising/Potts model on an $n \times n$ box Λ_n of the integer lattice \mathbb{Z}^2 , spin correlations decay exponentially fast; this property holds even arbitrarily close to the boundary of Λ_n and uniformly over all boundary conditions. A direct consequence of this property is that the corresponding single-site update Markov chain, known as the Glauber dynamics, mixes in optimal $O(n^2 \log n)$ steps on Λ_n for all choices of boundary conditions. We study the effect of boundary conditions on the FK-dynamics, the analogous Glauber dynamics for the random-cluster model.

On Λ_n the random-cluster model with parameters (p, q) has a sharp phase transition at $p = p_c(q)$. Unlike the Ising/Potts model, the random-cluster model has non-local interactions which can be forced by boundary conditions: external wirings of boundary vertices of Λ_n . We consider the broad and natural class of boundary conditions that are *realizable* as a configuration on $\mathbb{Z}^2 \setminus \Lambda_n$. Such boundary conditions can have many macroscopic wirings and impose long-range correlations even at very high temperatures ($p \ll p_c(q)$). In this paper, we prove that when $q > 1$ and $p \neq p_c(q)$ the mixing time of the FK-dynamics is polynomial in n for *every* realizable boundary condition. Previously, for boundary conditions that do not carry long-range information (namely wired and free), Blanca and Sinclair (2017) had proved that the FK-dynamics in the same setting mixes in optimal $O(n^2 \log n)$ time. To illustrate the difficulties introduced by general boundary conditions, we also construct a class of non-realizable boundary conditions that induce slow (stretched-exponential) convergence at high temperatures.

1 Introduction

Statistical physics models are designed to study physical phase transitions where a small change in a parameter which controls the local interactions, such as temperature, causes abrupt changes in the macroscopic behavior of the system. Phase transitions are captured by the onset of long-range correlations between vertices in the underlying graph, the infinite 2-dimensional integer lattice graph \mathbb{Z}^2 being a widely considered example. These long-range correlations manifest in the asymptotic effect of “boundary conditions” in large finite volumes. For example, if we take an $n \times n$ box Λ_n of \mathbb{Z}^2 and fix a configuration on the boundary of this box, as we formalize momentarily, this fixed boundary condition may affect the static (equilibrium state) and dynamic (approach to equilibrium) properties of the system.

The most notable and well-studied statistical physics model is the Ising/Potts model of ferromagnetism. The (ferromagnetic) Ising/Potts model on a (finite) graph, say the $n \times n$ box $\Lambda_n \subset \mathbb{Z}^2$ with nearest-neighbor edges $E(\Lambda_n)$, is defined on the set of spin assignments $\{1, \dots, q\}^{\Lambda_n}$. The probability of a configuration $\sigma \in \{1, \dots, q\}^{\Lambda_n}$ in the associated Gibbs distribution μ_{Λ_n} is proportional to $\exp(\beta H(\sigma))$, where $H(\sigma)$ is the number of edges of Λ_n whose endpoints are assigned the same spin in σ ; the parameter $\beta > 0$ corresponds to the inverse temperature and controls the strength of the nearest-neighbor interactions.

An Ising/Potts boundary condition τ is a fixed assignment of spins to $\partial\Lambda_n$, the (inner) boundary of Λ_n ; i.e., those vertices in Λ_n that are adjacent to vertices in $\mathbb{Z}^2 \setminus \Lambda_n$. The Gibbs distribution on Λ_n conditioned on the fixed assignment τ to $\partial\Lambda_n$, denoted $\mu_{\Lambda_n}^\tau$, is used for example to define the infinite Ising/Potts Gibbs measures on \mathbb{Z}^2 . These are obtained as the limits of the distributions on finite boxes for distinct boundary conditions τ ; i.e., $\lim_{n \rightarrow \infty} \mu_{\Lambda_n}^\tau$ for different τ .

On \mathbb{Z}^2 , it is known that the Ising/Potts model undergoes a sharp phase transition at a critical point $\beta = \beta_c(q) = \ln(1 + \sqrt{q})$ [31, 2]. This phase transition marks the onset of long-range correlations and can also be understood as a transition in the number of (unique vs. multiple) infinite-volume Gibbs measures. In finite regions of \mathbb{Z}^2 such as Λ_n , this phase transition corresponds to whether an arbitrary boundary condition τ on $\partial\Lambda_n$ may have macroscopic effects on the Gibbs distribution. For instance, in the low-temperature region $\beta > \beta_c(q)$, if τ is the all “1” configuration on $\partial\Lambda_n$, the spins of all vertices, even those near the center of Λ_n will prefer the spin “1” and thus align with the boundary. In contrast, in the high-temperature region $\beta < \beta_c(q)$, there is exponential decay (with distance) of spin correlations: crucially this holds uniformly over all boundary conditions and over all vertices (i.e., even for those near the boundary); this property is known as *strong spatial mixing (SSM)*.

This phase transition also exhibits itself in the dynamic properties of the system, e.g., through the speed of convergence to stationarity of natural Markov chains for the Ising/Potts model. The classical Glauber dynamics, for example, which in each step updates the spin of a random vertex according to the spins of its neighbors, is known to converge in $\Theta(n^2 \log n)$ steps when $\beta < \beta_c(q)$ [28, 8, 2, 1]; this bound relies on the SSM property described above and, as such, it holds for *every* fixed boundary condition. In contrast, when $\beta > \beta_c(q)$ the speed of convergence of the Glauber dynamics is expected to depend crucially on the boundary condition and understanding its behavior for general boundaries is a long-standing open problem. At the moment, it is known that Glauber dynamics requires exponentially (in n) many steps to converge for free (no boundary) and periodic (toroidal) boundary conditions [34, 7, 16] and, in the special case of the Ising model ($q = 2$), sub-exponentially many steps for uniform (e.g., all “1”) boundaries [25, 29].

Our focus here is the random-cluster (FK) model [13], which is a random graph model intimately connected to the Ising/Potts model. Indeed, it has been central to the study of the Ising/Potts phase transition (see, e.g., the recent breakthroughs on \mathbb{Z}^2 [2, 12, 11]) and plays an indispensable role in the design of efficient Markov Chain Monte Carlo (MCMC) algorithms for the Ising/Potts model (e.g., the Swendsen-Wang dynamics [33, 22]). We study the effects of boundary conditions on Λ_n on the speed of convergence of the FK-dynamics, the analog of the Ising/Potts Glauber dynamics for the random-cluster model. Despite the close connection between these models, the boundary effects are fundamentally different. Whereas the SSM property of the Ising/Potts model at $\beta < \beta_c(q)$ is uniform over the choice of boundary condition, in the random-cluster setting, SSM is limited to only a few select choices of boundary conditions.

We seek to understand the dynamics in situations where spatial mixing is destroyed near the boundary by the boundary condition. First we establish that for all *realizable* FK boundary conditions (those which are consistent with the planarity of \mathbb{Z}^2), the FK-dynamics converges in polynomially many (in n) steps, both at high and low temperatures. To illustrate the difficulties introduced by general boundary conditions, we also construct a class of non-realizable boundary conditions that induce slow (stretched-exponential) convergence at high temperatures.

The random-cluster model. For a graph $G = (V, E)$ and parameters $p \in (0, 1)$ and $q > 0$, random-cluster configurations are subsets of edges in $\Omega = \{S \subseteq E\}$, with the probability of $S \subseteq E$ given by

$$\pi_{G,p,q}(S) = \frac{1}{Z} p^{|S|} (1-p)^{|E \setminus S|} q^{c(S)}, \quad (1)$$

where $c(S)$ is the number of connected components (including isolated vertices) in the subgraph (V, S) , and $Z = Z_{G,p,q}$ is the normalizing constant that makes $\pi_{G,p,q}$ a probability measure.

For *integer* $q \geq 2$ connectivities in the random-cluster model correspond to spin correlations in the Ising/Potts setting, and it is consequently viewed as a generalization of the ferromagnetic Ising/Potts model to non-integer values of q . The random-cluster model, however, is not a spin system in the usual sense, as the weight of a configuration S is not a function of local interactions between edges in G , but instead of global connectivity properties. This non-local structure is a crucial feature of the model but significantly complicates its analysis; for example, it allows boundary conditions to induce long-range connections in G .

We consider the random-cluster model on the $n \times n$ box Λ_n of \mathbb{Z}^2 , where, for $q \geq 1$, the model is also known to exhibit a phase transition corresponding to the emergence of long-range correlations in the form of large connected components [2]. That is, there exists a critical value $p = p_c(q) = \sqrt{q}/(\sqrt{q} + 1)$ such that, with high probability, when $p < p_c(q)$ all connected components are of size $O(\log n)$ whereas when $p > p_c(q)$ there exists a “giant” component of size $\Theta(n^2)$ [2].

A random-cluster boundary condition ξ on $\partial\Lambda_n$ is a partition $\{\xi_1, \xi_2, \dots\}$ of the boundary vertices such that all vertices in ξ_i are connected via “ghost” (or external) wirings; these connections are considered in the counting of $c(S)$ in (1) and can therefore impose highly non-local interactions. Of particular interest are boundary conditions where the partition is induced by the connectivity components of a random-cluster configuration on $E(\mathbb{Z}^2) \setminus E(\Lambda_n)$. We call such boundary conditions *realizable*. In fact, many works, including the standard text [21], often restrict attention to realizable boundary conditions, but non-realizable boundary conditions are still relevant in some cases.

The FK-dynamics. In this paper we study the *mixing time* of the FK-dynamics in the presence of boundary conditions. (The mixing time is the number of steps until a Markov chain is close to its stationary distribution in total variation distance, starting from the worst possible initial configuration.) For a configuration $S_t \subseteq E(\Lambda_n)$, a transition $S_t \rightarrow S_{t+1} \subseteq E(\Lambda_n)$ of the FK-dynamics is defined as follows:

1. Choose an edge $e \in E(\Lambda_n)$ uniformly at random;
2. let $S_{t+1} = S_t \cup \{e\}$ with probability

$$\frac{\pi_{\Lambda_n, p, q}(S_t \cup \{e\})}{\pi_{\Lambda_n, p, q}(S_t \cup \{e\}) + \pi_{\Lambda_n, p, q}(S_t \setminus \{e\})} = \begin{cases} \frac{p}{q(1-p)+p} & \text{if } e \text{ is a "cut-edge" in } (\Lambda_n, S_t); \\ p & \text{otherwise;} \end{cases}$$

3. else let $S_{t+1} = S_t \setminus \{e\}$.

We say e is a *cut-edge* in (Λ_n, S_t) if the number of connected components in $S_t \cup \{e\}$ and $S_t \setminus \{e\}$ differ. Under a boundary condition ξ , the property of e being a cut-edge is defined with respect to the augmented graph (Λ_n, S_t^ξ) . The FK-dynamics converges to (1) by construction, and we study its mixing time. We say the dynamics is *rapidly mixing* if the mixing time is polynomial in $|V|$, and *torpidly mixing* when the mixing time is exponential in $|V|^\varepsilon$ for some $\varepsilon > 0$.

Results. The FK-dynamics is quite powerful since it is known to mix in $\Theta(n^2 \log n)$ steps for all $q > 1$ both at high and low temperatures (i.e., for all $p \neq p_c(q)$) for certain “nice” boundary conditions that do not carry information about random-cluster connectivities in non-local ways: namely, configurations in different regions of Λ_n do not interact through these boundaries [5]. (In comparison, the Ising/Potts Glauber dynamics is torpidly mixing in the low-temperature regime.) Specifically, the tight mixing time bound in [5] holds under boundary conditions that are free (no boundary condition), wired (all boundary vertices are connected to one another) or periodic (the torus). More recently, [15] examined the cutoff phenomenon in the FK-dynamics at $p \ll p_c(q)$; they also restricted attention to periodic boundaries. At the critical $p = p_c(q)$ the FK-dynamics may exhibit torpid mixing depending on the “order” (i.e., the continuity) of the phase transition [16, 18]; notably, when $q \gg 1$ and $p = p_c(q)$, the mixing time may be exponential or sub-exponential depending on the choice of boundary conditions [17].

The stability of the FK-dynamics to the choice of boundary conditions remained unclear at $p \neq p_c(q)$; we show that the FK-dynamics is in fact rapidly mixing for *all* realizable boundary conditions at $p \neq p_c(q)$.

► **Theorem 1.1.** *For every $q > 1$, $p \neq p_c(q)$, there exists a constant $C > 0$ such that the mixing time of the FK-dynamics on the $n \times n$ box $\Lambda_n \subset \mathbb{Z}^2$ with any realizable boundary condition is $O(n^C)$.*

We pause to comment on the proof of Theorem 1.1. The proofs of fast mixing when $p \neq p_c(q)$ have relied crucially on a strong spatial mixing property, which in the random-cluster model would say that correlations between edges (even near $\partial\Lambda_n$) decay exponentially in the graph distance between them. It is easy to construct examples of realizable boundary conditions where this correlation does not decay at all, even if $p \ll p_c(q)$, as the boundary can enforce long-range interactions. Since the exponential decay of correlations does hold for edges at distance $\Theta(\log n)$ away from $\partial\Lambda_n$, we are able to reduce the proof of Theorem 1.1 to proving a polynomial upper bound for the mixing time of the FK-dynamics on thin rectangles of dimension $n \times \Theta(\log n)$ with realizable boundary conditions. This reduction is a byproduct

of a more general framework we describe in Section 3 for deriving mixing time estimates from spatial mixing properties. The analysis of the FK-dynamics on thin rectangles is then the key technical challenge for us; see Theorem 4.1 and Section 4.1 for a detailed outline of its proof and the novelties therein.

Theorem 1.1 shows a polynomial upper bound on the mixing time, uniformly over all realizable boundary conditions. Utilizing this theorem we can prove near-optimal $\tilde{O}(n^2)$ mixing time for “typical” boundaries. The notion of typicality should be understood as with high probability under some distribution over realizable boundary conditions, with a natural choice being the marginal of the infinite-volume random-cluster measure $\pi_{\mathbb{Z}^2, p, q}$ on $E(\mathbb{Z}^2) \setminus E(\Lambda_n)$ (when $p \neq p_c(q)$ this measure is unique: see [21]).

► **Theorem 1.2.** *Let $q > 1$, $p \neq p_c(q)$ and suppose ω is a random-cluster configuration sampled from $\pi_{\mathbb{Z}^2, p, q}$. Let ξ_ω be the boundary condition on $\partial\Lambda_n$ induced by the edges of ω in $\mathbb{Z}^2 \setminus \Lambda_n$. Then, there exists a constant $C > 0$ such that with probability $1 - o(1)$ the mixing time of the FK-dynamics on the $n \times n$ box Λ_n with boundary condition ξ_ω is $O(n^2(\log n)^C)$.*

The proof of Theorem 1.2 uses Theorem 1.1 in a crucial way. Typical boundary conditions do not exhibit the strong spatial mixing property from [5]; however, for such boundary conditions we are able to prove that correlations between edges near the boundary decay exponentially in their graph distance divided by a $\Theta(\log n)$ factor. Using this spatial mixing bound, together with the aforementioned general framework in Section 3, we reduce bounding the mixing time on Λ_n with typical boundaries to bounding the mixing time on $\Theta((\log n)^2) \times \Theta((\log n)^2)$ rectangles with arbitrary realizable boundary conditions. Theorem 1.1 implies that the mixing time of the FK-dynamics in these smaller rectangles is at most poly-logarithmic in n . Similar classes of typical boundary conditions were considered in [18] at $p = p_c(q)$.

Given that our rapid mixing result for realizable boundaries relies heavily on the planarity of the boundary connections in $\mathbb{Z}^2 \setminus \Lambda_n$, one may wonder whether rapid mixing holds for all possible FK boundary conditions (including those not realizable as configurations on $\mathbb{Z}^2 \setminus \Lambda_n$). We answer this in the negative, showing that there exist (non-realizable) boundaries for which the FK-dynamics is torpidly mixing even while $p \neq p_c(q)$. In fact, this torpid mixing holds at $p \ll p_c(q)$, which may sound especially surprising as correlations in the Gibbs measure $\pi_{\Lambda_n, p, q}$ die off faster as p decreases.

► **Theorem 1.3.** *Let $q > 2$. For every $\alpha \in (0, \frac{1}{2}]$ and $\lambda > 0$ there exists a boundary condition ξ , such that when $p = \lambda n^{-\alpha}$ the mixing time of the FK-dynamics on the $n \times n$ box Λ_n with boundary condition ξ is $\exp(\Omega(n^\alpha))$.*

Our proof of this theorem is constructive: we take any graph G on m edges for which torpid mixing of the FK-dynamics is known at some value of $p(m) < p_c(q)$ and show how to embed G into the boundary of Λ_n . We then develop a procedure to transfer mixing time bounds from G to Λ_n . The high-level idea is that for sufficiently small $p(m)$ the effect of the configuration away from the boundary is negligible, and the mixing time of the FK-dynamics on G completely governs the mixing time of FK-dynamics near the boundary $\partial\Lambda_n$. Therefore, we can use known torpid mixing results for the mean-field random-cluster model (the case where G is the complete graph) in its critical window at $q > 2$ [20, 4, 14, 19].

We remark that the requirement $q > 2$ appears to be sharp for Theorem 1.3, since it was recently shown that the mixing time of FK-dynamics when $q = 2$ is at most polynomial in the number of vertices on *any* graph and at every $p \in (0, 1)$ [22]. It is expected that this rapid mixing holds for all $q \leq 2$. We believe that our torpid mixing result may extend to small, but $\Omega(1)$ values of $p < p_c(q)$, though our current proof does not allow for this. In

principle, one would want to embed a bounded degree graph into $\partial\Lambda_n$, so that the value of p at which it exhibits slow mixing is $\Omega(1)$. There are already several examples of bounded degree graphs where torpid mixing is known [10, 6, 7, 16, 17].

Finally, we remark that by slight adaptations of the comparison results in [35, 36, 4], our theorems translate (up to polynomial factors in n) to bounds for the mixing times of popular non-local dynamics like the Chayes-Machta dynamics [9] and the Swendsen-Wang dynamics on FK configurations [35, 36, 4].

The paper is organized as follows. In Section 2, we define various preliminary notions that are used in our proofs. In Section 3, we introduce a general framework to deduce mixing time estimates on Λ_n from spatial and local mixing properties. We then present our key rapid mixing result for thin rectangles (Theorem 4.1) in Section 4, before completing the proof of Theorem 1.1 in Section 5. The proofs from Section 4 are deferred to Section 6, and those of Theorems 1.2 and 1.3 are included in the full manuscript [3].

2 Preliminaries: the random-cluster model in \mathbb{Z}^2

In this section we introduce a number of definitions, notation, and background results that we will refer to repeatedly. More details and proofs can be found in the books [21, 24]. We will be considering the random-cluster model on rectangular subsets of \mathbb{Z}^2 of the form $\Lambda_{n,l} = \{0, \dots, n\} \times \{0, \dots, l\} = \llbracket 0, n \rrbracket \times \llbracket 0, l \rrbracket$. When $n = l$, we use Λ_n for $\Lambda_{n,n}$. For simplicity, in this preliminary section we shall focus on the $n = l$ case, but everything stated here holds more generally for rectangular subsets with $n \neq l$.

Abusing notation, we will also use Λ_n for the graph $(\Lambda_n, E(\Lambda_n))$ where $E(\Lambda_n)$ consists of all nearest neighbor pairs of vertices in Λ_n . We denote by $\partial\Lambda_n$ the (inner) boundary of Λ_n ; that is the vertex set consisting of all vertices in Λ_n adjacent to vertices in $\mathbb{Z}^2 \setminus \Lambda_n$. A *boundary condition* ξ of Λ_n is a partition of the vertices in $\partial\Lambda_n$. When $u, v \in \partial\Lambda_n$ are in the same element of ξ , we say that they are *wired* in ξ . If there exists a random-cluster configuration ω on $E(\mathbb{Z}^2) \setminus E(\Lambda_n)$ such that $u, v \in \partial\Lambda_n$ are connected in ω if and only if they are wired in ξ , we say that the boundary condition ξ is *realizable*.

For $p \in (0, 1)$ and $q > 0$, the *random-cluster model* on Λ_n with boundary conditions ξ is the probability measure $\pi_{\Lambda_n, p, q}^\xi$ over the subsets $S \subseteq E(\Lambda_n)$ given by (1) with the $q^{c(S)}$ term replaced by $q^{c(S; \xi)}$, where $c(S; \xi)$ corresponds to the number of connected components in the augmented graph (Λ_n, S^ξ) and S^ξ adds auxiliary edges between all pairs of vertices in $\partial\Lambda_n$ that are in the same element of ξ . Every random-cluster configuration $S \subseteq E(\Lambda_n)$, can be identified with some $\omega : E(\Lambda_n) \rightarrow \{0, 1\}$ via $\omega(e) = 1$ if $e \in S$ (e is *open*) and $\omega(e) = 0$ if $e \notin S$ (e is *closed*). We sometimes interchange vertex sets with the subgraph they induce; e.g., the random-cluster configuration on a set $B \subset \mathbb{Z}^2$ corresponds to the configuration in the subgraph induced by B . We omit the subscripts p, q when understood from context.

Exponential decay of connectivities (EDC). A consequence of the results in [1, 2] is that for every $q > 1$ and $p < p_c(q)$, there is a $c = c(p, q) > 0$ such that for every boundary condition ξ and all $u, v \in \Lambda_n$,

$$\pi_{\Lambda_n, p, q}^\xi(u \overset{\Lambda_n}{\longleftrightarrow} v) \leq e^{-cd(u, v)}, \quad (2)$$

where $d(u, v)$ is the graph distance between u, v in \mathbb{Z}^2 and $u \overset{\Lambda_n}{\longleftrightarrow} v$ denotes that there is an open path between u and v in the FK configuration on $E(\Lambda_n)$ (not using the connections of ξ).

Monotonicity. Define a partial order over boundary conditions by $\xi \leq \eta$ if the partition corresponding to ξ is *finer* than that of η . The extremal boundary conditions then, are the *free* boundary where $\xi = \{\{v\} : v \in \partial\Lambda_n\}$, which we denote by $\xi = 0$, and the *wired* boundary where $\xi = \{\partial\Lambda_n\}$, denoted by $\xi = 1$. When $q > 1$, the random-cluster model satisfies the following monotonicity in boundary conditions: if ξ, η are two boundary conditions on $\partial\Lambda_n$ with $\xi \leq \eta$, then $\pi_{\Lambda_n}^\xi \preceq \pi_{\Lambda_n}^\eta$, which is to say that $\pi_{\Lambda_n}^\eta$ stochastically dominates $\pi_{\Lambda_n}^\xi$ with respect to the natural partial order on FK configurations.

Planar duality. Let $\Lambda_n^* = (\Lambda_n^*, E(\Lambda_n^*))$ denote the planar dual of Λ_n . That is, Λ_n^* corresponds to the set of faces of Λ_n , and for each $e \in E(\Lambda_n)$, there is a dual edge $e^* \in E(\Lambda_n^*)$ connecting the two faces bordering e . The random-cluster distribution satisfies $\pi_{\Lambda_n, p, q}(S) = \pi_{\Lambda_n^*, p^*, q}(S^*)$, where S^* is the dual configuration to $S \subseteq E$ (i.e., $e^* \in S^*$ iff $e \notin S$), and $p^* = q(1-p)/(q(1-p) + p)$. Notice that the infinite graph \mathbb{Z}^2 is isomorphic to its dual. The unique value of p satisfying $p = p^*$, denoted $p_{sd}(q)$, is called the *self-dual point* and [2] established that $p_c(q) = p_{sd}(q)$; recall that $p_c(q)$ is the critical point for the phase transition in \mathbb{Z}^2 .

Mixing time and spectral gap. Consider an ergodic (i.e., irreducible and aperiodic) Markov chain \mathcal{M} with finite state space Ω , transition matrix P and stationary distribution μ . The *mixing time* of \mathcal{M} is given by $t_{\text{MIX}} := t_{\text{MIX}}(1/4)$, where $t_{\text{MIX}}(\varepsilon) = \min\{t : \max_{X_0 \in \Omega} \|P^t(X_0, \cdot) - \mu\|_{\text{TV}} \leq \varepsilon\}$ and $\|\cdot\|_{\text{TV}}$ denotes total-variation distance. For any positive $\varepsilon < 1/2$, we have $t_{\text{MIX}}(\varepsilon) \leq \lceil \log_2 \varepsilon^{-1} \rceil t_{\text{MIX}}$. We use $t_{\text{MIX}}(\Lambda_n^\xi)$ to denote the mixing time of the FK-dynamics on $\Lambda_n \subset \mathbb{Z}^2$ with boundary condition ξ . If P is irreducible and reversible with respect to μ , then it has real eigenvalues $1 = \lambda_1 > \lambda_2 \geq \dots \geq \lambda_{|\Omega|} \geq -1$. The *spectral gap* of P is defined by $\text{gap}(P) = 1 - \max\{|\lambda_2|, |\lambda_{|\Omega|}|\}$, and the inverse of the spectral gap captures the mixing time up to a $O(\log(\mu_{\min}^{-1}))$ factor, where $\mu_{\min} := \min_{\omega \in \Omega} \mu(\omega)$. For the various dynamics consider in this paper this factor is $\text{poly}(n)$.

FK-dynamics and duality. Each run of the FK-dynamics on Λ_n , with realizable boundary conditions ξ and parameters p, q , determines a valid run of the FK-dynamics on the dual graph Λ_n^* with boundary conditions ξ^* and parameters p^*, q . (Simply identify the FK configuration in each step with its dual configuration; it can be straightforwardly verified that the transitions of the FK-dynamics on the dual graph occur with the correct probabilities.) Hence, the two dynamics have the same mixing times.

► **Remark 2.1.** The edge-set of the dual graph Λ_n^* is not exactly in correspondence with the edge-set of a rectangle $\Lambda^* = \{-\frac{1}{2}, \dots, n + \frac{1}{2}\} \times \{-\frac{1}{2}, \dots, n + \frac{1}{2}\}$ as it does not include any edges that are between boundary vertices of Λ^* . All the proofs in the paper carry through, only with the natural minor geometric modifications, to the case of rectangles Λ_n with modified edge-set that only contains edges edges with at least one endpoint in $\Lambda_n \setminus \partial\Lambda_n$. The dual of this modified graph is then a $(n - 1) \times (n - 1)$ rectangle with all nearest-neighbor edges. With these considerations, it often suffices for us to prove our theorems for $p < p_c(q)$. For example, it is sufficient to prove Theorem 1.1 for $p < p_c(q)$.

3 Mixing time upper bounds: a general framework

In this section we introduce a general framework for bounding the mixing time of the FK-dynamics on $\Lambda_n = (\Lambda_n, E(\Lambda_n))$ by its mixing times on certain smaller subsets. In [5] it was shown that a strong form of spatial mixing (encoding exponential decay of correlations uniformly over subsets of Λ_n) implies optimal mixing of the FK-dynamics. However, this

notion, known as *strong spatial mixing (SSM)* and described in Remark 3.2, does not hold for many boundary conditions for which fast mixing of the FK-dynamics is still expected. To circumvent this, we introduce a weaker notion, which we call *moderate spatial mixing (MSM)*.

We introduce some notation first. For a set $R \subseteq \Lambda_n$, let $E(R) \subseteq E_n$ be the set of edges of $E(\Lambda_n)$ with both endpoints in R . We will denote by R^c the vertex set $\Lambda_n \setminus R$ and by $E^c(R)$ the edge-complement of R ; i.e., $E^c(R) := E(\Lambda_n) \setminus E(R)$. For a configuration $\omega : E(\Lambda_n) \rightarrow \{0, 1\}$, we will use $\omega(R)$, or alternatively $\omega(E(R))$, for the configuration of ω on $E(R)$. With a slight abuse of notation, for an edge set $F \subseteq E(\Lambda_n)$, we use $\{F = \omega\}$ for the event that the configuration on F is given by ω ; when ω is the all free or the all wired configuration, we simply use $\{F = 0\}$ and $\{F = 1\}$, respectively.

► **Definition 3.1.** Let $\mathcal{B} = \{B_1, B_2, \dots, B_k\}$ be a collection of subsets of $\Lambda_n = (\Lambda_n, E(\Lambda_n))$ and let ξ be a boundary condition on Λ_n . We say that moderate spatial mixing (MSM) holds on Λ_n for ξ , \mathcal{B} and $\delta > 0$ if for all $e \in E(\Lambda_n)$, there exists $B_j \in \mathcal{B}$ such that

$$\left| \pi_{\Lambda_n, p, q}^\xi(e = 1 \mid E(B_j^c) = 1) - \pi_{\Lambda_n, p, q}^\xi(e = 1 \mid E(B_j^c) = 0) \right| \leq \delta. \quad (3)$$

In words, MSM holds for \mathcal{B} if for every edge $e \in E(\Lambda_n)$ we can find B_j such that $e \in B_j$ and the “influence” of the configuration on $\Lambda_n \setminus B_j$ on the state of e is bounded by δ .

► **Remark 3.2.** SSM as defined in [5] holds when

MSM holds for a specific sequence of collections of subsets: if \mathcal{B}_r is the set of subsets containing all the square boxes of side length $2r$ centered at each $e \in E(\Lambda_n)$ (intersected with $E(\Lambda_n)$), then SSM holds if MSM holds for \mathcal{B}_r for every $r \geq 1$ with $\delta = \exp(-\Omega(r))$.

MSM does not capture the fast mixing of the FK-dynamics the way SSM does; it is easy to find collections of subsets for which MSM holds for *all* boundary conditions, including those boundary conditions for which we later prove slow mixing (Theorem 1.3). However, if, for a collection $\mathcal{B} = \{B_1, \dots, B_k\}$, we also bound the mixing time of the FK-dynamics on every B_j , we can deduce a mixing time bound for the FK-dynamics on Λ_n . Let $t_{\text{MIX}}(B^\tau)$ denote the mixing time of the FK-dynamics on $B \subseteq \Lambda_n$ with boundary condition τ .

► **Definition 3.3.** Let $\mathcal{B} = \{B_1, B_2, \dots, B_k\}$ be a collection of subsets of $\Lambda_n = (\Lambda_n, E(\Lambda_n))$ and let ξ be a boundary condition on Λ_n . We say that local mixing (LM) holds for \mathcal{B} and $T > 0$, if

$$t_{\text{MIX}}(B_j^{(1, \xi)}) \leq T \quad \text{and} \quad t_{\text{MIX}}(B_j^{(0, \xi)}) \leq T \quad \text{for all } j = 1, \dots, k$$

where $(1, \xi)$ (resp., $(0, \xi)$) denotes the boundary condition on B_j induced by the event $\{E(B_j^c) = 1\}$ (resp., $\{E(B_j^c) = 0\}$) and the boundary condition ξ .

► **Remark 3.4.** When $B_j \cap \partial\Lambda_n = \emptyset$, $(1, \xi)$ and $(0, \xi)$ are simply the wired and free boundary condition on B_j , respectively. When $B_j \cap \partial\Lambda_n \neq \emptyset$, ξ could also induce some connections in $(1, \xi)$ and $(0, \xi)$.

Our next theorem, roughly speaking, establishes the following implication:

$$\text{MSM} + \text{LM} \implies \text{upper bound for mixing time of FK-dynamics,}$$

with the quality of the bound depending on the T for which LM holds. A similar (and inspiring) implication for the Glauber dynamics of the Ising model in graphs of bounded degree was established by Mossel and Sly in [30]; there, the notion of MSM is replaced by a form of spatial mixing which is stronger than SSM. The proof of this theorem is provided in the full version of this paper [3].

► **Theorem 3.5.** Let ξ be a boundary condition on $\Lambda_n = (\Lambda_n, E(\Lambda_n))$ and let $\mathcal{B} = \{B_1, B_2, \dots, B_k\}$ with $B_j \subset \Lambda_n$ for all $j = 1, \dots, k$. If for ξ and \mathcal{B} , moderate spatial mixing holds for some $\delta \leq 1/(12|E(\Lambda_n)|)$ and local mixing holds for some $T > 0$, then $t_{\text{MIX}}(\Lambda_n^\xi) = O(Tn^2 \log n)$.

Figure 1 (a) A boundary condition for which no configuration in $B_W \cap B_E$ isolates $B_W \setminus B_E$ from $B_E \setminus B_W$. (b) A boundary condition ξ where every pair of overlapping rectangles must interact through ξ ; the two groups of rectangles $\mathcal{R}_1, \mathcal{R}_2$ do not interact through ξ . (c) A boundary condition with disconnecting intervals: $[[a_1, a_4]]$ of free-type; $[[a_1, a_2]], [[a_3, a_4]], [[a_0, a_6]]$ of free-wired-type; and $[[a_0, a_5]], [[a_5, a_6]]$ of wired-type.

4 Fast mixing on thin rectangles

The main difficulty in proving Theorem 1.1 using the general framework from Section 3 is obtaining mixing time estimates for the FK-dynamics on thin rectangles of dimension $\Theta(n) \times \Theta(\log n)$ with realizable boundary conditions. To motivate this we notice that in Λ_n , when $p \neq p_c(q)$, the influence of the boundary condition is lost with high probability at a distance $\Theta(\log n)$ from $\partial\Lambda_n$. (This is a consequence of the EDC property when $p < p_c(q)$, or the corresponding dual property when $p > p_c(q)$.) Consequently, the main challenge will be to establish the mixing time of the FK-dynamics in the annulus of width $\Theta(\log n)$ with realizable boundary conditions on the outside. The key ingredient in the proof of Theorem 1.1 will be the following mixing time estimate on thin rectangles. For an $n \times l$ rectangle $\Lambda_{n,l} = [0, n] \times [0, l]$, let $\partial_N\Lambda_{n,l}, \partial_E\Lambda_{n,l}, \partial_S\Lambda_{n,l}$ and $\partial_W\Lambda_{n,l}$ denote its north, east, south and west boundaries respectively.

► **Theorem 4.1.** *Consider $\Lambda_{n,l} = (\Lambda_{n,l}, E(\Lambda_{n,l}))$ for $l \leq n$ with an arbitrary realizable boundary condition ξ that is either free or wired on $\partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l} \cup \partial_S\Lambda_{n,l}$. Then, for every $q > 1$ and $p \neq p_c(q)$, the mixing time of the FK-dynamics on $\Lambda_{n,l}$ is at most $\exp(O(l + \log n))$.*

When $l = O(\log n)$, this implies the mixing time is $n^{O(1)}$, which will be the setting of interest in our proofs. Moreover, we note that it suffices to prove Theorem 4.1 for the set of realizable boundary conditions ξ that are free on $\partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l} \cup \partial_S\Lambda_{n,l}$ for all $p \neq p_c(q)$, as the set of boundary conditions dual to these are exactly the set of realizable boundary conditions that are wired on $\partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l} \cup \partial_S\Lambda_{n,l}$; see Remark 2.1.

4.1 Proof of Theorem 4.1

Remarks about previous methods. To motivate our proof approach, we first mention some obstructions that FK boundary conditions present if we tried to adapt methods for the analogous problems in the context of spin systems. A traditional technique to proving mixing time bounds for thin rectangles is the canonical paths method ([26, 27, 23, 32]), which gives an upper bound that is exponential in the shorter side length; however, this approach relies on bounding the *cut-width* of $\Lambda_{n,l}$ which can be significantly distorted in the augmented graph $\Lambda_{n,l}^\xi$ by the FK boundary conditions ξ .

A sharper technique is an inductive scheme [8, 27, 18], whereby, the mixing time of the FK-dynamics on the rectangle $\Lambda_{n \times l}$ is bounded by the mixing times in two smaller (overlapping) rectangular subsets, e.g., the left two-thirds $B_W = [0, \frac{2}{3}n] \times [0, l]$ and the right two-thirds $B_E = [\frac{1}{3}n, n] \times [0, l]$; see Figure 1(a). This approach requires bounding the spectral gap of a *block dynamics*, whose updates consist of resampling the configuration on a random block $B_i \in \{B_W, B_E\}$ from $\pi_{\Lambda_{n,l}}^\xi$ conditional on the configuration on $E^c(B_i)$.

It follows from classical results that the spectral gap of the FK-dynamics on $\Lambda_{n,l}$ is bounded from below by the spectral of the block dynamics times the worst spectral gap of the FK-dynamics in any block B_i , assuming a worst-case configuration on $E^c(B_i)$; see, e.g., Proposition 3.4 in [27]. With the choice of blocks B_W, B_E , applying this recursively, the spectral gap of the FK-dynamics on $\Lambda_{n,l}$ is bounded from below by the gap of the block dynamics raised to a $\Theta(\log n)$ power. Therefore, establishing Theorem 4.1 requires an $\Omega(1)$ lower bound on the spectral gap of the block dynamics.

The spectral gap of the block dynamics is typically bounded by showing that after the first block update in either B_W or B_E , the configuration in $B_W \cap B_E$ disconnects the influence of the configuration on $B_W \setminus B_E$ from $B_E \setminus B_W$ with probability $\Omega(1)$. This would then allow a standard coupling argument to lower bound the spectral gap by $\Omega(1)$. In the presence of long-range boundary connections, however, it could be that no configuration on $B_W \cap B_E$ would disconnect the two sides from one another and facilitate coupling; see Figure 1(b) for such an example. As such, our choices of blocks will depend on the boundary conditions and will be chosen to allow for the block dynamics to couple in $O(1)$ time, while ensuring that the blocks are still at most a fraction of the size of the original rectangle, so that after $O(\log n)$ recursive steps we arrive at a sufficiently small base scale.

Definitions and main results for thin rectangles. As Figure 1(b) demonstrates, there are realizable boundary conditions that would force the blocks for the block dynamics to not be single rectangles, but rather unions of rectangular subsets of $\Lambda_{n,l}$ of the form $R = \llbracket a, b \rrbracket \times \llbracket 0, l \rrbracket$ with $0 \leq a < b \leq n$; for ease of notation, let $\llbracket a, b \rrbracket^c = \llbracket 0, n \rrbracket \setminus \llbracket a, b \rrbracket$. Our recursive argument will proceed instead on *groups of rectangles*.

► **Definition 4.2.** Let $m = C_\star \log l$ where C_\star is a suitably large constant. A group of rectangles $\mathcal{R} = \bigcup_{i=1}^{N(\mathcal{R})} R_i$ is the union of $N(\mathcal{R})$ disjoint rectangular subsets $R_i = \llbracket a_i, b_i \rrbracket \times \llbracket 0, l \rrbracket$ of $\Lambda_{n,l}$ such that $W(R_i) := b_i - a_i \geq 2m$ for every $i = 1, \dots, N(\mathcal{R})$.

The requirement that the width $W(R_i)$ of every constituent rectangle R_i is at least $2m$, is so that the interior of the R_i 's can be isolated from the configuration on $E(\Lambda_{n,l}) \setminus E(\mathcal{R})$. Indeed, the constant C_\star is chosen so that $C_\star > c^{-1}$ with c being the constant from the EDC property (2).

We show that for every group of rectangle \mathcal{R} there is a choice of two suitable blocks, which in turn will be group of rectangles, for the block dynamics. By suitable we mean two group of rectangles whose width are a constant fraction of that of \mathcal{R} and that are sufficiently isolated from one another in ξ ; see Proposition 4.6. (The width of a group of rectangles $\mathcal{R} = \bigcup_{i=1}^{N(\mathcal{R})} R_i$, denoted $W(\mathcal{R})$, is simply the sum of the width of its constituent rectangles; that is $W(\mathcal{R}) = \sum_{i=1}^{N(\mathcal{R})} W(R_i)$.)

For this, we introduce the key notions of *disconnecting intervals* of a boundary condition ξ and *compatibility* of a group of rectangles $\mathcal{R} \subset \Lambda_{n,l}$ with ξ . These allow us to manage the unwieldy interactions that may be induced by the realizable boundary condition ξ . Roughly speaking, a disconnecting interval is a segment $\llbracket a, b \rrbracket \times \ell$ of $\partial_N \Lambda_{n,l}$ that has no interaction through ξ with the remaining vertices in $\partial_N \Lambda_{n,l}$.

► **Definition 4.3.** For a realizable boundary condition ξ on $\Lambda_{n,l}$ that is free on $\partial_E \Lambda_{n,l} \cup \partial_S \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$, an interval $\llbracket a, b \rrbracket \subset \llbracket 0, n \rrbracket$ is called *disconnecting* of

1. free-type: if there are no boundary connections in ξ between $\llbracket a, b \rrbracket \times \{l\}$ and $\llbracket a, b \rrbracket^c \times \{l\}$.
2. wired-type: if there is a boundary component in ξ that contains both vertices (a, l) and (b, l) .

Observe that an interval can be both of free-type and of wired-type if (a, l) and (b, l) are connected through ξ but are not connected to any boundary vertex in $\llbracket a, b \rrbracket^c \times \llbracket 0, l \rrbracket$; in this case, we may refer to the interval as being of *free-wired-type*; see Figure 1(c) for several examples.

We say a group of rectangles \mathcal{R} is compatible with ξ if the boundary interactions between the rectangular subsets of \mathcal{R} are limited in the following way.

► **Definition 4.4.** *Let $\mathcal{R} = \bigcup_{i=1}^{N(\mathcal{R})} R_i$ be a group of rectangles with $R_i = \llbracket a_i, b_i \rrbracket \times \llbracket 0, l \rrbracket$ and $a_1 < b_1 < \dots < a_{N(\mathcal{R})} < b_{N(\mathcal{R})}$. Let ξ be a realizable boundary condition on $\Lambda_{n,l}$ that is free on $\partial_S \Lambda_{n,l} \cup \partial_E \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$, and free in all vertices in $\partial_N \Lambda_{n,l}$ at distance at most m from $\partial_E \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$.*

We say \mathcal{R} is compatible with ξ , if

1. *Between every two consecutive rectangles $R_i = \llbracket a_i, b_i \rrbracket \times \llbracket 0, l \rrbracket$ and $R_{i+1} = \llbracket a_{i+1}, b_{i+1} \rrbracket \times \llbracket 0, l \rrbracket$ the interval $\llbracket b_i - m, a_{i+1} + m \rrbracket$ is a disconnecting interval; and*
2. *The interval $\llbracket a_1 + m, b_{N(\mathcal{R})} - m \rrbracket$ is also a disconnecting interval.*

It is clear from the definition that $\Lambda_{n,l}$ is compatible with ξ : the first condition is vacuous, while the second is satisfied by the additional assumption that all vertices a distance at most m from $\partial_E \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$ are free (i.e., they appear as singletons in the corresponding boundary partition)

With the definition of group of rectangles, disconnecting intervals and compatibility in hand, we can now design a “splitting” algorithm for picking two blocks $\mathcal{R}_{\text{INT}}, \mathcal{R}_{\text{EXT}}$ for the block dynamics with the desired properties. The following lemma, proved in Section 6, provides the basis of such an algorithm.

► **Lemma 4.5.** *Let ξ be a realizable boundary condition on $\partial \Lambda_{n,l}$ that is free on $\partial_S \Lambda_{n,l} \cup \partial_E \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$ and free in all vertices in $\partial_N \Lambda_{n,l}$ at distance at most m from $\partial_E \Lambda_{n,l} \cup \partial_W \Lambda_{n,l}$. For every group of rectangles $\mathcal{R} = \bigcup_{i=1}^{N(\mathcal{R})} R_i$ compatible with ξ , with $W(\mathcal{R}) \geq 100m$, there exists a disconnecting interval $\llbracket c_\star, d_\star \rrbracket$ such that $(c_\star, l), (d_\star, l) \in \partial_N \mathcal{R}$, are distance at least m from the vertical sides $\bigcup_{i=1}^{N(\mathcal{R})} \partial_W R_i \cup \partial_E R_i$ of \mathcal{R} , and*

$$\frac{1}{4}W(\mathcal{R}) \leq W(\mathcal{R} \cap (\llbracket c_\star, d_\star \rrbracket \times \llbracket 0, l \rrbracket)) \leq \frac{3}{4}W(\mathcal{R}).$$

With the disconnecting interval $\llbracket c_\star, d_\star \rrbracket$ from Lemma 4.5, we define $\mathcal{A}_{\text{INT}} = \mathcal{R} \cap (\llbracket c_\star, d_\star \rrbracket \times \llbracket 0, l \rrbracket)$ and $\mathcal{A}_{\text{EXT}} = \mathcal{R} \cap (\llbracket c_\star, d_\star \rrbracket^c \times \llbracket 0, l \rrbracket)$. Their enlargements by m will form the blocks \mathcal{R}_{INT} and \mathcal{R}_{EXT} :

$$\mathcal{R}_{\text{INT}} = \mathcal{R} \cap (\llbracket c_\star - m, d_\star + m \rrbracket \times \llbracket 0, l \rrbracket) \quad \text{and} \quad \mathcal{R}_{\text{EXT}} = \mathcal{R} \cap ((\llbracket 0, c_\star + m \rrbracket \cup \llbracket d_\star - m, l \rrbracket) \times \llbracket 0, l \rrbracket);$$

These sets are depicted in Figure 2(a)–(b). The requirement that the corners of $\llbracket c_\star, d_\star \rrbracket \times \llbracket 0, l \rrbracket$ are a distance at least m from the vertical sides of \mathcal{R} is so that when we enlarge the sets $\mathcal{A}_{\text{INT}}, \mathcal{A}_{\text{EXT}}$ by m , we do not overflow beyond the rectangles containing (c_\star, l) and (d_\star, l) . Crucially, our ability to pick disconnecting segments that satisfy this requirement is guaranteed by the compatibility of \mathcal{R} with ξ .

It follows from Lemma 4.5, and the definitions of disconnecting interval and compatibility, that \mathcal{R}_{INT} and \mathcal{R}_{EXT} have the following properties, which will facilitate our recursive argument to prove Theorem 4.1.

► **Proposition 4.6.** *If \mathcal{R} is a group of rectangles compatible with ξ , and moreover, $W(\mathcal{R}) \geq 100m$, then the sets \mathcal{R}_{INT} and \mathcal{R}_{EXT} are groups of rectangles satisfying the following properties:*

1. $\frac{1}{5}W(\mathcal{R}) \leq W(\mathcal{R}_{\text{INT}}) \leq \frac{4}{5}W(\mathcal{R})$ and likewise $\frac{1}{5}W(\mathcal{R}) \leq W(\mathcal{R}_{\text{EXT}}) \leq \frac{4}{5}W(\mathcal{R})$;
2. Both \mathcal{R}_{INT} and \mathcal{R}_{EXT} are compatible with ξ .

■ **Figure 2** (a) The cores \mathcal{A}_{INT} and \mathcal{A}_{EXT} and (b) the blocks \mathcal{R}_{INT} and \mathcal{R}_{EXT} . The blocks \mathcal{R}_{INT} and \mathcal{R}_{EXT} are the enlargements of \mathcal{A}_{INT} and \mathcal{A}_{EXT} by exactly m , and are thus, themselves, groups of rectangles.

Finally, we consider the spectral gap of the block dynamics $\{X_t\}$ on \mathcal{R} with blocks $\mathcal{B} = \{\mathcal{R}_{\text{INT}}, \mathcal{R}_{\text{EXT}}\}$. In this case, $\{X_t\}$ is the discrete-time Markov chain that in each step picks i uniformly at random from $\{\text{INT}, \text{EXT}\}$ and updates the configuration in $E(\mathcal{R}_i)$ with a sample from the stationary distribution of the chain conditional on the configuration on $E^c(\mathcal{R}_i)$. Let $\text{gap}(\mathcal{R}^\zeta; \mathcal{B})$ be the spectral gap of this block dynamics on the group of rectangle \mathcal{R} with boundary condition ζ induced on \mathcal{R} by ξ and a fixed random-cluster configuration $\omega_{\mathcal{R}^c}$ on $E^c(\mathcal{R}) = E(\Lambda_{n,l}) \setminus E(\mathcal{R})$; hence, we may identify ζ with the pair $(\xi, \omega_{\mathcal{R}^c})$.

► **Lemma 4.7.** *Let ξ be a realizable boundary condition on $\partial\Lambda_{n,l}$ that is free on $\partial_S\Lambda_{n,l} \cup \partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$ and free on vertices in $\partial_N\Lambda_{n,l}$ at distance at most m from $\partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$. For every $q > 1$ and $p \neq p_c(q)$, there exists $K = K(p, q) \geq 1$ such that for every group of rectangles \mathcal{R} compatible with ξ , and every configuration $\omega_{\mathcal{R}^c}$ on $E^c(\mathcal{R})$, we have $\text{gap}(\mathcal{R}^{(\xi, \omega_{\mathcal{R}^c})}; \mathcal{B}) \geq K^{-1}$.*

The proof of Lemma 4.7 is deferred to Section 6. We are now ready to prove Theorem 4.1.

Proof of Theorem 4.1. Fix $q > 1$, $p \neq p_c(q)$ and $\Lambda_{n,l}$ with a realizable boundary condition ξ' that is free on $\partial_E\Lambda_{n,l} \cup \partial_S\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$. We modify ξ' to a boundary condition ξ that is also free on all vertices a distance at most $m = C_* \log l$ from $\partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$ at a cost of an exponential in m factor in the mixing time of the FK-dynamics (see Lemma 2.3 in [3]). Let ξ be the resulting realizable boundary condition.

Let $\mathcal{R} \subset \Lambda_{n,l}$ be a group of rectangles that is compatible with ξ and has $W(\mathcal{R}) = s$ for $100m \leq s \leq n$. Let \mathcal{R}_{INT} and \mathcal{R}_{EXT} be the group rectangles defined earlier and consider the block dynamics with respect to these blocks. Recall that we use $\text{gap}(\mathcal{R}^\zeta)$ and $\text{gap}(\mathcal{R}^\zeta; \mathcal{B})$ for the spectral gaps of the FK-dynamics and the blocks dynamics with respect to $\mathcal{B} = \{\mathcal{R}_{\text{INT}}, \mathcal{R}_{\text{EXT}}\}$ respectively. As discussed earlier, for any boundary condition $\zeta = (\xi, \omega_{\mathcal{R}^c})$, Proposition 3.4 from [27] implies that for a suitable constant $\gamma \in (0, 1)$

$$\text{gap}(\mathcal{R}^\zeta) \geq \gamma \cdot \text{gap}(\mathcal{R}^\zeta; \mathcal{B}) \cdot \min_{\substack{i \in \{\text{INT}, \text{EXT}\} \\ \omega \in \Omega(\mathcal{R}_i^c)}} \text{gap}(\mathcal{R}_i^{(\xi, \omega)}) \geq \frac{\gamma}{K} \cdot \min_{\substack{i \in \{\text{INT}, \text{EXT}\} \\ \omega \in \Omega(\mathcal{R}_i^c)}} \text{gap}(\mathcal{R}_i^{(\xi, \omega)}), \quad (4)$$

where the second inequality follows from Lemma 4.7 and $\Omega(\mathcal{R}_i^c)$ is the set of FK configurations on $E(\mathcal{R}_i^c)$. Observe that Proposition 4.6 implies that $\max\{W(\mathcal{R}_{\text{INT}}), W(\mathcal{R}_{\text{EXT}})\} \leq 4s/5$. Therefore, applying (4) $O(\log n)$ times, we deduce that $\text{gap}(\mathcal{R}^\zeta) \geq \exp(\Omega(-\log n)) \cdot \text{gap}(\mathcal{R}_0^{\zeta_0})$, where \mathcal{R}_0 is a group of rectangles with $W(\mathcal{R}_0) \leq 100m$ and $\zeta_0 = (\xi, \omega_0)$ is an arbitrary boundary condition for \mathcal{R}_0 .

Finally, since $|\partial\mathcal{R}_0| = O(m + l) = O(l)$, the lower bound for $\text{gap}(\mathcal{R}_0^{\zeta_0})$ follows from the following crude argument. Observe that we can first modify the boundary condition ζ_0 to be all free on all of $\partial\mathcal{R}_0$, incurring a cost of a $q^{-\Omega(l)}$ factor in the spectral gap; see Lemma 2.3 in [3]. The fast mixing result from [5] for the free boundary condition then implies that $\text{gap}(\mathcal{R}_0^{\zeta_0}) \geq \exp(-\Omega(l))$ and so the result follows. ◀

■ **Figure 3** Subsets (a) C_{NE} , C_{NW} , C_{SE} , and C_{SW} and (b) R_N , R_E , R_W and R_S . (c) $B(e, r)$ for two edges e of Λ_n .

5 Polynomial mixing time for realizable boundary conditions

In this section we finalize the proof of Theorem 1.1 for $p < p_c(q)$ using the technology introduced in Section 3; namely, we construct a collection of subsets \mathcal{B} for which we can establish LM and MSM; see Definitions 3.1–3.3. To establish LM we crucially use Theorem 4.1. The results for $p > p_c(q)$ follow from the self-duality of the model and of realizable boundary conditions, as explained in Section 2.

For general realizable boundary conditions, proving LM for a collection of subsets \mathcal{B} for which MSM holds is the main challenge. This is because, for MSM to hold for a collection \mathcal{B} for all realizable boundary conditions, a subset in \mathcal{B} needs to contain $\Omega(n)$ edges. In particular, some element of \mathcal{B} must include most (or all) edges near $\partial\Lambda_n$, as otherwise it is easy to construct examples of realizable boundary conditions for which MSM does not hold. Thus, a trivial (exponential in the perimeter) upper bound for the mixing time on those subsets with $\Omega(n)$ edges would be unhelpful, and we ought to use Theorem 4.1 instead.

We define a collection of blocks for which we can establish both LM and MSM. Let $r \in \mathbb{N}$ and let $C_{NE}, C_{NW}, C_{SE}, C_{SW} \subset \Lambda_n$ be the four square boxes of side length $5r$ with a corner that coincides with a corner of Λ_n ; see Figure 3(a). Let $R_N \subset \Lambda_n$ be the $(n - 6r) \times 2r$ rectangle at distance $3r$ from both $\partial_W\Lambda_n, \partial_E\Lambda_n$ whose top boundary is contained in $\partial_N\Lambda_n$ and let R_E, R_W, R_S be defined analogously; see Figure 3(b). Let $R = R_N \cup R_E \cup R_W \cup R_S$. Now, for $e \in E(\Lambda_n)$, let $B(e, r) \subset \Lambda_n$ be the set of vertices in the minimal square box around e such that $d(\{e\}, \Lambda_n \setminus B(e, r)) \geq r$. If $d(\{e\}, \partial\Lambda_n) > r$, then $B(e, r)$ is just a square box of side length $2r + 1$ centered at e ; otherwise $B(e, r)$ intersects $\partial\Lambda_n$; see Figure 3(c). Finally, let

$$\mathcal{B}_r = \{C_{NE}, C_{NW}, C_{SE}, C_{SW}, R\} \cup \{B(e, r) : e \in E(\Lambda_n), d(\{e\}, \partial\Lambda_n) > r\}. \tag{5}$$

We claim that LM holds for \mathcal{B}_r with $r = \Theta(\log n)$ and $T = O(n^C)$ for some constant $C > 0$.

► **Theorem 5.1.** *Let $q \geq 1$, $p < p_c(q)$ and $r = c_0 \log n$ with $c_0 > 0$ independent of n . There exists a constant $C > 0$ such that LM holds for every realizable boundary condition ξ and \mathcal{B}_r with $T = O(n^C)$.*

The subsets $B(e, r)$ in \mathcal{B}_r and the corner boxes C_{NE}, C_{NW}, C_{SE} and C_{SW} are small enough that crude bounds for their mixing times are sufficient. As mentioned earlier, the main challenge for proving local mixing for \mathcal{B}_r is to derive a mixing time bound for $R = R_N \cup R_E \cup R_W \cup R_S$ as it intersects the boundary of Λ_n and contains $\Omega(n)$ vertices. To establish such a bound we rely on Theorem 4.1. In particular, we relate the mixing time of the FK-dynamics on R

to that of the FK-dynamics on a single thin rectangle by concatenating the four rectangles constituting R , one after another, such that the union of their outer boundaries make up the northern boundary of the new rectangle.

The final ingredient of the proof is establishing MSM for the collection \mathcal{B}_r . We show that MSM holds for \mathcal{B}_r with $r = \Theta(\log n)$ for all realizable boundary conditions ξ where the vertices in $\partial\Lambda_n$ at distance $5r$ from the corners of Λ_n are free in ξ . This is sufficient since any realizable boundary condition can be turned into a realizable boundary condition with this property by simply removing all connections in ξ involving vertices near the corners of Λ_n ; this modification can change the mixing time of the FK-dynamics by a factor of at most $\exp(O(r))$; see Lemma 2.3 in [3].

► **Theorem 5.2.** *Let $q \geq 1$, $p < p_c(q)$ and $r = c_0 \log n$ with $c_0 > 0$ independent of n . Let ξ be a realizable boundary condition with the property that every vertex $v \in \partial\Lambda_n$ at distance at most $5r$ from a corner of Λ_n is free in ξ . Then, for all sufficiently large $c_0 > 0$, MSM holds for ξ and \mathcal{B}_r with $\delta < 1/(12|E(\Lambda_n)|)$.*

Theorem 1.1 follows from Theorems 3.5 and 5.1–5.2. Their proofs are found in the full version [3].

6 Proofs from Section 4

We prove here the two key results from Section 4: Lemmas 4.5 and 4.7. We begin with the proof of Lemma 4.5 which describes how to find an appropriate disconnecting interval for the block dynamics in a group of rectangles \mathcal{R} . The proof uses the following important geometric observations regarding disconnecting intervals. For more details we refer to [3].

► **Lemma 6.1.** *Let ξ be a realizable boundary condition on $\Lambda_{n,l}$ that is free on $\partial_S\Lambda_{n,l} \cup \partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$ and let $a < b < c$. If both $\llbracket a, b \rrbracket$ and $\llbracket b, c \rrbracket$ are disconnecting intervals of wired-type, then so is $\llbracket a, c \rrbracket$. If both $\llbracket a, b \rrbracket$ and $\llbracket b+1, c \rrbracket$ are disconnecting intervals of free-type, then so is $\llbracket a, c \rrbracket$.*

► **Lemma 6.2.** *Let ξ be a realizable boundary condition on $\Lambda_{n,l}$ that is free on $\partial_S\Lambda_{n,l} \cup \partial_E\Lambda_{n,l} \cup \partial_W\Lambda_{n,l}$. Suppose there exist $a < b < c < d$ such that $\llbracket a, c \rrbracket$ and $\llbracket b, d \rrbracket$ are disconnecting intervals; then either both are of free-type or both are of wired-type. Moreover, if both are*

1. *of wired-type: then $\llbracket a, b \rrbracket$, $\llbracket b, c \rrbracket$, $\llbracket c, d \rrbracket$ and $\llbracket a, d \rrbracket$ are all disconnecting intervals of wired-type.*
2. *of free-type: then $\llbracket a, b-1 \rrbracket$, $\llbracket b, c \rrbracket$, $\llbracket c+1, d \rrbracket$ and $\llbracket a, d \rrbracket$ are all disconnecting intervals of free-type.*

Proof of Lemma 4.5. We find a candidate disconnecting interval $\llbracket c, d \rrbracket$ with $(c, l), (d, l) \in \partial_N\mathcal{R}$ satisfying:

$$\frac{1}{3}W(\mathcal{R}) \leq W(\mathcal{R} \cap (\llbracket c, d \rrbracket \times \llbracket 0, l \rrbracket)) \leq \frac{2}{3}W(\mathcal{R}). \quad (6)$$

In the second part of the proof we show how to modify $\llbracket c, d \rrbracket$ to obtain a disconnecting interval $\llbracket c_*, d_* \rrbracket$ with the added property that both (c_*, l) and (d_*, l) are distance at least m from $\partial_{\parallel}\mathcal{R} := \bigcup_{i=1}^{N(\mathcal{R})} \partial_W R_i \cup \partial_E R_i$.

If there exist vertices $(x, l), (y, l) \in \partial_N\mathcal{R}$ such that $\frac{1}{3}W(\mathcal{R}) \leq W(\mathcal{R} \cap (\llbracket x, y \rrbracket \times \llbracket 0, l \rrbracket)) \leq \frac{2}{3}W(\mathcal{R})$ with (x, l) connected to (y, l) through ξ , then we take $c = x$, $d = y$ and use $\llbracket c, d \rrbracket = \llbracket x, y \rrbracket$ as our candidate disconnecting interval. Suppose otherwise that there does not

exist any such boundary connection: then every pair $(x, l), (y, l) \in \partial_N \mathcal{R}$ connected through ξ is such that

$$W(\mathcal{R} \cap (\llbracket x, y \rrbracket \times \llbracket 0, l \rrbracket)) < \frac{1}{3}W(\mathcal{R}), \quad \text{or} \quad W(\mathcal{R} \cap (\llbracket x, y \rrbracket \times \llbracket 0, l \rrbracket)) > \frac{2}{3}W(\mathcal{R}). \quad (7)$$

If the latter holds, then there is a pair, say $(x_0, l), (y_0, l) \in \partial_N \mathcal{R}$, for which the latter holds with a minimal width. Consequently, all other connections through ξ between vertices $(x_1, l), (y_1, l) \in \partial_N \mathcal{R} \cap (\llbracket x_0 + 1, y_0 - 1 \rrbracket \times \llbracket 0, l \rrbracket)$ will be such that $W(\mathcal{R} \cap (\llbracket x_1, y_1 \rrbracket \times \llbracket 0, l \rrbracket)) < \frac{1}{3}W(\mathcal{R})$. We can then partition the vertices of $\partial_N \mathcal{R} \cap (\llbracket x_0 + 1, y_0 - 1 \rrbracket \times \{l\})$ into disjoint disconnecting intervals of free-wired-type as follows:

1. Let $\rho = \{C_1, \dots, C_k\}$ be the partition of $\partial_N \mathcal{R} \cap (\llbracket x_0 + 1, y_0 - 1 \rrbracket \times \{l\})$ induced by ξ ;
2. For each C_i , consider the disconnecting interval L_i of free-wired-type determined by the left-most and right-most vertices of C_i in $\partial_N \mathcal{R} \cap (\llbracket x_0 + 1, y_0 - 1 \rrbracket \times \{l\})$ (n.b. these may be singletons);
3. Let $\{L_{i_1}, \dots, L_{i_\ell}\}$ be those which are maximal, i.e., there does not exist j and k such that $L_{i_j} \subset L_{i_k}$.

The set of disconnecting intervals $\{L_{i_1}, \dots, L_{i_\ell}\}$ partitions $\llbracket x_0 + 1, y_0 - 1 \rrbracket$ into disjoint disconnecting intervals of free-wired-type with the property that $W(\mathcal{R} \cap (L_{i_j} \times \llbracket 0, l \rrbracket)) \leq \frac{1}{3}W(\mathcal{R})$ for every $j \in \{1, \dots, \ell\}$. We can then use Lemma 6.1 to merge adjacent disconnecting intervals until we obtain a candidate disconnecting interval $\llbracket c, d \rrbracket \subset \llbracket x_0, y_0 \rrbracket$ (of free-type), having width $W(\mathcal{R} \cap (\llbracket c, d \rrbracket \times \llbracket 0, l \rrbracket)) \in [\frac{1}{3}W(\mathcal{R}), \frac{2}{3}W(\mathcal{R})]$.

Now that we have found a candidate disconnecting interval $\llbracket c, d \rrbracket$ satisfying (6), we modify it to obtain a disconnecting interval $\llbracket c_\star, d_\star \rrbracket$ with the property that both $(c_\star, l), (d_\star, l)$ are distance at least m from $\partial_{\parallel} \mathcal{R}$.

If (c, l) is at distance at least m from $\partial_{\parallel} \mathcal{R}$, set $c_\star = c$, and similarly if (d, l) is at distance at least m from $\partial_{\parallel} \mathcal{R}$, then set $d_\star = d$. Otherwise, suppose (c, l) is at distance less than m from $\partial_W R_i$ for some constituent rectangular subset $R_i = \llbracket a_i, b_i \rrbracket \times \llbracket 0, l \rrbracket$ of \mathcal{R} . Since \mathcal{R} is compatible with ξ , the interval $\mathcal{I}_c = \llbracket b_{i-1} - m, a_i + m \rrbracket$ is a disconnecting interval, and we set

$$c_\star = \begin{cases} a_i + m, & \text{if } \mathcal{I}_c \text{ is of wired-type, or } i = 1, \text{ or } W(R_i) = 2m; \\ a_i + m + 1, & \text{if } \mathcal{I}_c \text{ is only of free-type, and } W(R_i) > 2m; \end{cases}$$

When (c, l) is at distance less than m from $\partial_E R_i$ for some i , then we simply set $c_\star = b_i - m$. Symmetrically, if (d, l) is at distance less than m from $\partial_E R_i$ for $R_i = \llbracket a_i, b_i \rrbracket \times \llbracket 0, l \rrbracket$, let $\mathcal{I}_d = \llbracket b_i - m, a_{i+1} + m \rrbracket$

$$d_\star = \begin{cases} b_i - m, & \text{if } \mathcal{I}_d \text{ is of wired-type, or } i = N(\mathcal{R}), \text{ or } W(R_i) = 2m; \\ b_i - m - 1, & \text{if } \mathcal{I}_d \text{ is only of free-type, and } W(R_i) > 2m. \end{cases}$$

When (d, l) is at distance less than m from $\partial_W R_i$, let $d_\star = a_i + m$. Since $W(R_i) \geq 2m$ for every i , the points $(c, l), (d, l)$ cannot be both less than m away from $\partial_E R_i$ and less than m away from $\partial_W R_i$.

One can check via a case analysis, exploiting the compatibility of \mathcal{R} with ξ and using Lemma 6.2, that in all of these cases the interval $\llbracket c_\star, d_\star \rrbracket$ is a disconnecting interval; we defer these details to the full manuscript [3]. The fact that $(c_\star, l), (d_\star, l) \in \partial_N \mathcal{R}$ are a distance at least m away from $\partial_{\parallel} \mathcal{R}$ follows directly from the construction. Finally, we claim that in all such situations, $\llbracket c_\star, d_\star \rrbracket$ satisfies

$$\frac{1}{4}W(\mathcal{R}) \leq W(\mathcal{R} \cap (\llbracket c_\star, d_\star \rrbracket \times \llbracket 0, l \rrbracket)) \leq \frac{3}{4}W(\mathcal{R}).$$

This follows from the facts that $W(\mathcal{R}) \geq 100m$, $|c - c_\star| \leq m$ and $|d - d_\star| \leq m$. ◀

■ **Figure 4** (a) The block \mathcal{R}_{INT} with its subsets \mathcal{A}_{INT} , Q_W and Q_E . (b) The block \mathcal{R}_{INT} with the dual-paths (dotted) of a configuration in Γ allowing coupling inside \mathcal{A}_{INT} .

We proceed with the proof of Lemma 4.7, where we establish a lower bound for the spectral gap of the block dynamics in the group of rectangles \mathcal{R} with blocks \mathcal{R}_{INT} and \mathcal{R}_{EXT} as defined in Section 4.1.

Proof of Lemma 4.7. We consider the $p < p_c(q)$ case; the case of $p > p_c(q)$ follows from a similar (dual) argument which we defer to the full manuscript [3]. Let $\{X_t\}, \{Y_t\}$ be two instances of the block dynamics on \mathcal{R} with boundary condition $\zeta = (\xi, \omega_{\mathcal{R}^c})$ started from initial configurations X_0, Y_0 . It suffices to construct a coupling \mathbb{P} of the steps of $\{X_t\}, \{Y_t\}$ such that $\min_{X_0, Y_0} \mathbb{P}(X_2 = Y_2) = \Omega(1)$; see [24].

With probability $1/4$ the first block to be updated is \mathcal{R}_{INT} and the second is \mathcal{R}_{EXT} . Suppose this is the case and let us consider the update on \mathcal{R}_{INT} . Let θ_ω be the boundary condition on $\partial\mathcal{R}_{\text{INT}}$ induced by ζ and the restriction of a configuration ω to $E(\mathcal{R}) \setminus E(\mathcal{R}_{\text{INT}})$, and let π^{θ_ω} be the FK distribution on \mathcal{R}_{INT} with boundary conditions θ_ω . As $X_1(\mathcal{R}_{\text{INT}}), Y_1(\mathcal{R}_{\text{INT}})$ have laws $\pi^{\theta_{X_0}}, \pi^{\theta_{Y_0}}$, respectively, a coupling for $\pi^{\theta_{X_0}}$ and $\pi^{\theta_{Y_0}}$ yields a coupling for X_1 and Y_1 .

We describe next such a coupling for $\pi^{\theta_{X_0}}$ and $\pi^{\theta_{Y_0}}$. Let $Q_W, Q_E \subset \mathcal{R}_{\text{INT}}$ be the two rectangles of width m that contain all the vertices in $\mathcal{R}_{\text{INT}} \setminus \mathcal{A}_{\text{INT}}$; i.e., $Q_W \cup \mathcal{A}_{\text{INT}} \cup Q_E = \mathcal{R}_{\text{INT}}$, $Q_W \cap \mathcal{A}_{\text{INT}} = \emptyset$ and $Q_E \cap \mathcal{A}_{\text{INT}} = \emptyset$ (see Figure 4(a)). Let $\partial E(Q_W)$ be the set of edges with one endpoint in Q_W and the other in \mathcal{A}_{INT} , and similarly define $\partial E(Q_E)$. Let Γ_W be the set of configurations in \mathcal{R}_{INT} that have a *dual-path* in $E(Q_W) \cup \partial E(Q_W)$ connecting the top-most edge in $\partial E(Q_W)$ to an edge in $\partial_s Q_W$, and similarly define Γ_E as the set of configurations in \mathcal{R}_{INT} that have a dual-path in $E(Q_E) \cup \partial E(Q_E)$ from the top-most edge in $\partial E(Q_E)$ to an edge in $\partial_s Q_E$. (A dual-path is an open path in the dual configuration.) Let $\Gamma = \Gamma_E \cap \Gamma_W$; see Figure 4(b). Let θ_1 be the boundary condition on $\partial\mathcal{R}_{\text{INT}}$ induced by ζ and the wired configuration on $E(\mathcal{R}) \setminus E(\mathcal{R}_{\text{INT}})$. The following lemma supplies the desired coupling.

► **Lemma 6.3.** *Let $q > 1$ and $p < p_c(q)$. There exists a coupling \mathbb{P}_1 of the distributions $\pi^{\theta_{X_0}}, \pi^{\theta_{Y_0}}, \pi^{\theta_1}$ such that if $(\omega^{\theta_X}, \omega^{\theta_Y}, \omega^{\theta_1})$ is sampled from \mathbb{P}_1 , the following hold:*

1. $\mathbb{P}_1(\omega^{\theta_X}(\mathcal{A}_{\text{INT}}) = \omega^{\theta_Y}(\mathcal{A}_{\text{INT}}) \mid \omega^{\theta_1} \in \Gamma) = 1$;
2. *There exists a constant $\rho = \rho(p, q) > 0$ such that $\mathbb{P}_1(\omega^{\theta_1} \in \Gamma) \geq \rho$.*

If we use the coupling \mathbb{P}_1 from Lemma 6.3 to couple the first step of the chains, then X_1 and Y_1 will agree on $E(\mathcal{A}_{\text{INT}})$ with probability at least $\rho > 0$. If this occurs, then we can couple the update on \mathcal{R}_{EXT} in the second step so that $X_2 = Y_2$ with probability one. This is because $X_1(E(\mathcal{A}_{\text{INT}})) = Y_1(E(\mathcal{A}_{\text{INT}}))$ implies $X_1(E(\mathcal{R}) \setminus E(\mathcal{R}_{\text{EXT}})) = Y_1(E(\mathcal{R}) \setminus E(\mathcal{R}_{\text{EXT}}))$, and thus the boundary conditions induced by the two instances of the chain on \mathcal{R}_{EXT} are identical. As a consequence, we obtain that for any X_0, Y_0 , $\mathbb{P}(X_2 = Y_2) \geq \rho/4$, which concludes the proof for $p < p_c(q)$. ◀

We conclude this section with the proof of Lemma 6.3.

Proof of Lemma 6.3. Let $L = \partial_W Q_W \cup \partial_N Q_W \cup \partial_E Q_E \cup \partial_N Q_E$. For a configuration ω on \mathcal{R}_{INT} let $F(\omega) := \mathcal{R}_{\text{INT}} \setminus \bigcup_{v \in L} C(v, \omega)$, where $C(v, \omega)$ is the vertex set of the connected component of v in ω , ignoring the boundary connections. Note that $\omega \in \Gamma$ if and only if the vertices in the boundary components of L , i.e., $\bigcup_{v \in L} C(v, \omega)$, are confined to $Q_W \cup Q_E$, in which case $\mathcal{A}_{\text{INT}} \subseteq F(\omega)$.

Clearly, $\pi^{\theta_1} \succeq \pi^{\theta_X}$ and $\pi^{\theta_1} \succeq \pi^{\theta_Y}$ and thus there exist monotone couplings \mathbb{P}_X (resp., \mathbb{P}_Y) for π^{θ_X} and π^{θ_1} (resp., π^{θ_Y} and π^{θ_1}). The coupling \mathbb{P}_1 is defined as follows. First sample $(\omega^{\theta_X}, \omega^{\theta_1})$ from \mathbb{P}_X and ω^{θ_Y} from $\mathbb{P}_Y(\cdot \mid \omega^{\theta_1})$. If $\mathcal{A}_{\text{INT}} \subseteq F(\omega^{\theta_1})$, then re-sample the configuration on $E(F(\omega^{\theta_1}))$ in ω^{θ_1} and update $\omega^{\theta_X}(F(\omega^{\theta_1}))$ and $\omega^{\theta_Y}(F(\omega^{\theta_1}))$ such that $\omega^{\theta_1}(F(\omega^{\theta_1})) = \omega^{\theta_X}(F(\omega^{\theta_1})) = \omega^{\theta_Y}(F(\omega^{\theta_1}))$.

To deduce part 1, it now suffices to show that if $\mathcal{A}_{\text{INT}} \subseteq F(\omega^{\theta_1})$ the three boundary conditions η_1, η_X, η_Y induced on $\partial F(\omega^{\theta_1})$ by the configurations of $\omega^{\theta_X}, \omega^{\theta_Y}, \omega^{\theta_1}$ on $E(\mathcal{R}_{\text{INT}}) \setminus E(F(\omega^{\theta_1}))$, respectively, and the corresponding boundary conditions $\theta_X, \theta_Y, \theta_1$ are identical; if this is the case part 1 follows from the domain Markov property (see [21]).

First observe that the boundary condition on $\partial_S \mathcal{A}_{\text{INT}}$ is always free by assumption. Also from the definition of $F(\omega^{\theta_1})$ every edge of $E(\mathcal{R}_{\text{INT}}) \setminus E(F(\omega^{\theta_1}))$ incident to $\partial F(\omega^{\theta_1})$ is closed in ω^{θ_1} , so by the monotonicity of the coupling, the same holds for ω^{θ_X} and ω^{θ_Y} . The remaining portion of $\partial F(\omega^{\theta_1})$ is precisely the set of vertices $(\partial \mathcal{A}_{\text{INT}} \cap \partial \mathcal{R}) \setminus \partial_S \mathcal{R}$. In order for the boundary conditions η_1, η_X, η_Y to differ on this set, there must be at least two distinct boundary components in $\zeta = (\xi, \omega_{\mathcal{R}^c})$ between $(\partial \mathcal{A}_{\text{INT}} \cap \partial \mathcal{R}) \setminus \partial_S \mathcal{R}$ and $\llbracket c_\star, d_\star \rrbracket^c \times \{l\}$; this cannot happen because $\llbracket c_\star, d_\star \rrbracket$ is disconnecting.

Part 2 of the lemma is a straightforward consequence of the EDC property of the random-cluster model at $p < p_c(q)$; see (2). Namely, since the width of Q_W is $m = C_\star \log l$, (2) implies that when C_\star is large enough there is a constant $\rho_W(p, q) > 0$ such that $\pi^{\theta_1}(\Gamma_W^c) \leq \pi_\Delta^1(L \xleftrightarrow{\Delta} \partial_W \mathcal{A}_{\text{INT}}) \leq 1 - \rho_W$, where Δ is the subgraph induced by the edges in $E(\mathcal{R}_{\text{INT}}) \setminus E(\mathcal{A}_{\text{INT}})$. A matching bound holds for Γ_E^c . Since Γ_E, Γ_W are both decreasing events, by the FKG inequality (see [21]), $\pi^{\theta_1}(\Gamma) \geq \rho_W \rho_E =: \rho$, concluding the proof. \blacktriangleleft

Abstract

We continue the study of list recovery properties of high-rate tensor codes, initiated by Hemenway, Ron-Zewi, and Wootters (FOCS'17). In that work it was shown that the tensor product of an efficient (poly-time) high-rate globally list recoverable code is *approximately* locally list recoverable, as well as globally list recoverable in *probabilistic* near-linear time. This was used in turn to give the first capacity-achieving list decodable codes with (1) local list decoding algorithms, and with (2) *probabilistic* near-linear time global list decoding algorithms. This also yielded constant-rate codes approaching the Gilbert-Varshamov bound with *probabilistic* near-linear time global unique decoding algorithms.

In the current work we obtain the following results:

1. The tensor product of an efficient (poly-time) high-rate globally list recoverable code is globally list recoverable in *deterministic* near-linear time. This yields in turn the first capacity-achieving list decodable codes with *deterministic* near-linear time global list decoding algorithms. It also gives constant-rate codes approaching the Gilbert-Varshamov bound with *deterministic* near-linear time global unique decoding algorithms.
2. If the base code is additionally locally correctable, then the tensor product is (genuinely) locally list recoverable. This yields in turn (non-explicit) constant-rate codes approaching the Gilbert-Varshamov bound that are *locally correctable* with query complexity and running time $N^{o(1)}$. This improves over prior work by Gopi et. al. (SODA'17; IEEE Transactions on Information Theory'18) that only gave query complexity N^ϵ with rate that is exponentially small in $1/\epsilon$.
3. A nearly-tight combinatorial lower bound on output list size for list recovering high-rate tensor codes. This bound implies in turn a nearly-tight lower bound of $N^{\Omega(1/\log \log N)}$ on the product of query complexity and output list size for locally list recovering high-rate tensor codes.

1 Introduction

Error-correcting codes enable protection of data from errors. They allow one to encode a message so that even after some symbols of the encoding get changed, the original message can still be recovered.

Formally, an *error-correcting code* of *blocklength* n over a finite alphabet Σ is a subset $C \subseteq \Sigma^n$. If k is such that $|C| = |\Sigma|^k$, then a k symbol *message* can be encoded using this code. The redundancy of the code is measured by the *rate* $\rho = k/n$ (so that $|C| = |\Sigma|^{\rho n}$). The robustness to errors is measured by its *relative distance* δ , defined to be the minimum, over all distinct $x, y \in C$, of the relative Hamming distance $\text{dist}(x, y)$. A basic but important observation is that for codes with relative distance δ , for every $w \in \Sigma^n$, there is at most one codeword $c \in C$ for which $\text{dist}(w, c) < \delta/2$. Finding this codeword given w is the algorithmic problem of *unique decoding* C upto half the minimum distance.

Given this setup, we now state some central goals of coding theory. First, we would like to understand the best possible *tradeoffs* for ρ and δ that are achievable. Next, we would like to have *explicit constructions* of codes that achieve this best possible tradeoff. Finally, we would like *efficient algorithms* for decoding such optimal codes upto half their minimum distance – this would give codes correcting the maximum possible fraction of (worst-case) errors for their rate.

For the case of $|\Sigma| = 2$ (the binary alphabet), the *Gilbert-Varshamov bound* states that for all $\delta \leq 1/2$ and $\gamma > 0$ there exist codes with $n \rightarrow \infty$ for which¹ $\rho \geq 1 - H_2(\delta) - \gamma$. In fact, a random linear code satisfies this with high probability. The Gilbert-Varshamov bound is the best known tradeoff in the setting where $\delta = \Omega(1)$, and surprisingly, it is not known to be tight. Furthermore, despite their abundance, we do not know how to explicitly construct codes achieving the Gilbert-Varshamov bound.

For growing alphabets, $|\Sigma| = \omega(1)$, the picture is almost completely understood. We know that the best tradeoff achievable is $\rho = 1 - \delta - \gamma$, and furthermore we know how to explicitly construct codes achieving this tradeoff that can be efficiently unique decoded upto half their minimum distance.

¹ Here H_2 is the binary entropy function.

1.1 The cast

In recent years, several important variations of the problem of unique decoding have been considered. We will need many of these, so we give below a quick and gentle introduction (without formal definitions).

List decoding

In list decoding we attempt to decode from an even larger fraction α of errors than $\delta/2$ – now there may be more than one nearby codeword, and our goal is to find the *list* of all of them. A basic limitation is that efficient list decoding is only possible if the number of nearby codewords is guaranteed to be polynomially bounded.

Unlike the case of unique decoding, the optimal tradeoff between the rate ρ and the *list decoding radius* α (for polynomial-size lists) is known for all alphabet sizes. The optimal rate for a given α is known as the *list decoding capacity*. For $|\Sigma| = 2$, the list decoding capacity is $\rho = 1 - H_2(\alpha) - \gamma$, while for $|\Sigma| = \omega(1)$, the list decoding capacity is $\rho = 1 - \alpha - \gamma$. Over large alphabets, this tradeoff can be achieved by explicit codes with efficient list decoding algorithms [21] (see also [27] for the state of the art). Over binary alphabet, we do not know how to explicitly construct codes achieving list decoding capacity.

List recovery

List recovery is a generalization of list decoding where we are given a small list of candidate alphabet symbols at each coordinate (these lists are called the *input lists*) and the goal is to find the *output list* of all codewords that are consistent with many of these input lists. In other words, we want all codewords such that for a $(1 - \alpha)$ -fraction of coordinates, the symbol of the codeword at that coordinate lies within the input list for that coordinate (we call these the “nearby codewords”). When the input list size is 1, then list recovery is the same as list decoding.

Local decoding

In local decoding, we want to unique decode in sublinear time. Standard decoding has linear output size, so we need to aim lower. For a given $w \in \Sigma^n$ and a given message coordinate $i \in [k]$, we only ask to recover symbol i of the message underlying the codeword c near w . We would like to run in sublinear time (and hence use only a sublinear number of queries to w), so we allow the algorithm to use randomness and allow a small probability of error.

Local correction is a variation of local decoding where one is required to recover *codeword* symbols as opposed to message symbols. In *approximate* local decoding (local correction, resp.) one is only required to recover correctly *most* of the message (codeword, resp.) coordinates.

Local list decoding

Local list decoding combines the notions of local decoding and list decoding. We are given some $w \in \Sigma^n$, and the goal is that for any nearby codeword, one can in sublinear time recover the i th symbol of the message corresponding to the codeword for any $i \in [k]$. In order to make this precise, the local list decoding algorithm first does some preprocessing and then produces as output a collection of algorithms A_j . For any nearby codeword c , with high

probability one of these algorithms corresponds to it.² These algorithms then behave like local decoding algorithms. On input $i \in [k]$, if the algorithm corresponded to a codeword c , then by making queries to only a sublinear number of coordinates, the algorithm with high probability outputs the correct value of the i th symbol of the message corresponding to c .

The above definition of local list decoding can be extended to *local list recovery* in a straightforward way where now the algorithms A_j correspond to all codewords that agree with most of the input lists. As above, we can also define a local correction version of local list decoding (or local list recovery) where the algorithms A_j are required to recover codeword symbols as opposed to message symbols. Finally, we can also define approximate local list decoding (or local list recovery) where the algorithms A_j are only required to recover correctly most of the message (or codeword in the local correction version) coordinates.

The context

The starting point for this paper is the recent result of [23] on high-rate list recoverable tensor codes, and its corollaries. Tensoring is a natural operation on codes that significantly enhances their local properties [5, 34, 9, 10, 15, 6, 7, 37, 28, 36, 26].

The main technical result of [23] was that the tensor product of an efficient (poly-time) high-rate globally list recoverable code is *approximately* locally list recoverable (in either the local decoding or local correction version). They then observed that the “approximately” modifier can be eliminated by pre-encoding the tensor product with a locally decodable code. This gave the first construction of codes with rate arbitrarily close to 1 that are locally list recoverable from an $\Omega(1)$ fraction of errors (however, only in the local decoding version). Finally, using the expander-based distance amplification method of [2, 3] (specialized to the setting of local list recovery [18, 17]), this gave the first capacity-achieving locally list recoverable (and in particular, list decodable) codes with sublinear (and in fact $N^{O(1/\log \log N)}$) query complexity and running time (once more, in the local decoding version).

The above result also yielded further consequences for global decoding. Specifically, [23] observed that the approximate local list recovery algorithm for tensor codes naturally gives a *probabilistic* near-linear time global list recovery algorithm. Once more, using the expander-based distance amplification method of [2, 3, 18], this gave the first capacity-achieving list recoverable (and in particular, list decodable) codes with *probabilistic* near-linear time global list recovery algorithms. Finally, via the random concatenation method of [33, 19], this yielded in turn a (randomized) construction of constant-rate binary codes approaching the Gilbert-Varshamov bound with a *probabilistic* near-linear time algorithm for global unique decoding upto half the minimum distance.

One could potentially hope (following [17] which implemented a local version of [33, 19]) for an analogous result that would give constant-rate codes approaching the Gilbert-Varshamov bound that are locally correctable (or locally decodable) with query complexity and running time $N^{o(1)}$. However, what prevented [23] from obtaining such a result was the fact that their capacity-achieving locally list recoverable codes only worked in the local decoding version (i.e., they were only able to recover message coordinates).

² Some of these algorithms A_j might not correspond to any codeword and might output garbage. Later in the paper we define local list decoding to not allow these garbage producing A_j 's. Eliminating the garbage can be easily done if the underlying code is also *locally testable*, and in this case the stronger notion can be achieved.

1.2 Results

We revisit the technique of [23] and show the following.

- The tensor product of an efficient (poly-time) high-rate globally list recoverable code is globally list recoverable in *deterministic* near-linear time. Plugging this into the machinery of [2, 3, 18], we get the first capacity-achieving list recoverable (and in particular, list decodable) codes with *deterministic* near-linear time global list recovery algorithms. Plugging this into the machinery of [33, 19], yields in turn constant-rate binary codes (with a randomized construction) approaching the Gilbert-Varshamov bound with *deterministic* near-linear time global unique decoding algorithms.

Our deterministic global list recovery algorithm is obtained by derandomizing the random choices of the [23] algorithm using appropriate samplers.

- An instantiation of the base code to produce tensor product codes which are themselves genuinely locally list recoverable (i.e., not just approximately locally list recoverable) in the *local correction version*. Once more, plugging this into the machinery of [2, 3, 17], we get capacity-achieving locally list recoverable codes, but now in the *local correction version*. This now plugs in turn into the machinery of [33, 19, 17] to give constant-rate binary codes (with a randomized construction) approaching the Gilbert-Varshamov bound that are locally decodable with query complexity and running time $N^{o(1)}$. This improves over prior work [17] that only gave query complexity N^ε with rate that is exponentially small in $1/\varepsilon$.

We obtain our result by taking the base code to be the *intersection* of an efficient (poly-time) high-rate globally list recoverable code and a high-rate locally correctable code. Assuming both codes are linear, we have that the intersection is a high-rate code that is both! The result of [23] already guarantees that this tensor product is approximately locally list recoverable (in the local correction version), and we use the fact that the tensor product of a locally correctable codes is also locally correctable [37] to remove the “approximately” modifier.³

- A combinatorial lower bound showing the limitations on the list recoverability of high-rate tensor codes. Specifically, we show that when the rate of the base code is high, every t -wise tensor product of this code has output list size *doubly-exponential* in t . This means that taking t to be more than $\log \log N$ leads to superpolynomial output list size, precluding the possibility of efficient list recovery.

Instantiating this appropriately, this implies in turn that there is a base code such that for every tensor power with block length N , the product of the query complexity and output list size for local list recovery is at least $N^{\Omega(1/\log \log N)}$. We note that in contrast, it could be that for every base code, there is a tensor power with block length N for which local correction can be done with query complexity $O(1)$.

A key observation that we use is that a high-rate code has many codewords with pairwise-disjoint supports. We combine this along with other linear-algebraic arguments to design a list recovery instance for the tensor product of a high-rate code which has many codewords that are consistent with it.

Below we give formal statements of our results. For formal definitions of the various notions of decoding in the following theorem statements, see Section 2.

³ To eliminate “garbage” we also use the fact that the tensor product is locally testable [37].

1.2.1 Deterministic near-linear time global list recovery

Our first main result shows that the tensor product of an efficient (poly-time) high-rate globally list recoverable code is globally list recoverable in *deterministic* near-linear time. In the theorem statement, one should think of all parameters δ, α, L, t , and consequently also s , as constants (or more generally, as slowly increasing/decreasing functions of n). In that case, the theorem says that if $C \subseteq \mathbb{F}^n$ is (α, ℓ, L) -globally list recoverable deterministically in time $T = \text{poly}(n)$, then the t -iterated tensor product $C^{\otimes t}$ of length $N := n^t$ is $(\Omega(\alpha), \ell, L^{O(1)})$ -globally list recoverable deterministically in time $O(n^t \cdot T) = n^{t+O(1)} = N^{1+O(1/t)}$.

► **Theorem 1** (Deterministic near-linear time list recovery of high-rate tensor codes). *The following holds for any $\delta, \alpha > 0$, and $s = \text{poly}(1/\delta, 1/\alpha)$. Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable deterministically in time T . Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(\alpha \cdot s^{-t^2}, \ell, L^{s^{t^3} \cdot L^t})$ -globally list recoverable deterministically in time $n^t \cdot T \cdot L^{s^{t^3} \cdot L^t}$.*

Applying the expander-based distance amplification method of [2, 3, 18] on the codes given by the above theorem, we obtain the first capacity-achieving list recoverable (and in particular, list decodable) codes with *deterministic* near-linear time global list recovery algorithms.

► **Corollary 2** (Deterministic nearly-linear time capacity-achieving list recoverable codes). *For any constants $\rho \in [0, 1]$, $\gamma > 0$, and $\ell \geq 1$ there exists an infinite family of codes $\{C_N\}_N$, where C_N has block length N , alphabet size $N^{o(1)}$, rate ρ , and is $(1 - \rho - \gamma, \ell, N^{o(1)})$ -globally list recoverable deterministically in time $N^{1+o(1)}$.*

Applying the random concatenation method of [33, 19], the above corollary yields in turn constant-rate codes approaching the Gilbert-Varshamov bound with *deterministic* near-linear time global unique decoding algorithms.

► **Corollary 3** (Deterministic near-linear time unique decoding up to the GV bound). *For any constants $\rho \in [0, 0.02]$ and $\gamma > 0$ there exists an infinite family of binary linear codes $\{C_N\}_N$, where C_N has block length N and rate ρ , and is globally uniquely decodable deterministically from $\frac{H_2^{-1}(1-\rho)-\gamma}{2}$ -fraction of errors in time $N^{1+o(1)}$.*

1.2.2 Local list recovery

Our second main result shows that if the base code is *both* globally list recoverable and locally correctable, then the tensor product is (genuinely) locally list recoverable (in the local correction version).

► **Theorem 4** (Local list recovery of high-rate tensor codes). *The following holds for any $\delta, \alpha > 0$, and $s = \text{poly}(1/\delta, 1/\alpha)$. Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable, and locally correctable from $(\delta/2)$ -fraction of errors with query complexity Q , and $t \geq 3$. Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(\alpha \cdot s^{-t^3}, \ell, L^{s^{t^3} \cdot \log^t L})$ -locally list recoverable with query complexity $n^{O(1)} \cdot Q^{O(t)} \cdot L^{s^{t^3} \cdot \log^t L}$.*

Once more, applying the expander-based distance amplification method of [2, 3, 18, 17], as well as the random concatenation method of [33, 19, 17], the above theorem yields constant-rate codes approaching the Gilbert-Varshamov bound that are *locally correctable* with query complexity $N^{o(1)}$.

► **Corollary 5** (Local correction up to the GV bound). *For any constants $\rho \in [0, 0.02]$ and $\gamma > 0$ there exists an infinite family of binary linear codes $\{C_N\}_N$, where C_N has block length N and rate ρ , and is locally correctable from $\frac{H_2^{-1}(1-\rho)-\gamma}{2}$ -fraction of errors with query complexity $N^{o(1)}$.*

1.2.3 Combinatorial lower bound on output list size

Our final main result shows a nearly-tight combinatorial lower bound on output list size for list recovering high-rate tensor codes.

► **Theorem 6** (Output list size for list recovering high-rate tensor codes). *Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of rate $1 - \gamma$, and that $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(0, \ell, L)$ -list recoverable. Then $L \geq \ell^{1/\gamma^t}$.*

The above bound can be instantiated concretely as follows.

► **Corollary 7.** *For any $\delta > 0$ and $\ell > 1$ there exists $L > 1$ such that the following holds for any sufficiently large n . There exists a linear code $C \subseteq \mathbb{F}^n$ of relative distance δ that is $(\Omega(\delta), \ell, L)$ -list recoverable, but $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is only $(0, \ell, L')$ -list recoverable for $L' \geq \exp((2\delta)^{-(t-3/2)} \cdot \sqrt{\log L})$.*

Finally, we also obtain a nearly-tight lower bound of $N^{\Omega(1/\log \log N)}$ on the product of query complexity and output list size for locally list recovering high-rate tensor codes.

► **Corollary 8.** *For any $\delta > 0$ and sufficiently large n there exists a linear code $C \subseteq \mathbb{F}^n$ of relative distance δ such that the following holds. Suppose that $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(\frac{1}{N}, 2, L)$ -locally list recoverable with query complexity Q . Then $Q \cdot L \geq N^{\Omega_\delta(1/\log \log N)}$.*

2 Preliminaries

For a prime power q we denote by \mathbb{F}_q the finite field of q elements. For any finite alphabet Σ and for any pair of strings $x, y \in \Sigma^n$, the relative distance between x and y is the fraction of coordinates $i \in [n]$ on which x and y differ, and is denoted by $\text{dist}(x, y) := |\{i \in [n] : x_i \neq y_i\}|/n$. For a subset $Y \subseteq \Sigma^n$, we denote by $\text{dist}(x, Y)$ the minimum relative distance of a string $y \in Y$ from x . For a positive integer ℓ we denote by $\binom{\Sigma}{\ell}$ the collection of all subsets of Σ of size ℓ and by $\binom{\Sigma}{\leq \ell}$ the collection of all nonempty subsets of Σ of size at most ℓ . For any string $x \in \Sigma^n$ and tuple $S \in \binom{\Sigma}{\leq \ell}^n$ we denote by $\text{dist}(x, S)$ the fraction of coordinates $i \in [n]$ for which $x_i \notin S_i$, that is, $\text{dist}(x, S) := |\{i \in [n] : x_i \notin S_i\}|/n$. For a string $x \in \Sigma^n$ and a subset $T \subseteq [n]$, we use $x|_T \in \Sigma^{|T|}$ to denote the restriction of x to the coordinates in T . Throughout the paper, we use $\exp(n)$ to denote $2^{\Theta(n)}$, and whenever we use \log , it is base 2, unless noted otherwise.

2.1 Error-correcting codes

An error-correcting code is simply a subset $C \subseteq \Sigma^n$. We call Σ the **alphabet** of the code, and n its block length. The elements of C are called **codewords**. If \mathbb{F} is a finite field and Σ is a vector space over \mathbb{F} , we say that a code $C \subseteq \Sigma^n$ is \mathbb{F} -linear if it is an \mathbb{F} -linear subspace of the \mathbb{F} -vector space Σ^n . If $\Sigma = \mathbb{F}$, we simply say that C is **linear**.

The rate of a code is the ratio $\rho := \frac{\log |C|}{\log(|\Sigma|^n)}$, which for \mathbb{F} -linear codes equals $\frac{\dim_{\mathbb{F}}(C)}{n \cdot \dim_{\mathbb{F}}(\Sigma)}$. The relative distance $\text{dist}(C)$ of C is the minimum $\delta > 0$ such that for every pair of distinct codewords $c_1, c_2 \in C$ it holds that $\text{dist}(c_1, c_2) \geq \delta$. We denote by $\Delta(C) := \text{dist}(C) \cdot n$ the (absolute) distance of C .

The best known general trade-off between rate and distance of codes is the Gilbert-Varshamov bound, attained by random (linear) codes. For $x \in [0, 1]$ let

$$H_q(x) = x \log_q(q-1) + x \log_q(1/x) + (1-x) \log_q(1/(1-x))$$

denote the q -ary entropy function.

► **Theorem 9** (Gilbert-Varshamov (GV) bound, [12, 35]). *For any prime power q , $\delta \in (0, 1 - \frac{1}{q})$, and $\rho \in (0, 1 - H_q(\delta))$, a random linear code $C \subseteq \mathbb{F}_q^n$ of rate ρ has relative distance at least δ with probability $1 - \exp(-n)$.*

► **Corollary 10.** *For any $\rho \in [0, 1]$ and $\gamma > 0$, and prime power $q \geq 2^{H_2(1-\rho-\gamma)/\gamma}$, a random linear code $C \subseteq \mathbb{F}_q^n$ of rate ρ has relative distance at least $1 - \rho - \gamma$ with probability $1 - \exp(-n)$.*

An encoding map for C is a bijection $E_C : \Sigma^k \rightarrow C$, where $|\Sigma|^k = |C|$. We call the elements in the domain of E_C **messages**, and k the **message length**. We say that C is **encodable** in time T if an encoding map for C can be computed in time T . For a code $C \subseteq \Sigma^n$ of relative distance δ and a given parameter $\alpha < \delta/2$, we say that C is **decodable from α -fraction of errors** in time T if there exists an algorithm, running in time T , that given a received word $w \in \Sigma^n$, computes the unique codeword $c \in C$ (if any) which satisfies $\text{dist}(c, w) \leq \alpha$.

► **Proposition 11** (Reed-Solomon codes, [29, 8]). *For any prime power q and integers $k \leq n \leq q$, there exists a linear code $C \subseteq \mathbb{F}_q^n$ of rate $\rho := k/n$ and relative distance at least $1 - \rho$ that is encodable and decodable from $\frac{1-\rho}{2}$ -fraction of errors in time $\text{poly}(n, \log q)$.*

Let $C \subseteq \mathbb{F}^n$ be a linear code of dimension k . A **generating matrix** for C is an $n \times k$ matrix G such that $\text{Im}(G) = C$. A **parity-check matrix** for C is an $(n-k) \times n$ matrix H such that $\ker(H) = C$. The dual code $C^\perp \subseteq \mathbb{F}^n$ is given by

$$C^\perp = \{y \in \mathbb{F}^n \mid \langle y, c \rangle = 0 \forall c \in C\}.$$

It is well-known that $C^{\perp\perp} = C$, and that a matrix G is a generating matrix for C if and only if G^T is a parity-check matrix for C^\perp .

2.2 List recoverable codes

List recovery is a generalization of the standard error-correction setting where each entry w_i of the received word w is replaced with a list S_i of ℓ possible symbols of Σ . Formally, for $\alpha \in [0, 1]$ and integers ℓ, L we say that a code $C \subseteq \Sigma^n$ is **(α, ℓ, L) -list recoverable** if for any tuple $S \in \binom{\Sigma}{\leq \ell}^n$ there are at most L different codewords $c \in C$ so that $\text{dist}(c, S) \leq \alpha$. We say that C is **(α, L) -list decodable** if it is $(\alpha, 1, L)$ -list recoverable.

► **Corollary 12** ([24], Corollary 2.2). *For any $\rho \in [0, 1]$, $\gamma > 0$, and $\ell \geq 1$, and for sufficiently large prime power q , a random linear code $C \subseteq \mathbb{F}_q^n$ of rate ρ is $(1 - \rho - \gamma, \ell, q^{O(\ell/\gamma)})$ -list recoverable with probability $1 - \exp(-n)$.*

We say that C is **(α, ℓ, L) -list recoverable in time T** if there exists an algorithm, running in time T , that given a tuple $S \in \binom{\Sigma}{\leq \ell}^n$, returns all codewords $c \in C$ (if any) which satisfy $\text{dist}(c, S) \leq \alpha$. The following theorem from [22, 20, 23] gives a family of high-rate linear codes which are efficiently list recoverable with constant alphabet size and nearly-constant output list size.

► **Theorem 13** ([24], Theorem A.1). *There exists an absolute constant b_0 so that the following holds. For any $\gamma > 0$, $\ell \geq 1$, $q \geq \ell^{b_0/\gamma}$ that is an even power of a prime⁴, and integer $n \geq q^{b_0\ell/\gamma}$, there exists a linear code $C \subseteq \mathbb{F}_q^n$ of rate $1 - \gamma$ and relative distance $\Omega(\gamma^2)$ that is $(\Omega(\gamma^2), \ell, L)$ -list recoverable for $L = q^{\ell/\gamma \cdot \exp(\log^* n)}$. Moreover, C can be encoded in time $\text{poly}(n, \log q)$ and list recovered in time $\text{poly}(n, L)$.*

2.3 Local codes

2.3.0.1 Locally testable codes

Intuitively, a code is said to be locally testable [11, 30, 16] if, given a string $w \in \Sigma^n$, it is possible to determine whether w is a codeword of C , or rather far from C , by reading only a small part of w . For our purposes, we shall also require an additional *tolerance* property of determining whether w is sufficiently close to the code.

► **Definition 14** (Tolerant locally testable code (Tolerant LTC)). *We say that a code $C \subseteq \Sigma^n$ is (Q, α, β) -tolerantly locally testable if there exists a randomized algorithm A that satisfies the following requirements:*

- **Input:** A gets oracle access to a string $w \in \Sigma^n$.
- **Query complexity:** A makes at most Q queries to the oracle w .
- **Completeness:** If $\text{dist}(w, C) \leq \alpha$, then A accepts with probability at least $\frac{2}{3}$.
- **Soundness:** If $\text{dist}(w, C) \geq \beta$, then A rejects with probability at least $\frac{2}{3}$.

► **Remark 15.** The definition requires $0 \leq \alpha < \beta \leq 1$. The above success probability of $\frac{2}{3}$ can be amplified using sequential repetition, at the cost of increasing the query complexity. Specifically, amplifying the success probability to $1 - \exp(-t)$ requires increasing the query complexity by a multiplicative factor of $O(t)$.

Locally correctable codes

Intuitively, a code is said to be locally correctable [4, 32, 25] if, given a codeword $c \in C$ that has been corrupted by some errors, it is possible to decode any coordinate of c by reading only a small part of the corrupted version of c .

► **Definition 16** (Locally correctable code (LCC)). *We say that a code $C \subseteq \Sigma^n$ is (Q, α) -locally correctable if there exists a randomized algorithm A that satisfies the following requirements:*

- **Input:** A takes as input a coordinate $i \in [n]$, and also gets oracle access to a string $w \in \Sigma^n$ that is α -close to a codeword $c \in C$.
- **Query complexity:** A makes at most Q queries to the oracle w .
- **Output:** A outputs c_i with probability at least $\frac{2}{3}$.

► **Remark 17.** The definition requires $\alpha < \text{dist}(C)/2$. The above success probability of $\frac{2}{3}$ can be amplified using sequential repetition, at the cost of increasing the query complexity. Specifically, amplifying the success probability to $1 - \exp(-t)$ requires increasing the query complexity by a multiplicative factor of $O(t)$.

⁴ That is, q is of the form p^{2t} for a prime p and for an integer t .

Locally list recoverable codes

The following definition from [14, 32, 17] generalizes the notion of locally correctable codes to the setting of list decoding/recovery. In this setting, the local list recovery algorithm is required to output in an implicit sense all codewords that are consistent with most of the input lists.

► **Definition 18** (Locally list recoverable code). *We say that a code $C \subseteq \Sigma^n$ is $(Q, \alpha, \varepsilon, \ell, L)$ -locally list recoverable if there exists a randomized algorithm A that satisfies the following requirements:*

- **Input:** A gets oracle access to a string $S \in \left(\sum_{\leq \ell}\right)^n$.
- **Query complexity:** A makes at most Q queries to the oracle S .
- **Output:** A outputs L randomized algorithms A_1, \dots, A_L , where each A_j takes as input a coordinate $i \in [n]$, makes at most Q queries to the oracle S , and outputs a symbol in Σ .
- **Completeness:** For any codeword $c \in C$ which satisfies $\text{dist}(c, S) \leq \alpha$, with probability at least $1 - \varepsilon$ over the randomness of A , the following event happens: there exists some $j \in [L]$ such that for all $i \in [n]$,

$$\Pr[A_j(i) = c_i] \geq \frac{2}{3}, \quad (1)$$

where the probability is over the internal randomness of A_j .

- **Soundness:** With probability at least $1 - \varepsilon$ over the randomness of A , the following event happens: for every $j \in [L]$, there exists some $c \in C$ such that for all $i \in [n]$,

$$\Pr[A_j(i) = c_i] \geq \frac{2}{3},$$

where the probability is over the internal randomness of A_j .

We say that A has preprocessing time T_{pre} if A outputs the description of the algorithms A_1, \dots, A_L in time at most T_{pre} , and has running time T if each A_j has running time at most T . As before, we say that the code C is $(Q, \alpha, \varepsilon, L)$ -locally list decodable if it is $(Q, \alpha, \varepsilon, 1, L)$ -locally list recoverable.

2.4 Tensor codes

In this paper we study the list recovery properties of the high-rate tensor product codes, defined as follows.

► **Definition 19** (Tensor product codes). *Let $C_1 \subseteq \mathbb{F}^{n_1}$, $C_2 \subseteq \mathbb{F}^{n_2}$ be linear codes. Their tensor product code $C_1 \otimes C_2 \subseteq \mathbb{F}^{n_1 \times n_2}$ consists of all matrices $M \in \mathbb{F}^{n_1 \times n_2}$ such that all the rows of M are codewords of C_2 and all the columns are codewords of C_1 .*

3 Deterministic near-linear time global list recovery

3.1 Deterministic near-linear time list recovery of high-rate tensor codes

In this section we prove Theorem 1, restated below, which shows that the tensor product of an efficient (poly-time) high-rate globally list recoverable code is globally list recoverable in deterministic near-linear time.

► **Theorem 1** (Deterministic near-linear time list recovery of high-rate tensor codes). *The following holds for any $\delta, \alpha > 0$, and $s = \text{poly}(1/\delta, 1/\alpha)$. Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable deterministically in time T . Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(\alpha \cdot s^{-t^2}, \ell, L^{s^{t^3}} \cdot L^t)$ -globally list recoverable deterministically in time $n^t \cdot T \cdot L^{s^{t^3}} \cdot L^t$.*

Theorem 1 follows by applying the lemma below iteratively.

► **Lemma 20.** *The following holds for any $\delta, \alpha, \delta_{\text{dec}}, \delta'_{\text{dec}} > 0$, and $\bar{s} = \text{poly}(1/\delta, 1/\alpha, 1/\delta_{\text{dec}}, 1/\delta'_{\text{dec}})$.*

Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable deterministically in time T , and $C' \subseteq \mathbb{F}^{n'}$ is a linear code that is (α', ℓ, L') -globally list recoverable deterministically in time T' . Suppose furthermore that C, C' are uniquely decodable deterministically from $\delta_{\text{dec}}, \delta'_{\text{dec}}$ -fraction of errors in times $T_{\text{dec}}, T'_{\text{dec}}$, respectively.

Then $C \otimes C' \subseteq \mathbb{F}^{n \times n'}$ is $(\alpha'/\bar{s}, \ell, (L')^{\bar{s} \cdot L/(\alpha')^2})$ -globally list recoverable deterministically in time

$$(L')^{\bar{s} \cdot L/(\alpha')^2} \cdot n \cdot (n' \cdot (T + T_{\text{dec}}) + n \cdot T'_{\text{dec}} + T').$$

We now sketch the proof of Lemma 20. Our plan is to derandomize the approximate local list recovery algorithm for high-rate tensor codes of [23]. Recall that an approximate local list recovery algorithm (local correction version) is a randomized algorithm A that outputs a collection of (without loss of generality, deterministic) local algorithms A_j satisfying the following: for any codeword c that is consistent with most of the input lists, with high probability (over the randomness of A) one of the local algorithms A_j locally corrects most of the coordinates of c .

As observed in [23], an approximate local list recovery algorithm naturally gives a *probabilistic* near-linear time *global* list recovery algorithm as follows. First run the algorithm A to obtain the collection of local algorithms A_j . Then for each A_j , output a codeword that is obtained by applying A_j on each codeword coordinate, and then uniquely decoding the resulting word to the closest codeword. The guarantee now is that any codeword that is consistent with most of the input lists will be output with high probability.

To derandomize the probabilistic global algorithm described above, we note that the preprocessing algorithm A in [23] produces the collection of local algorithms A_j by choosing a random subset of rows in the tensor product,⁵ that is chosen uniformly at random amongst all subsets of the appropriate size. We then observe that this subset can be alternatively chosen using a randomness-efficient *sampler* without harming much the performance. Finally, since the sampler uses a small amount of randomness (logarithmic in the blocklength of C), we can afford to iterate over all seeds and return the union of all output lists. This gives a *deterministic* near-linear time global list recovery algorithm that outputs all codewords that are consistent with most of the input lists.

3.1.1 Samplers

We start by defining the appropriate samplers we use.

⁵ In [23], the role of columns and rows is swapped.

► **Definition 21** ((averaging) sampler). An (n, η, γ) -sampler with randomness r and sample size m is a randomized algorithm that tosses r random coins and outputs a subset $I \subseteq [n]$ of size m such that the following holds. For any function $f : [n] \rightarrow [0, 1]$, with probability at least $1 - \eta$ over the choice of I ,

$$|\mathbb{E}_{i \in I} [f(i)] - \mathbb{E}_{i \in [n]} [f(i)]| \leq \gamma.$$

We shall use the following construction from Goldreich [13].

► **Theorem 22** ([13], Corollary 5.6). For any $\eta, \gamma > 0$ and integer n , there exists an (n, η, γ) -sampler with randomness $\log(n/\gamma)$, sample size $O(1/(\eta\gamma^2))$, and running time $\text{poly}(\log n, 1/\eta, 1/\gamma)$.

In what follows, let Γ denote the (n, η, γ) -sampler promised by the above theorem, where we set $\eta := \frac{0.1}{L} \cdot \frac{\delta_{\text{dec}} \cdot \delta'_{\text{dec}}}{3}$ and $\gamma := \alpha' \cdot \frac{\delta \cdot \delta_{\text{dec}} \cdot \delta'_{\text{dec}}}{24}$. Let $r := \log(n/\gamma) \leq \log(n \cdot \bar{s}/\alpha')$ and $m := O(1/(\eta\gamma^2)) \leq L \cdot \bar{s}/(\alpha')^2$ denote the randomness and sample size of Γ , respectively (assuming that \bar{s} is a sufficiently large polynomial).

3.1.2 Randomness-efficient algorithm

We first describe a randomness-efficient global list recovery algorithm \tilde{A} for $C \otimes C'$ that is obtained by replacing the choice of a uniform random subset of rows made in [23] with a sample from Γ . We will later observe that the randomness can be eliminated by iterating over all seeds of Γ and returning the union of all output lists.

The algorithm \tilde{A} behaves as follows. First, it uses Γ to sample a subset of m rows $I = \{i_1, \dots, i_m\} \subseteq [n]$. Then for $k = 1, \dots, m$, it runs the list recovery algorithm A' for C' on the i_k -th row $S|_{\{i_k\} \times [n']}$; let $\mathcal{L}'_{i_1}, \mathcal{L}'_{i_2}, \dots, \mathcal{L}'_{i_m} \subseteq C'$ denote the lists output by A' on each of the rows in I . Finally, for any choice of codewords $c'_1 \in \mathcal{L}'_{i_1}, c'_2 \in \mathcal{L}'_{i_2}, \dots, c'_m \in \mathcal{L}'_{i_m}$, the algorithm \tilde{A} outputs a codeword $\tilde{c} \in C \otimes C'$ that is obtained as follows.

For each column $j \in [n']$, the algorithm \tilde{A} runs the list recovery algorithm A for C on the j -th column $S|_{[n] \times \{j\}}$; let $\mathcal{L}_1, \mathcal{L}_2, \dots, \mathcal{L}_{n'} \subseteq C$ denote the lists output by A on each of the n' columns. Then the algorithm \tilde{A} chooses for each column $j \in [n']$ the codeword $c_j \in \mathcal{L}_j$ whose restriction to I is closest to $((c'_1)_j, (c'_2)_j, \dots, (c'_m)_j)$ (i.e., the restriction of c'_1, c'_2, \dots, c'_m to the j -th column). Finally, the algorithm \tilde{A} sets the value of each column $j \in [n']$ to c_j , and uniquely decodes the resulting word \tilde{c}_0 to the nearest codeword $\tilde{c} \in C \otimes C'$, assuming there is one at distance at most $\delta_{\text{dec}} \cdot \delta'_{\text{dec}}$. If $\text{dist}(\tilde{c}, S) \leq \alpha'/\bar{s}$, then \tilde{A} includes \tilde{c} in the output list $\tilde{\mathcal{L}}$. The formal description is given in Algorithm 1.

3.2 Deterministic nearly-linear time capacity-achieving list recoverable codes

In this section we prove the following lemma which implies Corollary 2 from the introduction.

► **Lemma 23.** For any constants $\rho \in [0, 1]$, $\gamma > 0$, and $\ell \geq 1$ there exists an infinite family of codes $\{C_N\}_N$ that satisfy the following.

- C_N is an \mathbb{F}_2 -linear code of block length N and alphabet size $N^{o(1)}$.
- C_N has rate ρ and relative distance at least $1 - \rho - \gamma$.
- C_N is $(1 - \rho - \gamma, \ell, N^{o(1)})$ -globally list recoverable deterministically in time $N^{1+o(1)}$.
- C_N is encodable deterministically in time $N^{1+o(1)}$.

■ **Algorithm 1** The randomness-efficient global list recovery algorithm \tilde{A} for $C \otimes C'$.

function $\tilde{A}(S \in \binom{\mathbb{F}^{n \times n'}}{\leq \ell})$
 Sample $I = \{i_1, \dots, i_m\} \subseteq [n]$ of size m using sampler Γ .
for $k = 1, \dots, m$ **do**
 Run the list recovery algorithm A' for C' on the i_k -th row $S|_{\{i_k\} \times [n']}$, and let $\mathcal{L}'_{i_k} \subseteq C'$ be the list of codewords output by A' .
end for
 Initialize $\tilde{c}_0 \in \mathbb{F}^{n \times n'}$, $\tilde{\mathcal{L}} \leftarrow \emptyset$.
for any choice of codewords $c'_1 \in \mathcal{L}'_{i_1}, c'_2 \in \mathcal{L}'_{i_2}, \dots, c'_m \in \mathcal{L}'_{i_m}$ **do**
 for $j \in [n']$ **do**
 Run the list recovery algorithm A for C on the j -th column $S|_{[n] \times \{j\}}$, and let $\mathcal{L}_j \subseteq C$ be the list of codewords output by A .
 Choose a codeword $c_j \in \mathcal{L}_j$ for which $c_j|_I$ is closest to $((c'_1)_j, (c'_2)_j, \dots, (c'_m)_j)$ (breaking ties arbitrarily).
 Set the j -th column of \tilde{c}_0 to c_j .
 end for
 Uniquely decode \tilde{c}_0 from $(\delta_{\text{dec}} \cdot \delta'_{\text{dec}})$ -fraction of errors, and let $\tilde{c} \in C \otimes C'$ be the resulting codeword (if exists). If $\text{dist}(\tilde{c}, S) \leq \alpha/\bar{s}$, add \tilde{c} to $\tilde{\mathcal{L}}$.
end for
end function

To prove the above lemma, we first use Theorem 1 to obtain deterministic nearly-linear time *high-rate* list recoverable codes, and then use the Alon-Edmonds-Luby (AEL) distance amplification method [2, 3] to turn these codes into deterministic nearly-linear time *capacity-achieving* list recoverable codes.

3.3 Deterministic near-linear time unique decoding up to the GV bound

In this section we prove the following lemma which implies Corollary 3 from the introduction.

► **Lemma 24.** *For any constants $\rho \in [0, 0.02]$ and $\gamma > 0$ there exists an infinite family of binary linear codes $\{C_N\}_N$, where C_N has block length N and rate ρ , and is globally uniquely decodable deterministically from $\frac{H_2^{-1}(1-\rho)-\gamma}{2}$ -fraction of errors in time $N^{1+o(1)}$.*

Furthermore, there exists a randomized algorithm which, on input N , runs in time $N^{1+o(1)}$ and outputs with high probability a description of a code C_N with the properties above. Given the description, the code C_N can be encoded deterministically in time $N^{1+o(1)}$.

To prove the above lemma, we rely on a lemma from [33, 23] which says that one can turn a code that approximately satisfies the Singleton bound into one that approximately satisfies the GV bound via random concatenation.

4 Local list recovery

4.1 Local list recovery of high-rate tensor codes

In this section we prove the following lemma which implies Theorem 4 from the introduction.

68:14 On List Recovery of High-Rate Tensor Codes

► **Lemma 25.** *The following holds for any $\delta, \alpha, \varepsilon > 0$ and $s = \text{poly}(1/\delta, 1/\alpha)$. Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable, and $(Q, \delta/2)$ -locally correctable, and $t \geq 3$. Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(\tilde{Q}, \alpha \cdot s^{-t^3}, \varepsilon, \ell, L^{s^{t^3} \cdot \log^t L} \cdot \log(1/\varepsilon))$ -locally list recoverable for*

$$\tilde{Q} = n^3 \cdot (Q \log Q)^t \cdot L^{s^{t^3} \cdot \log^t L} \cdot \log^2(1/\varepsilon).$$

Moreover, if C is globally list recoverable in time $\text{poly}(n)$, locally correctable in time T , and globally decodable for $(\delta/2)$ -fraction of errors in time $\text{poly}(n)$, then the local list recovery algorithm for $C^{\otimes t}$ has preprocessing time $\text{poly}(n) \cdot L^{s^{t^3} \cdot \log^t L} \cdot \log^2(1/\varepsilon)$ and running time $\text{poly}(n) \cdot (T \log T)^t \cdot (s^{t^3} \log^t L)$.

The above lemma relies on the following lemma from [23] which says that the tensor product of a high-rate globally list recoverable code (which is not necessarily locally correctable) is *approximately* locally list recoverable. Approximate local list recovery is a relaxation of local list recovery, where the local algorithms in the output list are not required to recover *all* the codeword coordinates, but only *most* of them. Formally, a β -approximately $(Q, \alpha, \varepsilon, \ell, L)$ -locally list recoverable code $C \subseteq \Sigma^n$ satisfies all the requirements of Definition 18, except that the requirement (1) is replaced with the relaxed condition that

$$\Pr_{i \in [n]} [A_j(i) = c_i] \geq 1 - \beta, \quad (2)$$

where the probability is over the choice of uniform random $i \in [n]$, and the soundness requirement is eliminated.

► **Lemma 26** (Approximate local list recovery of high-rate tensor codes, [24], Lemma 4.1). *The following holds for any $\delta, \alpha, \beta, \varepsilon > 0$ and $s = \text{poly}(1/\delta, 1/\alpha, 1/\beta)$. Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ that is (α, ℓ, L) -globally list recoverable. Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is β -approximately $(n \cdot (s^{t^2} \log^t L), \alpha \cdot s^{-t^2}, \varepsilon, \ell, L^{s^{t^2} \cdot \log^t L} \cdot \log(1/\varepsilon))$ -locally list recoverable.*

Moreover, if C is globally list recoverable in time $\text{poly}(n)$, then the approximate local list recovery algorithm for $C^{\otimes t}$ has preprocessing time $\log(n) \cdot L^{s^{t^2} \cdot \log^t L} \cdot \log(1/\varepsilon)$ and running time $\text{poly}(n) \cdot (s^{t^2} \log^t L)$.

To turn the approximate local list recovery algorithm given by the above lemma into a local list recovery algorithm we shall use the fact that the tensor product of a locally correctable code is also locally correctable with slightly worse parameters. A similar observation was made in [37, Proposition 3.15].

► **Lemma 27** (Local correction of tensor codes). *Suppose that $C \subseteq \mathbb{F}^n$ is a linear code that is (Q, α) -locally correctable. Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $((O(Q \log Q))^t, \alpha^t)$ -locally correctable.*

Moreover, if C is locally correctable in time T , then the local correction algorithm for $C^{\otimes t}$ runs in time $(O(T \log T))^t$.

To guarantee the soundness property we shall also use the following lemma which says that high-rate tensor codes are tolerantly locally testable.

► **Lemma 28** (Tolerant local testing of high-rate tensor codes). *Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of relative distance δ , and $t \geq 3$. Then $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(n^2 \cdot \delta^{-O(t)}, \delta^{O(t)}, (\delta/2)^t)$ -tolerantly locally testable.*

Moreover, if C is globally decodable from $(\delta/2)$ -fraction of errors in time T , then the tolerant local testing algorithm for $C^{\otimes t}$ runs in time $T \cdot n \cdot \delta^{-O(t)}$.

Finally, we show a general transformation that turns an approximately locally list recoverable code that is also locally correctable and tolerantly locally testable into a (genuinely) locally list recoverable code.

► **Lemma 29.** *Suppose that $C \subseteq \Sigma^n$ is a β -approximately $(Q, \alpha, \varepsilon, \ell, L)$ -locally list recoverable code that is also $(Q_{\text{corr}}, \gamma)$ -locally correctable and $(Q_{\text{test}}, \beta, \gamma)$ -tolerantly locally testable. Then C is $(\tilde{Q}, \alpha, 2\varepsilon, \ell, L)$ -locally list recoverable for*

$$\tilde{Q} = \max\{Q \cdot Q_{\text{test}} \cdot O(|L| \log(|L|/\varepsilon)), Q \cdot Q_{\text{corr}}\}.$$

Moreover, if the approximate local list recovery algorithm has preprocessing time T_{pre} and running time T , and the local correction and tolerant local testing algorithms run in times $T_{\text{test}}, T_{\text{corr}}$, respectively, then the local list recovery algorithm has preprocessing time $T_{\text{pre}} + T \cdot T_{\text{test}} \cdot O(|L| \log(|L|/\varepsilon))$ and running time $T \cdot T_{\text{corr}}$.

4.2 Capacity-achieving locally list recoverable codes

In this section we prove the following lemma which shows the existence of capacity-achieving locally list recoverable codes. An analogous lemma was proven in [24, Lemma 5.3], however only for local decoding *message* coordinates, and without the soundness property. The fact that we are able to locally correct *codeword* coordinates, as well as guarantee the soundness property, will be crucial for our GV bound local correction application.

► **Lemma 30.** *For any constants $\rho \in [0, 1]$, $\gamma > 0$, $\varepsilon > 0$, and $\ell \geq 1$ there exists an infinite family of codes $\{C_N\}_N$ that satisfy the following.*

- C_N is an \mathbb{F}_2 -linear code of block length N and alphabet size $N^{o(1)}$.
- C_N has rate ρ and relative distance at least $1 - \rho - \gamma$.
- C_N is $(N^{o(1)}, 1 - \rho - \gamma, \varepsilon, \ell, N^{o(1)})$ -locally list recoverable with preprocessing and running time $N^{o(1)}$.
- C_N is encodable in time $N^{1+o(1)}$.

As in the proof of Lemma 23, we first use Lemma 25 to obtain *high-rate* locally list recoverable codes, and then use the Alon-Edmonds-Luby (AEL) distance amplification method [2, 3] to turn these codes into *capacity-achieving* locally list recoverable codes. However, this time we use a version of the AEL method for *local* list recovery from [17].

4.3 Local correction up to the GV bound

In this section we prove the following lemma which implies Corollary 5 from the introduction.

► **Lemma 31.** *For any constants $\rho \in [0, 0.02]$ and $\gamma > 0$ there exists an infinite family of binary linear codes $\{C_N\}_N$, where C_N has block length N and rate ρ , and is locally correctable from $\frac{H_2^{-1}(1-\rho)-\gamma}{2}$ -fraction of errors with query complexity $N^{o(1)}$.*

Furthermore,

- The local correction algorithm for C_N runs in time $N^{o(1)}$.
- There exists a randomized algorithm which, on input N , runs in time $N^{1+o(1)}$ and outputs with high probability a description of a code C_N with the properties above. Given the description, the code C_N can be encoded deterministically in time $N^{1+o(1)}$.

The proof is analogous to that of Lemma 24 and relies on concatenation.

► **Lemma 32** (Concatenation for local list recovery). *Suppose that $C \subseteq (\Sigma^{\rho' \cdot t})^n$ is $(Q, \alpha, \varepsilon, \ell, L)$ -locally list recoverable, and $C_{\text{con}} \subseteq \Sigma^{tn}$ is a code obtained from C by applying a code $C^{(i)} \subseteq \Sigma^t$ of rate ρ' on each coordinate $i \in [n]$ of C . Suppose furthermore that at least $(1 - \gamma)$ -fraction of the codes $C^{(i)}$ are (α', ℓ', ℓ) -globally list recoverable. Then C_{con} is $(Q \cdot t, (\alpha - \gamma) \cdot \alpha', \varepsilon, \ell', L)$ -locally list recoverable.*

Moreover, if the local list recovery algorithm for C has preprocessing time T_{pre} and running time T , and each $C^{(i)}$ can be globally list recovered in time T' , then the local list recovery algorithm for C_{con} has preprocessing time $T_{\text{pre}} + Q \cdot T'$ and running time $T + Q \cdot T'$.

A Combinatorial lower bound on output list size

In this appendix, we first provide a *combinatorial* lower bound on the output list size for list recovering a high-rate tensor product $C^{\otimes t}$, even in the noiseless setting. In particular, we show that the output list size must be doubly-exponential in t . From this, we are able to deduce certain corollaries demonstrating that our algorithms nearly achieve optimal parameters.

Recall that given vectors $v_1 \in \mathbb{F}^{n_1}, v_2 \in \mathbb{F}^{n_2}, \dots, v_t \in \mathbb{F}^{n_t}$, their tensor product $v_1 \otimes v_2 \otimes \dots \otimes v_t$ is the t -dimensional box whose value in the $(i_1, i_2, \dots, i_t) \in n_1 \times n_2 \dots \times n_t$ coordinate is given by the product

$$(v_1 \otimes v_2 \otimes \dots \otimes v_t)_{i_1, i_2, \dots, i_t} = (v_1)_{i_1} \cdot (v_2)_{i_2} \dots (v_t)_{i_t} .$$

For the special case of $t = 2$, the tensor product $v \otimes u$ can be thought of as the outer product vu^T .

We also record the following standard fact regarding tensor products.

► **Proposition 33.** *Let $v_1, \dots, v_{t_1} \in \mathbb{F}^{n_1}$ and $u_1, \dots, u_{t_2} \in \mathbb{F}^{n_2}$ be sets of linearly independent vectors. Then the collection $\{v_i \otimes u_j \mid i \in [t_1], j \in [t_2]\}$ is linearly independent in $\mathbb{F}^{n_1 \times n_2}$.*

A.1 Output list size for list recovering high-rate tensor codes

In this section we prove Theorem 6 from the introduction, which we restate here for convenience.

► **Theorem 6** (Output list size for list recovering high-rate tensor codes). *Suppose that $C \subseteq \mathbb{F}^n$ is a linear code of rate $1 - \gamma$, and that $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is $(0, \ell, L)$ -list recoverable. Then $L \geq \ell^{1/\gamma^t}$.*

To prove this theorem, we first prove the following proposition. Informally speaking, we iteratively apply the Singleton bound to conclude that linear codes of rate $1 - \gamma$ contain about $1/\gamma$ codewords with pairwise disjoint supports. Recall that, for a vector $v \in \mathbb{F}^n$, the support of v is $\text{Supp}(v) = \{i \in [n] \mid v_i \neq 0\}$.

► **Proposition 34.** *Let $C \subseteq \mathbb{F}^n$ be a subspace of dimension k , and let r be a positive integer. Suppose that*

$$\left(1 - \frac{1}{r}\right) \cdot n + 1 \leq k . \tag{3}$$

Then there exist non-zero vectors $c_1, \dots, c_r \in C$ such that for all $i \neq j$, $\text{Supp}(c_i) \cap \text{Supp}(c_j) = \emptyset$.

Proof. Let $m := n - k + 1$, and note that Condition (3) is equivalent to

$$(r - 1)m \leq k - 1 .$$

Take a basis for C of the form $(e_1, u_1), \dots, (e_k, u_k)$, where $e_i \in \mathbb{F}^k$ is the i th standard basis vector, and $u_1, \dots, u_k \in \mathbb{F}^{n-k}$ are vectors. For $j = 1, \dots, r - 1$, we can find a nontrivial linear combination of the vectors $u_{(j-1)m+1}, \dots, u_{j \cdot m}$ summing to zero, as they

are a (multi-)set of $m = n - k + 1$ vectors lying in \mathbb{F}^{n-k} . Taking this linear combination of $(e_{(j-1)\cdot m+1}, u_{(j-1)\cdot m+1}), \dots, (e_{j\cdot m}, u_{j\cdot m})$, we obtain a nonzero vector whose support is contained in the interval $\{(j-1)\cdot m+1, \dots, j\cdot m\}$; denote this vector by c_j . In this manner, we obtain $r-1$ nonzero vectors $c_1, \dots, c_{r-1} \in C$ with pairwise disjoint support. Finally, we may add the vector $c_r := (e_k, u_k)$ to this collection, yielding r vectors, as desired. \blacktriangleleft

Next we prove Theorem 6, based on the above proposition.

Proof of Theorem 6. Let $r := 1/\gamma$, and recall wish to come up with ℓ^{r^t} codewords in $C^{\otimes t}$ that are contained in the output list for appropriately chosen input lists.

In order to accomplish this, we first use Proposition 34 to obtain a subset $C' \subseteq C$ of r nonzero codewords with pairwise disjoint support. We then consider the subset $C'' \subseteq C^{\otimes t}$ containing all tensor products $c_1 \otimes c_2 \otimes \dots \otimes c_t$ of t (not necessarily distinct) codewords $c_1, \dots, c_t \in C'$, and our main observation is that all these r^t tensor products are also nonzero with pairwise disjoint support. Finally, we let $B \subseteq \mathbb{F}$ be an arbitrary subset of size ℓ , and consider the subset $\bar{C} \subseteq C^{\otimes t}$ containing all linear combinations of codewords in C'' with coefficients in B . Since all codewords in C'' are nonzero with pairwise disjoint support, they are in particular linearly independent, so the set \bar{C} contains ℓ^{r^t} distinct codewords in $C^{\otimes t}$.

Moreover, since codewords in C'' have pairwise disjoint support, for each coordinate $(i_1, \dots, i_t) \in [n]^t$, there is at most one codeword $c \in C''$ for which c_{i_1, \dots, i_t} is nonzero. Therefore this is the only term which can contribute nontrivially to the value in the (i_1, \dots, i_t) coordinate of a codeword in \bar{C} . So we can let the corresponding input list S_{i_1, \dots, i_t} contain all ℓ multiples of c_{i_1, \dots, i_t} by elements in B . Details follow.

Since C has rate $1 - \gamma$, it has dimension $k = (1 - \gamma)n$, and so Proposition 34 guarantees the existence of a subset $C' \subseteq C$ of $r = 1/\gamma$ nonzero codewords with pairwise disjoint support.

Next we let

$$C'' := \{c_1 \otimes c_2 \otimes \dots \otimes c_t \mid c_1, c_2, \dots, c_t \in C'\}$$

be the subset of $C^{\otimes t}$ containing all tensor products of t (not necessarily distinct) codewords in C' . Since all codewords in C' are nonzero, their t -wise tensor products are nonzero as well.

To see that all codewords in C'' have pairwise disjoint support, suppose that $c = c_1 \otimes c_2 \otimes \dots \otimes c_t \in C''$, and $(i_1, i_2, \dots, i_t) \in \text{Supp}(c)$. Then

$$0 \neq c_{i_1, i_2, \dots, i_t} = (c_1)_{i_1} \cdot (c_2)_{i_2} \cdot \dots \cdot (c_t)_{i_t},$$

so we must have that $(c_1)_{i_1}, (c_2)_{i_2}, \dots, (c_t)_{i_t}$ are all nonzero. We conclude that

$$\text{Supp}(c) \subseteq \text{Supp}(c_1) \times \text{Supp}(c_2) \times \dots \times \text{Supp}(c_t).$$

Now, suppose that $c = c_1 \otimes \dots \otimes c_t$, $c' = c'_1 \otimes \dots \otimes c'_t$ are a pair of codewords in C'' with $c_j \neq c'_j$ for some $j \in [t]$. Since all codewords in C' have pairwise disjoint support it must hold that $\text{Supp}(c_j) \cap \text{Supp}(c'_j) = \emptyset$, and we conclude that $\text{Supp}(c) \cap \text{Supp}(c') = \emptyset$.

Now, let $B \subseteq \mathbb{F}$ be an arbitrary subset of size ℓ , and let

$$\bar{C} := \left\{ \sum_{c \in C''} \beta_c \cdot c \mid \beta_c \in B \text{ for all } c \in C'' \right\}$$

be the subset of $C^{\otimes t}$ containing all linear combinations of codewords in C'' with coefficients in B . Since all codewords in C'' are nonzero with pairwise disjoint support, they are in particular linearly independent in \mathbb{F}^{n^t} ,⁶ so the set \bar{C} contains ℓ^{r^t} distinct codewords in $C^{\otimes t}$.

⁶ This also follows from the fact that all codewords in C'' are linearly independent together with Proposition 33.

Finally, we wish to define input lists S_{i_1, \dots, i_t} for any coordinate $(i_1, \dots, i_t) \in [n]^t$ so that for any codeword $c \in \bar{C}$, and for any coordinate $(i_1, \dots, i_t) \in [n]^t$, it holds that $c_{i_1, \dots, i_t} \in S_{i_1, \dots, i_t}$.

To this end, we observe that since codewords in C'' have pairwise disjoint support, for each coordinate $(i_1, \dots, i_t) \in [n]^t$, there is at most one codeword $c \in C''$ for which c_{i_1, \dots, i_t} is nonzero. Therefore this is the only term which can contribute nontrivially to the value in the (i_1, \dots, i_t) coordinate of a codeword in \bar{C} . So we can define the corresponding input list S_{i_1, \dots, i_t} as

$$S_{i_1, \dots, i_t} := \{\beta \cdot c_{i_1, \dots, i_t} \mid \beta \in B\}$$

if such a codeword c exists, and as $S_{i_1, \dots, i_t} = \{0\}$ otherwise. Note that each set S_{i_1, \dots, i_t} has size at most ℓ , and that they satisfy the required property.

This yields a set of ℓ^t codewords from $C^{\otimes t}$ that are contained in the output list for the input list tuple S defined above, proving the theorem. \blacktriangleleft

A.2 Concrete lower bound on output list size

In this section, we demonstrate a setting of parameters that yields Corollary 7 from the introduction, restated below.

► **Corollary 7.** *For any $\delta > 0$ and $\ell > 1$ there exists $L > 1$ such that the following holds for any sufficiently large n . There exists a linear code $C \subseteq \mathbb{F}^n$ of relative distance δ that is $(\Omega(\delta), \ell, L)$ -list recoverable, but $C^{\otimes t} \subseteq \mathbb{F}^{n^t}$ is only $(0, \ell, L')$ -list recoverable for $L' \geq \exp((2\delta)^{-(t-3/2)} \cdot \sqrt{\log L})$.*

We use the following result on the list-recoverability of random linear codes from [31].

► **Theorem 35** ([31], Corollary 3.3). *There exists an absolute constant b_0 so that the following holds. For any $\gamma > 0$, $\ell \geq 1$, and a prime power $q \geq \ell^{b_0/\gamma}$, a random linear code $C \subseteq \mathbb{F}_q^n$ of rate $1 - \gamma$ is $(\Omega(\gamma), \ell, L)$ -list recoverable for*

$$L \leq \left(\frac{q\ell}{\gamma}\right)^{(\log \ell)/\gamma} \cdot \exp\left(\frac{\log^2 \ell}{\gamma^3}\right)$$

with probability $1 - \exp(-n)$.

Proof of Corollary 7. Let $C \subseteq \mathbb{F}_q^n$ be the linear code given by Theorem 35 of rate $1 - 2\delta$ and $q = \ell^{O(1/\delta)}$ that is $(\Omega(\delta), \ell, L)$ -list recoverable for $L = \exp((\log^2 \ell)/\delta^3)$, or equivalently, $\ell = \exp(\delta^{3/2} \cdot \sqrt{\log L})$. By Corollary 10, we may further assume that the code C has relative distance at least δ . Now, by Theorem 6 we have that $L' \geq \ell^{(2\delta)^{-t}} = \exp((2\delta)^{-(t-3/2)} \cdot \sqrt{\log L})$. \blacktriangleleft

A.3 Lower bound for local list recovering

We now prove Corollary 8 from the introduction, restated below.

► **Corollary 8.** *For any $\delta > 0$ and sufficiently large n there exists a linear code $C \subseteq \mathbb{F}^n$ of relative distance δ such that the following holds. Suppose that $C^{\otimes t} \subseteq \mathbb{F}^{N^t}$ is $(\frac{1}{N}, 2, L)$ -locally list recoverable with query complexity Q . Then $Q \cdot L \geq N^{\Omega_\delta(1/\log \log N)}$.*

We first show the following lemma which says that a locally list decodable (and in particular locally list recoverable) code with output list size L and query complexity Q is also locally correctable with query complexity roughly $Q \cdot L$.

► **Lemma 36.** *Suppose that $C \subseteq \Sigma^n$ is a code of relative distance δ that is $(Q, \alpha, 0.1, L)$ -locally list decodable for $\alpha < \delta/2$. Then C is $\left(O\left(Q \cdot L \cdot \frac{\log^2 n}{(\delta/2 - \alpha)^2}\right), \alpha\right)$ -locally correctable.*

So to prove Corollary 8, it is enough to show a lower bound on the query complexity for local correcting $C^{\otimes t}$, assuming that the output list for list recovering $C^{\otimes t}$ is small. To show such a lower bound, we first observe that for any linear code C , the (absolute) distance of C^\perp is a lower bound on the query complexity for local correcting C .

► **Lemma 37.** *Suppose that $C \subseteq \mathbb{F}^n$ is a linear code that is $(Q, \frac{1}{n})$ -locally correctable. Then $Q \geq \Delta(C^\perp) - 2$.*

We prove the above lemma in Section A.3.1. To apply this lemma to $C^{\otimes t}$ we further observe that the tensor product preserves the dual distance of the base code.

► **Lemma 38.** *Suppose that $C_1 \subseteq \mathbb{F}^{n_1}$, $C_2 \subseteq \mathbb{F}^{n_2}$ are linear codes, and that C_1^\perp, C_2^\perp have distances Δ_1, Δ_2 , respectively. Then $(C_1 \otimes C_2)^\perp$ has distance $\min\{\Delta_1, \Delta_2\}$. In particular, if $C \subseteq \mathbb{F}^n$ is a linear code, and C^\perp has distance Δ , then $(C^{\otimes t})^\perp$ has distance Δ for any $t \geq 1$.*

We prove the above lemma in Section A.3.2. We now proceed to the proof of Corollary 8.

Proof of Corollary 8. Let $C \subseteq \mathbb{F}^n$ be a random linear code of rate $1 - 2\delta$. By Corollary 10, for sufficiently large field size, the code C will have relative distance at least δ with high probability. Moreover, since C^\perp has rate 2δ , by the same corollary we also have that C^\perp has relative distance at least $1 - 3\delta$ with high probability. We conclude for any sufficiently large n the existence of a linear code $C \subseteq \mathbb{F}^n$ of rate $1 - 2\delta$ and relative distance at least δ such that C^\perp has relative distance at least $1 - 3\delta$.

Next observe that for the code $C^{\otimes t}$ to be $(Q, \frac{1}{N}, 0.1, 2, L)$ -locally list recoverable, it in particular must be $(0, 2, L)$ -list recoverable, so the lower bound from Theorem 6 implies that $L \geq 2^{1/(2\delta)^t}$. Now, if $2^{1/(2\delta)^t} \geq N$ then we have that $Q \cdot L \geq 2^{1/(2\delta)^t} \geq N$, and we are done. So we may assume that $2^{1/(2\delta)^t} < N$ which implies in turn that $t = O_\delta(\log \log N)$ and $n = N^{1/t} = N^{\Omega_\delta(1/\log \log N)}$.

Moreover, as we have assumed we have a $(Q, \frac{1}{N}, 0.1, 2, L)$ -local list recovery algorithm for $C^{\otimes t}$, we also have a $(Q, \frac{1}{N}, 0.1, L)$ -local list decoding algorithm for $C^{\otimes t}$. Lemma 36 then promises that we have a $(O(Q \cdot L \cdot \frac{\log^2 N}{(\delta^t/2 - 1/N)^2}), \frac{1}{N})$ -local correction algorithm for $C^{\otimes t}$. Now, by Lemma 38 we have that $(C^{\otimes t})^\perp$ has (absolute) distance at least $(1 - 3\delta)n$, and consequently Lemma 37 implies that

$$O\left(Q \cdot L \cdot \frac{\log^2 N}{(\delta^t/2 - \frac{1}{N})^2}\right) \geq (1 - 3\delta)n - 2 = N^{\Omega_\delta(1/\log \log N)}.$$

This implies $Q \cdot L \geq N^{\Omega_\delta(1/\log \log N)}$, as desired. ◀

A.3.1 Dual distance is a lower bound on query complexity – proof of Lemma 37

First, we recall the standard fact that (absolute) dual distance Δ implies that the uniform distribution over the code is $(\Delta - 1)$ -wise independent.

► **Proposition 39 ([1]).** *Suppose that $C \subseteq \mathbb{F}_q^n$ is a linear code, and that C^\perp has (absolute) distance Δ . Then for all $1 \leq i_1 < \dots < i_s \leq n$ with $s < \Delta$, and all $a_1, \dots, a_s \in \mathbb{F}_q$,*

$$\Pr_{c \in C} [c_{i_1} = a_1 \wedge \dots \wedge c_{i_s} = a_s] = \frac{1}{q^s}.$$

68:22 On List Recovery of High-Rate Tensor Codes

In what follows let $\Delta := \Delta(C^\perp)$, and let q denote the alphabet size of C . Now, making use of Yao's principle, it suffices to show a distribution \mathcal{D} over vectors w at absolute distance at most 1 from C such that the following holds. For any *deterministic* algorithm making at most $\Delta - 2$ queries to its input w sampled according to \mathcal{D} , the probability that it correctly computes c_1 is at most $1/3$, where c is the unique codeword in C at absolute distance at most 1 from w . We will in fact show that no deterministic query algorithm can correctly compute c_1 with probability greater than $1/q$.

Let \mathcal{D} denote the distribution that samples $c \in C$ uniformly at random and then sets $c_1 = 0$. Let A be a deterministic algorithm making at most $\Delta - 2$ queries, and let $j_1, \dots, j_s \in [n]$ denote the queries made by A , where we assume $s \leq \Delta - 2$. Note that querying 1 does not help A , as it will always read 0. Hence, without loss of generality, $1 \notin \{j_1, \dots, j_s\}$.

Now, by Proposition 39 and Bayes' rule, for any $b_1, \dots, b_s, a \in \mathbb{F}_q$,

$$\Pr_{c \in C} [c_1 = a | c_{j_1} = b_1, \dots, c_{j_s} = b_s] = \frac{\Pr [c_1 = a, c_{j_1} = b_1, \dots, c_{j_s} = b_s]}{\Pr [c_{j_1} = b_1, \dots, c_{j_s} = b_s]} = \frac{q^{-(s+1)}}{q^{-s}} = \frac{1}{q}.$$

Additionally, observe that the distribution of the tuple $(c_{j_1}, \dots, c_{j_s})$ is the same if c is a uniformly random codeword from C or if it is sampled according to \mathcal{D} .

Hence, if we think of the query algorithm as implementing a (deterministic) function $g : \mathbb{F}_q^s \rightarrow \mathbb{F}_q$ from the responses to its queries to its guess for c_1 , regardless of the responses b_1, \dots, b_s to the queries, we have

$$\Pr_{w \in \mathcal{D}} [c_1 = g(b_1, \dots, b_s) | w_{j_1} = b_1, \dots, w_{j_s} = b_s] = \frac{1}{q},$$

where c is the unique codeword in C for which $\text{dist}(c, w) \leq \frac{1}{n}$. That is, the query algorithm will not be able to guess c_1 with probability greater than $1/q$, as claimed.

A.3.2 Tensor product preserves dual distance – proof of Lemma 38

First note that we clearly have that $\Delta((C_1 \otimes C_2)^\perp) \leq \min\{\Delta_1, \Delta_2\}$: for example, the matrix whose first column is a vector from C_1^\perp of weight Δ_1 and all other columns are 0 gives a matrix in $(C_1 \otimes C_2)^\perp$ of weight Δ_1 , and similarly a matrix in $(C_1 \otimes C_2)^\perp$ of weight Δ_2 can be constructed. We now establish the opposite inequality of $\Delta((C_1 \otimes C_2)^\perp) \geq \min\{\Delta_1, \Delta_2\}$.

It is well-known (and not hard to show) that the (absolute) distance of a code C is the minimum number of linearly dependent columns in a parity-check matrix for C . Furthermore, by duality we have that if G is a generating matrix for C then G^T is a parity-check matrix for C^\perp . We conclude that the distance of C^\perp is the minimum number of linearly dependent rows in a generating matrix for C .

Let G_1, G_2 be generating matrices for C_1, C_2 , respectively, and note that by the above, any collection of $t_1 < \Delta_1, t_2 < \Delta_2$ rows of G_1, G_2 , respectively, are linearly independent. Next recall that $G_1 \otimes G_2$ is a generating matrix for $C_1 \otimes C_2$, and so it suffices to show that for any $t < \min\{\Delta_1, \Delta_2\}$, any collection of t rows of $G_1 \otimes G_2$ are linearly independent.

Let u_1, u_2, \dots, u_{n_1} and v_1, v_2, \dots, v_{n_2} denote the rows of G_1, G_2 , respectively, and note that each row in $G_1 \otimes G_2$ is of the form $u_i \otimes v_j$ for some $i \in [n_1], j \in [n_2]$. Fix $t < \min\{\Delta_1, \Delta_2\}$, and suppose that $u_{i_1} \otimes v_{j_1}, u_{i_2} \otimes v_{j_2}, \dots, u_{i_t} \otimes v_{j_t}$ is a collection of t rows of $G_1 \otimes G_2$. Then by the above we have that both collections $u_{i_1}, u_{i_2}, \dots, u_{i_t}$ and $v_{j_1}, v_{j_2}, \dots, v_{j_t}$ are linearly independent (ignoring duplications). Proposition 33 implies in turn that the collection $u_{i_1} \otimes v_{j_1}, u_{i_2} \otimes v_{j_2}, \dots, u_{i_t} \otimes v_{j_t}$ are also linearly independent which concludes the proof of the lemma.

Abstract

We study the problem of constructing a linear sketch of minimum dimension that allows approximation of a given real-valued function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ with small expected squared error. We develop a general theory of linear sketching for such functions through which we analyze their dimension for most commonly studied types of valuation functions: additive, budget-additive, coverage, α -Lipschitz submodular and matroid rank functions. This gives a characterization of how many bits of information have to be stored about the input x so that one can compute f under additive updates to its coordinates.

Our results are tight in most cases and we also give extensions to the distributional version of the problem where the input $x \in \mathbb{F}_2^n$ is generated uniformly at random. Using known connections with dynamic streaming algorithms, both upper and lower bounds on dimension obtained in our work extend to the space complexity of algorithms evaluating $f(x)$ under long sequences of additive updates to the input x presented as a stream. Similar results hold for simultaneous communication in a distributed setting.

1 Introduction

Linear sketching is a fundamental tool in efficient algorithm design that has enabled many of the recent breakthroughs in fast graph algorithms and computational linear algebra. It has a wide range of applications, including randomized numerical linear algebra (see survey [56]), graph sparsification (see survey [44]), frequency estimation [3], dimensionality reduction [34], various forms of sampling, signal processing, and communication complexity. In fact, linear sketching has been shown to be the optimal algorithmic technique [41, 2] for dynamic data streams, where elements can be both inserted and deleted. Linear sketching is also a frequently used tool in distributed computing – summaries communicated between the processors in massively parallel computational models are often linear sketches.

In this paper we introduce a study of approximate linear sketching over \mathbb{F}_2 (approximate \mathbb{F}_2 -sketching). This is a previously unstudied but natural generalization of the work of [35], which studies exact \mathbb{F}_2 -sketching. For a set $S \subseteq [n]$ let $\chi_S: \mathbb{F}_2^n \rightarrow \mathbb{F}_2$ be a parity function defined as $\chi_S(x) = \sum_{i \in S} x_i$. Given a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, we are looking for a distribution

69:2 Approximate \mathbb{F}_2 -Sketching of Valuation Functions

over k subsets $\mathbf{S}_1, \dots, \mathbf{S}_k \subseteq [n]$ such that for any input x , it should be possible to compute $f(x)$ with expected squared error at most ϵ from the parities $\chi_{\mathbf{S}_1}(x), \chi_{\mathbf{S}_2}(x), \dots, \chi_{\mathbf{S}_k}(x)$ computed over these sets. While looking only at linear functions over \mathbb{F}_2 as candidate sketches for evaluating f might seem restrictive, this view turns out to be optimal in a number of settings. In the light of recent results of [35, 32], the complexity of \mathbb{F}_2 -sketching also characterizes the space complexity of streaming algorithms in the XOR-update model as well as communication complexity of one-way multiplayer broadcasting protocols for XOR-functions.

In matrix form, \mathbb{F}_2 -sketching corresponds to multiplication over \mathbb{F}_2 of the row vector $x \in \mathbb{F}_2^n$ by a random $n \times k$ matrix whose i -th column is the characteristic vector of $\chi_{\mathbf{S}_i}$:

$$(x_1 \quad x_2 \quad \dots \quad x_n) \begin{pmatrix} \vdots & \vdots & \vdots & \vdots \\ \chi_{\mathbf{S}_1} & \chi_{\mathbf{S}_2} & \dots & \chi_{\mathbf{S}_k} \\ \vdots & \vdots & \vdots & \vdots \end{pmatrix} = (\chi_{\mathbf{S}_1}(x) \quad \chi_{\mathbf{S}_2}(x) \quad \dots \quad \chi_{\mathbf{S}_k}(x))$$

The goal is to minimize k , ensuring that the sketch alone is sufficient for computing f with expected squared error at most ϵ for any fixed input x . For a fixed distribution \mathbf{D} of x , the definition of error is modified to include an expectation over \mathbf{D} in the error guarantee. We give formal definitions below.

► **Definition 1** (Exact \mathbb{F}_2 -sketching, [35]). *The exact randomized \mathbb{F}_2 -sketch complexity with error δ of a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ (denoted as $R_\delta^{lin}(f)$) is the smallest integer k such that there exists a distribution $\chi_{\mathbf{S}_1}, \chi_{\mathbf{S}_2}, \dots, \chi_{\mathbf{S}_k}$ over k linear functions over \mathbb{F}_2^n and a post-processing function $g: \mathbb{F}_2^k \rightarrow \mathbb{R}$ that satisfies:*

$$\forall x \in \mathbb{F}_2^n: \Pr_{\mathbf{S}_1, \dots, \mathbf{S}_k} [g(\chi_{\mathbf{S}_1}(x), \chi_{\mathbf{S}_2}(x), \dots, \chi_{\mathbf{S}_k}(x)) = f(x)] \geq 1 - \delta.$$

The number of parities k in the definition above is referred to as the *dimension* of the \mathbb{F}_2 -sketch.

► **Definition 2** (Approximate \mathbb{F}_2 -sketching). *The ϵ -approximate randomized \mathbb{F}_2 -sketch complexity of a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ (denoted as $\bar{R}_\epsilon^{lin}(f)$) is the smallest integer k such that there exists a distribution $\chi_{\mathbf{S}_1}, \chi_{\mathbf{S}_2}, \dots, \chi_{\mathbf{S}_k}$ over k linear functions over \mathbb{F}_2^n and a post-processing function $g: \mathbb{F}_2^k \rightarrow \mathbb{R}$ that satisfies:*

$$\forall x \in \mathbb{F}_2^n: \mathbb{E}_{\mathbf{S}_1, \dots, \mathbf{S}_k} [(g(\chi_{\mathbf{S}_1}(x), \chi_{\mathbf{S}_2}(x), \dots, \chi_{\mathbf{S}_k}(x)) - f(x))^2] \leq \epsilon$$

If g is an unbiased estimator of f , then this corresponds to an upper bound on the variance of the estimator. For example, functions with small spectral norm (e.g. coverage functions, [57]) admit such approximate \mathbb{F}_2 -sketches. Moreover, observe that Definition 2 is not quite comparable with an epsilon-delta guarantee, which only promises that $|g(\chi_{\mathbf{S}_1}(x), \chi_{\mathbf{S}_2}(x), \dots, \chi_{\mathbf{S}_k}(x)) - f(x)| \leq \epsilon$ with probability $1 - \delta$, but guarantees nothing for δ fraction of the inputs.

In addition to this worst-case guarantee, we also consider the same problem for x from a certain distribution. In this case, a weaker guarantee is required, i.e. the bound on expected squared error should hold only over some fixed known distribution \mathbf{D} . An important case is $\mathbf{D} = U(\mathbb{F}_2^n)$, the uniform distribution over all inputs.

► **Definition 3** (Approximate distributional \mathbb{F}_2 -sketching). *For a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, we define its ϵ -approximate randomized distributional \mathbb{F}_2 -sketch complexity with respect to a distribution D over \mathbb{F}_2^n (denoted as $\bar{\mathcal{D}}_\epsilon^{\text{lin}, D}(f)$) as the smallest integer k such that there exists a distribution $\chi_{\mathbf{S}_1}, \chi_{\mathbf{S}_2}, \dots, \chi_{\mathbf{S}_k}$ over k linear functions over \mathbb{F}_2 and a post-processing function $g: \mathbb{F}_2^k \rightarrow \mathbb{F}_2$ that satisfies:*

$$\mathbb{E}_{x \sim D} \mathbb{E}_{\mathbf{S}_1, \dots, \mathbf{S}_k} [(g(\chi_{\mathbf{S}_1}(x), \chi_{\mathbf{S}_2}(x), \dots, \chi_{\mathbf{S}_k}(x)) - f(x))^2] \leq \epsilon.$$

1.1 Applications to Streaming and Distributed Computing

One of the key applications of our results is to the dynamic streaming model. In this model, the input x is generated via a sequence of additive updates to its coordinates, starting with $x = 0^n$. If $x \in \mathbb{R}^n$, then updates are of the form (i, Δ_i) (turnstile model), where $i \in [n]$, and $\Delta_i \in \mathbb{R}$, which adds Δ_i to the i -th coordinate of x . For $x \in \mathbb{F}_2^n$, only the coordinate i is specified and the corresponding bit is flipped, which is known as the XOR-update model [52]¹. Dynamic streaming algorithms aim to minimize space complexity of computing a given function f for an input generated through a sequence of such updates while also ensuring fast update and function evaluation times.

Note that linear sketching over the reals and \mathbb{F}_2 -sketching can be used directly in the respective streaming update models. Most interestingly, these techniques turn out to achieve almost optimal space complexity. It is known that linear sketching over the reals gives (almost) optimal space complexity for processing dynamic data streams in the turnstile model for *any* function f [41, 2]. However, the results of [41, 2] require adversarial streams of length triply exponential in n . In the XOR-update model, space optimality of \mathbb{F}_2 -sketching has been shown recently in [32]. This optimality result holds even for adversarial streams of much shorter length $\Omega(n^2)$. Hence, lower bounds on \mathbb{F}_2 -sketch complexity obtained in our work extend to space complexity of dynamic streaming algorithms for streams of quadratic length.

A major open question in this area is the conjecture of [35] that the same holds even for streams of length only $2n$. We thus complement our lower bounds on dimension of \mathbb{F}_2 -sketches with one-way two-player communication complexity lower bounds for the corresponding XOR functions $f^+(x, y) = f(x + y)$. Such lower bounds translate to dynamic streaming lower bounds for streams of length $2n$. Furthermore, whenever our communication lower bounds hold for the uniform distribution, the corresponding streaming lower bound applies to streaming algorithms under uniformly random input updates.

Finally, our upper bounds can be used for distributed algorithms computing $f(x_1 + \dots + x_M)$ over a collection of distributed inputs $x_1, \dots, x_M \in \mathbb{F}_2^n$ as \mathbb{F}_2 -sketches can be used for distributed inputs. On the other hand, our communication lower bounds also apply to the simultaneous message passing (SMP) communication model, since it is strictly harder than one-way communication.

¹ By slightly changing the function to $f'(x_1, \dots, x_n, y_1, \dots, y_n) = f(x_1 + y_1, x_2 + y_2, \dots, x_n + y_n)$, it is easy to see that there are functions for which knowledge of the sign of the update (i.e. whether it is +1 or -1) is not a stronger model than the XOR-update model. For some further motivation of the XOR-update model, consider dynamic graph streaming algorithms, i.e. the setting when x represents the adjacency matrix of a graph and updates correspond to adding and removing the edges. Almost all known dynamic graph streaming algorithms (except spectral graph sparsification of [36]) are based on the ℓ_0 -sampling primitive [26]. As shown recently, ℓ_0 -sampling can be implemented optimally using \mathbb{F}_2 -sketches [37] and hence almost all known dynamic graph streaming algorithms can handle XOR-updates, i.e. knowing whether an edge was inserted or deleted does not help.

1.2 Valuation Functions and Sketching

Submodular valuation functions, originally introduced in the context of algorithmic game theory and optimization, have received a lot of interest recently in the context of learning theory [10, 9, 18, 29, 47, 23, 22, 24, 25]², approximation [27, 7] and property testing [16, 49, 12]. As we show in this work, valuation functions also represent an interesting study case for linear sketching and streaming algorithms. While a variety of papers exists on streaming algorithms for optimizing various submodular objectives, e.g. [48, 20, 8, 17, 15, 21, 30, 4, 11], to the best of our knowledge no prior work considers the problem of evaluating such functions under a changing input.

A systematic study of \mathbb{F}_2 -sketching has been initiated for Boolean functions in [35]. This paper can be seen as a next step, as we introduce approximation into the study of \mathbb{F}_2 -sketching. One of the consequences of our work is that the Fourier ℓ_1 -sampling technique, originally introduced by Bruck and Smolensky [14] (see also [28, 45]), turns out to be optimal in its dependence on both spectral norm and the error parameter. For Boolean functions, a corresponding result is not known as Boolean functions with small spectral norm and necessary properties are hard to construct. Another technical consequence of our work is that the study of learning and sketching algorithms turn out to be related on a technical level despite pursuing different objectives (in learning the specific function is unknown, while in sketching it is). In particular, our hardness result for Lipschitz submodular functions uses a construction of a large family of matroids from [10] (even though in a very different parameter regime), who designed such a family to fool learning algorithms.

1.3 Our Results

A function $f: 2^{[n]} \rightarrow \mathbb{R}$ is α -Lipschitz if for any $S \subseteq [n]$ and $i \in [n]$, it holds that $|f(S \cup \{i\}) - f(S)| \leq \alpha$ for some constant $\alpha > 0$. A function $f: 2^{[n]} \rightarrow \mathbb{R}$ is submodular if:

$$f(A \cup \{i\}) - f(A) \geq f(B \cup \{i\}) - f(B) \quad \forall A \subseteq B \subseteq [n] \text{ and } i \notin B.$$

We consider the following classes of valuation functions of the form $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ (all of them submodular) sometimes treating them as $f: 2^{[n]} \rightarrow \mathbb{R}$ and vice versa. These classes mostly cover all of existing literature on submodular functions³. See Table 1 for a summary of the results.

- **Additive (linear).** $f(x) = \sum_{i=1}^n w_i x_i$, where $w_i \in \mathbb{R}$.
Our results: For additive functions, it is easy to show that dimension of \mathbb{F}_2 -sketches is $O(\min(\|w\|_1^2/\epsilon, n))$ and give a matching communication lower bound for all $\epsilon \geq \|w\|_2^2$ [57].
- **Budget-additive.** $f(x) = \min(b, \sum_{i=1}^n w_i x_i)$ where $b, w_i \in \mathbb{R}$. An example of such functions is the “hockey stick” function $hs_\alpha(x) = \min(\alpha, \frac{2\alpha}{n} \sum_{i=1}^n x_i)$.
Our results: For budget-additive functions, it is easy to show that dimension of \mathbb{F}_2 -sketches is $O(\min(\|w\|_1^2/\epsilon, n))$ [57]. We give a matching communication bound for the “hockey stick” function for constant ϵ [57], which holds even under the uniform distribution of the input.

² We remark that in this literature the term “sketching” is used to refer to the space complexity of representing the function f itself under the assumption that it is unknown but belongs to a certain class. This question is orthogonal to our work as we assume f is known and fixed while the input x is changing.

³ We do not discuss some other subclasses of subadditive functions because they are either superclasses of classes for which we already have an $\Omega(n)$ lower bound (e.g. submodular, subadditive, etc.) or because such a lower bound follows trivially (e.g. for OXS/XOS since for XS-functions a lower bound of $\Omega(n)$ is easy to show, see [57]).

■ **Table 1** Linear sketching complexity of classes of valuation functions. We defer the proofs of several results to the full version [57].

Class	Error	Distribution	Complexity	Result
Additive/Budget additive $\min(b, \sum_{i=1}^n w_i x_i)$	ϵ	any	$\Theta\left(\frac{\ w\ _1^2}{\epsilon}\right)$	[57]
$\min(c\sqrt{n}, \frac{2c}{\sqrt{n}} \sum_{i=1}^n x_i)$	constant	uniform	$\Omega(n)$	[57]
Coverage	ϵ	any	$O\left(\frac{1}{\epsilon}\right)$	[57]
Matroid Rank 2	exact	any	$\Theta(1)$	Theorem 12
Graphic Matroids Rank r	exact	any	$O(r^2 \log r)$	Theorem 16
Matroid Rank r	exact	any	$\Omega(r)$	Corollary 35
Matroid Rank r	exact	uniform	$O((r \log r + c)^{r+1})$	[57]
Matroid Rank	$1/\sqrt{n}$	uniform	$\Theta(1)$	[57]
$\frac{\epsilon}{n}$ -Lipschitz Submodular	constant	any	$\Theta(n)$	Theorem 28

- **Coverage.** A function f is a *coverage function* on some universe U of size m if there exists a collection A_1, \dots, A_n of subsets of U and a vector of non-negative weights (w_1, \dots, w_m) such that:

$$f(S) = \sum_{i \in \cup_{j \in S} A_j} w_i.$$

Our results: We show a simple upper bound of $O(1/\epsilon)$ for such functions [57].

- **Matroid rank.** A pair $M = ([n], \mathcal{I})$ is called a matroid if $\mathcal{I} \subseteq 2^{[n]}$ is a non-empty set family such that the following two properties are satisfied:

- If $I \in \mathcal{I}$ and $J \subseteq I$, then $J \in \mathcal{I}$
- If $I, J \in \mathcal{I}$ and $|J| < |I|$, then there exists an $i \in I \setminus J$ such that $J \cup \{i\} \in \mathcal{I}$.

The sets in \mathcal{I} are called *independent*. A maximal independent set is called a *base* of M . All bases have the same size, which is called the *rank* of the matroid and is denoted as $rk(M)$. The *rank function* of the matroid is the function $rank_M: 2^{[n]} \rightarrow \mathbb{N}_+$ defined as:

$$rank_M(S) := \max\{|I|: I \subseteq S, I \in \mathcal{I}\}.$$

It follows from the definition that $rank_M$ is always a submodular 1-Lipschitz function.

Our results: In order to have consistent notation with the rest of the manuscript we always assume that matroid rank functions are scaled so that their values are in $[0, 1]$. Some of our results are exact, i.e. the corresponding matroid rank function is computed exactly (and in this case rescaling does not matter) while others allow approximation of the function value. In the latter case, the approximation guarantees are multiplicative with respect to the rescaled function.

Our main theorem regarding sketching of matroid rank functions is as follows:

- **Theorem 4 (Sketching matroid rank functions).** *For (scaled) matroid rank functions:*
 - There exists an exact \mathbb{F}_2 -sketch of size $O(1)$ for matroids of rank 2 (Theorem 12) and graphic matroids (Theorem 16).
 - There exists $c = \Omega(1)$ and a matroid of rank r such that a c -approximation of its matroid rank function has randomized linear sketch complexity $\Omega(r)$. Furthermore, this lower bound also holds for the corresponding one-way communication problem (Theorem 34, Corollary 35).

This can be contrasted with the results under the uniform distribution for which matroids of rank r have an exact \mathbb{F}_2 -sketch of size $O\left(\left(r \log r + \log \frac{1}{\epsilon}\right)^{r+1}\right)$, where ϵ is the probability of failure ([57], follows from the junta approximation of [13]). Furthermore, matroids of high rank $\Omega(n)$ can be trivially approximately sketched under product distributions, due to their concentration around their expectation (see [57] for details).

- **Lipschitz submodular.** A function $f: 2^{[n]} \rightarrow \mathbb{R}$ is α -Lipschitz submodular if it is both submodular and α -Lipschitz.

Our results: We show an $\Omega(n)$ communication lower bound (and hence a lower bound on \mathbb{F}_2 -sketch complexity) for constant error for monotone non-negative $O(1/n)$ -Lipschitz submodular functions (Theorem 28). We note that this hardness result crucially uses a non-product distribution over the input variables since Lipschitz submodular functions are tightly concentrated around their expectation under product distributions (see e.g. [55, 10]) and hence can be approximated using their expectation without any sketching at all.

1.4 Overview and Techniques

1.4.1 Basic Tools: XOR Functions, Spectral Norm, Approximate Fourier Dimension

In Section 2, we introduce the basics of approximate \mathbb{F}_2 -sketching. Most definitions and results in this section can be seen as appropriate generalizations regarding Boolean functions (such as in [35]) to the case of real-valued functions where we replace Hamming distance with expected squared distance. We then define the randomized one-way communication complexity of the two-player XOR-function $f^+(x, y) = f(x + y)$ corresponding to f . This communication problem plays an important role in our arguments as it gives a lower bound on the sketching complexity of f . We then introduce the notion of approximate Fourier dimension developed in [35]. The key structural results of [35], which characterize both the sketching complexity of f and the one-way communication complexity of f^+ under the uniform distribution using the approximate Fourier dimension, can be extended to the real-valued case as shown in Proposition 10 and Theorem 11. This characterization is our main tool for showing lower bounds under the uniform distribution of x .

Another useful basic tool is a bound on the linear sketching complexity based on the spectral norm of f , which we develop in [57]. In particular, as we show in [57], analogously to the Boolean case, we can leverage properties of the Fourier coefficients of a function f to show that the ϵ -approximate randomized sketching complexity of f is at most $O(\|\hat{f}\|_1^2/\epsilon)$. Thus, we can determine the dimension of \mathbb{F}_2 -sketches for classes of functions whose spectral norms are well-bounded as well as functions which can be computed as Lipschitz compositions of a small number of functions with bounded spectral norm [57]. Examples of such classes include additive (linear), budget-additive and coverage functions. Finally, we argue that the dependence on the parameters in the spectral norm bound cannot be substantially improved in the real-valued case by presenting a subclass of linear functions which require sketches of size $\Omega(\|\hat{f}\|_1^2/\epsilon)$ [57]. This is in contrast with the case of Boolean functions studied in [35] for which such tightness result is not known.

1.4.2 Matroid Rank Functions, LTF, LTF \circ OR

In Section 3, we present our results on sketching matroid rank and Lipschitz submodular functions. In Section 3.1 we show that matroid rank functions of matroids of rank 2 and graphic matroids have constant randomized sketching complexity. This is done by first

observing that rank functions of such matroids can be expressed as a threshold function over a number of disjunctions. Therefore, it remains to determine the sketching complexity of the threshold function on a collection of disjunctions. Unfortunately, known upper bounds for the sketching complexity of even the simpler class of linear threshold functions have a dependence on n and hence one cannot get a constant upper bound directly.

Hence we show how to remove this dependence in Section 3.1.1, also resolving an open question of Montanaro and Osborne [45]. Recall that a linear threshold function (LTF) can be represented as $f(x) = \text{sgn}(\sum_{i=1}^n w_i x_i - \theta)$ for some weights w_i and threshold θ , where we slightly alter the traditional definition of the sign function sgn to output 0 if the input is negative and 1 otherwise. An important parameter of an LTF is its *margin* m , which corresponds to the difference between the threshold and the value of the linear combination closest to it. We first observe that the terms with insignificant coefficients, i.e. weights that are small in absolute value, do not contribute to the final output and thus, we can ignore them. Similarly, the remaining weights can be rounded, without altering the output of the function, to a collection of weights whose size is bounded, independent of n . Furthermore, $f(x) = 0$ only if $x_i = 1$ for at most $\frac{\theta}{2m}$ of these “significant” indices i of x . Thus, we hash the significant indices to a large, but independent of n , number of buckets. As a result, either there are a small number of significant indices i with $x_i = 1$ and there are no collisions, or there is a large number of significant indices i with $x_i = 1$. Since we can differentiate between these two cases, the sketch can output whether $f(x) = 0$ or $f(x) = 1$ with constant probability. With a more careful choice of hash functions this idea can be extended to linear thresholds of disjunctions. We show in Section 3.1.2 that a threshold function over a number of disjunctions (LTF \circ OR) also has linear sketch complexity independent of n .

In Section 3.2.1, we show that there exists an $\Omega(n)$ -Lipschitz submodular function f that requires a randomized linear sketch of size $\Omega(n)$. We construct such a function probabilistically by using a large family of matroid rank functions constructed by [10] with an appropriately chosen set of parameters. We show any fixed deterministic sketch fails on a matroid chosen uniformly at random from this parametric family with very high probability. In fact, even if we take a union bound over all possible sketches of bounded dimension, the failure of probability is still negligibly close to 1. By Yao’s principle, the randomized linear sketch complexity follows. We then extend this result to a communication lower bound for f^+ in Section 3.2.2. In the one-way communication complexity setting, we show that there exists an $\Omega(n)$ -Lipschitz submodular function f whose f^+ requires communication $\Omega(n)$.

1.4.3 Uniform Distribution

In [57], we show lower bounds for a budget additive “hockey stick” function under the uniform distribution. The lower bounds follow from a characterization of communication complexity using approximate Fourier dimension, and to complete the analysis, we lower bound the Fourier spectrum of the hockey stick function in [57]. Although our approach for matroids of rank 2 does not seem to immediately generalize to matroids of higher rank under arbitrary distributions, we show in [57] that under the uniform distribution, we can use ϵ -approximations of disjunctive normal forms (DNFs) by juntas to obtain a randomized linear sketch whose size is independent of n . Furthermore, rank functions of matroids of very high rank admit trivial *approximate* sketches under the uniform distribution as follows from standard concentration results [55] (see [57]).

2 Basics of Approximate \mathbb{F}_2 -Sketching

2.1 Communication Complexity of XOR functions

In order to analyze the optimal dimension of \mathbb{F}_2 -sketches, we need to introduce a closely related communication complexity problem. For $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ define the XOR-function $f^+: \mathbb{F}_2^n \times \mathbb{F}_2^n \rightarrow \mathbb{R}$ as $f^+(x, y) = f(x + y)$ where $x, y \in \mathbb{F}_2^n$. Consider a communication game between two players Alice and Bob holding inputs x and y respectively. Given access to a shared source of random bits Alice has to send a single message to Bob so that he can compute $f^+(x, y)$. This is known as the one-way communication complexity problem for XOR-functions (see [50, 58, 45, 39, 40, 51, 42, 53, 43, 31, 35] for related communication complexity results).

► **Definition 5** (Randomized one-way communication complexity of XOR function). *For a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, the randomized one-way communication complexity with error δ (denoted as $R_{\delta}^{\rightarrow}(f^+)$) of its XOR-function is defined as the smallest size⁴ (in bits) of the (randomized using public randomness) message $M(x)$ from Alice to Bob, which allows Bob to evaluate $f^+(x, y)$ for any $x, y \in \mathbb{F}_2^n$ with error probability at most δ .*

It is easy to see that $R_{\delta}^{\rightarrow}(f^+) \leq R_{\delta}^{lin}(f)$ as using shared randomness Alice can just send k bits $\chi_{\mathbf{s}_1}(x), \chi_{\mathbf{s}_2}(x), \dots, \chi_{\mathbf{s}_k}(x)$ to Bob, who can for each $i \in [k]$ compute $\chi_{\mathbf{s}_i}(x + y) = \chi_{\mathbf{s}_i}(x) + \chi_{\mathbf{s}_i}(y)$, which is an \mathbb{F}_2 -sketch of f on $x + y$ and hence suffices for computing $f^+(x, y)$ with probability $1 - \delta$.

Replacing the guarantee of exactness of the output in the above definition with an upper bound on expected squared error, we obtain the following definition.

► **Definition 6** (Randomized one-way communication complexity of approximating an XOR function). *For a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, the randomized one-way communication complexity (denoted as $\bar{R}_{\epsilon}^{\rightarrow}(f^+)$) of approximating its XOR-function with error ϵ is defined as the smallest size (in bits) of the (randomized using public randomness) message $M(x)$ from Alice to Bob, which allows Bob to evaluate $f^+(x, y)$ for any $x, y \in \mathbb{F}_2^n$ with expected squared error at most ϵ .*

Distributional communication complexity is defined analogously for the corresponding XOR function and is denoted as \mathcal{D}_{ϵ} .

Finally, in the simultaneous model of computation [6, 5], also called simultaneous message passing (SMP) model, there exist two players and a coordinator, who are all aware of a function f . The two players maintain x and y respectively, and must send messages of minimal size to the coordinator so that the coordinator can compute $f(x \oplus y)$.

► **Definition 7** (Simultaneous communication complexity of XOR function). *For a function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, the simultaneous one-way communication complexity with error δ (denoted as $R_{\delta}^{sim}(f^+)$) of its XOR-function is defined as the smallest sum of the sizes (in bits) of the (randomized using public randomness) messages $M(x)$ and $M(y)$ from Alice and Bob, respectively, to a coordinator, which allows the coordinator to evaluate $f^+(x, y)$ for any $x, y \in \mathbb{F}_2^n$ with error probability at most δ .*

Observe that a protocol for randomized one-way communication complexity of XOR function translates to a protocol for the simultaneous model of computation.

⁴ Formally the minimum here is taken over all possible protocols where for each protocol the size of the message $M(x)$ refers to the largest size (in bits) of such message taken over all inputs $x \in \mathbb{F}_2^n$. See [38] for a formal definition.

2.2 Distributional Approximate \mathbb{F}_2 -Sketch Complexity

Fourier analysis plays an important role in the analysis of distributional \mathbb{F}_2 -sketch complexity over the uniform distribution. In our discussion below, we make use of some standard facts from Fourier analysis of functions over \mathbb{F}_2^n . For definitions and basics of Fourier analysis of functions of such functions we refer the reader to the standard text [46] and [57]. In particular, Fourier concentration on a low-dimensional subspace implies existence of a small sketch which satisfies this guarantee:

► **Definition 8** (Fourier concentration). *A function $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ is γ -concentrated on a linear subspace A_d of dimension d if for this subspace it satisfies:*

$$\sum_{S \in A_d} \hat{f}(S)^2 \geq \gamma.$$

We also use the following definition of approximate Fourier dimension from [35], adapted for the case of real-valued functions.

► **Definition 9** (Approximate Fourier dimension). *Let \mathcal{A}_k be the set of all linear subspaces of \mathbb{F}_2^n of dimension k . For $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$ and $\epsilon \in (0, \|f\|_2^2]$ the ϵ -approximate Fourier dimension $\dim_\epsilon(f)$ is defined as:*

$$\dim_\epsilon(f) = \min_k \left\{ \exists A \in \mathcal{A}_k : \sum_{\alpha \in A} \hat{f}^2(\alpha) \geq \epsilon \right\}.$$

► **Proposition 10.** *For any $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, it holds that:*

$$\bar{\mathcal{D}}_\epsilon^{\text{lin}, U}(f) \leq \dim_{\|f\|_2^2 - \epsilon}(f).$$

Furthermore, approximate Fourier dimension can be used as a lower bound on the one-way communication complexity of the corresponding XOR-function. We defer the proof of the following result to [57] as it follows closely an analogous result for Boolean functions from [35].

► **Theorem 11.** *For any $f: \mathbb{F}_2^n \rightarrow \mathbb{R}$, $\delta \in [0, 1/2]$ and $\xi = \|f\|_2^2 - \epsilon(1 + 2\delta)$ it holds that:*

$$\bar{\mathcal{D}}_\epsilon^{\rightarrow, U}(f^+) \geq \frac{\delta}{2} \cdot \dim_\xi(f).$$

3 Sketching Matroid Rank Functions

In this section we analyze sketching complexity of matroid rank functions. We start by considering the most fundamental possible matroids (of rank 2) in Section 3.1 and showing that exactly sketching the matroid rank function requires $O(1)$ complexity. Similarly, we show that exactly sketching the rank of graphic matroids only uses $O(1)$ complexity. On the other hand, we show a lower bound in Section 3.2.1 that even approximating the rank r of general matroids up to certain constant factors requires $\Omega(r)$ complexity.

To sketch matroids of rank 2, we leverage a result by Acketa [1] which characterizes the collection of independent sets of such matroids. This allows us to represent matroid rank functions for matroids of rank 2 as a linear threshold of disjunctions. Thus, we first show the randomized linear sketch complexity of (θ, m) -linear threshold functions, resolving an open question by Montanaro and Osborne [45].

3.1 Matroids of Rank 2 and Graphic Matroids

In this section, we show that there exists a constant-size sketch that can be used to compute exact values of matroid rank functions for matroids of rank 2.

► **Theorem 12.** *For every matroid M of rank 2 it holds that $R_{\frac{1}{3}}^{lin}(rank_M) = O(1)$.*

It is well-known that matroids of rank 2 admit the following characterization (see e.g. [1]).

► **Fact 13.** *The collection of size 2 independent sets of a rank 2 matroid can be represented as the edges in a complete graph that has edges of some number of disjoint cliques removed.*

We define the following function as a threshold on the Hamming weight of a binary vector x

$$\text{HAM}_{\leq d}(x) = \begin{cases} 0, & \text{if } \sum_{i=1}^n x_i \leq d + \frac{1}{2} \\ 1, & \text{otherwise.} \end{cases}$$

We use a series of technical lemmas in the following section to prove the following result, which says that linear threshold functions can be succinctly summarized:

► **Theorem 14.** *The function $\text{HAM}_{\leq d}(\bigvee_{i \in S_1} x_i, \bigvee_{i \in S_2} x_i, \dots)$ has a randomized linear sketch of size $O(d^2 \log d)$.*

The following fact that upper bounds the sketch complexity for functions with small support:

► **Fact 15** (Folklore, see e.g. [45, 35]). *For any function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ with $\min_{z \in \{0, 1\}} \Pr_{x \in \{0, 1\}^n}(f(x) = z) \leq \epsilon$ it holds that $R_{\delta}^{lin}(f) \leq \log \frac{2^{n+1}\epsilon}{\delta}$.*

Using Fact 13, Theorem 14, and Fact 15, we prove Theorem 12 by writing the matroid rank function for M as a linear threshold function of disjunctions.

Proof of Theorem 12. We first claim \mathbb{F}_2 -sketching complexity of the rank function of any rank 2 matroid M is essentially the same as the complexity of the corresponding Boolean function that takes value 1 if $rank_M(x) = 2$ and takes value 0 otherwise. Indeed, let the function above be denoted as f_M . Without loss of generality, we can assume that all singletons are independent sets in M as otherwise the rank function of M does not depend on the corresponding input. Hence $rank_M(x) = 0$ if and only if $x = 0^n$. Thus $R_{\delta}^{lin}(rank_M) = R_{\delta}^{lin}(f_M) + O(\log 1/\delta)$ as by Fact 15 we can use $O(\log 1/\delta)$ -bit sketch to check whether $x = 0^n$ first and then evaluate $rank_M$ using f_M . Recall from Fact 13 that matroids of rank 2 can be represented as edges in a complete graph with edges corresponding to some disjoint union of cliques removed.

Let S_1, \dots, S_t be the collection of vertex sets of disjoint cliques defining a rank 2 matroid M in Fact 13. Without loss of generality, we can assume that $|\cup_{i=1}^t S_i| = n$ by adding singletons. Then:

$$f_M(x) = \text{HAM}_{\geq 2} \left(\bigvee_{j \in S_1} x_j, \bigvee_{j \in S_2} x_j, \dots, \bigvee_{j \in S_t} x_j \right),$$

where $\text{HAM}_{\geq 2}(z_1, \dots, z_t) = 1$ if and only if $\sum_{i=1}^t z_i \geq 2$ is the threshold Hamming weight function. By Theorem 14, the sketch complexity of $f_M(x)$ is $O(1)$, since the Hamming weight threshold is $d = 2$. ◀

Since the independent bases of a graphic matroid $M(G)$ are the spanning forests of G , the matroid rank function of a graphic matroid of rank r can be expressed as

$$f_M(x) = \text{HAM}_{\geq r} \left(\bigvee_{j \in S_1} x_j, \bigvee_{j \in S_2} x_j, \dots, \bigvee_{j \in S_t} x_j \right),$$

where each S_i is a separate spanning forest. Therefore, Theorem 14 yields a $O(r^2 \log r)$ space linear sketch for graphic matroids of rank r .

► **Theorem 16.** *For every graphic matroid M of rank r , it holds that $R_{\frac{1}{3}}^{\text{lin}}(\text{rank}_M) = O(r^2 \log r)$.*

We use the remainder of the Section 3.1 to prove Theorem 14, while resolving an open question by Montanaro and Osborne [45].

3.1.1 Linear Threshold Functions

We first define linear threshold functions (LTFs) and (θ, m) -LTFs.

► **Definition 17.** *A function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is a linear threshold function (LTF) if there exist constants $\theta, w_1, w_2, \dots, w_n$ such that $f(x) = \text{sgn}(-\theta + \sum_{i=1}^n w_i x_i)$, where $\text{sgn}(y) = 0$ for $y < 0$ and $\text{sgn}(y) = 1$ for $y \geq 0$ is the Heaviside step function.*

► **Definition 18.** *A monotone linear threshold function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ is a (θ, m) -LTF if $m \leq \min_{x \in \{0, 1\}^n} |-\theta + \sum_{i=1}^n w_i x_i|$, where θ is referred to as the threshold and m as the margin of the LTF.*

Although (θ, m) -LTFs have previously been shown to have randomized linear sketch complexity $O(\frac{\theta}{m} \log n)$ [42], Montanaro and Osborne asked whether any (θ, m) -LTF can be represented in the simultaneous model with $O(\frac{\theta}{m} \log \frac{\theta}{m})$ communication.

► **Question 19** ([45]). *Let $g(x, y) = f(x \oplus y)$, where f is a (θ, m) -LTF. Does there exist a protocol for g in the simultaneous model with communication complexity $O(\frac{\theta}{m} \log \frac{\theta}{m})$?*

Note that the difference between $\log n$ and $\log \frac{\theta}{m}$ is crucial for obtaining constant randomized linear sketch complexity for functions for matroid rank 2. We answer Question 19 in the affirmative and show the stronger result that (θ, m) -LTFs admit a randomized linear sketch of size $O(\frac{\theta}{m} \log \frac{\theta}{m})$. We first show that we can completely ignore all variables whose weights are significantly smaller than $2m$ in evaluating a (θ, m) -LTF.

► **Lemma 20.** *Let $f(x) = \text{sgn}(-\theta + \sum_{i=1}^n w_i x_i)$ be a (θ, m) -LTF. For $1 \leq i \leq n$, let $w'_i = w_i$ if $w_i \geq 2m$ and $w'_i = 0$ otherwise. Then $f(x) = \text{sgn}(-\theta + \sum_{i=1}^n w'_i x_i)$.*

As noted, Lemma 20 implies that we can ignore not only variables with zero weights, but all variables whose weights are less than $2m$. We now bound the support of the set $\{x \mid f(x) = 0\}$, where f is a (θ, m) -LTF, and apply Fact 15.

► **Lemma 21.** *For any (θ, m) -LTF, there exists a randomized linear sketch of size $O(\frac{\theta}{m} \log n)$.*

Proof. Let $f(x) = \text{sgn}(-\theta + \sum_{i=1}^n w_i x_i)$ be a (θ, m) -LTF. By Lemma 20, the output of f remains the same even if we only consider the variables S with weight at least $2m$. On the other hand, if $f(x) = 0$, then at most $\frac{\theta}{2m}$ variables in S can have value 1. Equivalently, at most $\frac{\theta}{2m}$ indices i can have $x_i = 1$ if $f(x) = 0$. Thus, the number of $x \in \{0, 1\}^n$ with $f(x) = 0$ is at most $\sum_{0 \leq i \leq \theta/2m} \binom{n}{i} \leq (n+1)^{\lceil \theta/2m \rceil}$. Applying Fact 15, there exists a randomized linear sketch for f , of size $O(\frac{\theta}{m} \log n)$. ◀

69:12 Approximate \mathbb{F}_2 -Sketching of Valuation Functions

In order to fully prove Question 19 and obtain a dependence on $\log \frac{\theta}{m}$ rather than $\log n$, we use the following two observations. First, we show in Lemma 22 that the weights of a (θ, m) -LTF can be rounded to a set that contains $O\left(\frac{\theta}{m}\right)$ elements. Second, we show in Theorem 25 that we can then use hashing to reduce the number of variables down to $\text{poly}\left(\frac{\theta}{m}\right)$ before applying Lemma 21.

► **Lemma 22.** *Let $f(x) = \text{sgn}\left(-\theta + \sum_{i=1}^n w_i x_i\right)$ be a (θ, m) -LTF. Then there exists a set W with $|W| = O\left(\frac{\theta}{m} \log \frac{\theta}{m}\right)$, and a margin $m' = \Theta(m)$ such that $f(x) = \text{sgn}\left(-\theta + \sum_{i=1}^n w'_i x_i\right)$, where each $w'_i \in W$ and f is a (θ, m') -LTF.*

The following result is also useful for our construction of a sketch for a (θ, m) -LTF.

► **Lemma 23** ([33]). *There is a randomized linear sketch with size $O(1)$ for the function*

$$\text{HAM}_{n,d|2d}(x) = \begin{cases} 1, & \text{if } \|x\|_0 \leq d \\ 0, & \text{if } \|x\|_0 \geq 2d \end{cases}$$

on instances $\{x \mid x \in \{0, 1\}^n \text{ and } \|x\|_0 \leq d \text{ or } \|x\|_0 \geq 2d\}$.

► **Fact 24.** *If $h : [n] \rightarrow [M]$ is a random hash function and $S \subseteq [n]$, then the probability that there exist $x, y \in S$ with $h(x) = h(y)$ is at most $\frac{|S|^2}{M}$.*

► **Theorem 25.** *Any (θ, m) -LTF admits a randomized linear sketch of size $O\left(\frac{\theta}{m} \log \frac{\theta}{m}\right)$.*

Proof. Let $f(x) = \text{sgn}\left(-\theta + \sum_{i=1}^n w_i x_i\right)$ be a (θ, m) -LTF. By Lemma 22, we can assume that $w_i \in W = \{2m(1 + \epsilon)^i\}_{i=0}^t$ so that the new margin $m' = \frac{4}{5}m$ and $t = \lceil \log_{1+\epsilon} \frac{\theta}{m} \rceil$ for $\epsilon = \frac{\theta}{10m}$. Recall from Lemma 21, $f(x) = 0$ only if $x_i = 1$ for at most $\frac{\theta}{2m}$ indices i of x . From Lemma 23, we can detect the instances where at least $\frac{\theta}{2m}$ indices i of x satisfy $x_i = 1$.

On the other hand, if less than $\frac{\theta}{2m}$ indices i of x satisfy $x_i = 1$, we can identify these indices and corresponding weights via hashing. Let $h : [n] \rightarrow [M]$, where $M = 5\left(\frac{\theta}{m}\right)^2$, and S be a set of indices of x , of size at most $\frac{\theta}{m}$. Then by Fact 24, the probability of a collision in h under elements of S is at most $\frac{1}{5}$. We partition $[n]$ into sets $S_{w,j}$ where $w \in W$ and $j \in [M]$ so that $S_{w,j} = \{i \mid h(i) = j \wedge w_i = w\}$. Therefore with probability at least $\frac{4}{5}$, there are no collisions in h under elements of S and $|S_{w,j}| \leq 1$ for all $w \in W$ and $j \in [M]$.

Let $y_{w,j} = \sum_{i \in S_{w,j}} x_i$ and note that if there are no collisions in h under elements of S , then

$$\sum_{i=1}^n w_i x_i = \sum_{(j,w) \in [M] \times W} w \left(\sum_{i \in S_{w,j}} x_i \right) = \sum_{(j,w) \in [M] \times W} w \cdot y_{w,j}.$$

Thus, $f(x)$ is equivalent to the function $g(y) = \text{sgn}\left(-\theta + \sum_{w,j} w \cdot y_{w,j}\right)$. Since $|W| = O\left(\frac{\theta}{m} \log \frac{\theta}{m}\right)$, $M = 5\left(\frac{\theta}{m}\right)^2$ and $m' = \frac{4}{5}m$ is the margin for $g(y)$, then $g(y)$ depends on $O\left(\left(\frac{\theta}{m}\right)^3 \log \frac{\theta}{m}\right)$ variables $y_{w,j}$. By Lemma 21, there exists a randomized sketch for $g(y)$ of size $O\left(\frac{\theta}{m} \log \frac{\theta}{m}\right)$. ◀

We can also show that Theorem 25 is tight by recalling the function

$$\text{HAM}_{\leq d}(x) = \begin{cases} 0, & \text{if } \sum_{i=1}^n x_i \leq d + \frac{1}{2} \\ 1, & \text{otherwise.} \end{cases}$$

Since this function is a $(d + \frac{1}{2}, \frac{1}{2})$ -LTF, it can be represented by a randomized linear sketch of size $O(d \log d)$. On the other hand, Dasgupta, Kumar and Sivakumar [19] notes that the one-way complexity of small set disjointness for two vectors x and y of weight d , which reduces to the function $\text{HAM}_{\leq d}(x \oplus y)$, is $\Omega(d \log d)$. Thus, $\text{HAM}_{\leq d}(x \oplus y)$ also requires a sketch of size $\Omega(d \log d)$.

3.1.2 Linear Threshold of Disjunctions

In this section, we describe a randomized linear sketch for functions that can be represented as 2-depth circuits where the top gate is a monotone linear threshold function with threshold θ and margin m , and the bottom gates are OR functions. Formally, if $g_S(x) = \bigvee_{i \in S} x_i$, q is a linear threshold function, and $w_S \geq 0$, then $f(x) = q(\dots, g_S(x), \dots) = \text{sgn}(-\theta + \sum_{S \in 2^{[n]}} w_S \cdot g_S(x))$.

► **Lemma 26.** *Let $f(x) = \text{sgn}(-\theta + \sum_{i=1}^n w_i x_i)$ be a (θ, m) -LTF where $w_i \in W$ for some set W . Let $h : [n] \rightarrow [M]$ be a random hash function where $M = \frac{50\theta^2}{m^2}$ and*

$$f_h(x) = \text{sgn} \left(-\theta + \sum_{(j,w) \in [M] \times W} w \left(\bigvee_{\substack{i:h(i)=j \\ w_i=w}} x_i \right) \right).$$

Then for all x , $\Pr[f_h(x) \neq f(x)] \leq \frac{1}{50}$.

► **Theorem 27.** *Let $g_S(x) = \bigvee_{i \in S} x_i$ with $w_S \geq 0$, q be a (θ, m) -LTF, and*

$$f(x) = q(\dots, g_S(x), \dots) = \text{sgn} \left(-\theta + \sum_{S \in 2^{[n]}} w_S \cdot g_S(x) \right).$$

Then there is a randomized linear sketch for f of size $O\left(\left(\frac{\theta}{m}\right)^4 \log^2 \frac{\theta}{m}\right)$, where m is the margin of q .

Proof. We first apply Lemma 20 and Lemma 22 to q so that weights w_i can be rounded to elements of a set W with $|W| = O\left(\frac{\theta}{m} \log \frac{\theta}{m}\right)$. For each $w_i \in W$, it again suffices to detect whether $\Theta\left(\frac{\theta}{m}\right)$ disjunctions are nonzero. Hence to hash $O\left(\left(\frac{\theta}{m}\right)^2 \log \frac{\theta}{m}\right)$ disjunctions, it suffices to use a hash function with $M = O\left(\left(\frac{\theta}{m}\right)^4 \log^2 \frac{\theta}{m}\right)$ buckets. By Lemma 26, our resulting randomized linear sketch has size $O\left(\left(\frac{\theta}{m}\right)^4 \log^2 \frac{\theta}{m}\right)$. ◀

Proof of Theorem 14. Recall that $\text{HAM}_{\leq d}(x)$ is a $(d + \frac{1}{2}, \frac{1}{2})$ -LTF. Furthermore, the set of weights W for $\text{HAM}_{\leq d}(x)$ consists of a single element $\{1\}$, since the coefficient of each disjunction is one. Since $M = O(d^2 \log d)$, we can construct a randomized linear sketch with size $O(d^2 \log d)$ by Lemma 26. ◀

We note that our approach can be easily generalized to the case where the disjunction include the negations of some variables as well.

3.2 Communication Complexity of Lipschitz Submodular Functions

We discuss the communication complexity of Lipschitz submodular functions in this section. We first show in Section 3.2.1 that there exists an $\Omega(n)$ -Lipschitz submodular function f that requires a randomized linear sketch of size $\Omega(n)$. We then show in Section 3.2.2 that in the one-way communication complexity model for XOR functions, there exists an $\Omega(n)$ -Lipschitz submodular function f that has communication complexity $\Omega(n)$.

3.2.1 Approximate \mathbb{F}_2 -Sketching of Lipschitz Submodular Functions

► **Theorem 28.** *There exist constants $c_1, c_2, \epsilon \geq 0$ and a monotone non-negative $(\frac{c_1}{n})$ -Lipschitz submodular function f (a scaling of a matroid rank function) such that $\bar{R}_\epsilon^{\text{lin}}(f) \geq c_2 n$.*

Proof. Our proof uses a construction of a large family of matroid rank functions given in [10], Theorem 8. The construction uses the following notion of lossless bipartite expanders:

► **Definition 29** (Lossless bipartite expander). *Let $G = (U \cup V, E)$ be a bipartite graph. For $J \subseteq U$ let $\Gamma(J) = \{v \mid \exists u \in U: \{u, v\} \in E\}$. Graph G is a (D, L, ϵ) -lossless expander if:*

$$\begin{aligned} |\Gamma(\{u\})| &= D \quad \forall u \in U \\ |\Gamma(J)| &\geq (1 - \epsilon)D|J| \quad \forall J \subseteq U, |J| \leq L. \end{aligned}$$

Here we need different parameters than in [10] so we restate their theorem as follows:

► **Theorem 30** ([10]). *Let $(U \cup V, E)$ be a (D, L, ϵ) -lossless expander with $|U| = k$ and $|V| = n$ and let $b = 8 \log k$. If $D \geq b$, $L = 4D/b - 2$ and $\epsilon = \frac{b}{4D}$ then there exists a family of sets $\mathcal{A} \subseteq 2^{[n]}$ and a family of matroids $\{M_{\mathcal{B}}: \mathcal{B} \subseteq \mathcal{A}\}$ with the following properties:*

- $|\mathcal{A}| = k$ and for every $A \in \mathcal{A}$ it holds that $|A| = D$.
- For every $\mathcal{B} \subseteq \mathcal{A}$ and every $A \in \mathcal{A}$, we have:

$$\text{rank}_{M_{\mathcal{B}}}(A) = \begin{cases} b & \text{if } A \in \mathcal{B} \\ D & \text{if } A \in \mathcal{A} \setminus \mathcal{B} \end{cases}$$

We use the following construction of lossless expanders from [54], see also [10].

► **Theorem 31** ([54]). *Let $k \geq 2$ and $\epsilon \geq 0$. For any $L \leq k$, let $D \geq 2 \log k / \epsilon$ and $n \geq 6DL / \epsilon$. Then a (D, L, ϵ) -lossless expander exists.*

In the above theorem we can set parameters as follows:

$$D = \frac{n}{3 \cdot 2^7}, \quad L = 2^3, \quad \epsilon = 2^{-3}, \quad k = 2^{n/3 \cdot 2^{11}}, \quad b = \frac{n}{3 \cdot 2^8}.$$

Note that under this choice of parameters we have $6DL/\epsilon = n$ and $\frac{2 \log k}{\epsilon} = D$ and hence a (D, L, ϵ) -lossless expander with parameters set above exists.

Now consider the family of matroids \mathcal{M} given by Theorem 30 using the expander construction above. The rest of the proof uses the probabilistic method. We will show non-constructively that there exists a matroid in this family whose rank function does not admit a sketch of dimension $d = o(n)$. Let $\mathcal{D} = U(\mathcal{A})$ be the uniform distribution over \mathcal{A} . By Yao's principle it suffices to show that there exists a matroid rank function for which any deterministic sketch fails with a constant probability over this distribution. In the proof below we first show that any fixed deterministic sketch succeeds on a randomly chosen matroid from \mathcal{M} with only a very tiny probability, probability $2^{2^{-\Omega(n)}}$, and then take a union bound over all 2^{dn} sketches of dimension at most d .

Indeed, fix any deterministic sketch \mathcal{S} of dimension $d = n/2^{11}$. Let $\{b_1, \dots, b_{2^d}\}$ be the set of all possible binary vectors of length d corresponding to the possible values of the sketch, so that each $b_i \in \{0, 1\}^d$.

Let $S_{b_i} = \{A \in \mathcal{A} : \mathcal{S}(A) = b_i\}$. Let $t = \frac{1}{4}2^{n/2^{11}}$ and $G = \{b_i \in \{0, 1\}^d \mid |S_{b_i}| \geq t\}$. The following proposition follows by a simple calculation.

► **Proposition 32.** *If $t = \frac{1}{4}2^{n/2^{11}}$ then $\frac{1}{k} \sum_{b_i \in G} |S_{b_i}| \geq \frac{3}{4}$.*

Proof. We have:

$$\frac{1}{k} \sum_{b_i \in G} |S_{b_i}| \geq 1 - \frac{1}{k} \sum_{b_i : |S_{b_i}| < \frac{k}{4 \cdot 2^d}} |S_{b_i}| \geq 1 - \frac{1}{k} \cdot \frac{k}{4 \cdot 2^d} \cdot 2^d \geq \frac{3}{4}. \quad \blacktriangleleft$$

Let $S_{b_i}^1 = \{A \in S_{b_i} : \text{rank}_{M_{\mathcal{B}}}(A) = b\}$ and $S_{b_i}^2 = \{A \in S_{b_i} : \text{rank}_{M_{\mathcal{B}}}(A) = D\}$. We require the following lemma.

► **Lemma 33.** *Let $t = \frac{1}{4}2^{n/2^{11}}$ and $d = n/2^{11}$. There exists a matroid $M_{\mathcal{B}} \in \mathcal{M}$ such that for all deterministic sketches \mathcal{S} of dimension d and all $b_i \in G$, $\min(|S_{b_i}^1|, |S_{b_i}^2|) \geq \frac{1}{4}|S_{b_i}|$.*

Fix the set \mathcal{B} constructed in Lemma 33 and consider the function $\text{rank}_{M_{\mathcal{B}}}$. Consider distribution \mathcal{D} over the inputs. The probability that any deterministic sketch over this distribution makes error at least $D - b$ is at least:

$$\frac{1}{k} \sum_{b_i \in \{0,1\}^n} \min(|S_{b_i}^1|, |S_{b_i}^2|) \geq \frac{1}{k} \sum_{b_i \in G} \min(|S_{b_i}^1|, |S_{b_i}^2|) \geq \frac{1}{k} \sum_{b_i \in G} \frac{1}{4}|S_{b_i}|,$$

where the last inequality holds by Lemma 33. Thus by Proposition 32, the probability is at least $\frac{3}{4} \times \frac{1}{4} \geq \frac{1}{6}$.

Finally, the construction of [10] ensures that the function $\text{rank}_{M_{\mathcal{B}}}$ takes integer values between 0 and D . Using this and the fact that matroid rank functions are 1-Lipschitz, we can normalize it by dividing all values by D and ensure that the resulting function is $O(1/n)$ -Lipschitz and takes values in $[0, 1]$, while the sketch makes error at least $(D - b)/D = \frac{1}{2}$. ◀

3.2.2 One-Way Communication of Lipschitz Submodular Functions

In this section, we strengthen the lower bound shown above, extending it to the corresponding one-way communication problem. We use the same notation as in the previous section.

► **Theorem 34.** *There exists a constant $c_1 > 0$ and a $\frac{c_1}{n}$ -Lipschitz submodular function such that $R_{1/3}^{\rightarrow} = \Omega(n)$.*

By restricting the n -dimensional elements to r coordinates and observing that the construction outputs matroids of rank b or D that are separated by a constant gap, we obtain the following result using the same proof:

► **Corollary 35.** *There exists $c = \Omega(1)$ such that a c -approximation of matroid rank functions has randomized one-way communication complexity $R_{1/3}^{\rightarrow} = \Omega(r)$ where r is the rank of the underlying matroid.*

A Missing Proofs

Proof of Proposition 10. Indeed, let A_d be a d -dimensional subspace such that $\sum_{S \in A_d} \hat{f}^2(S) \geq \|f\|_2^2 - \epsilon$ and consider the function $g(x) = \sum_{S \in A_d} \hat{f}(S) \chi_S(x)$. Note that in order to compute all values $\chi_S(x)$ for $S \in A_d$ it suffices to evaluate d parities corresponding to sets S_1, \dots, S_d forming a basis in A_d . Values of all other parities can be computed as linear combinations. Let $\Delta(x) = f(x) - g(x)$. Then the desired guarantee follows from the following calculation:

$$\mathbb{E}_{x \sim U(\{0,1\}^n)} [\Delta(x)^2] = \mathbb{E}_{S \sim U(\{0,1\}^n)} [\hat{\Delta}(S)^2] = \sum_{S \in \{0,1\}^n} (\hat{f}(S) - \hat{g}(S))^2 = \sum_{S \notin A_d} \hat{f}(S)^2 \leq \epsilon,$$

where the first equality holds from Parseval's identity. ◀

Proof of Lemma 20. We show the stronger result that for any j such that $w_j < 2m$, then $f(x) = f(x \oplus e_j)$, where e_j is the elementary unit vector with one in the j th position, and zeros elsewhere. This implies the lemma since it shows that any variable whose weight is less than $2m$ does not affect the output of the function or the margin of the function and thus might as well have weight zero.

Suppose, by way of contradiction, that $f(x) \neq f(x \oplus e_j)$ and without loss of generality, $f(x) = 0$ with $x_j = 0$. Since f is a linear threshold function and $f(x) = 0$, then $-\theta + \sum_{i=1}^n w_i x_i < 0$. Moreover, f is a (θ, m) -LTF, so $-\theta + \sum_{i=1}^n w_i x_i < -m$. Because $w_j < 2m$, $-\theta + w_j + \sum_{i=1}^n w_i x_i < -\theta + 2m + \sum_{i=1}^n w_i x_i < m$. But because m is the margin of the function, if $-\theta + w_j + \sum_{i=1}^n w_i x_i < m$, then it must hold that $-\theta + w_j + \sum_{i=1}^n w_i x_i < -m$. Therefore, $f(x \oplus e_j) = 0$, so x_j does not affect the output of the function or the margin of the function. ◀

Proof of Lemma 22. Observe that for any $w_i \geq 2\theta$, if $x_i = 1$, then $f(x) = 1$. Thus, if $f(x) = 1$, it suffices to consider $2m \leq w_i \leq 2\theta$.

Let $W = \{2m(1 + \epsilon)^i\}_{i=0}^t$ for $t = \lceil \log_{1+\epsilon}(\frac{\theta}{m}) \rceil$, where ϵ is some fixed constant that we set at a later time. For each i , let w'_i be the largest element in W that does not exceed w_i . Thus, $w'_i \leq w_i < (1 + \epsilon)w'_i$. Observe that since $w'_i \leq w_i$ and f is a (θ, m) -LTF, then $f(x) = 0$ implies $-m > -\theta + \sum_{i=1}^n w_i x_i \geq -\theta + \sum_{i=1}^n w'_i x_i$, so that $\text{sgn}(-\theta + \sum_{i=1}^n w'_i x_i) = 0 = f(x)$ and a margin of m remains.

On the other hand, if $f(x) = 1$, then $\sum_{i=1}^n w_i x_i > \theta + m$ as f is a (θ, m) -LTF. Since $w'_i \leq w_i < (1 + \epsilon)w'_i$, then $\sum_{i=1}^n w'_i x_i > \frac{\theta+m}{1+\epsilon} > (1 - \epsilon)(\theta + m)$. Observe that $\theta \geq m$ and hence, $\sum_{i=1}^n w'_i x_i > \theta - \epsilon\theta + m - \epsilon m \geq \theta + m - 2\epsilon\theta$. Setting $\epsilon = \frac{\theta}{10m}$ shows that $\text{sgn}(-\theta + \sum_{i=1}^n w'_i x_i) = 1 = f(x)$ and a margin of $m' = \frac{4}{5}m$ remains. ◀

Proof of Lemma 26. As by Lemma 22, we can assume without loss of generality that $w_i \geq 2m$ and $w \geq 2m$. Let $S = \{i | x_i = 1\}$ so that if there are no collisions under h in S , then

$$\sum_{(j,w) \in [M] \times W} w \left(\bigvee_{\substack{i: h(i)=j \\ w_i=w}} x_i \right) = \sum_i w_i x_i.$$

If $f(x) = 0$, then $|S| \leq \frac{\theta}{2m}$ so that the probability there are collisions under h in S is at most $\frac{1}{200}$ by Fact 24. Thus if $f(x) = 0$, then $f_h(x) = 0$ with probability at least $1 - \frac{1}{200}$.

69:20 Approximate \mathbb{F}_2 -Sketching of Valuation Functions

If $f(x) = 1$, then either $|S| < \frac{\theta}{m}$ or $|S| \geq \frac{\theta}{m}$. If $|S| < \frac{\theta}{m}$, then the probability there are collisions under h in S is at most $\frac{1}{50}$ by Fact 24, so then $f_h(x) = 1$ with probability at least $1 - \frac{1}{50}$. If $|S| \geq \frac{\theta}{m}$, with probability at least $1 - \frac{1}{50}$, there exist $\frac{\theta}{m}$ values j such that there exists $x_i = 1$ and $h(i) = j$. Therefore, we set $f_h(x) = 1$ whenever at least $\frac{\theta}{m}$ buckets of h are non-empty. In all cases, $f_h(x) = f(x)$ with probability at least $1 - \frac{1}{50}$. \blacktriangleleft

Proof of Lemma 33. The proof uses the probabilistic method to show the existence of \mathcal{B} with desired properties. Consider drawing a random matroid from the family \mathcal{M} , i.e. pick \mathcal{B} to be a uniformly random subset of \mathcal{A} and consider $M_{\mathcal{B}}$. Fix any deterministic sketch \mathcal{S} and any $b_i \in G$. Since $|S_{b_i}| \geq t$, by the Chernoff bound, it holds that:

$$\Pr_{\mathcal{B} \subseteq \mathcal{A}} \left[|S_{b_i}^1| > \left(\frac{1}{2} + \delta \right) |S_{b_i}| \right] \leq e^{-c\delta^2 |S_{b_i}|} \leq e^{-c\delta^2 t}.$$

Setting $\delta = 1/4$, we have that the above probability is at most e^{-Ct} for some constant $C > 0$. Applying the argument above to both $S_{b_i}^1$ and $S_{b_i}^2$, we have that:

$$\Pr_{\mathcal{B} \subseteq \mathcal{A}} \left[\min(|S_{b_i}^1|, |S_{b_i}^2|) < \frac{1}{4} |S_{b_i}| \right] \leq 2e^{-Ct}.$$

Let \mathcal{E} denote the event that $\min(|S_{b_i}^1|, |S_{b_i}^2|) \geq \frac{1}{4} |S_{b_i}|$.

Note that the total number of deterministic sketches of dimension d is at most 2^{dn} , since each sketch is specified by a collection of d linear functions over \mathbb{F}_2^n . Also note that for each sketch $|G| \leq 2^d$. Taking a union bound over all sketches and all sets G by the choice of t and d event \mathcal{E} holds for all \mathcal{S} and $b_i \in G$ with probability at least $1 - 2^{(n+1)d+1} e^{-Ct} \geq 1 - 2^{(n+1)d+1} 2^{-\frac{C}{4} 2^{n/2^{11}}} = 1 - o(1)$. Thus, there exists some set \mathcal{B} for which the statement of the lemma holds. \blacktriangleleft

Proof of Theorem 34. Let $\alpha = \frac{1}{3 \cdot 2^{11}}$ and $|\mathcal{A}| = k = 2^{\alpha n}$. Suppose Alice holds $x \in \mathcal{A} \subseteq \{0, 1\}^n$ and Bob holds $y \in \{0, 1\}^n$. Recall that in the one-way communication model for XOR functions, Alice must pass a message of minimal length to Bob, who must then compute $f(x \oplus y)$ with some probability, say $\frac{2}{3}$. Here, we let specifically let f be a scaling of a matroid rank function, which is some monotone non-negative $\left(\frac{cn}{n}\right)$ -Lipschitz submodular function. By Yao's principle, it suffices to show that every deterministic one-way communication protocol using at most $\frac{\alpha}{4}n$ bits fails with probability greater than $\frac{1}{3}$ over \mathcal{A} . Suppose by way of contradiction, that Alice and Bob succeed through a deterministic one-way communication protocol, using at most $\frac{\alpha}{4}n$ bits. For the purpose of analysis, we furthermore suppose that Bob's input is fixed.

We now claim that if Alice passes a message to Bob using at most $\frac{\alpha}{4}n$ bits, then there are at least $2^{\alpha n} - 4 \cdot 2^{\alpha n/4}$ points in \mathcal{A} that are represented by the same message as at least five other points. Note that Alice can partition the input space \mathcal{A} into at most $2^{\alpha n/4}$ parts, each part with its own distinct representative message. The number of points *not* in parts containing at least five other points is at most $4 \cdot 2^{\alpha n/4}$. The remaining points, at least $2^{\alpha n} - 4 \cdot 2^{\alpha n/4}$ in quantity, are represented by the same message as at least five other points.

Let S be the set of points in \mathcal{A} represented by a given message from Alice. Hence, Alice assigns the same message to each of these points and passes the state of the protocol to Bob. Because Bob cannot distinguish between these points and must perform a deterministic protocol, then Bob must output the same result for each of these points. Recall that we consider Bob's input $y \in \{0, 1\}^n$ as fixed. Consider the family of functions

$$\mathcal{F} = \{f : f(x \oplus y) = b \text{ or } f(x \oplus y) = D \text{ for all } x \in \mathcal{A}\}.$$

Thus, if S contains at least five points, there exists $f \in \mathcal{F}$ such that Bob errs on at least $\frac{2}{5}$ fraction of the points in S by setting $f(x \oplus y) = b$ to at least $\lfloor \frac{|S|-1}{2} \rfloor$ of the points $x \in S$ and similarly for $f(x \oplus y) = D$. Moreover, since Alice partitions the points in \mathcal{A} , then there exists an $f \in \mathcal{F}$ such that Bob errs on at least $\frac{2}{5}$ fraction on *all* points that are represented by the same message as at least five other points. Hence, the total number of inputs that Bob errs is at least $\frac{2}{5} (2^{\alpha n} - 6 \cdot 2^{\alpha n/4}) > \frac{1}{3} \cdot 2^{\alpha n}$ for sufficiently large values of n . This contradicts the assumption that the communication protocol, using at most $\frac{\alpha}{4}n$ bits, succeeds with probability $\frac{2}{3}$. ◀

Streaming Verification of Graph Computations via Graph Structure

Amit Chakrabarti 

Dartmouth College, Hanover, NH, USA

Prantar Ghosh

Dartmouth College, Hanover, NH, USA

Abstract

We give new algorithms in the annotated data streaming setting – also known as verifiable data stream computation – for certain graph problems. This setting is meant to model outsourced computation, where a space-bounded verifier limited to sequential data access seeks to overcome its computational limitations by engaging a powerful prover, without needing to trust the prover. As is well established, several problems that admit no sublinear-space algorithms under traditional streaming do allow protocols using a sublinear amount of prover/verifier communication and sublinear-space verification. We give algorithms for many well-studied graph problems including triangle counting, its generalization to subgraph counting, maximum matching, problems about the existence (or not) of short paths, finding the shortest path between two vertices, and testing for an independent set. While some of these problems have been studied before, our results achieve new tradeoffs between space and communication costs that were hitherto unknown. In particular, two of our results disprove explicit conjectures of Thaler (ICALP, 2016) by giving triangle counting and maximum matching algorithms for n -vertex graphs, using $o(n)$ space and $o(n^2)$ communication.

1 Introduction

A major philosophical message of theoretical computer science is that a computationally bounded entity can greatly expand its space of tractable problems with access to a more powerful entity, *without* having to trust the latter. The celebrated $IP = PSPACE$ [28] and PCP Theorems [3, 4] are perhaps the best known such results. In the realm of space-efficient computations on large data streams, there is a growing trend towards results of this flavor [26]. In this case, the powerful entity (henceforth named Prover) is often thought of as a cloud computing service that is free of the space limitations that the computationally bounded data streaming process (henceforth named Verifier) is subject to. This work designs new algorithms for graph computations on data streams in such Verifier/Prover models and proves some related complexity-theoretic results.

Early works on such “prover-enhanced data streaming algorithms” considered the *annotated streams* model [10, 22], where Prover reads the input data stream together with Verifier and, during stream processing and/or at the end, supplies Verifier with a *proof* (streamed to him) that convinces him of the correct answer to what he wants to compute on the stream. Subsequent works [11, 14] considered a more general model of *streaming interactive proofs* (SIPs), where the communication between Verifier and Prover is more general, rather

than one way. Several recent works in the annotated stream and the SIP models have focused on basic algorithmic problems on graphs [2, 13, 29], often giving sublinear-space algorithms for problems that provably do not admit sublinear solutions in the basic (sans prover) streaming setting.

In this work, we give new algorithms in the annotated streaming setting for certain graph problems, including triangle counting, its generalization to subgraph counting, maximum matching, problems about the existence (or not) of short paths, finding the shortest path between two vertices, and testing for an independent set. Two of our results provide “unexpected” new upper bounds, disproving published conjectures [29] asserting that such bounds would be unattainable.

1.1 Our Results and Techniques

Background and Motivation. Suppose that we wish to compute a function $f(\sigma)$ on an input stream σ consisting of *tokens* from some universe. For instance, for a graph computation, σ could be a stream of vertex pairs (u, v) specifying the input graph’s edges, or it could be a stream of edge insertions and/or deletions to an evolving (multi)graph. Following established terminology [10], an *online scheme* is a protocol between Prover and Verifier wherein they observe σ together and, after each token appears, Prover provides zero or more bits of “help” to Verifier (as specified by the protocol). After σ is fully consumed, if Prover has followed the protocol faithfully, Verifier is very likely to output $f(\sigma)$; otherwise, he is very likely to “reject.” If Verifier does all his work using at most $O(v)$ bits of working memory and Prover sends at most $O(h)$ bits of help, we call this an (h, v) -*scheme*.¹ A scheme is interesting if we can use $h > 0$ to achieve a value of v asymptotically smaller than what is feasible or known for a basic streaming algorithm, where $h = 0$.

All interesting schemes from previous work in fact use the prover in a more restricted way: Verifier processes all of σ on his own and *then* interacts with Prover. This work continues the tradition. There is practical motivation for building this restriction into the model of computation. Think of a cloud computing service where compute cycles are available only at certain times of day, or need to be booked in advance, whereas the client needs to access and process the input earlier, when it is made available to him. In such a setting, a scheme is most useful if the client can do its own processing first and wait for its time slot with the cloud service to finalize its computation.

Further, we focus only on *schemes*, which feature a single streamed message from Prover to Verifier, rather than the more general setting of SIPs, which allow rounds of interaction. This too is practically motivated: the cloud service need not dedicate a chunk of time to interact with the client, but need only promise that it will perform its portion of the computation *by* an agreed-upon deadline, at which time the client will download the “proof” it has constructed. In view of this latter style of computation, we also consider *multi-pass schemes*, where Verifier may use a “few” passes over its input σ and later receive a single streamed message from Prover, after which he produces his output. Most of our schemes will be single-pass (and we shall call them simply “schemes”), but in a few cases, we will give multi-pass schemes when they can achieve provably better costs than single-pass schemes.

Setup and Terminology. All problems studied in this paper involve an input graph, multigraph, or digraph $G = (V, E)$ on the vertex set $[n] := \{1, 2, \dots, n\}$. We shall reserve the

¹ We will drop the qualifier “online” and simply call our protocols “schemes” because we will not be considering the more powerful setting of “prescient schemes” [10] in this paper.

basic term “graph” for simple, undirected graphs. The input is described either as a stream of edges (the default case) or as a stream of edge insertions and deletions: the latter type of stream is called a *dynamic* or *turnstile* graph stream. For an (h, v) -scheme to be interesting we at least require $v = o(n^2)$. If we also have $h = o(n^2)$, we call it a *sublinear* scheme. If we have $v = o(n)$ while $h = o(n^2)$, we call it a *frugal* scheme. This is an especially interesting setting of parameters, because most interesting graph problems provably require $\Omega(n)$ space in the basic streaming setting [15]. A frugal scheme shows that one can beat this space bound with the aid of only a sublinear-length proof. Recall that while $h \gg v$ is allowed, the proof must be processed using only $O(v)$ space.

For an (h, v) -scheme we refer to h as its hcost (short for “help cost”) and v as its vcost (short for “verification cost”). We use the notation $[h, v]$ -scheme as a shorthand for an $(\tilde{O}(h), \tilde{O}(v))$ -scheme.² An $[n, n]$ -scheme is called a *semi-streaming* scheme.

Subgraph Counting. The literature on graph streaming contains many works on the central problem of triangle counting (henceforth, TRIANGLECOUNT): given a multigraph G as a dynamic stream, compute T , the number of triangles in G [6, 7, 18, 25, 29]. In Section 3, we study this and the more general problem of subgraph-counting (SUBGRAPHCOUNT $_k$) [7, 19, 20, 29], where the goal is to compute T_H , the number of copies of a fixed, k -sized graph H , where k is a constant. In the basic streaming model, computing T or T_H exactly is impossible in sublinear space and it becomes necessary to approximate. In contrast, we design a family of $(o(n^2), o(n))$ -schemes for TRIANGLECOUNT that give exact answers. Such a frugal scheme had been conjectured not to exist [29]. We extend our ideas to give sublinear $(o(n^2), o(n^2))$ -schemes for SUBGRAPHCOUNT $_k$.

Maximum Matching. Determining $\alpha'(G)$, the cardinality of a maximum-sized matching in G , is a central problem in graph algorithms and has received a lot of attention in the recent literature on streaming algorithms [5, 12, 15, 16, 21, 24]. In Section 4, we consider this problem (henceforth, MAXMATCHING) for multigraphs given by dynamic streams. As with TRIANGLECOUNT, we give a frugal scheme for MAXMATCHING, which had been conjectured to be impossible [29]. In the process, we present a frugal scheme for the subproblem of verifying that the purported connected components of a graph are indeed disconnected from each other, which might be of independent interest for future work on connectivity-related problems.

Independent Sets and Length-Three Paths. In Section 5, we study the independent set testing problem (INDSETTEST), where we are given a multigraph G and a set $U \subseteq V$ (also streamed and interleaved with the edge stream arbitrarily) and we must determine whether or not U is independent. We also study the ST-3PATH problem, where G (which might be a digraph) has two designated vertices v_s and v_t and we must determine whether G has a path of length at most 3 from v_s to v_t . By results from prior work, any (h, v) -scheme for these problems must have total cost $h + v = \Omega(n)$. We therefore design two-pass schemes for these problems, achieving $h + v = \tilde{O}(n^{2/3})$. In fact, we obtain a more general tradeoff, giving a two-pass $[t^2, s]$ -scheme for any parameters t, s with $ts = n$. Our schemes instantiate a protocol for the abstract problem CROSSEGECOUNT, which asks for a count of the number of edges in G from $U \subseteq V$ to $W \subseteq V$, where these sets U and W are also streamed.

² The notation $\tilde{O}(\cdot)$ hides factors polynomial in $\log n$.

In each case, we *can* design ordinary (one-pass) schemes with the same complexity parameters under a natural assumption on the way the stream is ordered, and these schemes still beat the space bound achievable by basic (sans prover) streaming algorithms.

Short Paths and Shortest Path. Finally, in Section 6, we consider shortest path problems, perhaps the most basic problem in classic graph algorithms. We study the ST-KPATH problem, which is to detect whether or not G has a path of length at most k from v_s to v_t , where k , v_s , and v_t are prespecified. We first present a $[kn, n]$ -scheme for ST-KPATH. This gives a semi-streaming scheme for detecting short (of length polylogarithmic in n) paths, which is optimal in terms of total cost. It also implies a $[kn, n]$ -scheme for ST-SHORTESTPATH problem – where k is the length of the shortest path from v_s to v_t – which is to find the shortest path between vertices v_s and v_t , and output NO if none exists. For directed graphs of small (polylogarithmic in n) diameter, it implies a semi-streaming scheme for checking s, t -connectivity. Note that these problems require $\Omega(n^2)$ space in the basic data streaming model, even for constant k or constant-diameter graphs [15].

Targeting a different cost regime, we generalize our result for ST-3PATH from Section 5 to obtain multi-pass (h, v) -schemes for ST-KPATH with total cost $h + v = o(n)$, for constant k . To be precise, we present a $\lceil k/2 \rceil$ -pass $[n^{1-1/k}, n^{1-1/k}]$ -scheme for ST-KPATH.

Our Techniques. Similar to past work in the area of streaming verification – indeed, harkening back to classic interactive proof protocols [23, 28] – our schemes make heavy use of “arithmetization,” i.e., they recast the underlying problem in terms of evaluating certain polynomials and exploit the encoding properties of polynomials (as captured in the Schwartz-Zippel Lemma) to protect the verifier from a cheating prover. Also as in past work, we use what we call the *shaping technique*, where we conceptually shape a data vector into an array with two or more dimensions. This seemingly innocuous trick allows us to consider input data as a table of values of a *multivariate* polynomial and we can use the “separation” afforded by these multiple variables to divide up work between Verifier and Prover.

The novelty in our algorithms comes from a twist on the shaping technique that was hitherto unexploited. At a high level, almost all earlier annotation schemes or SIPs for graph problems viewed the edge stream as a flat vector (a characteristic vector in the case of graphs or a frequency vector in the case of multigraphs). We crucially exploit the fact that the index set of this vector has additional structure: it consists of pairs of *vertices* and these vertices are very meaningful entities in the context of graph problems. Simply put, we exploit *graph structure* more fully in our use of the shaping technique.

Another novel feature of our schemes is that they involve Prover sending *multivariate* polynomials; their correctness analysis then involves the full multivariate strength of the Schwartz-Zippel Lemma. In all past work on interactive proofs and schemes, Prover only sent univariate polynomials (and the corresponding analyses used the more basic statement that a nonzero, degree- d , univariate polynomial has at most d roots). Thus, our scheme designs can be seen as exploiting the power of arithmetization more fully.

1.2 Related Work

The annotated data streaming model of computation was motivated in part by the need to develop a theory to capture ideas such as the stream punctuations of Tucker et al. [30] and the stream outsourcing framework of Yi et al. [31]. Chakrabarti et al. [10] formulated the model and provided the first theoretical results, focusing largely on the traditional statistical problems of frequency moments and heavy hitters, but also giving a handful of basic results for graph problems. Other early works in the same model include Klauck and Prakash [22]

and Chakrabarti et al. [9]. Cormode et al. [14] generalized the model to SIPs, which allow a few interactive rounds of communication between Verifier and Prover; this generalized setting was studied further in Chakrabarti et al. [11] and Abdullah et al. [2]. We refer the reader to the expository article of Mitzenmacher and Thaler [26] for a more detailed survey of this area.

We turn to graph computations and the specific problems studied in this work. For simplicity, we state complexities in terms of n alone, rather than using both m and n (m being the number of edges of the input graph). Cormode et al. [13] gave annotated data stream algorithms (schemes, in our terminology) for many canonical graph problems, often exploiting linear programming formulations of the problems. In particular, they gave an $[n^2, 1]$ -scheme For MAXMATCHING. For a weighted version of ST-SHORTESTPATH, on simple graphs (not multigraphs) they gave $[h, v]$ -schemes with $hv \geq dn^2$ and $h \geq dn$, where d is the maximum distance to *any* node reachable from v_s . Contrast this with our $[kn, n]$ -scheme for unweighted multigraphs, where k is the length of the shortest v_s, v_t -path.

Thaler [29] studied the problems TRIANGLECOUNT, MAXMATCHING, and SUBGRAPH-COUNT $_k$. He gave semi-streaming schemes for the first two. In the same paper, he explicitly conjectured that these two problems would not admit frugal schemes: he imagined that achieving $\text{vcost} = o(n)$ would bump up the hcost to $\Omega(n^2)$. Our results here disprove these conjectures. For SUBGRAPHCOUNT $_k$, Thaler gave a $[k^3n, kn]$ -SIP with $k - 2$ rounds of interaction. We achieve sublinear cost with just a single Prover-to-Verifier message. Sublinear schemes for SUBGRAPHCOUNT $_k$ were hitherto unknown for any $k > 3$.

For the TRIANGLECOUNT problem, Chakrabarti et al. [10] gave an $[h, v]$ -scheme for any h, v with $hv = n^3$, and also an $[n^2, 1]$ -scheme. For the same problem, Abdullah et al. [2] gave a $(\log^2 n, \log^2 n)$ -SIP that uses $\log n$ rounds of interaction, and a $(n^{1/\gamma} \log n, \log n)$ -SIP with $\gamma = O(1)$ rounds of interaction. The latter paper also studied MAXMATCHING, giving a $(\rho + n^{1/\gamma'} \log n, \log n)$ -SIP with γ rounds of interaction, where γ' is a linear function of γ , and ρ is the weight of an optimal matching (weighted or unweighted).

Guruswami and Onak [17] show a space lower bound of $\Omega(n^{1+\Omega(1/k)}/k^{O(1)})$ for ST-KPATH (where k is even) in $k/2 - 1$ passes in the basic streaming model. In contrast, our results show that, for any k , with the help of a prover, one can get a total cost of $\tilde{O}(n^{1-1/k})$ in $\lceil k/2 \rceil$ passes.

2 Preliminaries

For a positive integer n , we denote the set $\{1, 2, \dots, n\}$ by $[n]$ and the set $\{-n, -n+1, \dots, n-1, n\}$ by $\llbracket n \rrbracket$. The ring of polynomials in variables X_1, \dots, X_k with coefficients in the ring R is denoted by $R[X_1, \dots, X_k]$. If S is a finite set, we write $r \in_R S$ to say that r is a random element drawn uniformly from S . In an undirected graph $G = (V, E)$, the i th neighborhood of a vertex v is the set of vertices u such that there is a walk of length i from v to u . We denote this set by $N_i(v)$. We put $N(v) := N_1(v)$ and $N[v] := N_1(v) \cup \{v\}$.

Following Chakrabarti et al. [10], an annotated data streaming algorithm, a.k.a. *scheme*, is a pair $\mathcal{A} = (\mathfrak{h}, \mathcal{B})$, where \mathfrak{h} is a help function and \mathcal{B} is a data stream algorithm that computes a function f of an input $\mathbf{x} \in \mathcal{U}^m$, where \mathcal{U} is some universe. We see \mathfrak{h} as an m -tuple $(\mathfrak{h}_1, \dots, \mathfrak{h}_m)$, where $\mathfrak{h}_i : \mathcal{U}^i \rightarrow \{0, 1\}^*$ is the *annotation* provided to \mathcal{B} after the i th stream update x_i , depending on the elements seen so far, i.e. x_1, \dots, x_i . Thus, \mathcal{B} sees the *annotated* stream $\mathbf{x}^{\mathfrak{h}} := (x_1, \mathfrak{h}_1(x_1), x_2, \mathfrak{h}_2(x_1, x_2), \dots, x_m, \mathfrak{h}_m(x_1, \dots, x_m))$. Using a random string R , it processes this annotated stream, giving an output $\text{out}(\mathcal{B}; \mathbf{x}^{\mathfrak{h}}, R)$. We say that \mathcal{A} is a δ -error scheme if

- (completeness) for all $\mathbf{x} \in \mathcal{U}^m$: $\Pr_R[\text{out}(\mathcal{B}; \mathbf{x}^{\mathfrak{h}}, R) \neq f(\mathbf{x})] \leq \delta$; and

- (soundness) for all $\mathbf{x} \in \mathcal{U}^m$, $\mathbf{h}' = (h'_1, h'_2, \dots, h'_m) \in (\{0, 1\}^*)^m$:
 $\Pr_R[\text{out}(\mathcal{B}; \mathbf{x}^{\mathbf{h}'}, R) \notin \{f(\mathbf{x}), \perp\}] \leq \delta$,

where “ \perp ” is a special symbol indicating that \mathcal{B} rejects the annotation (proof) provided, having detected cheating. When δ is left unspecified, we assume a default value of $1/3$. The hcost (help cost) of \mathcal{A} is $\max_{\mathbf{x} \in \mathcal{U}^m} \sum_i |h_i(\mathbf{x})|$, and the vcost (verification cost) is the space usage of \mathcal{B} .

The scheme \mathcal{A} is said to be an (h, v) -scheme (resp. $[h, v]$ -scheme) if its hcost is $O(h)$ (resp. $\tilde{O}(h)$) and its vcost is $O(v)$ (resp. $\tilde{O}(v)$). The sum hcost + vcost is called the *total cost* of \mathcal{A} . In the context of problems on n -vertex graphs, an $(o(n^2), o(n^2))$ -scheme is called a *sublinear* scheme, an $[n, n]$ -scheme is called a *semi-streaming* scheme and an $(o(n^2), o(n))$ -scheme is called a *frugal* scheme.

A *multi-pass scheme* – more precisely, a p -pass scheme with $p \geq 2$ – is a scheme $\mathcal{A} = (\mathbf{h}, \mathcal{B})$ where \mathcal{B} makes $p - 1$ passes over the input \mathbf{x} followed by a final pass over the annotated stream $\mathbf{x}^{\mathbf{h}}$. As discussed in Section 1.1, all schemes and multi-pass schemes we design in this work have the feature that the entire annotation $\mathbf{h}(\mathbf{x})$ arrives only after \mathcal{B} is done processing the plain stream \mathbf{x} . That said, the negative results in this work do not require the scheme to be restricted in this way.

Let f be a k -dimensional array with dimensions (s_1, \dots, s_k) each of whose entries is an integer in $\llbracket M \rrbracket$. Equivalently, we have a function $f: [s_1] \times \dots \times [s_k] \rightarrow \llbracket M \rrbracket$. For a finite field \mathbb{F} of sufficiently large characteristic,³ we define the \mathbb{F} -extension of f to be the unique polynomial $\tilde{f}(X_1, \dots, X_k) \in \mathbb{F}[X_1, \dots, X_k]$ such that

- for all $(x_1, \dots, x_k) \in [s_1] \times \dots \times [s_k]$, we have $\tilde{f}(x_1, \dots, x_k) = f(x_1, \dots, x_k)$, and
- for all $i \in [k]$, we have $\deg_{X_i} \tilde{f} \leq s_i - 1$.

Note that \tilde{f} can be described explicitly using Lagrange interpolation:

$$\tilde{f}(X_1, \dots, X_k) = \sum_{(u_1, \dots, u_k) \in [s_1] \times \dots \times [s_k]} f(u_1, \dots, u_k) \delta_{u_1, \dots, u_k}(X_1, \dots, X_k), \quad \text{where} \quad (1)$$

$$\delta_{u_1, \dots, u_k}(X_1, \dots, X_k) = \prod_{i=1}^k \prod_{x_i \in [s_i] \setminus \{u_i\}} (u_i - x_i)^{-1} (X_i - x_i). \quad (2)$$

In particular, if f is built up from a stream of pointwise updates, where the j th update adds Δ_j to entry $(u_1, \dots, u_k)_j$ of the array, then

$$\tilde{f}(X_1, \dots, X_k) = \sum_j \Delta_j \delta_{(u_1, \dots, u_k)_j}(X_1, \dots, X_k). \quad (3)$$

This leads to the following fact that we use in all our protocols. For details and a thorough discussion, including implementation considerations, see Cormode et al. [14].

► **Fact 1.** *Given a point $(p_1, \dots, p_k) \in \mathbb{F}^k$ and a stream of pointwise updates to an array with dimensions (s_1, \dots, s_k) that is initially all-zero, we can keep track of the value $\tilde{f}(p_1, \dots, p_k)$ using $O(\log |\mathbb{F}|)$ space, performing $O(k)$ field arithmetic operations after each update.*

We record results proved in Chakrabarti et al. [9, 10] that can be seen as generalizing the Aaronson-Wigderson protocol for Merlin-Arthur communication complexity of set disjointness [1].

³ We need the characteristic to be at least $\max\{s_1, \dots, s_k, 2M + 1\}$ to avoid “wrap around problems,” i.e., to ensure that all integers in each $[s_i]$ as well as all integers in $\llbracket M \rrbracket$ have distinct images under the ring homomorphism from \mathbb{Z} to \mathbb{F} .

► **Fact 2** (SUBSET and INTERSECTION schemes; Prop. 4.1 of [10] and Thm. 5.3 of [9]). *Consider a stream consisting of elements of two sets $S, T \subseteq [N]$ interleaved arbitrarily. Then, for any h, v with $hv \geq N$, there are $[h, v]$ -schemes to compute $|S \cap T|$ and to determine whether $S \subseteq T$. For the latter problem, there is a $[h, v]$ -scheme handling the more general setting where S and T are multisets updated dynamically by the stream and the multiplicity of each element is at most ℓ .*

► **Fact 3** (Schwartz-Zippel Lemma). *For a nonzero polynomial $P(X_1, \dots, X_n) \in \mathbb{F}[X_1, \dots, X_n]$ of total degree d , where \mathbb{F} is a finite field, $\Pr_{(r_1, \dots, r_n) \in \mathbb{F}^n} [P(r_1, \dots, r_n) = 0] \leq d/|\mathbb{F}|$.*

3 Subgraph Counting

We begin by describing a frugal scheme for TRIANGLECOUNT and then extend our ideas to obtain a sublinear scheme for the more general problem SUBGRAPHCOUNT. Throughout, we assume that the input is an n -vertex multigraph $G = (V, E)$ with adjacency matrix A , built up through a stream of edge insertions and deletions.

3.1 Triangle Counting

Let $T = T(G)$ be the number of triangles in G taking edge multiplicities into account, i.e., two triangles are considered distinct iff their corresponding sets of *edges* are distinct. Then,

$$6T = \sum_{v_1, v_2, v_3 \in V} A_{v_1 v_2} A_{v_2 v_3} A_{v_3 v_1}. \quad (4)$$

Let t and s be integer-valued parameters such that $ts = n$. Using a canonical bijection, we represent each vertex $v \in V$ by a pair of integers $(x, y) \in [t] \times [s]$. This transforms the matrix A into a 4-dimensional array a , given by $a(x_1, y_1, x_2, y_2) = A_{v_1 v_2}$. Let \tilde{a} be the \mathbb{F} -extension of a for a sufficiently large finite field \mathbb{F} to be chosen later. Equation (4) now gives

$$6T = \sum_{x_1, x_2, x_3 \in [t]} p(x_1, x_2, x_3), \quad \text{where} \quad (5)$$

$$p(X_1, X_2, X_3) = \sum_{y_1, y_2, y_3 \in [s]} \tilde{a}(X_1, y_1, X_2, y_2) \tilde{a}(X_2, y_2, X_3, y_3) \tilde{a}(X_3, y_3, X_1, y_1). \quad (6)$$

Note that, for each $i \in \{1, 2, 3\}$, we have $\deg_{X_i} p \leq 2t - 2$. Thus, the number of monomials in p is at most $(2t - 1)^3 \leq 8t^3$ and the total degree $\deg p \leq 6t - 6 \leq 6t$.

Our scheme for triangle counting operates as follows.

Stream processing. Verifier starts by picking $r_1, r_2, r_3 \in_R \mathbb{F}$. As the edge stream arrives, he maintains the three 2-dimensional arrays $\tilde{a}(r_1, w, r_2, z)$, $\tilde{a}(r_2, w, r_3, z)$, and $\tilde{a}(r_3, w, r_1, z)$, for all $(w, z) \in [s] \times [s]$ (using Fact 1). At the end of the stream, he uses these arrays to compute $p(r_1, r_2, r_3)$, using Equation (6).

Help message. Prover sends Verifier a polynomial $\hat{p}(X_1, X_2, X_3)$ that she claims equals $p(X_1, X_2, X_3)$; in particular, for each $i \in \{1, 2, 3\}$, $\deg_{X_i} \hat{p} \leq 2t - 2$. She streams the coefficients of \hat{p} one at a time, according to some canonical ordering of the possible monomials.

Verification and output. As \hat{p} is streamed in, Verifier computes the check value $C := \hat{p}(r_1, r_2, r_3)$ and the result value $\hat{T} := \frac{1}{6} \sum_{x_1, x_2, x_3 \in [t]} \hat{p}(x_1, x_2, x_3)$. If he finds that $C \neq p(r_1, r_2, r_3)$, he outputs \perp . Otherwise, he believes that $\hat{p} \equiv p$ and accordingly, based on Equation (5), outputs \hat{T} as the answer.

The analysis of this scheme is along now-standard lines.

Error probability. Clearly, if Prover is honest (i.e., $\hat{p} \equiv p$), then the output is always correct.

So the scheme errs only when $\hat{p} \not\equiv p$ but Verifier's check passes. This means that the random point $(r_1, r_2, r_3) \in \mathbb{F}^3$ is a root of the nonzero polynomial $\hat{p} - p$, which has total degree at most $6t$. By the Schwartz-Zippel Lemma (Fact 3), the probability of this event is at most $6t/|\mathbb{F}| < 1/n$, by choosing $|\mathbb{F}|$ large enough.

Help and Verification costs. The number of bits used to describe the polynomial \hat{p} is the hcost. As noted, the polynomial \hat{p} has $O(t^3)$ many coefficients, each of which is an element of \mathbb{F} , and hence has size $O(\log n)$. So the hcost is $\tilde{O}(t^3)$. The Verifier maintains three $s \times s$ arrays, where each entry is an element of \mathbb{F} . Hence, the vcost is $\tilde{O}(s^2)$. Therefore, we get a $[t^3, s^2]$ -scheme for triangle counting, for parameters t, s with $ts = n$. Setting $t = n^\alpha$ for $\alpha \in (1/2, 2/3)$, we get a $(o(n^2), o(n))$ -scheme, which is frugal.

The result in this section is captured in the theorem below.

► **Theorem 4.** *For any parameters t, s with $ts = n$, there is a $[t^3, s^2]$ -scheme for TRIANGLECOUNT. In particular, there is an $(o(n^2), o(n))$ -scheme for TRIANGLECOUNT.*

This disproves Thaler's conjecture [29], which stated that TRIANGLECOUNT has no frugal scheme.

3.2 Generalization to Counting Copies of an Arbitrary Subgraph

Now we consider the SUBGRAPHCOUNT $_k$ problem. Let H be a fixed k -vertex graph. The goal is to determine $T_H = T_H(G)$, the number of copies of H in the n -vertex multigraph G given by an input stream: n is growing whereas $k = O(1)$. As before, we take edge multiplicities into account.

Fix a numbering of the vertices of H as $1, 2, \dots, k$. Write $i \sim j$ to denote $\{i, j\} \in E(H) \wedge i < j$. To generalize Equation (4), note that the expression $\prod_{i \sim j} A_{v_i v_j}$ counts the number of copies of H occurring amongst vertices v_1, \dots, v_k in G where $i \in V(H)$ is mapped to $v_i \in V$, provided that v_1, \dots, v_k are distinct. This subtlety of explicitly requiring the v_i s to be distinct did not arise for TRIANGLECOUNT because $A_{v_1 v_2} A_{v_2 v_3} A_{v_3 v_1}$ is zero unless v_1, v_2, v_3 are distinct. To enforce the distinctness condition in our more general setting, define an $n \times n$ Boolean matrix B by $B_{uv} = 1$ iff $u \neq v$. Then, defining α_H to be the number of automorphisms of H ,

$$\alpha_H T_H = \sum_{v_1, \dots, v_k \in V} \left(\prod_{i \sim j} A_{v_i v_j} \right) \left(\prod_{i \neq j \in [k]} B_{v_i v_j} \right). \quad (7)$$

As before, we shape V into $[t] \times [s]$ for parameters t and s with $ts = n$. This turns the 2-dimensional matrices A, B into 4-dimensional arrays a, b , which in turn have \mathbb{F} -extensions \tilde{a}, \tilde{b} . Equation (7) gives

$$\alpha_H T_H = \sum_{x_1, \dots, x_k \in [t]} p(x_1, \dots, x_k), \quad \text{where} \quad (8)$$

$$p(X_1, \dots, X_k) = \sum_{y_1, \dots, y_k \in [s]} \left(\prod_{i \sim j} \tilde{a}(X_i, y_i, X_j, y_j) \right) \left(\prod_{i \neq j \in [k]} \tilde{b}(X_i, y_i, X_j, y_j) \right). \quad (9)$$

For each $i \in [k]$, $\deg_{X_i} p \leq 2(k-1)(t-1) = O(t)$. So the total degree $\deg p = O(t)$ and p has at most $O(t^k)$ monomials. This leads to a scheme for subgraph counting that naturally generalizes our earlier scheme for triangle counting. We sketch the salient features and the analysis.

Stream processing. Verifier picks $r_1, \dots, r_k \in_R \mathbb{F}$ and maintains (using Fact 1) $O(k^2) = O(1)$ many $s \times s$ arrays: $\tilde{a}(r_i, w, r_j, z)$ for each $i \sim j \in [k]$ and $\tilde{b}(r_i, w, r_j, z)$ for each $i \neq j \in [k]$, where $(w, z) \in [s] \times [s]$. The \tilde{b} arrays do not depend on the input stream and can be computed once and for all. At the end of the stream, he computes $p(r_1, \dots, r_k)$ with the help of these values, using Equation (9).

Help message. Prover sends a polynomial $\hat{p}(X_1, \dots, X_k)$ that she claims to be $p(X_1, \dots, X_k)$. She streams the $O(t^k)$ coefficients of \hat{p} , using some canonical ordering of the monomials.

Verification and output. Verifier computes the check value $C := \hat{p}(r_1, \dots, r_k)$ and the result value $\hat{T}_H := \alpha_H^{-1} \sum_{x_1, \dots, x_k \in [t]} \hat{p}(x_1, \dots, x_k)$. He outputs \perp if $C \neq p(r_1, \dots, r_k)$. Else, believing $\hat{p} \equiv p$, he outputs \hat{T}_H as the answer, in view of Equation (8).

Error probability. By a Schwartz-Zippel Lemma (Fact 3) argument as before, the error probability is at most $\deg p / |\mathbb{F}| = O(t) / |\mathbb{F}| < 1/n$, by choosing $|\mathbb{F}|$ large enough.

Help and Verification costs. The hcost is $\tilde{O}(t^k)$, by the bound on the number of monomials in \hat{p} . Verifier stores $O(1)$ many $s \times s$ arrays, leading to a vcost of $\tilde{O}(s^2)$.

In summary, we obtain a $[t^k, s^2]$ -scheme for counting copies of a fixed k -vertex subgraph H , for all choices of parameters t, s with $ts = n$. Setting $t = n^{2/(k+2)}$ and $s = n^{k/(k+2)}$ gives a scheme where both these costs are $\tilde{O}(n^{2k/(k+2)})$, which is $o(n^2)$ for constant k . Thus, we get the following theorem.

► **Theorem 5.** *For any parameters t, s such that $ts = n$, there is a $[t^k, s^2]$ -scheme for SUBGRAPHCOUNT $_k$, where k is a constant. In particular, there is a sublinear scheme for SUBGRAPHCOUNT $_k$ with total cost $\tilde{O}(n^{2k/(k+2)})$.*

4 Maximum Matching

We now turn to the MAXMATCHING problem, again giving a frugal scheme. Our input is an edge stream of an n -vertex graph $G = (V, E)$ and we would like to determine $\alpha'(G)$, the cardinality of a maximum matching in G . We follow the broad outline of the semi-streaming scheme for MAXMATCHING by Thaler [29]. That scheme has two parts. In the first part, Prover convinces Verifier that $\alpha'(G) \geq k$, for some integer k . In the second part, she convinces him that $\alpha'(G) \leq k$. For the former, Prover simply provides a suitable matching M and convinces Verifier that $M \subseteq E$ using the SUBSET scheme from Fact 2. For the latter, Prover uses the Tutte-Berge formula [8], which states that

$$\alpha'(G) = \frac{1}{2} \min_{U \subseteq V} \left(|U| + |V| - \text{odd}(G \setminus U) \right), \quad (10)$$

where $\text{odd}(G \setminus U)$ denotes the number of connected components in $G \setminus U$ with an odd number of vertices. The most challenging part of the scheme is evaluating $\text{odd}(G \setminus U)$, which involves the sub-problem of verifying whether all the connected components of a graph (as claimed by the Prover) are disconnected from each other. Thaler comments that this is the part that acts as a barrier in reducing the vcost to $o(n)$ without increasing the hcost to $\Omega(n^2)$. We present a novel frugal scheme for this sub-problem. The rest of the protocol solves the same sub-problems as the aforementioned paper. Most of their sub-schemes for these sub-problems, however, were trivial for $\tilde{O}(n)$ space. We need schemes for the same problems that use only $o(n)$ space and hence require more work. We describe our protocol below.

To convince the Verifier that the size of a maximum matching in G is k , Prover proves that it is (a) at least k , and (b) at most k . For (a), she simply sends (as a stream) a set M of k edges that constitutes a matching of G . Verifier can easily check using $O(\log n)$ space that

70:10 Streaming Verification of Graph Computations via Graph Structure

the set has size k . Next, he needs to check that $M \subseteq E$, and that M is indeed a matching. For the former, we can use Fact 2 and get an $[h, v]$ -scheme, where v is the $o(n)$ value we are aiming for and $h = n^2/v$. To verify that M is a matching, we check whether every vertex in M appears exactly once in this stream. Treating M as a stream of vertices, we can do this as follows: First, compute F_2 , the second frequency moment of the stream, using an $[h, v]$ -scheme where v is the $o(n)$ vcost we want, and $h = n/v$ ([10], Theorem 4.1). Next, verify that it equals $2k$ (this happens iff all $2k$ elements are distinct).

For (b), we apply Equation (10). Prover sends $U^* \subseteq V$ and claims that $k = 1/2 \cdot (|U^*| + |V| - \text{odd}(G \setminus U^*))$. To check this, Verifier just needs to compute $\text{odd}(G \setminus U^*)$. We do this in the following way.

Let $[C]$ be the set of C connected components of $G \setminus U^*$. For $c \in [C]$ and $u \in G \setminus U^*$, Prover sends an array L of pairs (c, u) such that $u \in c$. The array L is sorted in non-decreasing order of c , i.e., she first sends the vertices in connected component 1, followed by those in component 2, and so on. If L is indeed as Prover claims, then $\text{odd}(G \setminus U^*)$ is equal to the number of components c that arrive with odd number of vertices in L . Since L is sorted with respect to c , Verifier can count this number easily using $O(\log n)$ space. He can verify that the vertices in the tuples of L constitute $G \setminus U^*$, and that no vertex u is repeated in different tuples of L , using frugal schemes implied by the standard protocols mentioned above.

Thus, it only remains to verify that L is as claimed. For this, we need to check whether the following two properties hold:

- (i) For each $c \in [C]$, the vertices in $G \setminus U^*$ that are claimed to be in component c are all connected in $G \setminus U^*$.
- (ii) For every pair (u, v) of vertices in $G \setminus U^*$ that are claimed to be in different components, we have $(u, v) \notin E$.

For Property (i), Prover sends a spanning tree for each connected component c and Verifier can check if all of them are valid using an $[n^{1+\alpha}, n^{1-\alpha}]$ -scheme, for any $\alpha \in [0, 1]$ ([10], Theorem 7.7) so as to get the desired $o(n)$ vcost.

Checking Property (ii) is the most challenging part. We give a novel protocol for this part that uses $o(n)$ vcost and $o(n^2)$ hcost. Slightly abusing notation, consider the array L in the form of a $C \times |G \setminus U^*|$ matrix, such that $L_{cu} = 1$ if $u \in c$, and $L_{cu} = 0$ otherwise. Denote the ones' complement of this matrix by \bar{L} . Let A be the adjacency matrix of $G \setminus U^*$. Finally, let γ denote the total number of cross edges that go between two connected components in $G \setminus U^*$. Then, we have

$$2\gamma = \sum_{\substack{c \in [C] \\ u, v \in G \setminus U^*}} L_{cu} \bar{L}_{cv} A_{uv}. \quad (11)$$

Property (ii) is satisfied iff $\gamma = 0$. Recalling that $C = O(n)$ and $|G \setminus U^*| = O(n)$, we note that Equation (11) has a similar form as that of Equation (4). Thus, it can be exploited in essentially the same way as the $[t^3, s^2]$ -scheme for TRIANGLECOUNT, for parameters t, s with $ts = n$. Once again, setting $t = n^\alpha$ for $\alpha \in (1/2, 2/3)$, we get a frugal scheme.

The next theorem summarizes the result in this section.

► **Theorem 6.** *For any parameters t, s with $ts = n$, there is a $[t^3, s^2]$ -scheme for MAXMATCHING. In particular, there is an $(o(n^2), o(n))$ -scheme for MAXMATCHING.*

This disproves yet another conjecture of Thaler [29], which stated that MAXMATCHING has no frugal scheme.

5 Counting Cross-edges and its Applications to Other Problems

Consider the problems `INDSETTEST` and `ST-3PATH` defined in Section 1.1. The key task underlying these problems is counting the number of edges crossing between two subsets U and W of V that arrive in some adversarial streaming order along with the edges: for `INDSETTEST`, U and W are the same set; for `ST-3PATH`, they are (closed) neighborhoods of the designated vertices v_s and v_t . This is precisely the abstract problem of `CROSSEGE``COUNT`. Clearly, a scheme for this problem can be used as a subroutine to solve `INDSETTEST` and `ST-3PATH`.

Any one-pass (h, v) -scheme for `CROSSEGE``COUNT`, `INDSETTEST`, or `ST-3PATH` must have $hv \geq n^2$ and hence, total cost $h + v = \Omega(n)$. In Appendix A.1, we outline how these lower bounds are obtained. We therefore consider *two-pass* schemes for these problems. In particular, we design such a scheme for `CROSSEGE``COUNT` with total cost $\tilde{O}(n^{2/3})$ and apply it to obtain similar bounds for other graph problems. In Appendix A.2, we discuss these applications. We also note that our schemes can be implemented in one pass each, under natural assumptions on the way the stream is ordered; see Appendix A.3.

5.1 Two-pass Scheme for `CrossEdgeCount`

We now design a two-pass scheme for `CROSSEGE``COUNT`, aiming for total cost $o(n)$.

Let $\gamma = \gamma(U, W, G)$ denote the number of Cross-edges between U and W in a (directed or undirected) graph G . Formally, it is the number of ordered pairs $(u, w) \in U \times W$ such that $(u, w) \in E$. Note that, in an undirected graph, γ counts an edge (u, w) with multiplicity 2 whenever $u, w \in U \cap W$. For some applications (e.g., counting number of 3-walks in an undirected graph), we *do* need to count them with multiplicity. We discuss later how we can remove this multiplicity if needed.

We describe a scheme that works even on turnstile graph streams, i.e., a stream of the vertices in U and W intermixed with *updates* to edge multiplicities. Let L and F denote the characteristic vectors of the sets U and W respectively and let A be the (weighted) adjacency matrix of G . Then,

$$\gamma = \sum_{u \in U, w \in W} L_u A_{u,w} F_w. \quad (12)$$

Let t and s be integer parameters such that $ts = n$. As usual, using a canonical bijection, we represent each vertex $v \in V$ by a pair of integers $(x, y) \in [t] \times [s]$. As a result, the vectors L, F transform into 2-dimensional arrays ℓ, f given by $\ell(x, y) = L_v$ and $f(x, y) = F_v$. As before, the adjacency matrix A turns into a 4-dimensional array a , such that $a(x_1, y_1, x_2, y_2) = A_{v_1 v_2}$. Let $\tilde{\ell}, \tilde{f}$ and \tilde{a} be \mathbb{F} -extensions of ℓ, f and a respectively, for a sufficiently large finite field \mathbb{F} . Now, Equation (12) yields

$$\gamma = \sum_{x_1, x_2 \in [t]} p(x_1, x_2), \quad \text{where} \quad (13)$$

$$p(X_1, X_2) = \sum_{y_1, y_2 \in [s]} \tilde{\ell}(X_1, y_1) \tilde{a}(X_1, y_1, X_2, y_2) \tilde{f}(X_2, y_2). \quad (14)$$

For $i \in \{1, 2\}$, $\deg_{X_i} p = 2t - 2$. Thus, it follows that the number of monomials in p is at most $O(t^2)$, and the total degree of p is $O(t)$.

We are now ready to design a two-pass scheme for `CROSSEGE``COUNT`.

Stream processing. Verifier first chooses $r_1, r_2 \in_R \mathbb{F}$. For $y \in [s]$, define

$$g(y) := \sum_{y' \in [s]} \tilde{a}(r_1, y, r_2, y') \tilde{f}(r_2, y') \quad (15)$$

70:12 Streaming Verification of Graph Computations via Graph Structure

Thus,

$$p(r_1, r_2) = \sum_{y \in [s]} \tilde{\ell}(r_1, y) g(y). \quad (16)$$

Pass 1. Only process the vertices in L and F in the stream. Maintain (using Fact 1) two s -dimensional vectors: $\tilde{\ell}(r_1, y)$ and $\tilde{f}(r_2, y)$, where $y \in [s]$.

Pass 2. Only process the edges in the stream. We want to maintain the s -dimensional vector $g(y)$ so that we can compute $p(r_1, r_2)$ using Equation (16). Suppose that the j th edge update $(x_1, y_1, x_2, y_2)_j$ adds Δ_j to that edge's multiplicity. This results in updates to several entries of \tilde{a} , but we want to use only $O(s)$ space, so we cannot afford to maintain \tilde{a} directly. Instead, for each $j \in [m]$, let g_j and \tilde{a}_j denote the values of g and \tilde{a} (respectively) after the j th stream update. Then

$$\begin{aligned} g_j(y) &= \sum_{y' \in [s]} \tilde{f}(r_2, y') \tilde{a}_j(r_1, y, r_2, y') \\ &= \sum_{y' \in [s]} \tilde{f}(r_2, y') (\tilde{a}_{j-1}(r_1, y, r_2, y') + \Delta_j \delta_{(x_1, y_1, x_2, y_2)_j}(r_1, y, r_2, y')) \\ &= g_{j-1}(y) + h_j(y), \end{aligned} \quad (17)$$

where Equation (17) follows from Equation (3) and

$$h_j(y) := \sum_{y' \in [s]} \tilde{f}(r_2, y') \Delta_j \delta_{(x_1, y_1, x_2, y_2)_j}(r_1, y, r_2, y'). \quad (18)$$

Hence, after the j th update, the Verifier can compute $h_j(y)$ and maintain the vector $g(y)$.

Help message. After the second pass, Prover sends a polynomial $\hat{p}(X_1, X_2)$ (as a stream of coefficients) that she claims equals $p(X_1, X_2)$.

Verification and output. At the end of the second pass, Verifier gets $g(y)_m = g(y)$ for each y . Now, he uses Equation (16) to compute the check value $p(r_1, r_2)$ and the result value $\hat{\gamma} := \sum_{x_1, x_2 \in [t]} \hat{p}(x_1, x_2)$. If he finds that $p(r_1, r_2) \neq \hat{p}(r_1, r_2)$, he outputs \perp . Otherwise, he believes that $\hat{p} \equiv p$ and exploiting Equation (13), outputs $\hat{\gamma}$ as the answer.

Now, we analyze the correctness and complexity parameters of the scheme.

Error probability. The protocol errs only when $\hat{p} \not\equiv p$, but Verifier's check passes. Then, $(r_1, r_2) \in \mathbb{F}^2$ must be a root of the nonzero polynomial $\hat{p} - p$. We noted that its total degree is $O(t)$. Thus, the Schwartz-Zippel Lemma bounds the error probability by at most $O(t)/|\mathbb{F}| < 1/n$, for large enough choice of $|\mathbb{F}|$.

Help and Verification costs. The polynomial \hat{p} has $O(t^2)$ monomials, and so, the hcost is $\tilde{O}(t^2)$. Verifier stores constant many vectors of size s at a time and incurs a vcost of $\tilde{O}(s)$. Thus, we obtain a two-pass $[t^2, s]$ -scheme for CROSSEGECOUNT, for parameters t, s with $ts = n$. Setting $t = n^{1/3}$ and $s = n^{2/3}$, we get a scheme with total cost $\tilde{O}(n^{2/3})$.

Finally, we discuss how one can count cross-edges between U and W when they are defined as unordered pairs. Define this problem as CROSSEGECOUNT-UNIQ. Let γ' be the number of edges that γ counts with multiplicity 2, i.e., the number of undirected edges $(u, w) \in U \times W$ such that $u, w \in U \cap W$. Then,

$$\gamma' = \sum_{u \in U, w \in W} L_u F_u A_{u,w} L_w F_w. \quad (19)$$

Hence, we modify the definitions of $p(X_1, X_2)$ and $g(y)$ as

$$p(X_1, X_2) := \sum_{y_1, y_2 \in [s]} \tilde{\ell}(X_1, y_1) \tilde{f}(X_1, y_1) \tilde{a}(X_1, y_1, X_2, y_2) \tilde{\ell}(X_2, y_2) \tilde{f}(X_2, y_2). \quad (20)$$

$$g(y) := \sum_{y' \in [s]} \tilde{a}(r_1, y, r_2, y') \tilde{\ell}(r_2, y') \tilde{f}(r_2, y'). \quad (21)$$

Then, proceeding as in `CROSSEDGECOUNT`, we compute γ' . Thus, we can compute γ and γ' in parallel and finally output $\gamma - \gamma'$ as the answer to `CROSSEDGECOUNT-UNIQU`.

► **Theorem 7.** *For parameters t, s with $ts = n$, there are two-pass $[t^2, s]$ -schemes for `CROSSEDGECOUNT` and `CROSSEDGECOUNT-UNIQU`. In particular, there are two-pass schemes with total cost $\tilde{O}(n^{2/3})$. If the vertices appear first in the stream, we need only one pass.*

6 Path Problems

In this section, we focus on path-related problems. Specifically, we study `ST-KPATH` for $k \geq 3$ and the fundamental `ST-SHORTESTPATH` problem (defined in Section 1.1). It follows from simple reduction from `INDEXN` for $N = n^2$ that a one-pass algorithm for both of these problems requires $\Omega(n^2)$ space in the basic (sans prover) streaming model, and a one-pass scheme requires a total cost of $\Omega(n)$. We present a scheme for `ST-KPATH` for general k that can also be used to solve `ST-SHORTESTPATH`. It is a semi-streaming scheme when k is polylogarithmic in n , and hence matches the lower bound (up to polylogarithmic factors). Next, we explore if we can break the $\Omega(n)$ barrier for schemes for `ST-KPATH` at the cost of allowing a few more passes over the input. We achieve this for constant k by generalizing the protocol for `ST-3PATH`. We present all our schemes for undirected graphs, but they can be very easily modified to work for directed graphs as well.

6.1 A Single-Pass Semi-Streaming Scheme for Detecting Short Paths

For `ST-3PATH`, it is easy to obtain a semi-streaming scheme by checking (using Fact 2) whether the set $N[v_s] \times N[v_i]$ and the edge set E are disjoint. For $k > 3$, it's not that direct and requires more work. We describe the protocol below for a multigraph G .

Let A denote the adjacency matrix of the graph G and let \tilde{A} be the \mathbb{F} -extension of A , for some large finite field \mathbb{F} . For $u \in N_{i+1}(v_s)$, let $d_{u,i}$ be the number of (in-)neighbors of u in $N_i(v_s)$. It follows that

$$d_{u,i} = \sum_{v \in N_i(v_s)} A(v, u). \quad (22)$$

We are now ready to describe the protocol.

Stream processing. Verifier picks $r \in_R \mathbb{F}$ and stores $\tilde{A}(v, r)$ for each $v \in [n]$, maintaining them dynamically as the stream arrives (Fact 1). He also stores the set $N_1(v_s)$.

Help message. At the end of the stream, Prover sends Verifier $k-1$ polynomials $\hat{p}_1, \dots, \hat{p}_{k-1}$, and she claims $\hat{p}_i \equiv p_i$ for each $i \in [k]$, where

$$p_i(U) = \sum_{v \in N_i(v_s)} \tilde{A}(v, U). \quad (23)$$

Verifier's computation. Verifier iteratively constructs $N_i(v_s)$ for $i \in [k]$. Each time after computing $N_i(v_s)$ for an i , he checks if t is in the set. If so, he stops and outputs YES. Otherwise, he proceeds to compute $N_{i+1}(v_s)$. If he finds that $t \notin N_i(v_s)$ for any $i \in [k]$, then he outputs NO. The inductive neighborhood computation is done as follows.

Assume that Verifier has the set $N_i(v_s)$ for some $i \in [k-1]$; this holds initially, since he has stored $N_1(v_s)$. He computes $p_i(r)$ using Equation (23) and checks whether $\hat{p}_i(r) = p_i(r)$. If the check passes, he believes that $\hat{p}_i \equiv p_i$ and evaluates $\hat{p}_i(u)$ for each $u \in V$. By Equation (22), $p_i(u)$ equals $d_{u,i}$, which is non-zero iff $u \in N_{i+1}(v_s)$. Hence, he sets $N_{i+1}(v_s) = \{u : \hat{p}_i(u) \neq 0\}$.

Error probability. The protocol errs when we have $\hat{p}_i \not\equiv p_i$ for some i , but Verifier's check passes. This implies that r is a root of the non-zero polynomial $\hat{p}_i - p_i$. For a given i , the total degree of this polynomial is at most $2n$. Then, probability that r is a root is at most $2n/|\mathbb{F}| < 1/n^2$, for large enough choice of $|\mathbb{F}|$. Taking a union bound over all $i \in [k]$, we get that the probability that r is a root of $\hat{p}_i - p_i$ for some i is at most $1/n$.

Help and Verification costs. Since degree of each p_i is $2n$, the total hcost is $\tilde{O}(kn)$. Verifier stores $\tilde{A}(v, r)$ for each $v \in [n]$, which requires $\tilde{O}(n)$ space. Additionally, to compute $N_{i+1}(v_s)$ for some $i \in [k]$, he needs only the set $N_i(v_s)$. Thus, we can store the $N_i(v_s)$ sets by reusing space repeatedly, and this requires $O(n)$ space. Hence, the total vcost of this protocol is $\tilde{O}(n)$. Therefore, we get a $[kn, n]$ -scheme for checking the existence of a path of length at most k between vertices v_s and v_t .

► **Theorem 8.** *Given an n -vertex (directed or undirected) multigraph $G(V, E)$ and specified vertices $v_s, v_t \in V$, for any $k \leq n - 1$, there is a $[kn, n]$ -scheme for ST-KPATH. In particular, there is a semi-streaming scheme for ST-KPATH when k is polylogarithmic in n .*

Application to Shortest Path. Based on the scheme in Theorem 8, we have the following straightforward corollary.

► **Corollary 9.** *Given a (directed or undirected) multigraph $G(V, E)$ (with edge multiplicity polylogarithmic in n) and specified vertices $v_s, v_t \in V$, there is a $[kn, n]$ -scheme for ST-SHORTESTPATH, where k is length of the shortest v_s, v_t -path.*

Proof. If there is no v_s, v_t -path, Prover sends the connected component C that v_s is in. The Verifier first checks that C is indeed connected ([10], Theorem 7.7). Next, he verifies that there is no edge going out from C by checking whether the set $C \times (V \setminus C)$ and the edge set E are disjoint (Fact 2). Both of these are $[n, n]$ -schemes.

If there is a v_s, v_t -path, and the shortest such path H has length k , then Prover sends it to the Verifier, and he can check whether H is indeed a v_s, v_t -path and that $H \subseteq E$ using an $[n, n]$ -scheme, as edge multiplicity is polylogarithmic in n (Fact 2). Parallely, he uses a $[kn, n]$ -scheme to verify that there is no v_s, v_t -path of length at most $k - 1$ (Theorem 8). ◀

6.2 A Multi-Pass Scheme for Detecting Short Paths

In Section 5, we obtained a scheme for ST-3PATH of total cost $o(n)$ using two passes over the input. We investigate if the same is true for ST-KPATH (for $k > 3$) if we allow “a few” more passes. For constant k , we answer this in the affirmative as we generalize the scheme for ST-3PATH and obtain such a scheme for ST-KPATH with $\lceil k/2 \rceil$ passes.

As usual, A denotes the adjacency matrix of the graph G . Let L and F be the characteristic vectors of $N[v_s]$ and $N(v_t)$ respectively. Let $\kappa = \kappa(G)$ denote the number of walks of length

at most k from v_s to v_t in G . Then,

$$\kappa = \sum_{u_1, \dots, u_{k-1} \in V} L_{u_1} \left(\prod_{i=1}^{k-2} A_{u_i, u_{i+1}} \right) F_{u_{k-1}}. \quad (24)$$

Note that there is a path of length at most k from v_s to v_t iff $\kappa > 0$. Therefore, computing κ suffices.

Let h and v be integer parameters with $hv = n$. Again, using a canonical bijection, we represent each vertex $u \in V$ by a pair of integers $(x, y) \in [h] \times [v]$. The vectors L and F become 2-dimensional arrays ℓ and f , given by $\ell(x, y) = L_u$ and $f(x, y) = F_u$. Again, the adjacency matrix A turns into a 4-dimensional array a , such that $a(x, y, x', y') = A_{uu'}$. Let $\tilde{\ell}$, \tilde{f} and \tilde{a} be \mathbb{F} -extensions of ℓ , f and a respectively, for a sufficiently large finite field \mathbb{F} . Thus, Equation (24) gives

$$\kappa = \sum_{x_1, \dots, x_{k-1} \in [h]} p(x_1, \dots, x_{k-1}), \quad \text{where} \quad (25)$$

$$p(X_1, \dots, X_{k-1}) = \sum_{y_1, y_2 \in [v]} \tilde{\ell}(X_1, y_1) \left(\prod_{i=1}^{k-2} \tilde{a}(X_i, y_i, X_{i+1}, y_{i+1}) \right) \tilde{f}(X_{k-1}, y_{k-1}). \quad (26)$$

For $i \in [k-1]$, $\deg_{X_i} p = 2h - 2$. Therefore, the number of monomials in p is at most $O(h^{k-1})$ and the total degree is $O(kh)$.

We present a $\lceil k/2 \rceil$ -pass protocol for ST-KPATH.

Stream processing. First, Verifier chooses $r_1, \dots, r_{k-1} \in_R \mathbb{F}$.

Pass 1. Process only the vertices in $N_1[v_s]$ and $N_1[v_t]$ in the stream. We maintain, for each $y \in [v]$, two vectors of size v : $\tilde{\ell}(r_1, y)$ and $\tilde{f}(r_{k-1}, y)$, where $y \in [s]$.

Pass i , for $2 \leq i \leq \lceil k/2 \rceil$. Define $g_0(y) := \tilde{\ell}(r_1, y)$ and $g_k(y) = \tilde{f}(r_{k-1}, y)$. For each $y \in [v]$, compute $g_{i-1}(y) := \sum_{y' \in [v]} \tilde{a}(r_{i-1}, y, r_i, y') g_{i-2}(y')$ as well as $g_{k-i+1}(y) := \sum_{y' \in [v]} \tilde{a}(r_{k-i}, y, r_{k-i+1}, y') g_{k-i+2}(y')$. The $g_j(y)$ values are updated dynamically with the stream updates in a similar way as in the protocol for CROSSEDGECOUNT in Section 5.1.

Help message. At the end of the final pass, Prover sends a polynomial $\hat{p}(X_1, \dots, X_{k-1})$ (as a stream of coefficients) that she claims equals $p(X_1, \dots, X_{k-1})$.

Verification and output. After the final pass, Verifier computes $\sum_{y \in [v]} g_{\lceil k/2 \rceil}(y) g_{\lceil k/2 \rceil + 1}(y)$, which, by Equation (26), equals $p(r_1, \dots, r_{k-1})$. If he finds that it doesn't equal $\hat{p}(r_1, \dots, r_{k-1})$, he outputs \perp . Otherwise, he believes that $\hat{p} \equiv p$ and, following Equation (25), computes $\hat{\kappa} := \sum_{x_1, \dots, x_{k-1} \in [h]} \hat{p}(x_1, \dots, x_{k-1})$. He outputs YES if $\hat{\kappa} > 0$ and NO otherwise.

Error probability. We err only when $\hat{p} \not\equiv p$, but Verifier's check passes. In this case, $(r_1, \dots, r_{k-1}) \in \mathbb{F}^{k-1}$ is a root of the nonzero polynomial $\hat{p} - p$. We noted that its total degree is at most $O(kh)$. By the Schwartz-Zippel Lemma (Fact 3), the probability of this event is at most $O(kh)/|\mathbb{F}| < 1/n$, when $|\mathbb{F}|$ is large enough.

Help and Verification costs. The number of monomials of \hat{p} is $O(h^{k-1})$, giving an hcost of $\tilde{O}(h^{k-1})$. Verifier reuses space and, during each pass, stores $O(1)$ many v -dimensional vectors, each entry of which is $O(\log n)$ bits long. Thus, the vcost is $\tilde{O}(v)$.

This gives a $\lceil k/2 \rceil$ -pass $[h^{k-1}, v]$ -scheme for ST-KPATH, for parameters h, v with $hv = n$. Setting $h = n^{1/k}$ and $v = n^{1-1/k}$, we get a scheme with total cost $\tilde{O}(n^{1-1/k})$.

► **Theorem 10.** *For any constant k , there is a $\lceil k/2 \rceil$ -pass $[n^{1-1/k}, n^{1-1/k}]$ -scheme for ST-KPATHCOUNT in a (directed or undirected) graph.*

70:16 Streaming Verification of Graph Computations via Graph Structure

We note the contrast between this result and that of Guruswami and Onak [17]. They showed a lower bound of $\Omega(n^{1+\Omega(1/k)}/k^{O(1)})$ for ST-KPATH in $k/2 - 1$ passes in the basic (sans prover) streaming model (for even k). Our results show that using $\lceil k/2 \rceil$ passes, we can obtain a scheme for the same problem with total cost of $\tilde{O}(n^{1-1/k})$.

A Missing Details from Section 5

Here, we give the missing proofs of lower bounds for `CROSSEGE`COUNT, `INDSETTEST` and `ST-3PATH`. Then, we discuss applications of `CROSSEGE`COUNT to some standard graph problems. Finally, we show how our two-pass schemes can be made single-pass under certain assumptions on the stream order.

A.1 One-Pass Lower Bounds

We quickly review some relevant material from communication complexity. In the `INDEXN` problem, there are two players: Alice, who holds a vector $\mathbf{x} \in \{0, 1\}^N$, and Bob, who holds an index $k \in [N]$. Their goal is to output the bit \mathbf{x}_k . To prove lower bounds for one-pass schemes, we consider the *Online Merlin–Arthur* (OMA) communication model.⁴ Here, in addition to Alice and Bob, there is a super-player, Merlin, who knows both their inputs, but is not to be blindly trusted. Merlin sends a message to Bob; then Alice sends a randomized

⁴ Note that our semantics are slightly different from the usual definition of Merlin–Arthur where Bob is supposed “accept” each 1-input and reject each 0-input with probability at least $2/3$.

message to Bob; finally, Bob either outputs either a bit or \perp . If Merlin is honest, Bob should output \mathbf{x}_k with probability at least $2/3$; if he is dishonest, Bob should output \perp with probability at least $2/3$.

The cost of an OMA protocol is the total number of bits communicated to Bob. The OMA complexity of a communication game is the minimum cost of a correct OMA protocol for it. Chakrabarti et al. [10, Theorem 3.1] showed that the OMA Complexity of INDEX_N is $\Omega(\sqrt{N})$. Our lower bounds follow from this result, using simple reductions from INDEX_N to the various graph problems.

Using a canonical bijection from $[n]^2$ to $[N]$, Alice rewrites her input vector $\mathbf{x} \in \{0, 1\}^N$ as a matrix $(\mathbf{x}_{ij})_{i,j \in [n]}$, while Bob looks at his input index $k \in [N]$ as $(y, z) \in [n]^2$. Our reduction creates a graph $G = (V, E)$ on $2n$ vertices: the vertex set V is $L \uplus R$ (here, \uplus denotes disjoint union), where $|L| = |R| = n$. We denote the i th vertex of L (resp. R) by ℓ_i (resp. r_i). The edge set E is given by $\{(\ell_i, r_j) : \mathbf{x}_{ij} = 1\}$. Now, by checking if (ℓ_y, r_z) is an independent set in G , or whether there's a cross-edge between the sets $\{\ell_y\}$ and $\{r_z\}$, or solving ST-3PATH in the graph $G' = (V \cup \{v_s, v_t\}, E \cup \{(v_s, \ell_y), (r_z, v_t)\})$, Bob can solve the INDEX_N problem. Thus, a one-pass scheme that solves any of these problems must have a total cost of $\Omega(n)$. We remark that Fact 2 implies matching semi-streaming upper bounds for each of them.

A.2 Applications of CrossEdgeCount

As we noted earlier, a scheme for CROSSEGECOUNT can be used as a blackbox for solving a number of other problems. These include standard problems like INDSETTEST and ST-3PATH , as well as their generalizations or variations like the following problems.

- INDUCEDGECOUNT : Given a graph $G = (V, E)$ and a subset U of V , find the number of edges in G that are induced by U .
- $\text{ROOTEDTRIANGLECOUNT}$: Given a (directed or undirected) graph $G = (V, E)$ and a vertex $v_r \in V$, find the number of triangles in G that are rooted at v_r .

► **Corollary 11.** *Let t and s be parameters such that $ts = n$. Then each of the problems INDUCEDGECOUNT , INDSETTEST , ST-3PATH , and $\text{ROOTEDTRIANGLECOUNT}$ admits a two-pass $[t^2, s]$ -scheme; in particular, a two-pass scheme with total cost $\tilde{O}(n^{2/3})$.*

Proof. For INDUCEDGECOUNT , if the input graph is undirected, then considering U and W as the same set, solve $\text{CROSSEGECOUNT-UNIQ}$. (Alternatively, solve CROSSEGECOUNT and divide the answer by two.) If the graph is directed, then solve CROSSEGECOUNT .

For INDSETTEST , solve INDUCEDGECOUNT on U and check whether the answer equals zero.

For ST-3PATH , use a scheme for CROSSEGECOUNT to find the number of cross-edges between the closed neighborhoods $N[v_s]$ and $N[v_t]$ of vertices v_s and v_t . This actually solves the more general problem of counting the number of walks of length at most 3 from v_s to v_t . Checking whether this number is non-zero decides ST-3PATH .

Finally, for $\text{ROOTEDTRIANGLECOUNT}$, if the input graph is undirected, solve INDUCEDGECOUNT on $N(v_r)$. Otherwise, solve CROSSEGECOUNT on the out-neighborhood $N^+(v_r)$ and in-neighborhood $N^-(v_r)$ of v_r . ◀

A.3 One-Pass Schemes for Certain Stream Orderings

Our two-pass solution to the `CROSSEGE`COUNT problem, as well as its corollaries, allowed the vertices and edge updates to be arbitrarily intermixed in the input stream. That said, it is interesting to focus on a natural restriction of these problems where the vertices are streamed first, followed by the edge updates. For the `ST-3PATH` problem, the corresponding restriction is that the edges incident to v_s and v_t appear before any other edges in the stream; for `ROOTEDTRIANGLE`COUNT, it is that the edges incident to v_r appear first.

Under such a restriction on the stream ordering, our two-pass solutions natural become one-pass, as we now note.

► **Corollary 12.** *The schemes for `CROSSEGE`COUNT and `CROSSEGE`COUNT-UNIQ in Theorem 7 and for `INDUCEDEDGE`COUNT, `INDSET`TEST, `ST-3PATH`, and `ROOTEDTRIANGLE`COUNT in Corollary 11 can each be implemented in one pass under a restricted stream ordering as noted above.*

Proof. Consider the protocol described in Section 5.1. Note that the first pass processes only vertices and the second pass processes only edges. This implies the claimed results for `CROSSEGE`COUNT, `CROSSEGE`COUNT-UNIQ, `INDUCEDEDGE`COUNT, and `INDSET`TEST. For `ST-3PATH`, note that requiring edges incident to v_s and v_t to arrive first is equivalent to the vertex sets $N(v_s)$ and $N(v_t)$ arriving first. A similar consideration applies to `ROOTEDTRIANGLE`COUNT. ◀

It is important to note that despite the restriction on the stream ordering, the schemes in Corollary 12 are nontrivial. Without Prover’s help, the problems remain hard, even with multiple passes. We give the simple proof for the basic problem `CROSSEGE`COUNT.

► **Proposition 13.** *Any p -pass streaming algorithm for `CROSSEGE`COUNT, with vertices streamed before edges, requires $\Omega(n/p)$ space, even for insertion-only streams.*

Proof. We reduce from `DISJ` $_n$, the set-disjointness communication problem on the universe $[n]$. Recall that, in `DISJ` $_n$, Alice holds a set $x \subseteq [n]$ and Bob holds a set $y \subseteq [n]$. Their goal is to determine whether or not $x \cap y = \emptyset$. This problem has randomized communication complexity $R(\text{DISJ}_n) = \Omega(n)$ [27].

Consider an $(n+1)$ -vertex graph G where $V(G) = \{0, \dots, n\}$ and $E(G) = \{\{0, i\} : i \in y\}$. Let $U = \{0\}$ and $W = x$. Then the number of cross edges in G from U to W is non-zero iff $x \cap y \neq \emptyset$. The result now follows along standard lines. ◀

Approximate Degree, Secret Sharing, and Concentration Phenomena

Abstract

The ε -approximate degree $\widetilde{\deg}_\varepsilon(f)$ of a Boolean function f is the least degree of a real-valued polynomial that approximates f pointwise to within ε . A sound and complete certificate for approximate degree being at least k is a pair of probability distributions, also known as a *dual polynomial*, that are perfectly k -wise indistinguishable, but are distinguishable by f with advantage $1 - \varepsilon$. Our contributions are:

- We give a simple, explicit new construction of a dual polynomial for the AND function on n bits, certifying that its ε -approximate degree is $\Omega\left(\sqrt{n \log 1/\varepsilon}\right)$. This construction is the first to extend to the notion of weighted degree, and yields the first explicit certificate that the $1/3$ -approximate degree of any (possibly unbalanced) read-once DNF is $\Omega(\sqrt{n})$. It draws a novel connection between the approximate degree of AND and anti-concentration of the Binomial distribution.
- We show that any pair of *symmetric* distributions on n -bit strings that are perfectly k -wise indistinguishable are also statistically K -wise indistinguishable with at most $K^{3/2} \cdot \exp\left(-\Omega\left(k^2/K\right)\right)$ error for all $k < K \leq n/64$. This bound is essentially tight, and implies that any symmetric function f is a reconstruction function with constant advantage for a ramp secret sharing scheme that is secure against size- K coalitions with statistical error $K^{3/2} \cdot \exp\left(-\Omega\left(\widetilde{\deg}_{1/3}(f)^2/K\right)\right)$ for all values of K up to $n/64$ simultaneously. Previous secret sharing schemes required that K be determined in advance, and only worked for $f = \text{AND}$. Our analysis draws another new connection between approximate degree and concentration phenomena.

As a corollary of this result, we show that for any $d \leq n/64$, any degree d polynomial approximating a symmetric function f to error $1/3$ must have coefficients of ℓ_1 -norm at least $K^{-3/2} \cdot \exp\left(\Omega\left(\widetilde{\deg}_{1/3}(f)^2/d\right)\right)$. We also show this bound is essentially tight for any $d > \widetilde{\deg}_{1/3}(f)$. These upper and lower bounds were also previously only known in the case $f = \text{AND}$.

1 Introduction

The ε -approximate degree of a function $f: \{-1, 1\}^n \rightarrow \{0, 1\}$, denoted $\widetilde{\deg}_\varepsilon(f)$, is the least degree of a multivariate real-valued polynomial p such that $|p(x) - f(x)| \leq \varepsilon$ for all inputs $x \in \{-1, 1\}^n$.¹ Such a p is said to be an approximating polynomial for f . This is a central object of study in computational complexity, owing to its polynomial equivalence to many other complexity measures including sensitivity, exact degree, deterministic and randomized query complexity [20], and quantum query complexity [6].

By linear programming duality, f has ε -approximate degree more than k if and only if there exist a pair of probability distributions μ and ν over the domain of f such that μ and ν are perfectly k -wise indistinguishable (i.e., all k -wise projections of μ and ν are identical), but are $(1 - \varepsilon)$ -distinguishable by f , namely $\mathbb{E}_{X \sim \mu}[f(X)] - \mathbb{E}_{Y \sim \nu}[f(Y)] \geq 1 - \varepsilon$. Said equivalently, a dual polynomial $q = (\mu - \nu)/2$ that contains no monomials of degree k or less, and such that $\sum_x |q(x)| = 1$ and $\sum_x q(x)f(x) \geq \varepsilon$.

Dual polynomials have immediate applications to cryptographic secret sharing: a dual polynomial $q = (\mu - \nu)/2$ for f is a description of a cryptographic scheme for sharing a 1-bit secret amongst n parties, where the secret can be reconstructed by applying f to the shares, and the scheme is secure against coalitions of size k (see [4] for details).

Motivation for explicit constructions of dual polynomials. Recent years have seen significant progress in proving new approximate degree lower bounds by explicitly constructing dual polynomials exhibiting the lower bound [8, 24, 9, 25, 10, 7, 11, 27]. These new lower bounds have in turn resolved significant open questions in quantum query complexity and communication complexity. At the technical core of these results are techniques for constructing a dual polynomial for composed functions $f \circ g := f(g, \dots, g)$, given dual polynomials for f and g individually.

Often, an explicitly constructed dual polynomial showing that $\widetilde{\deg}_\varepsilon(g) \geq d$ exhibits additional metric properties, beyond what is required simply to witness $\widetilde{\deg}_\varepsilon(g) \geq d$. Much of the major recent progress in proving approximate degree lower bounds has exploited these additional metric properties [10, 7, 11, 27]. Accordingly, even in cases where an approximate degree lower bound for a function g is known, it can often be useful to construct an explicit dual polynomial witnessing the lower bound. Hence, we are optimistic that the new constructions of dual polynomials given in this work will find future applications.

¹ In this work, for convenience we also consider functions mapping $\{0, 1\}^n$ to $\{0, 1\}$.

Explicit constructions of dual polynomials are also necessary to implement the corresponding secret-sharing scheme, and to analyze the complexity of the algorithm that samples the shares of the secret.

Our results in a nutshell. Our results fall into two categories. In the first category, we reprove several known approximate degree lower bounds by giving the first explicit constructions of dual polynomials witnessing the lower bounds. Specifically, our dual polynomial certifies that the ε -approximate degree of the n -bit AND function is $\Theta(\sqrt{n \log 1/\varepsilon})$. This construction is the first to extend to the notion of weighted degree, and yields the first explicit certificate that the $1/3$ -approximate degree of any (possibly unbalanced) read-once DNF is $\Omega(\sqrt{n})$. Interestingly, our dual polynomial construction draws a novel and clean connection between the approximate degree of AND and anti-concentration of the Binomial distribution.

In the second category, we prove new and tight results about the size of the coefficients of polynomials that approximate symmetric functions. Specifically, we show that for any $d \leq n/64$, any degree d polynomial approximating f to error $1/3$ must have coefficients of weight (ℓ_1 -norm) at least $d^{3/2} \cdot \exp\left(\Omega\left(\widetilde{\deg}_{1/3}(f)^2/d\right)\right)$. We show this bound is tight (up to logarithmic factors in the exponent) for any $d > \widetilde{\deg}_{1/3}(f)$. These bounds were previously only known in the case $f = \text{AND}$ [23, 5]. Our analysis actually establishes a considerably more general result, and as a consequence we obtain new cryptographic secret sharing schemes with symmetric reconstruction procedures (see Section 1.2 for details).

1.1 A New Dual Polynomial for AND

To describe our dual polynomial for AND, it will be convenient to consider the AND function to have domain $\{-1, 1\}^n$ and range $\{0, 1\}$, with $\text{AND}(x) = 1$ if and only if $x = 1^n$. In their seminal work, Nisan and Szegedy [20] proved that the $1/3$ -approximate degree of the AND function on n inputs is $\Theta(\sqrt{n})$. More generally, it is now well-known that the ε -approximate degree of AND is $\Theta(\sqrt{n \log(1/\varepsilon)})$ [15, 6]. These works do not construct explicit dual polynomials witnessing the lower bounds; this was achieved later in works of Špalek [28] and Bun and Thaler [8].

Our first contribution is the construction of a new dual polynomial ϕ for AND, which is simple enough to describe in a single equation:

$$\phi(x) = \frac{(-1)^n}{Z} \left(\prod_{i \in [n]} x_i \right) \left(\mathbb{E}_S \prod_{i \in S} x_i \right)^2. \quad (1)$$

Here, S is a random subset of $\{1, \dots, n\}$ of size at most $\frac{1}{2}(n-d)$ (where d determines the degree of the polynomials against which the exhibited lower bound holds), and Z is an (explicit) normalization constant.

In the language of secret sharing, to share a secret $s \in \{-1, 1\}$, the dealer samples shares $x \in \{-1, 1\}^n$ with probability proportional to $(\mathbb{E}_S \prod_{i \in S} x_i)^2$, conditioned on the parity of the shares $\prod x_i$ being equal to s .

In Corollary 8 we show that ϕ certifies that every degree- d polynomial must differ from the AND function by $2^{-n} \sum_{k=0}^{(n-d)/2} \binom{n}{k}$ at some input. In other words, the approximation error of a degree- d polynomial is lower bounded by the probability that a sum of unbiased independent bits deviates from its mean by $d/2$.

Our function ϕ given in (1), unlike previous dual polynomials [15, 28, 9, 26], also certifies that the *weighted* $1/3$ -approximate degree of AND with weights $w \in \mathbb{R}_{\geq 0}^n$ is $\Omega(\|w\|_2)$ (see Corollary 9).² This lower bound is tight for all w , matching an upper bound of Ambainis [1]. The only difference in our dual polynomial construction for the weighted case is in the distribution over sets S , and the lower bound in the weighted case is derived from anti-concentration of *weighted* sums of Bernoulli random variables.

Both statements are corollaries of the following theorem.

► **Theorem 1.** *Define AND: $\{-1, 1\}^n \rightarrow \{0, 1\}$ as $\text{AND}(x) = 1$ if and only if $x = 1^n$. The function ϕ defined in Equation (1) is a dual witness for $\widetilde{\text{deg}}_{w,\varepsilon}(\text{AND}) \geq d$ for $\varepsilon = \Pr_{X \sim \{-1, 1\}^n}[\langle w, X \rangle \geq d]$.*

By combining, in a black-box manner, the dual polynomial for the weighted-approximate degree of AND with prior work (e.g., [16, Proof of Theorem 7]), one obtains, for any read-once DNF f , an explicit dual polynomial for the fact that $\widetilde{\text{deg}}_{1/3}(f) \geq \Omega(n^{1/2})$. Very recent work of Ben-David et al. [2] established this result for the first time, shaving logarithmic factors off of prior work [9, 16]. In fact, Ben-David et al. [2] prove more generally that any depth- d read-once AND-OR formula has approximate degree $2^{-O(d)}\sqrt{n}$. Their method, however, does not appear to yield an explicit dual polynomial, even in the case $d = 2$.

Discussion. It has been well known that the ε -approximate degree of the AND function on n variables is $\Theta(\sqrt{n \log(1/\varepsilon)})$ [20, 6], a fact which has many applications in theoretical computer science. This is superficially reminiscent of Chernoff bounds, which state that the middle $\Theta(\sqrt{n \log(1/\varepsilon)})$ layers of the Hamming cube contain a $1 - \varepsilon$ fraction of all inputs (i.e., “most” n -bit strings have Hamming weight close to $n/2$). However, these two phenomena have not previously been connected, and it is not a priori clear why approximate degree should be related to concentration of measure. An approximating polynomial p for f must approximate f at *all* inputs in $\{-1, 1\}^n$. Why should it matter that *most* (but very far from all) inputs have Hamming weight close to $n/2$?

The new dual witness for AND constructed in Equation (1) above provides a surprising answer to this question. The connection between (anti-)concentration and approximate degree of AND arises not because of the number of *inputs* to f that have Hamming weight close to $n/2$, but because of the number of *parity functions* on n bits that have *degree* close to $n/2$. This connection appears to be rather deep, as evidenced by our construction’s ability to yield a tight lower bound in the case of weighted approximate degree.

1.2 Indistinguishability for Symmetric Distributions

In this section, for convenience we consider functions mapping $\{0, 1\}^n$ to $\{0, 1\}$. Two distributions μ and ν over $\{0, 1\}^n$ are (*statistically*) (k, δ) -*wise indistinguishable* if for all subsets $S \subseteq \{1, \dots, n\}$ of size k , the induced marginal distributions $\mu|_S$ and $\nu|_S$ are within statistical distance δ . When $\delta = 0$, we say they are (*perfectly*) k -*wise indistinguishable*.

² For a polynomial $p(x_1, \dots, x_n)$, a weight vector $w \in \mathbb{R}_{\geq 0}^n$ assigns weight w_i to variable x_i . The weighted degree of p is the maximum weight over all monomials appearing in p , where the weight of a monomial is the sum of the weights of the variables appearing within it. The weighted ε -approximate degree of f , denoted $\widetilde{\text{deg}}_{w,\varepsilon}(f)$, is the least weighted degree of any polynomial that approximates f pointwise to error ε .

For general pairs of distributions, perfect k -wise indistinguishability does not imply any sort of security against distinguishers of size $k + 1$. Any binary linear error-correcting code of distance $k + 1$ and block length n induces a pair of distributions (the uniform distribution over codewords and one of its affine shifts) that are perfectly k -wise indistinguishable, yet perfectly $(k + 1)$ -wise distinguishable.

In contrast, we prove that perfect k -wise indistinguishability for *symmetric* distributions implies strong statistical security against larger adversaries:

► **Theorem 2.** *If μ and ν are symmetric over $\{0, 1\}^n$ and perfectly k -wise indistinguishable, then they are statistically $(K, O(K^{3/2}) \cdot e^{-k^2/1156K})$ -wise indistinguishable for all $1 \leq k < K \leq n/64$.*

Theorem 2 has the following direct consequence for secret sharing schemes over bits with symmetric reconstruction. We say (μ, ν) are α -reconstructible by f if $\mathbb{E}_{X \sim \mu}[f(X)] - \mathbb{E}_{Y \sim \nu}[f(Y)] \geq \alpha$.

► **Corollary 3.** *Let f be a symmetric Boolean function. There exists a pair of distributions μ and ν that are $(K, K^{3/2} \cdot e^{-\Omega(\deg_{1/3}(f)^2/K)})$ -indistinguishable for all $K \leq n/64$, but are $\Omega(1)$ -reconstructible by f .*

Corollary 3 is an immediate consequence of our Theorem 2, and the fact that any symmetric function has an optimal dual polynomial that is itself symmetric. In the special case $f = \text{AND}$ (or equivalently $f = \text{OR}$), Corollary 3 implies the existence of a *visual secret sharing scheme* (see, for example [19]) that is $(K, K^{3/2} \cdot e^{-\Omega(n/K)})$ -statistically secure against all coalitions of size K , simultaneously for all K up to size $n/64$. This property, where security guarantees are in place for many coalition sizes at the same time, is in contrast to an earlier result of Bogdanov and Williamson [5] where they proved that for any fixed coalition size K , there is a visual secret sharing scheme that is $(K, e^{-\Omega(n/K)})$ -statistically secure. In their construction, the distribution of shares μ and ν depend on the value of K .

We remark that the bound of Corollary 3 cannot hold in general for $K = n$, since there exists distributions that are perfectly $\Omega(n)$ -wise indistinguishable but are reconstructible by the majority function on all n inputs. We do not however know if a bound of the form $K \leq (1 - \Omega(1))n$ is tight in this context.

Tight weight-degree tradeoffs for polynomials approximating symmetric functions

Let $f: \{0, 1\}^n \rightarrow \{0, 1\}$ be any function. For any integer $d \geq 0$, denote by $W_\varepsilon(f, d)$ the minimum *weight* of any degree- d polynomial that approximates f pointwise to error ε . By the weight of a polynomial, we mean the ℓ_1 -norm of its coefficients over the parity (Fourier) basis³. In Section B, we observe that Corollary 3 implies weight-degree trade-off lower bounds for symmetric functions.

► **Corollary 4.** *For any symmetric function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, any constant $\varepsilon \in (0, 1/2)$, and any integer K where $n/64 \geq K \geq \widetilde{\deg}_\varepsilon(f)$, we have $W_\varepsilon(f, K) \geq K^{-3/2} \cdot 2^{\Omega(\widetilde{\deg}_{1/3}(f)^2/K)}$.*

The following theorem shows that the lower bound obtained in Corollary 4 is tight (up to polylogarithmic factors in the exponent) for all symmetric functions.

³ In fact, our main weight lower bound (Corollary 4) holds over any set of functions (not just parities) that each depend on at most d variables.

► **Theorem 5.** For any symmetric function $f: \{0, 1\}^n \rightarrow \{0, 1\}$, any constant $\varepsilon \in (0, 1/2)$ and $K > \widetilde{\deg}_\varepsilon(f) \cdot \sqrt{\log n}$, $W_\varepsilon(f, K) \leq 2^{\widetilde{O}(\widetilde{\deg}_{1/3}(f)^2/K)}$.⁴

Theorem 5 also implies that Corollary 3 is tight (up to polylogarithmic factors in the exponent) for all symmetric f and for all $K \geq \widetilde{\deg}_{1/3}(f)\sqrt{\log n}$. This is because any improvement to Corollary 3 would yield an improvement to Corollary 4, contradicting Theorem 5.

Essentially Optimal Ramp Visual Secret Sharing Schemes. The following result shows that in the case $f = \text{AND}$, Corollary 3 is essentially tight for all $K \geq 2$, and Theorem 2 is tight as a reduction from perfect to approximate indistinguishability for symmetric distributions. It does so by constructing essentially optimal ramp visual secret sharing schemes.⁵

► **Theorem 6.** For all $2 \leq k < K \leq n$ there exist symmetric k -wise indistinguishable distributions μ and ν over n -bit strings that are $\sqrt{2^{-4K+3} \cdot \sum_{d>k} \binom{2K}{K+d}^2}$ -reconstructible by AND_K , where $\text{AND}_K(x)$ is the AND of the first K bits of x .

Discussion of Theorem 6. This theorem gives the existence of a ramp visual secret sharing scheme that is perfectly secure against any k parties, but in which any $K > k$ parties can reconstruct the secret with the above advantage. This generalizes the schemes in [5] where only reconstruction by all n parties was considered.

Let us express the reconstruction advantage appearing in Theorem 6 in a manner more easily comparable to other results in this manuscript. Standard results on anti-concentration of the Binomial distribution state that $2^{-2K} \cdot \sum_{d>k} \binom{2K}{K+d} = e^{-\Theta(k^2/K)}$ (see, e.g., [17]). The Cauchy-Schwarz inequality then implies that the reconstruction advantage appearing in Theorem 6 is at least $K^{-1/2} \cdot e^{-O(k^2/K)}$.⁶

Hence, the visual secret sharing schemes given in Theorem 6 are nearly optimal; if the reconstruction advantage could be improved by more than the leading $\text{poly}(K)$ factor (or the constant factor in the exponent), then this would contradict Theorem 2 which upper bounds the distinguishing advantage of any statistical test over K bits against symmetric, perfectly k -wise indistinguishable distributions. Theorem 6 also shows that the indistinguishability parameter in Theorem 2 cannot be significantly improved, even in the restricted case where the only statistical test is AND_K .

In Section 4 we describe another application of Theorem 2 to security against share consolidation and “downward self-reducibility” of visual secret shares.

⁴ Here and throughout, the \widetilde{O} notation hides polylogarithmic factors in n .

⁵ A visual secret sharing scheme is a scheme where the reconstruction function is the AND of some subset of the shares. A ramp scheme is one where there is not necessarily a sharp threshold between the perfect secrecy and reconstruction thresholds; in particular, we allow for $K > k + 1$.

⁶ Theorem 6 is closely related to Theorem 1, in that Theorem 6 gives *another* anti-concentration-based proof that $\widetilde{\deg}_\varepsilon(\text{AND}_K) \geq k$ for $\varepsilon = K^{-1/2} \cdot e^{-\Theta(k^2/K)}$. However, the two results are incomparable. Theorem 6 does not yield an explicit dual polynomial for AND_K , and the ε -approximate degree lower bound for AND_K implied by Theorem 6 is loose by the $K^{-1/2}$ factor appearing in the expression for ε . On the other hand, Theorem 1 only yields a visual secret sharing scheme with reconstruction by all n parties, while Theorem 6 yields a ramp scheme with non-trivial reconstruction advantage by the AND of the first K (out of n) parties.

1.3 Related Works

Prior Work. Servedio, Tan, and Thaler [23] established Corollary 4 and Theorem 5 in the special case $f = \text{OR}$, showing that degree d polynomials that approximate the OR function require weight $2^{\tilde{\Theta}(n/d)} = 2^{\tilde{\Theta}(\deg_{1/3}(\text{OR})^2/d)}$.⁷ They used this result to establish tight weight-degree tradeoffs for polynomial threshold functions computing decision lists. As previously mentioned, Bogdanov and Williamson [5] generalized the weight-vs-degree lower bound from [23] beyond polynomials, thereby obtaining a visual secret-sharing scheme for any fixed K that is $(K, e^{-\Omega(n/K)})$ -statistically secure.

Elkies [13] and Sachdeva and Vishnoi [22] exploit concentration of measure to prove a tight upper bound on the degree of univariate polynomials that approximate the function $t \mapsto t^n$ over the domain $[-1, 1]$. Their techniques inspired our (much more technical) proof of Theorem 2.

Other Related Work. This work subsumes Bogdanov’s manuscript [3], which shows a slightly weaker lower bound on the weighted approximate degree of AND, and does not derive an explicit dual polynomial. In independent work, Huang and Viola [14] prove a weaker form of our Corollary 3: their distributions μ, ν depend on the value of K . They also prove (a slightly tighter version of) Theorem 5, thereby establishing that the statistical distance in Corollary 3 is tight.

1.4 Techniques and Organization

The proof of Theorem 1 (Section 2) is an elementary verification that the function ϕ given in (1) is a dual polynomial. The only property that is not immediate is correlation with AND. Verifying this property amounts to upper bounding the normalization constant Z , which follows from orthogonality of the Fourier characters.

In the proof of Theorem 2 (Section 3), a K -bit statistical distinguisher for symmetric distribution is first decomposed into a sum of at most $K + 1$ tests Q_w that evaluate to 1 only when the input has Hamming weight exactly w . Lemma 13 shows that the univariate symmetrizations p_w of these distinguishers can be pointwise approximated by a degree- k polynomial with error at most $O(K^{1/2}) \cdot e^{-\Omega(k^2/K)}$.

To construct the desired approximation, we derive an identity relating the moment generating function of the squared Chebyshev coefficients of p_w (interpreted as relative probabilities) to the average magnitude of a polynomial g related to p_w on the unit complex circle (Claims 16 and 17). We bound these magnitudes analytically (Claim 18) and derive tail inequalities for the Chebyshev coefficients from bounds on the moment generating function as in standard proofs of Chernoff-Hoeffding bounds.

In the special case when the secrecy parameters k and K are fixed and the number of parties n approaches infinity, $p_w(t)$ turns out to equal $C_w(t - 1)^w(t + 1)^{K-w}$, where C_w is some quantity independent of t . In this case, the Chebyshev coefficients are the regular coefficients of the polynomial $g^\infty(s) = 2^{-w}C_w(s - 1)^{2w}(s + 1)^{2(K-w)}$.⁸ When $w = 0, K/2$, or 1, the coefficients of g^∞ are exponentially concentrated around the middle as they follow

⁷ These bounds for OR were implicit in [23], but not explicitly highlighted. The upper bound was explicitly stated in [12, Lemma 4.1], which gave applications to differential privacy, and the lower bound in [9, Lemma 32], which used it to establish tight weight-degree tradeoffs for polynomial threshold functions computing read-once DNFs.

⁸ The i -th coefficient of g^∞ is the value of the i -th Kravchuk polynomial with parameter $2K$ evaluated at $2w$.

the binomial distribution. We prove that this exponential decay in magnitudes happens for all values of w , which requires understanding complicated cancellations in the algebraic expansion of $g^\infty(s)$.

We generalize this analysis to the finitary setting $n \geq 64K$.

We prove Theorem 5 (Section B) by writing any symmetric function f as a sum of at most $\ell := \min\{|f^{-1}(0)|, |f^{-1}(1)|\}$ many conjunctions, and approximating each conjunction to such low error (namely error $\ll \ell$) that the sum of all approximations is an approximation for f itself. Theorem 5 then follows by constructing low-weight, low-degree polynomial approximations for each conjunction in the sum.

Theorem 6 (Section C) is proved by lower bounding the error of degree k polynomial approximations to the symmetrization f of the function $\text{AND}_K(x_{\{1, \dots, K\}})$. By duality, a lower bound on approximation error translates into a secret sharing scheme with the same reconstruction advantage. To lower bound the error, we estimate the values of the coefficients in the Chebyshev expansion of f with indices larger than k . Owing to orthogonality, the largest of these coefficients lower bounds the approximation error of any degree- k polynomial.

In Section 4 we formulate a security of secret sharing against consolidation and downward self-reducibility of visual schemes, and derive these properties from the main results.

2 Dual Polynomial For the Weighted Approximate Degree of AND

In this section we prove Theorem 1 and derive its two corollaries about the unweighted and weighted approximate degree of AND.

Notation and Definitions. Let $[n] = \{1, \dots, n\}$. Given a vector $w \in \mathbb{R}_{\geq 0}^n$, define the weight of a monomial $\chi_S(x) = \prod_{i \in S} x_i$, $x_i \in \{-1, 1\}$ to equal $\sum_{i \in S} w_i$. Define the w -weighted degree of a polynomial to be the maximum weight of a monomial in it. That is, if $p = \sum_{S \subseteq [n]} c_S \chi_S$, then define

$$\deg_w(p) = \max_{S: c_S \neq 0} w(S).$$

Define the w -weighted ε -approximate degree $\widetilde{\deg}_{w, \varepsilon}(f)$ to be the minimum w -weighted degree of a polynomial p that satisfies $|p(x) - f(x)| \leq \varepsilon$ for all x in the domain of f . Given two real-valued functions f, g over domain $\{-1, 1\}^n$, define $\langle f, g \rangle := \frac{1}{2^n} \sum_{x \in \{-1, 1\}^n} f(x) \cdot g(x)$.

► **Lemma 7.** *For any finite set X and any function $f: X \rightarrow \mathbb{R}$, $\widetilde{\deg}_{w, \varepsilon}(f) \geq d$ iff there exists a function $\phi: X \rightarrow \mathbb{R}$ satisfying the following conditions.*

- Pure high degree: For any real polynomial p of weighted degree is at most d , $\langle \phi, p \rangle = 0$.
- Normalization: $\sum_{x \in X} |\phi(x)| = 1$,
- Correlation: $\langle \phi, f \rangle \geq \varepsilon$,

We call ϕ a dual witness for $\widetilde{\deg}_{w, \varepsilon}(f) \geq d$. The lemma follows by linear programming duality and is a straightforward generalization of previous results (see e.g. [28, 9]). We prove the “if” direction, which is sufficient for our purposes.

Proof. For any p of weighted degree at most d ,

$$\|f - p\|_\infty = \|f - p\|_\infty \|\phi\|_1 \geq \langle \phi, f - p \rangle = \langle \phi, f \rangle - \langle \phi, p \rangle \geq \varepsilon. \quad \blacktriangleleft$$

The dual polynomial of interest is

$$\phi(x) = \frac{(-1)^n}{Z} \chi_{[n]}(x) \cdot \mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)]^2,$$

where $x \in \{-1, 1\}^n$, \mathcal{H} is the uniform distribution over the sets $\{S \subseteq [n] : w(S) \leq (\|w\|_1 - d)/2\}$, and Z is the normalization constant

$$Z = \sum_{x \in \{-1, 1\}^n} \mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)]^2.$$

Proof of Theorem 1. We prove the theorem by showing that ϕ satisfies the three conditions of Lemma 7. The expression $\mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)]^2$ can be written as a sum of products of pairs of monomials of weight at most $(\|w\|_1 - d)/2$, so its weighted degree is at most $\|w\|_1 - d$. Thus every monomial that occurs in the expansion of $\chi_{[n]}(x) \mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)]^2$ must have weighted degree *at least* d , and so ϕ has pure high weighted degree at least d as desired.

The scaling by Z in the definition of ϕ ensures that ϕ has L_1 norm 1. The correlation of ϕ and AND is given by $\langle \phi, \text{AND} \rangle = \phi(1^n) = \frac{1}{Z}$. Finally, the normalization constant Z evaluates to

$$\begin{aligned} Z &= \sum_{x \in \{-1, 1\}^n} \mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)]^2 = \sum_{x \in \{-1, 1\}^n} \mathbb{E}_{S \sim \mathcal{H}} [\chi_S(x)] \mathbb{E}_{T \sim \mathcal{H}} [\chi_T(x)] \\ &= \sum_{x \in \{-1, 1\}^n} \mathbb{E}_{S, T \sim \mathcal{H}} [\chi_{S \Delta T}(x)] = \mathbb{E}_{S, T \sim \mathcal{H}} \sum_{x \in \{-1, 1\}^n} \chi_{S \Delta T}(x) \\ &= 2^n \Pr[S = T] = \frac{2^n}{|\mathcal{H}|}, \end{aligned}$$

since the inner summation over x evaluates to 2^n when $S = T$, and zero otherwise.

It remains to show that $1/Z = |\mathcal{H}|/2^n$ equals the desired expression for ε . For a set $S \subseteq [n]$, let $X(S) \in \{-1, 1\}^n$ be the string that assigns values 1 and -1 to elements inside and outside S , respectively. Then $w(S) = \|w\|_1/2 + \langle w, X(S) \rangle/2$, so

$$\frac{|\mathcal{H}|}{2^n} = \Pr_{S \subseteq [n]} [w(S) \geq \|w\|_1/2 + d/2] = \Pr_{X \sim \{-1, 1\}^n} [\langle w, X \rangle \geq d]. \quad \blacktriangleleft$$

► **Corollary 8** (Approximate degree of AND). *Recall that $\text{AND}: \{-1, 1\}^n \rightarrow \{0, 1\}$ denotes the function satisfying $\text{AND}(x) = 1$ if and only if $x = 1^n$. If p has degree at most d , then $|p(x) - \text{AND}(x)| \geq \Pr[X \leq (n - d)/2]$ for some x , where X is a Binomial($n, 1/2$) random variable.*

The expression on the right is lower bounded by the larger of $1/2 - O(d/\sqrt{n})$ and $2^{-O(d^2/n)}$. In the large d regime ($d \geq \sqrt{n}$), this bound is tight [15, 6].

Proof. Apply Theorem 1 to the weight vector $w = (1, 1, \dots, 1)$. ◀

Earlier constructions of dual polynomials for AND are quite different from our Corollary 8 [15, 28, 9, 26] and are based on real-valued polynomial interpolation. Specifically, for a carefully chosen set $T \subseteq \{0, 1, \dots, n\}$ of size $|T| = 2d$, the prior constructions consider a *univariate* polynomial $p(t) = \prod_{i \in [n] \setminus T} (t - i)$, and they define $\psi(x) = p(|x|)$, where $|x|$ denotes the Hamming weight of x . Clearly ψ has degree at most $n - |T|$. A fairly complicated calculation is required to show that, for an appropriate choice of T , defining ψ in this way ensures that $|\psi(1^n)|$ captures an ε -fraction of the L_1 -mass of ψ .

► **Corollary 9** (Weighted approximate degree of AND). $\widetilde{\text{deg}}_{w, 3/32}(\text{AND}) \geq \|w\|_2/2$.

The proof uses the Paley-Zygmund inequality:

► **Lemma 10** (Paley-Zygmund inequality). *Let $Z \geq 0$ be any random variable with finite variance. Then, for any $0 < \theta < 1$,*

$$\Pr[Z \geq \theta \mathbb{E}(Z)] \geq (1 - \theta)^2 \frac{(\mathbb{E}[Z])^2}{\mathbb{E}[Z^2]}.$$

Proof of Corollary 9. We apply the Paley-Zygmund inequality to $\langle w, X \rangle^2$. First, $\mathbb{E}[\langle w, X \rangle^2] = \|w\|_2^2$ and $\mathbb{E}[\langle w, X \rangle^4] = \sum w_i^4 + 3 \sum w_i^2 w_j^2 \leq 3\|w\|_2^2$. Then

$$\Pr \left[\langle w, X \rangle \geq \frac{\|w\|_2}{2} \right] = \frac{1}{2} \Pr \left[|\langle w, X \rangle| \geq \frac{\|w\|_2}{2} \right] = \frac{1}{2} \Pr \left[\langle w, X \rangle^2 \geq \frac{\|w\|_2^2}{4} \right] \geq \frac{1}{2} \cdot \frac{9}{16} \cdot \frac{1}{3} = \frac{3}{32},$$

where the first equality follows from the sign-symmetry of X . Applying Theorem 1 with $d = \|w\|_2/2$ yields the claim. ◀

3 Approximate Indistinguishability from Perfect Indistinguishability

In this section, we prove Theorem 2, which states that any pair of symmetric and perfectly k -wise indistinguishable distributions over $\{0, 1\}^n$ are also approximately indistinguishable against statistical tests that observe $K > k$ of the bits. We may and will assume without loss of generality that the statistical test is a symmetric function,⁹ meaning that it depends only on the Hamming weight of the observed bits of its input.

Let X and Y denote an arbitrary pair of symmetric $(k, 0)$ -wise indistinguishable distributions over $\{0, 1\}^n$. We will be interested in obtaining an upper bound on the statistical distance of their projections to any K indices of $[n]$, namely the advantage $\mathbb{E}_X[T(X|_S)] - \mathbb{E}_Y[T(Y|_S)]$ where $T : \{0, 1\}^K \rightarrow \{0, 1\}$ is a symmetric function and $S \subseteq [n]$ is any set of size K . We can decompose T into a sum of tests $Q_w : \{0, 1\}^K \rightarrow \{0, 1\}$, where Q_w outputs 1 if and only if the Hamming weight of its input is exactly w . Specifically, we decompose T as

$$T = \sum_{w=0}^K b_w Q_w, \tag{2}$$

where each b_w is either zero or one. We will bound the distinguishing advantage of each Q_w in the sum individually. This advantage is captured by a univariate function p_w that expresses Q_w in terms of the Hamming weight of its input, after shifting and scaling the Hamming weight to reside in the interval $[-1, 1]$.

► **Fact 11.** *Let $S \subseteq [n]$ be any set of size K . There exists a univariate polynomial p_w of degree at most K such that the following holds. For all $t \in \{-1, -1 + 2/n, \dots, 1 - 2/n, 1\}$, $p_w(t) = \mathbb{E}_Z[Q_w(Z|_S)]$ where Z is a random string of Hamming weight $\phi^{-1}(t) = (1 - t)n/2 \in \{0, 1, \dots, n\}$.*

Proof. This statement is a simple extension of Minsky and Papert's classic symmetrization technique [18]. Specifically, Minsky and Papert showed that for any polynomial $p_n : \{0, 1\}^n \rightarrow \mathbb{R}$, there exists a univariate polynomial P of degree at most the total degree of p_n , such that for all $i \in \{0, \dots, n\}$, $P(i) = \mathbb{E}_{|x|=i}[p_n(x)]$. Apply this result to $p_n(x) = Q_w(x|_S)$ and let $p_w(t) = P(\phi^{-1}(t)) = P((1 - t)n/2)$. The fact then follows from the observation that the total degree of $Q_w(x|_S)$ is at most K , since this function is a K -junta. ◀

⁹ In the full version, we include simple proofs that (1) the marginal distributions of a symmetric distribution are symmetric and that (2) the best distinguisher between a pair of symmetric distributions is a symmetric function.

In particular, the value $p_w(t)$ is a probability for every $t \in \{-1, -1 + 2/n, \dots, 1 - 2/n, 1\}$. Moreover, this probability must equal zero when the Hamming weight of Z is less than w or greater than $n - K + w$. Therefore p_w has K distinct zeros at the points $Z_w = Z_- \cup Z_+$, where

$$Z_- = \{-1 + 2h/n : h = 0, \dots, K - w - 1\}, \quad Z_+ = \{1 - 2h/n : h = 0, \dots, w - 1\}. \quad (3)$$

and so p_w must have the form

$$p_w(t) = C_w \cdot \prod_{z \in Z_w} (t - z) \quad (4)$$

for some C_w that does not depend on t .¹⁰ As $p_w(t)$ is probability when $t \in \{-1, -1 + 2/n, \dots, 1 - 2/n, 1\}$, the function p_w is 1-bounded at those inputs. In fact, p_w is uniformly bounded on the interval $[-1, 1]$:

▷ **Claim 12.** Assuming $n \geq 64K$, $|p_w(t)| \leq 2$ for all $t \in [-1, 1]$.

The proof is omitted due to space limitations but follows a similar structure as the proof of Claim 18 which appears in Section A. Formula (4) and Claim 12 will be applied to show that p_w has a good uniform polynomial approximation on the interval $[-1, 1]$.

► **Lemma 13.** Assuming $n \geq 64K$, there exists a degree- k polynomial q_w such that $|p_w(t) - q_w(t)| \leq 4\sqrt{K} \exp(-k^2/1156K)$ for all $t \in [-1, 1]$.

Lemma 13 is the main technical result of this section. It is proved in Section 3.1.

Proof of Theorem 2. Now let T be a general distinguisher on K inputs, which we may and will assume to be a symmetric Boolean-valued function. We bound the distinguishing advantage as follows. Recalling that X and Y are $(k, 0)$ -indistinguishable symmetric distributions over $\{0, 1\}^n$, for any set $S \subseteq [n]$ of size K we have:

$$\begin{aligned} & \mathbb{E}[T(X|_S)] - \mathbb{E}[T(Y|_S)] \\ &= \sum_{w=0}^K b_w (\mathbb{E}[Q_w(X|_S)] - \mathbb{E}[Q_w(Y|_S)]) \quad (\text{by (2)}) \\ &\leq \sum_{w=0}^K |\mathbb{E}[Q_w(X|_S)] - \mathbb{E}[Q_w(Y|_S)]| \quad (\text{by boundedness of } b_w) \\ &= \sum_{w=0}^K |\mathbb{E}[p_w(\phi(|X|))] - \mathbb{E}[p_w(\phi(|Y|))]| \quad (\text{by symmetry of } X, Y, \text{ and Fact 11}) \\ &\leq \sum_{w=0}^K |\mathbb{E}[q_w(\phi(|X|))] - \mathbb{E}[q_w(\phi(|Y|))]| + 8\sqrt{K} \exp(-k^2/1156K) \quad (\text{by Lemma 13}) \\ &= O(K^{3/2}) \cdot e^{-k^2/1156K} \quad (\text{by } k\text{-wise indistinguishability of } X, Y) \end{aligned}$$

Therefore, X and Y are $(K, O(K^{3/2}) \cdot e^{-k^2/1156K})$ -wise indistinguishable for $2 \leq K \leq n/64$. ◀

¹⁰ p_w , C_w , and Z_w also depend on K and n but we omit those arguments from the notation as they will be fixed in the proof.

3.1 Proof of Lemma 13

We will prove Lemma 13 by studying the Chebyshev expansion of p_w . To this end we take a brief detour into Chebyshev polynomials and an even briefer one into Fourier analysis.

Chebyshev polynomials

The Chebyshev polynomials are a family of real polynomials $\{T_d\}$, 1-bounded on $[-1, 1]$, with T_d having degree d . We extend the definition to negative indices by setting $T_{-d} = T_d$. The Chebyshev polynomials are orthogonal with respect to the measure $d\sigma(t) = (1 - t^2)^{-1/2}dt$ supported on $[-1, 1]$. Therefore every degree- K polynomial $p: \mathbb{R} \rightarrow \mathbb{R}$ has a unique (symmetrized) Chebyshev expansion

$$p(t) = \sum_{d=-K}^K c_d T_d(t), \quad c_{-d} = c_d$$

where c_{-K}, \dots, c_K are the *Chebyshev coefficients* of p .

The Chebyshev polynomials satisfy the following identity, which plays an important role in our analysis:

► **Fact 14.** $t \cdot T_d(t) = \frac{1}{2}T_{d-1}(t) + \frac{1}{2}T_{d+1}(t)$.

This formula, together with the “base cases” $T_0(t) = 1$ and $T_1(t) = t$, specifies all Chebyshev polynomials.

We will also need the following form of Parseval’s identity for univariate polynomials.

▷ **Claim 15 (Parseval’s identity).** For every complex polynomial h , the sum of the squares of the magnitudes of the coefficients of h equals $\mathbb{E}_z[|h(z)|^2]$, where z is a random complex number of magnitude 1.

Proof outline

We will argue that the Chebyshev expansion $\sum_{d=-K}^K c_d T_d(t)$ of $p_w(t)$ has small weight on the coefficients c_d when $|d| > k$. Zeroing out those coefficients then yields a good degree- k approximation of p_w as desired.

The upper bound on the Chebyshev coefficients of p_w is derived in two steps. The first step, which is of an algebraic nature, expresses the Chebyshev coefficients of p_w as regular coefficients of a related polynomial g .¹¹ We are interested in the coefficients of the derived polynomial $g_\varepsilon(s) = g((1 + \varepsilon)s)$, which represent the Chebyshev coefficients c_d of p_w amplified by the exponential scaling factor $(1 + \varepsilon)^d$.

The second step, which is analytic, upper bounds the magnitude of the coefficients of $g_\varepsilon(s)$. The main tool is Parseval’s identity, which identifies the sum of the squares of these coefficients by the average magnitude of g_ε over the complex unit circle $\mathbb{E}_\theta |g((1 + \varepsilon)e^{i\theta})|^2$. We bound the *maximum* magnitude $\max_\theta |g((1 + \varepsilon)e^{i\theta})|^2$ by explicitly analyzing the function g . This step comprises the bulk of our proof.

The third step translates the bound on the squared 2-norm $\sum_{d=-K}^K (1 + \varepsilon)^{2d} c_d^2$ of the amplified coefficients into a tail bound on c_d by optimizing over a suitable value of ε . This is analogous to the standard derivation of Chernoff-Hoeffding bounds by analysis of the moment generating function of the relevant random variable.

¹¹ We omit the dependence on w as this parameter remains constant throughout the proof.

We now sketch how this outline is executed for the special case where n tends to infinity while k and K remain fixed. Although this setting is technically much easier, it allows us to highlight the main conceptual points of our argument. The analysis for finite n can be viewed as an approximation of this proof strategy.

Sketch of the limiting case $n \rightarrow \infty$

By the expansion (4) of p_w , as n tends to infinity p_w converges uniformly to the function

$$p_w^\infty(t) = C_w \cdot (t - 1)^w (t + 1)^{K-w},$$

as this corresponds to Fact 11 when the bits of the string Z are independent and $(1 - t)/2$ -biased. As $p_w^\infty(t)$ is a probability for every $t \in [-1, 1]$, Claim 12 follows immediately.

Step 1. Our algebraic treatment of the Chebyshev transform yields that the Chebyshev coefficient c_d of p_w^∞ is the $(K + d)$ -th regular coefficient of the polynomial

$$g^\infty(s) = C_w \left(\frac{s - 1}{\sqrt{2}} \right)^{2w} \left(\frac{s + 1}{\sqrt{2}} \right)^{2(K-w)}. \tag{5}$$

Step 2. The evaluation of the polynomial $g_\varepsilon^\infty(s) = g^\infty((1 + \varepsilon)s)$ at $s = e^{i\theta}$ satisfies the identity

$$|g^\infty((1 + \varepsilon)e^{i\theta})| = (1 + \varepsilon)^K \cdot (1 + \delta)^K \cdot C_w \cdot \left(1 - \frac{\cos \theta}{1 + \delta} \right)^w \left(1 + \frac{\cos \theta}{1 + \delta} \right)^{K-w}, \tag{6}$$

where $\delta = \varepsilon^2/2(1 + \varepsilon)$. This happens to equal

$$(1 + \varepsilon)^K (1 + \delta)^K p_w(\cos \theta / (1 + \delta)), \tag{7}$$

and is in particular uniformly bounded by $(1 + \varepsilon)^K (1 + \delta)^K$ for all θ . This similarity between p_w^∞ and g_ε^∞ is the crux of our analysis.

Step 3. By Parseval’s identity, after suitable shifting and cancellation, the amplified sum of Chebyshev coefficients $\sum_{d=-K}^K (1 + \varepsilon)^{2d} c_d^2$ is upper bounded by $(1 + \delta)^{2K}$. Therefore the tail $\sum_{k \geq d} c_d^2$ can have value at most $(1 + \delta)^{2K} / (1 + \varepsilon)^{2k} \leq \exp(2K\varepsilon^2 - 2(\varepsilon - \varepsilon^2/2)k)$. This upper bound holds for all $\varepsilon \in [0, 1]$, and plugging in the approximate minimizer $\varepsilon = k/2K$ yields a bound of the desired form $\exp(-\Omega(k^2/K))$.

Outline of the general case

We now give the outline of our full proof for the general case and relevant technical statements that we use to prove our main upper bound. Identity (5) generalizes to the following statement:

▷ **Claim 16.** The Chebyshev coefficient c_d of p_w is the $(K + d)$ -th regular coefficient of the polynomial

$$g(s) = C_w \prod_{z \in Z_w} \left(\frac{s^2 - 2sz + 1}{2} \right),$$

where C_w is as in Equation (4).

71:14 Approximate Degree, Secret Sharing, and Concentration Phenomena

The general form of identity (6) is:

▷ **Claim 17.** For $\varepsilon > 0$, $\delta = \varepsilon^2/2(1 + \varepsilon)$, and $\theta \in [-\pi, \pi]$,

$$|g((1 + \varepsilon)e^{i\theta})|^2 = (1 + \varepsilon)^{2K}(1 + \delta)^{2K} \cdot C_w^2 \prod_{z \in Z_w} h_{\delta(1+1/(1+\delta))} \left(\frac{\cos \theta}{1 + \delta}, z \right)$$

where $h_\delta(s, z) = (s - z)^2 + \delta(1 - z^2)$.

Owing to the second term in h_δ , there is no identity analogous to (7) when n is finite and p_w has zeros inside $(-1, 1)$. Nevertheless, $\prod_{z \in Z_w} h_\delta(s, z)$ can be uniformly bounded either by a sufficiently small multiple of $p_w(s)^2$, or a fixed quantity that is constant in the parameter range of interest.

▷ **Claim 18.** Assume $n \geq 64K$ and $w \leq K/2$. Then

$$C_w^2 \cdot \prod_{z \in Z_w} h_\delta(s, z) \leq \begin{cases} e^{65\delta K} \cdot p_w(s)^2 & \text{if } |s| \leq 1 - w/16K \\ e^{65\delta K} & \text{if } 1 - w/16K \leq |s| \leq 1. \end{cases}$$

We now prove Lemma 13. Due to space limitations, we omit the proof of Claim 16, which follows via induction and is an application of Fact 14, and the proof of Claim 17, which consists of a lengthy but relatively straightforward calculation. Claim 18 is proved in Section A.

► **Fact 19.** $p_w(t) = p_{K-w}(1 - t)$.

Proof. By Fact 11, both sides are degree- K polynomials that agree on $n + 1 > K$ points so they are identical. ◀

Proof of Lemma 13. By Fact 19 we may and will assume that $w \leq K/2$. Let $p_w = \sum_{d=-K}^K c_d T_d$. The approximating polynomial q_w is $\sum_{|d| < k} c_d T_d$. It remains to prove a tail upper bound on the Chebyshev coefficients. By Claim 16, the $(K + d)$ -th coefficient of $g(s)$ is c_d . Therefore the polynomial $g_\varepsilon(s) = g((1 + \varepsilon)s)$ has coefficients $(1 + \varepsilon)^{K+d} c_d$ as d ranges from $-K$ to K . We apply Parseval's identity (Claim 15) to g_ε .

It follows that

$$\begin{aligned} \sum_{d=-K}^K (1 + \varepsilon)^{2(K+d)} c_d^2 &= \mathbb{E}_\theta |g((1 + \varepsilon)e^{i\theta})|^2 \\ &\leq \max_{\theta \in [-\pi, \pi]} |g((1 + \varepsilon)e^{i\theta})|^2 \\ &= \max_{s \in [-1, 1]} (1 + \varepsilon)^{2K} (1 + \delta)^{2K} \cdot C_w^2 \prod_{z \in Z_w} h_{\delta(1+1/(1+\delta))}(s/(1 + \delta), z), \end{aligned}$$

by Claim 17. Since $0 \leq \delta = \varepsilon^2/2(1 + \varepsilon) \leq 1/2$, for simplicity we may replace $h_{\delta(1+1/(1+\delta))}(s/(1 + \delta), z)$ by $h_{2\delta}(s, z)$ in the above inequality. This gives the following approximation bound for $\alpha = \max_{t \in [-1, 1]} |p_w(t) - q_w(t)|$:

$$\begin{aligned} \alpha &= \max_{t \in [-1, 1]} \left| \sum_{|d| \geq k} c_d T_d(t) \right| \\ &\leq \sum_{|d| \geq k} |c_d| \max_{t \in [-1, 1]} |T_d(t)| \\ &\leq 2 \sum_{d \geq k} |c_d| \quad (\text{by symmetry and boundedness of } T_d) \end{aligned}$$

$$\begin{aligned}
\dots &\leq 2\sqrt{K} \cdot \sqrt{\sum_{d \geq k} c_d^2} \quad (\text{by Cauchy-Schwarz}) \\
&\leq 2\sqrt{K} \cdot \sqrt{(1+\varepsilon)^{-2(K+k)} \sum_{d \geq k} (1+\varepsilon)^{2(K+d)} c_d^2} \\
&\leq 2\sqrt{K} \sqrt{(1+\varepsilon)^{-2k} \cdot (1+\delta)^{2K} \cdot \max_{s \in [-1,1]} C_w^2 \prod_{z \in Z_w} h_{2\delta}(s, z)}.
\end{aligned}$$

By the boundedness of p_w (Claim 12), the upper bounds in Claim 18 can be unified by the inequality $C_w^2 \prod_{z \in Z_w} h_{2\delta}(s, z) \leq 4e^{130\delta K}$ that is valid for all $s \in [-1, 1]$. Since $1 + \delta \leq e^\delta$ and $1 + \varepsilon \geq e^{\varepsilon - \varepsilon^2/2}$ for $0 \leq \varepsilon \leq 1$,

$$\alpha \leq 2\sqrt{K} \cdot \sqrt{\frac{(1+\delta)^{2K}}{(1+\varepsilon)^{2k}} \cdot 4e^{130\delta K}} \leq 4\sqrt{K} \cdot \sqrt{e^{132\delta K - 2\varepsilon k + \varepsilon^2 k}} \leq 4\sqrt{K} \cdot \sqrt{e^{67\varepsilon^2 K - 2\varepsilon k}},$$

where the last inequality follows from the definition $\delta = \varepsilon^2/2(1+\varepsilon)$. Setting $\varepsilon = k/34K$ we obtain that $\alpha \leq 4\sqrt{K} \cdot e^{-k^2/1156K}$. \blacktriangleleft

4 Robustness of Symmetric Secret Sharing Against Consolidation

Consider a secret sharing scheme with tn parties, divided in n blocks of size t , that is perfectly secure against size- k coalitions. If all parties in each block come together and consolidate their information even into a single bit, the number of *blocks* against which the scheme remains secure drops to k/t . In general this is the best possible, with linear schemes providing tight examples.

The following corollary, proven in the full version, shows that if the distribution over shares is symmetric then much better security against this type of attack can be obtained.

► Corollary 20. *Let $f_1, \dots, f_n: \{0, 1\}^t \rightarrow \{0, 1\}$. Assume X, Y are k -wise indistinguishable symmetrically distributed random variables over tn -bit strings. Write $X = X_1 \dots X_n$, $Y = Y_1 \dots Y_n$, where all blocks X_i, Y_i have size t . For every K , the n -bit random variables $X' = f_1(X_1) \dots f_n(X_n)$ and $Y' = f_1(Y_1) \dots f_n(Y_n)$ are $O((tK)^{3/2} n^K e^{-k^2/1156tK})$ -close to being perfectly K -wise indistinguishable, assuming $K \leq n/64$.*

A Proof of Claim 18

The objective is to uniformly bound the value of the function

$$h_\delta(s) = C_w^2 \cdot \prod_{z \in Z_w} h_\delta(s, z), \quad \text{where} \quad h_\delta(s, z) = (s - z)^2 + \delta(1 - z^2)$$

for $s \in [-1, 1]$. When k, K are fixed and n becomes large, all zeros in Z_w approach -1 or $+1$, $h_\delta(s, z)$ uniformly approaches $h_0(s, z) = (s - z)^2$, $h_w(s)$ approaches $h_0(s) = p_w^\infty(s)$ and is therefore uniformly bounded.

The main difficulty in extending this argument to finite n is that $h_\delta(s, z)$ can no longer be uniformly bounded by a multiple of $(s - z)^2$ since when s equals z , the latter function vanishes but the former one doesn't. For this reason, we divide the analysis into two parameter regimes. When s is bounded away from the set of zeros Z_w , an approximation of the infinitary term-by-term argument can be carried out. When s is near the zeroes, we argue that $h_\delta(s)$ cannot be much larger than $h_\delta(s_0)$ for an s_0 that is even farther away from Z_w , and then argue that $h_0(s_0) = p_w(s_0)^2$ must be small because it represents the square of a probability of a rare event.

► **Fact 21.** $h_\delta(s, z)h_\delta(s, -z) = h_\delta(-s, z)h_\delta(-s, -z)$.

► **Fact 22.** $h_\delta(s, z) \leq h_\delta(|s|, z)$ when $z \leq 0$ and $s \geq 0$.

► **Fact 23.** $h_\delta(s, z) \leq h_\delta(s_0, z)$ when $s_0 \leq s \leq 1$, $s_0 \leq 2z - 1$, and $|z| \leq 1$.

Proof. The fact is equivalent to checking that $(s_0 - z)^2 - (s - z)^2 \geq 0$ when $s_0 \leq s \leq 1$ and $s_0 \leq 2z - 1$. If $s \leq z$ then we have that $s_0 \leq s \leq z$ from which it immediately follows that $(s_0 - z)^2 \geq (s - z)^2$. If $s > z$ then $(s - z)^2$ is at most $(1 - z)^2$. However, since $|z| \leq 1$, we have that $s_0 \leq 2z - 1 \leq z$ and thus $(s_0 - z)^2$ is always at least $(z - (2z - 1))^2 = (1 - z)^2$. Again we have that $(s_0 - z)^2 \geq (s - z)^2$. ◀

We begin by reducing to the case of non-negative inputs $s \in [0, 1]$.

▷ **Claim 24.** Assuming $w \leq K/2$, $h_\delta(s) \leq h_\delta(|s|)$.

Proof. When $w \leq K/2$ then elements of Z_w (3) can be split into w pairs of the form $A = \{(-1 + 2h/n, 1 - 2h/n) : 0 \leq h < w\}$, and $K - 2w$ remaining elements $B = \{-1 + 2h/n : w \leq h < K - w\}$ are all non-positive. By Fact 21, $\prod_{(-z, z) \in A} h_\delta(s, z)h_\delta(s, -z) = \prod_{(-z, z) \in A} h_\delta(|s|, z)h_\delta(|s|, -z)$. By Fact 22, $\prod_{z \in B} h_\delta(s, z) \leq \prod_{z \in B} h_\delta(|s|, z)$. Therefore the product $\prod_{z \in Z_w} h_\delta(s, z) \leq \prod_{z \in Z_w} h_\delta(|s|, z)$. ◁

The following claim handles values of s in the range $[0, 1 - w/16K]$.

71:18 Approximate Degree, Secret Sharing, and Concentration Phenomena

▷ **Claim 25.** Assuming $0 \leq s \leq 1 - w/16K$,

$$h_\delta(s, z) \leq \begin{cases} (1 + \delta)(s - z)^2, & \text{if } z \leq -1/\sqrt{2}. \\ (1 + (64K/w)\delta)(s - z)^2, & \text{if } z \geq 1 - w/32K \end{cases}$$

Proof. The ratio $h_\delta(s, z)/(s - z)^2$ equals $1 + ((1 - z^2)/(s - z)^2)\delta$. The number $(1 - z^2)/(s - z)^2$ is at most 1 when $s \geq 0$ and $z \leq -1/\sqrt{2}$ and at most the following when $z \geq 1 - w/32K$.

$$\frac{1 - (1 - w/32K)^2}{((1 - w/16K) - (1 - w/32K))^2} \leq \frac{2w/32K}{(w/32K)^2} = 64K/w. \quad \triangleleft$$

► **Corollary 26.** Assuming $0 \leq s \leq 1 - w/16K$ and $n \geq 64K$, $h_\delta(s) \leq e^{65\delta K} h_0(s)$.

Proof. By the choice of parameters, all zeros in Z_- meet the criterion for the first inequality in Claim 25, while all zeros in Z_+ meet the criterion for the second one. Therefore

$$\begin{aligned} h_\delta(s) &= C_w^2 \prod_{z \in Z_-} h_\delta(s, z) \prod_{z \in Z_+} h_\delta(s, z) \\ &\leq C_w^2 \prod_{z \in Z_-} (1 + \delta)(s - z)^2 \prod_{z \in Z_+} (1 + (64K/w)\delta)(s - z)^2 \\ &\leq (1 + \delta)^{K-w} (1 + (64K/w)\delta)^w \cdot C_w^2 \prod_{z \in Z_-} h_0(s, z) \prod_{z \in Z_+} h_0(s, z) \\ &\leq e^{\delta K} \cdot e^{64\delta K} \cdot h_0(s). \end{aligned}$$

◀

The following two claims handle values of s in the range $[1 - w/16K, 1]$.

▷ **Claim 27.** Assuming $w \leq K$ and $1 - w/8K \leq s_0 \leq 1 - w/16K \leq s \leq 1$,

$$h_\delta(s, z) \leq \begin{cases} h_\delta(s_0, z), & \text{if } z \geq 1 - w/32K \\ (1 + w/8K)^2 \cdot h_\delta(s_0, z), & \text{if } z \leq -w/8K. \end{cases}$$

Proof. By the choice of parameters the first inequality follows from Fact 23. For the second one, we upper bound the ratio

$$\frac{(s - z)^2}{(s_0 - z)^2} \leq \frac{(1 - z)^2}{(1 - z - w/8K)^2} = \left(1 + \frac{w/8K}{1 - z - w/8K}\right)^2 \leq \left(1 + \frac{w}{8K}\right)^2.$$

This is greater than one, so $(s - z)^2 + \delta(1 - z^2) \leq (1 + w/8K)^2((s_0 - z)^2 + \delta(1 - z^2))$ as desired. \triangleleft

► **Corollary 28.** Assuming $1 - w/8K \leq s_0 \leq 1 - w/16K \leq s \leq 1$ and $n \geq 2K$, $h_\delta(s) \leq e^{w/4} h_\delta(s_0)$.

Proof. By the choice of parameters, all zeros in Z_- meet the criterion for the first inequality in Claim 27, while all zeros in Z_+ meet the criterion for the second one. Therefore

$$\begin{aligned} h_\delta(s) &= C_w^2 \prod_{z \in Z_-} h_\delta(s, z) \prod_{z \in Z_+} h_\delta(s, z) \\ &\leq C_w^2 \prod_{z \in Z_-} (1 + w/8K)^2 \cdot h_\delta(s_0, z) \prod_{z \in Z_+} h_\delta(s_0, z) \\ &= (1 + w/8K)^{2|Z_-|} \cdot h_\delta(s_0) \\ &\leq (1 + w/8K)^{2K} \cdot h_\delta(s_0) \leq e^{w/4} h_\delta(s_0). \end{aligned}$$

◀

▷ Claim 29. If s_0 is of the form $1 - 2h/n$ for some integer $0 \leq h \leq wn/e^2K$ then $0 \leq p_w(s_0) \leq e^{-w}$.

Proof. By Fact 11, $p_w(s_0)$ is the probability that a random string of Hamming weight h and length n has exactly w ones in its first K positions. The probability that it has at least w ones in its first K positions is at most

$$\binom{K}{w} \cdot \frac{h}{n} \cdot \frac{h-1}{n-1} \cdots \frac{h-w+1}{n-w+1} \leq \left(\frac{eK}{w}\right)^w \left(\frac{h}{n}\right)^w \leq e^{-w}. \quad \triangleleft$$

Proof of Claim 18. By Claim 24 we may assume $s \in [0, 1]$. When $0 \leq s \leq 1 - w/16K$ the result follows from Corollary 26. When $1 - w/16K \leq |s| \leq 1$, by the assumption $n \geq 64K$ there must exist a value s_0 between $1 - w/8K$ and $1 - w/16K$ that is of the form $1 - 2h/n$. In particular $h \leq wn/e^2K$. Then

$$h_\delta(s) \leq e^{w/4} h_\delta(s_0) \leq e^{w/4} e^{65\delta K} p_w(s_0)^2 \leq e^{65\delta K - 7w/4},$$

where the inequalities follow from Corollary 28, Corollary 26, and Claim 29, respectively. \triangleleft

B Proofs of Corollary 4 and Theorem 5

B.1 Proof of Corollary 4

Proof of Corollary 4. Corollary 3 implies the existence of a $\phi (= \frac{\mu-\nu}{2})$ satisfying $\|\phi\|_1 = 1$, $\langle f, \phi \rangle = \varepsilon$ for some $\varepsilon = \Omega(1)$ and $\langle \phi, q \rangle \leq K^{3/2} \cdot 2^{-\Omega(\widetilde{\deg}_{1/3}(f)^2/K)}$ for any parity of degree at most K .

For any p of degree K and weight at most w ,

$$\|f - p\|_\infty = \|f - p\|_\infty \|\phi\|_1 \geq \langle \phi, f - p \rangle = \langle \phi, f \rangle - \langle \phi, p \rangle \geq \varepsilon - w \cdot K^{3/2} \cdot 2^{-\Omega(\widetilde{\deg}_{1/3}(f)^2/K)}.$$

Thus, we conclude that $W_{\varepsilon/2}(f, K) = K^{-3/2} \cdot 2^{\Omega(\widetilde{\deg}_{1/3}(f)^2/K)}$. Corollary 4 now follows using standard error reduction techniques that show that $\widetilde{\deg}_\varepsilon(f) = \Theta(\widetilde{\deg}_{1/3}(f))$ for all constants $0 < \varepsilon < 1/2$. \blacktriangleleft

B.2 Proof of Theorem 5

We first require the following lemma. This lemma builds on ideas in [23, Claim 2], which showed a similar result for $t = \Theta(1)$.

► **Lemma 30.** *For any $y \in \{0, 1\}^n$, denote by EQ_y the function on $\{0, 1\}^n$ that outputs 1 on input y , and 0 otherwise. Then for any $t > 0$ and $d > \sqrt{nt \log n}$, we have $W_{n^{-\Omega(t)}}(\text{EQ}_y, d) \leq 2^{O(nt \log^2(n)/d)}$.*

Proof. Note that for any $y \in \{-1, 1\}^n$, the function EQ_y is just the AND function on n input bits (with 0-1 valued output), with possibly negated input variables. Thus it suffices to give an approximating polynomial for the AND function on n bits. We now express AND_n as $\text{AND}_\ell \circ \text{AND}_{n/\ell}$, where ℓ is a parameter we will set later. We compute the inner $\text{AND}_{n/\ell}$ exactly and approximate the outer AND_ℓ to error $n^{-\Omega(t)}$. This can be done with a polynomial p of degree $O(\sqrt{\ell \log(n^t)})$ [15, 6]. Combining the fact that p is bounded by $1 + n^{-\Omega(t)} \leq 2$ at all Boolean inputs with Parseval's identity and the Cauchy-Schwarz inequality, it can

be seen that the weight of p is at most $\ell^{O(\sqrt{\ell \log(n^t)})}$.¹² It is well known that the exact multilinear polynomial representation of $\text{AND}_{n/\ell}$ has constant weight. Hence, by composing p with the multilinear polynomial that exactly computes $\text{AND}_{n/\ell}$, we obtain an approximation q for AND_n of degree $O\left(n\sqrt{\frac{t \log n}{\ell}}\right)$, error $n^{-\Omega(t)}$, and weight $2^{O(\sqrt{\ell t \log^3 n})}$. We now fix the value of ℓ to $\ell := \frac{n^2 t \log n}{d^2} < n$, thereby ensuring that the degree of q is at most d . With this setting of ℓ , the weight of q is at most $2^{O(nt \log^2(n)/d)}$, proving the lemma. ◀

Proof of Theorem 5. Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be any symmetric function, corresponding to the univariate predicate $D_f : \{0\} \cup [n] \rightarrow \{0, 1\}^n$. For the purpose of this proof, let us denote by k_f the smallest i for which f is constant on inputs of Hamming weight in the interval $[i + 1, n - i - 1]$. Without loss of generality, $f(x) = 0$ for strings of x Hamming weight between $k_f + 1$ and $n - k_f - 1$. The case where $f = 1$ on input strings of Hamming weight between $k_f + 1$ and $n - k_f - 1$ can be proved using a similar argument. Define $\text{supp}(f) := \{x \in \{0, 1\}^n : f(x) = 1\}$. Note that $|\text{supp}(f)| \leq 2 \cdot n^{k_f}$.

Observe that $f(x) = \sum_{y \in \text{supp}(f)} \text{EQ}_y(x)$. Lemma 30 implies, for each $y \in \text{supp}(f)$, the existence of polynomials p_y of degree K and weight $2^{O(nk_f \log^2(n)/K)}$, which approximate EQ_y to error $\frac{1}{6} \cdot n^{-k_f}$. Define a polynomial $p : \{0, 1\}^n \rightarrow \mathbb{R}$ by $p(x) = \sum_{y \in \text{supp}(f)} p_y(x)$. Clearly p has degree K , weight at most $n^{O(k_f)} \cdot 2^{O(nk_f \log^2(n)/K)} = 2^{\tilde{O}(nk_f/K)}$, and error at most $|\text{supp}(f)| \cdot n^{-k_f}/6 \leq 1/3$, where the upper bounds on the weight and error follow from the triangle inequality.

The theorem now follows standard error reduction techniques and Paturi's theorem [21], which states that for symmetric functions, $\widehat{\deg}(f) = \Theta(\sqrt{n \cdot k_f})$. ◀

► **Remark 31.** The upper bound obtained in Theorem 5 is more general than as stated, and the only property of symmetric functions it exploits is that symmetric functions of low approximate degree are highly biased. More specifically, the proof of Theorem 5 shows that any function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ with $\min\{|f^{-1}(0)|, |f^{-1}(1)|\} \leq n^t$ satisfies $W_\varepsilon(f, K) \leq 2^{\tilde{O}(nt/K)}$ for any $K \geq \sqrt{nt \log n}$.

C Proof of Theorem 6

Proof outline. As we explain in more detail in the proof itself, it is sufficient to establish the theorem for fixed k and K and infinitely many n because the statement is downward reducible in n .

Using the Chebyshev approximation formulas from Section 3 we derive explicit lower bounds on the large Chebyshev coefficients on the polynomial p_0 representing the distinguishing advantage of the AND function on K inputs. Owing to orthogonality and boundedness of the Chebyshev polynomials, this is a lower bound on the approximate degree of AND_K . By strong duality as given in the following Claim (see [4]) we obtain Theorem 6.

▷ **Claim 32.** If $\widetilde{\deg}_{\varepsilon/2}(F_n) \geq k$ then there exists a pair of perfectly k -wise indistinguishable distributions μ, ν over $\{0, 1\}^n$ such that $\mathbb{E}_{X \sim \mu}[F_n(X)] - \mathbb{E}_{Y \sim \nu}[F_n(Y)] \geq \varepsilon$.

¹²Building on [6], It is possible to derive explicit ε -approximating polynomials for AND where the degree is $O\left(\sqrt{\ell \log(1/\varepsilon)}\right)$ and the weight is $2^{O(\sqrt{\ell \log(1/\varepsilon)})}$ rather than $\ell^{O(\sqrt{\ell \log(1/\varepsilon)})}$. Using this tighter weight bound would improve our final result by a factor of $\log n$ in the exponent. We omit this tighter result for brevity.

Recall that the Chebyshev polynomials are orthogonal under the measure $d\sigma(t) = (1 - t^2)^{-1/2}dt$ supported on $[-1, 1]$. We will need the following identity for their average square magnitude under this measure:

$$\mathbb{E}_{t \sim \sigma}[T_d(t)^2] = 1/2 \quad \text{when } d > 0. \tag{8}$$

Proof of Theorem 6. By symmetry of the distinguishers, μ and ν can be assumed symmetric. Let F_n denote the function on $\{0, 1\}^n$ that outputs $\text{AND}_K(x_{\{1, \dots, K\}})$, i.e., F_n outputs the AND of the first $K < n$ bits of the input. We prove the theorem for $G_n(x_1, \dots, x_n) = \text{NOR}(x_{\{1, \dots, K\}})$. By the symmetry of 0 and 1 inputs the theorem also holds for F_n .

First, we claim that the statement of Theorem 6 is stronger as n becomes larger, so it is sufficient to prove it in the limiting case when n approaches infinity and k, K are fixed. Suppose that μ and ν are distributions over n bit strings that are k -wise indistinguishable yet are ε -reconstructable by G_n . We must show that there are distributions μ' and ν' over $\{0, 1\}^{n-1}$ are k -wise indistinguishable yet are ε -reconstructable by G_{n-1} . But this holds for μ' (respectively ν') that generate a random sample from μ (respectively, ν) and then throw away the last bit.

If the statement was false then by Claim 32 there would exist degree- k polynomials \tilde{G}_n that approximate G_n pointwise on $\{0, 1\}^n$ to within error $\varepsilon = \sqrt{2^{-4K+1} \sum_{d>K} \binom{2K}{K+d}^2}$ for almost all n . Applying the construction from the proof of Fact 11 to \tilde{G}_n , there exist univariate degree- k polynomials \tilde{p}_0^n approximating p_0^n on the set of points $W_n = \{-1 + 2h/n : 0 \leq h \leq n\}$ to within error ε . We emphasize the dependence on n as it will play a role in the proof.

By Formula (3) the polynomial p_0^n has the form

$$p_0^n(t) = C_0^n \prod_{z \in Z_0^n} (t - z),$$

where $Z_0^n = \{-1 + 2h/n : 0 \leq h < K\}$ (the set Z_+ is empty). The value $p_0^n(1)$ is the probability that G_n accepts the all-zero string, so it must equal one. The constant C_0^n must therefore equal $\prod_{z \in Z_0^n} (1 - z)^{-1}$. As n tends to infinity, the set Z_0 converges to a single zero at -1 of multiplicity K , so the sequence p_0^n converges uniformly to the polynomial

$$p_0^\infty(t) = 2^{-K}(t + 1)^K.$$

By the triangle inequality, for every $\delta > 0$ and all sufficiently large n , \tilde{p}_0^n is within $\varepsilon + \delta$ of p_0^∞ on the set W_n . A degree- k polynomial is determined by its values on W_{k+1} and the set of degree- k polynomials that are within $\varepsilon + \delta$ of p_0^∞ on W_{k+1} is compact. Therefore the sequence of approximating polynomials \tilde{p}_0^n must contain a subsequence (for values of n that are multiples of $k + 1$) that converges (uniformly) to a limiting degree- k polynomial \tilde{p}_0^∞ . Since \tilde{p}_0^n is within $\varepsilon + \delta$ of p_0^∞ on W_n for infinitely many n , \tilde{p}_0^∞ must be within $\varepsilon + 2\delta$ of p_0^∞ on W_n for infinitely many n . The union of these sets W_n is dense in $[-1, 1]$, and by continuity p_0^∞ can be $\varepsilon + \delta$ -approximated by the degree- k polynomial \tilde{p}_0^∞ everywhere on $[-1, 1]$. As δ was arbitrary it follows that the ε -approximate degree of p_0^∞ can be at most k .

All that remains to prove that this is not true, i.e., to show a lower bound of k on the ε -approximate degree of p_0^∞ . This lower bound is known (see, e.g., [13]); we provide the details in the full version. \blacktriangleleft

Improved Extractors for Recognizable and Algebraic Sources

Abstract

We study the task of seedless randomness extraction from recognizable sources, which are uniform distributions over sets of the form $\{x : f(x) = 1\}$ for functions f in some specified class \mathcal{C} . We give two simple methods for constructing seedless extractors for \mathcal{C} -recognizable sources.

Our first method shows that if \mathcal{C} admits XOR amplification, then we can construct a seedless extractor for \mathcal{C} -recognizable sources by using a mildly hard function for \mathcal{C} as a black box. By exploiting this reduction, we give polynomial-time, seedless randomness extractors for three natural recognizable sources: (1) constant-degree algebraic sources over any prime field, where constant-degree algebraic sources are uniform distributions over the set of zeros of a system of constant degree polynomials; (2) sources recognizable by randomized multiparty communication protocols of cn bits, where $c > 0$ is a small enough constant; (3) halfspace sources, or sources recognizable by linear threshold functions. In particular, the new extractor for each of these three sources has linear output length and exponentially small error for min-entropy $k \geq (1 - \alpha)n$, where $\alpha > 0$ is a small enough constant.

Our second method shows that a seed-extending pseudorandom generator with exponentially small error for \mathcal{C} yields an extractor with exponentially small error for \mathcal{C} -recognizable sources, improving a reduction by Kinne, Melkebeek, and Shaltiel [16]. Using the hardness of the parity function against AC^0 [13], we significantly improve Shaltiel's extractor [25] for AC^0 -recognizable sources. Finally, assuming sufficiently strong one-way permutations, we construct seedless extractors for sources recognizable by BPP algorithms, and these extractors run in quasi-polynomial time.

1 Introduction

Randomness is needed for many applications, such as statistics, algorithms and cryptography. However, most physical sources are not truly random, in the sense that they can have substantial biases and correlations. Weak random sources can also arise in cryptography when an adversary can learn partial information about a uniformly random string.

A natural approach to dealing with weak random sources is to apply a randomness extractor – a function that transforms a weak random source into an almost-perfect random source. However, it is impossible to give a single function that extracts even one bit of randomness from sufficiently general classes of sources [24]. There are two ways to combat this. One is to extract with the help of another short random string. An object constructed in this manner is called a seeded extractor [21]. The focus of this paper is the second way: to extract from more structured sources (without using additional random bits). Such a function is called a seedless, or deterministic, extractor.

More formally, a random source X is modeled as a probability distribution over n bit strings with some entropy k . In the context of randomness extraction, the standard measure of entropy is the so called min-entropy – the min-entropy k of a source X is defined as $H_\infty(X) = \min_s(\log(1/\Pr[X = s]))$. Then, the definition of a seedless extractor can be presented as follows.

► **Definition 1** (Seedless extractors for structured sources). *Let \mathcal{D} be a class of distributions over $\{0, 1\}^n$. We say a function $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ is a (k, ϵ) -extractor for \mathcal{D} if for any distribution $D \in \mathcal{D}$ with min-entropy at least k , we have*

$$\text{Ext}(D) \approx_\epsilon U_m,$$

where U_m denotes the uniform distribution over $\{0, 1\}^m$ and \approx_ϵ stands for ϵ -close in statistical distance (Definition 16).

By the probabilistic method, it is known that for any constant $\alpha > 0$ and any distribution family \mathcal{D} of at most $2^{2^{(1-\alpha)k}}$ sources of min-entropy k , there is a seedless extractor outputting $m = (1 - \alpha)k$ bits with error $2^{-\alpha k/3}$.

A large body of research has been devoted to constructing explicit seedless extractors for various structured sources. There are mainly two natural perspectives to limit the structure of a distribution: an algebraic perspective and a computational perspective.

The algebraic perspective is to impose some algebraic structure on the distribution, such as an affine source [5]. Later, affine sources were generalized to distributions defined using low-degree polynomials. On one hand, Dvir, Gabizon and Wigderson [10] studied polynomial sources, which are the images of low-degree polynomial maps. On the other hand, viewing an affine source as the kernel, or set of zeros, of an affine mapping, Dvir [9] introduced the class of sources sampled uniformly from kernels or sets of common zeros of one or more polynomials, which he called algebraic sources¹.

The computational perspective is to assume a distribution has “low complexity”. This started with Trevisan and Vadhan [27], who considered distributions that can be sampled by efficient algorithms. They showed that constructing a seedless extractor for this class is closely related to proving lower bound for circuits and gave a conditional construction of such an extractor based on lower bound assumptions. Later, in [15], an unconditional extractor was constructed for sources generated by space-bounded algorithms. More recently, Viola [29] constructed a seedless extractor for AC^0 -samplable sources.

¹ For clarification, in [9], Dvir mentioned sources which are distributed uniformly on varieties. A variety is also a set of common zeros of one or more polynomials, but it is often defined to require the ground field to be algebraically closed.

1.1 Recognizable sources

We focus on recognizable sources, first suggested by Shaltiel [25]. Recognizable sources are uniform distributions over sets of the form $\{x : f(x) = v\}$ for functions f coming from some specified class. Formally, for any boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, define the source recognizable by f , denoted by U_f , as the uniform distribution over $f^{-1}(1)$. For short, we call this distribution the f -recognizable source. For any boolean function family \mathcal{C} , the set of \mathcal{C} -recognizable sources is the set of f -recognizable sources, for each $f \in \mathcal{C}$.

This notion naturally interacts with the algebraic and computational perspectives to limit the structure of a distribution, and also captures several distributions that were widely studied. For example, distributions with algebraic structures are those distributions recognizable by algebraic classes – affine sources are distributions recognizable by affine functions and algebraic sources are distributions recognizable by products of low-degree polynomials. Moreover, distributions that have “low complexity” could also be the distributions recognizable by low-complexity classes, such as small circuits.

Shaltiel [25] initially proposed an extractor for recognizable sources. He showed that such extractors produced randomness that was in some sense not correlated with the input and hence could be used for derandomization. In particular, to derandomize any class of randomized algorithms, he needed to explicitly construct an extractor for distributions recognizable by the class. He showed that without further changes, some appropriate known extractors could work for distributions recognizable by decision trees, streaming algorithms, and AC^0 . What’s more, assuming average-case hardness against polynomial-size circuits, he showed that applying the hard function on disjoint blocks of the input was an extractor for distributions recognizable by general polynomial-time algorithms.

Later, Kinne, Melkebeek and Shaltiel [16] improved the derandomization results in [25] by using “seed-extending pseudorandom generators”, which are pseudorandom generators that reveal their seed. They gave reductions between seed-extending PRGs and extractors for recognizable sources. However, both Shaltiel [25] and this later paper [16] focused on derandomization rather than constructing new extractors.

1.2 XOR Amplification

Given a boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, let $f^{\oplus m}(x_1, \dots, x_m) := \bigoplus_{i \in [m]} f(x_i)$ denote the XOR of m independent copies of f . The XOR Amplification Lemma² states that if a function f is hard on average for some computational class \mathcal{C} , (i.e., f cannot be computed correctly by any function in \mathcal{C} on at most a $(1/2 + p)$ -fraction of of the inputs), then $f^{\oplus m}$ cannot be computed correctly on at most a $(1/2 + p^{\Omega(m)})$ -fraction of of the inputs. Loosely speaking, the hardness of f is amplified when the outputs of independent copies of f are XOR together. Indeed, this idea is analogous to the information theoretic setting. If f is a biased coin with $\Pr[f = 1] = 1/2 + p$, then the XOR of m independent biased coins, $f^{\oplus m}$, induces a coin with $\Pr[f^{\oplus m} = 1] = 1/2 - (-2p)^m/2$. However, showing that such an idea holds in the computational setting is significantly more involved.

There are several works dedicated to proving XOR amplification for computational models. Yao [31] first suggested XOR amplification, and proved that XOR (hardness) amplification held for polynomial-size circuits. Unfortunately, the amplification stops when XORing more than logarithmically many copies, which makes it not so useful for us. Later, Viola and

² This is usually called simply the XOR lemma, or Yao’s XOR lemma, but we want to distinguish it from a different XOR lemma.

Wigderson [30] showed XOR amplification for multi-party communication complexity and polynomials over $\text{GF}(2)$. Subsequently, their proof was extended by Bogdanov, Kawachi and Tanaka [4], to prove XOR amplification for polynomials over any prime field.

In this paper, we give a new application of XOR amplification – constructing seedless extractors for recognizable sources.

2 Overview of our results

2.1 From XOR amplification to Extractors for recognizable sources

It is folklore that one can use correlation bounds to extract a single bit. In this paper, we use XOR amplification to extend the output length from one bit to linear in the input length.

Intuitively, XOR amplification states that if a function f is hard on average for some complexity class \mathcal{C} of Boolean functions, then $f^{\oplus m}(x_1, \dots, x_m) = f(x_1) \oplus \dots \oplus f(x_m)$ is exponentially harder on average. We actually only need a weaker condition: that there exists some h for which $h^{\oplus k}$ gets exponentially harder.

More precisely, let $\mathcal{C} \subseteq \{\{0, 1\}^* \rightarrow \{0, 1\}\}$ be a class of Boolean functions. For a positive constant α , we say \mathcal{C} has α -XOR amplification if there exists a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$ such that for any positive integer k , the correlation between $h^{\oplus k}$ and g is no more than $2^{-\alpha k}$, for any $g \in \mathcal{C}$.

We show that if \mathcal{C} is closed under restrictions and \mathcal{C} has α -XOR amplification, then there is an efficient extractor for \mathcal{C}_n -recognizable sources, where \mathcal{C}_n denotes the set of all n -variate functions in \mathcal{C} .

► **Theorem 2.** *Let $\mathcal{C} \subseteq \{\{0, 1\}^* \rightarrow \{0, 1\}\}$ be any boolean function class closed under restrictions and α be any positive constant. If \mathcal{C} has α -XOR amplification, then for any positive integer n , there is an explicit seedless $((1 - \beta)n, 2^{-\Omega(\alpha n)})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ for \mathcal{C}_n -recognizable sources, where $\beta = \Theta(\alpha) > 0$, $m = \Omega(\alpha n)$, and \mathcal{C}_n denotes the set of all n -variate functions in \mathcal{C} .*

Our construction uses $h : \{0, 1\}^t \rightarrow \{0, 1\}$ from the definition of XOR amplification. Since the function h is fixed, its input length t is a constant, and it is computable efficiently (by hardwiring it). We also use the generator matrix M of an asymptotically good $[l, m, r]$ -code, where $l = n/t$, so the distance $r = \Omega(l) = \Omega(n/t)$. Then $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ is simply

$$\text{Ext}(x) = h^{(l)}(x)M, \text{ where } h^{(l)}(x = (x_1, \dots, x_l)) = (h(x_1), \dots, h(x_l)).$$

Occasionally we will apply a variation of this theorem when t grows with n , in which case we need h to be computable in time polynomial in n . For example, if the input length of h is $t = O(\log n)$, then h should be computable in exponential time.

Li [18] uses a similar construction to extend the output length of two-source extractors from one bit to more. Raz [22] had a related but different way to extend the output length of his specific extractor using small biased spaces. Raz uses the XOR lemma, but his method would not work with any asymptotically good code (as ours and Li's does); in fact, Raz does not even mention codes or distance.

2.1.1 Algebraic sources

An algebraic set is a set of common zeros of one or more multivariate polynomials defined over a finite field \mathbb{F} . An *algebraic source* is a random variable distributed uniformly over an algebraic set, which was originally introduced by Dvir [9]. Algebraic sources are a natural

generalization of affine sources that have been widely studied. Furthermore, we say that an algebraic source has degree d if the algebraic source can be defined by polynomials of degree at most d .

► **Definition 3** (Algebraic extractor). *We say that $\text{Ext} : \mathbb{F}^n \rightarrow \mathbb{F}^m$ is a (k, d, ϵ) -algebraic extractor over \mathbb{F} if for any degree- d algebraic source U_V with $|V| \geq |\mathbb{F}|^k$, $\text{Ext}(U_V) \approx_\epsilon U_m$.*

Dvir obtained explicit extractors for degree- d algebraic sources with entropy rate greater than $1/2$ over moderately sized fields, where $|\mathbb{F}| = \text{poly}(d)$, and with small entropy rate over large fields, where $|\mathbb{F}| = d^{\Omega(n^2)}$.

Golovnev and Kulikov [12] related the study of Boolean dispersers for quadratic algebraic sets to improving circuit lower bounds. A disperser is a relaxation of an extractor, which is only required to output a non-constant bit from a weak random source. They posed the open question of constructing a disperser for any algebraic set of size $2^{0.03n}$ and defined by using at most $1.78n$ quadratic polynomials. Such a disperser yields a new circuit lower bound.

Nevertheless, to our knowledge, there were only two papers on explicitly constructing dispersers or extractors for algebraic sources over $\text{GF}(2)$. Cohen and Tal [8] constructed an extractor for algebraic sources defined by at most $(\log \log n)^{1/(2e)}$ quadratic polynomials. They also constructed dispersers for algebraic sources defined by at most n^α polynomials of degree at most $\log^{0.1}(n)$ for some constant $\alpha < 1$. Our extractor construction subsumes both their extractor and disperser, outputting n^γ random bits for algebraic sources with higher degree $c \log n$ and the same bound n^α for the number of defining polynomials, where γ, c are constants. Remscrem [23] constructed the best extractors before our work, outputting one bit with error $O(1/\sqrt{n})$ for min-entropy $n - n^c$ for any $c < 1/2$. It can handle fairly large degree, up to $n^{1/2-\alpha}$, where $\alpha > 0$ is a constant. Our construction significantly improves the extractor for constant-degree algebraic sources, outputting more bits and handling lower min-entropy.

Using Theorem 2, we construct a seedless extractor for algebraic sources of constant degree for some linear min-entropy. In particular, the new extractor has linear output length and exponentially small error for min-entropy $k \geq (1 - \alpha)n$, where $\alpha > 0$ is a small enough constant.

► **Theorem 4.** *For any positive integer d , there is an efficient $((1 - 1/c_d)n, d, 2^{-\Omega(n/c_d)})$ -algebraic extractor $\text{Ext} : \mathbb{F}_2^n \rightarrow \mathbb{F}_2^m$, where $c_d = \Theta(d^2 4^d)$, $m = \Omega(n/c_d)$.*

Even for degree $c \log n$ for a small enough constant $c > 0$, our extractor outputs n^γ bits with error $2^{-\Omega(n^\alpha)}$ for $n - n^\alpha$ min-entropy, where $\gamma, \alpha > 0$ are some constants.

We can extend our algebraic extractor to any prime field \mathbb{F}_q .

► **Theorem 5.** *For any positive integer d and any prime field \mathbb{F}_q , there is an efficient $((1 - 1/c_{d,q})n, d, q^{-\Omega(n/c_{d,q})})$ -algebraic extractor $\text{Ext} : \mathbb{F}_q^n \rightarrow \mathbb{F}_q^m$, where $c_{d,q} = \Theta(d^2 2^{2d} q^3 \log q)$, $m = \Omega(n/c_{d,q})$.*

2.1.2 Sources recognizable by communication protocols

We consider a boolean function class that has low communication complexity. Communication complexity was defined by Yao [32], who introduced a standard 2-party communication model. Later, Chandra, Furst, and Lipton [6] generalized this to the multiparty model. In a t -party communication NOF (number-on-forehead) model, each party holds a separate input and each party knows all but its own input. These parties attempt to compute (or approximate) a given function of these t inputs by exchanging few bits of communication. The

complexity of a communication protocol is the number of bits exchanged on the worst input. Both deterministic and randomized communication protocols are considered. A randomized protocol can be viewed as a distribution on deterministic protocols.

For deterministic 2-party protocols, Shaltiel [25] already constructed an efficient extractor that has linear output for linear min-entropy and exponentially small error. To do this, he proved that 2-source extractors are also extractors for sources recognizable by deterministic 2-party protocols, and hence some known constructions of 2-source extractors could be used. However, this approach is tailored to the 2-party case and does not generalize to the t -party case for some $t > 2$.

We construct an extractor for sources recognizable by randomized t -party protocols. Formally, we prove the following theorem.

► **Theorem 6.** *There exists an explicit seedless $((1 - 1/c_t)n, 2^{-c_1 n/c_t})$ extractor $\text{Ext} : (\{0, 1\}^{n/t})^t \rightarrow \{0, 1\}^{c_2 n/c_t}$ for sources recognizable by randomized t -party communication protocols of at most $c_3 n/4^t$ bits, where $c_t = \Theta(t4^t)$ and c_1, c_2, c_3 are some positive constants.*

This extractor has linear output for linear min-entropy and exponentially small error, and is simply $\text{Ext}(x) = \left(\bigwedge_t^{(l)}(x)\right) M$, where $l = n/t$, \bigwedge_t is the AND function over t variables and M is the $l \times (c_2 n/c_t)$ generator matrix of a good linear code.

2.1.3 Halfspace sources

Halfspace sources are sources recognizable by linear threshold functions. A linear threshold function (abbreviated LTF) is a boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$ that can be represented as $f(x) = \mathbf{1}_{\sum_{i \in n} a_i x_i > a_0}$ for some constants $a_0, a_1, \dots, a_n \in \mathbb{R}$. From a geometric perspective, a boolean LTF is a halfspace-indicator to the discrete cube $\{0, 1\}^n$.

We construct an efficient extractor that has linear output for linear min-entropy and exponentially small error for halfspace sources.

► **Theorem 7.** *There exists an explicit seedless $((1 - c_1)n, 2^{-c_2 n})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{c_3 n}$ for halfspace sources, where c_1, c_2, c_3 are some positive small enough constants.*

The construction of this extractor is simply $\text{Ext}(x) = \left(\bigwedge_2^{(l)}(x)\right) M$, where $l = n/2$, M is the $l \times c_3 n$ generator matrix of a good linear code.

2.2 From Seed-extending PRGs to Extractors for recognizable sources

The Kinne et al. reductions between seed-extending pseudorandom generators and extractors for recognizable distributions were asymmetric. They showed that an extractor with exponentially small error yielded a seed-extending pseudorandom generator with exponentially small error. However, they proved a weak converse.

In this paper, we prove that a seed-extending pseudorandom generator with exponentially small error yields an extractor with exponentially small error. This applies to flip-invariant families of boolean functions, which are invariant under flipping input bits (see Definition 26).

► **Theorem 8.** *Let \mathcal{C} be a flip-invariant family of boolean functions over n bits. If G is a seed-extending (d, ϵ) -pseudorandom generator $G : \{0, 1\}^d \rightarrow \{0, 1\}^n$ for \mathcal{C} , then for any $\Delta = \Delta(n) > 0$ we can construct an $(n - \Delta, 2^\Delta \epsilon)$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-d}$ for \mathcal{C} -recognizable sources. Specifically, if $G(x) = (x, E(x))$ fools any function in \mathcal{C} , then $\text{Ext}(x \circ y) = y \oplus E(x)$ is an $(n - \Delta, 2^\Delta \epsilon)$ -extractor for \mathcal{C} -recognizable sources, where $x \in \{0, 1\}^d, y \in \{0, 1\}^m$, where $m = n - d$.*

In particular, the reduction in [16] requires a tiny $\epsilon \leq 2^{-(m+2\Delta)}$ for the seed-extending PRG to get an $(n - \Delta, 2^{-\Delta})$ -extractor. Moreover, the reduction in [16] breaks down for a seed-extending PRG, $G(x) = (x, E(x))$, where $E(x)$ is longer than x . We improve the reduction from seed-extending PRGs to extractors to require only $\epsilon \leq 2^{-2\Delta}$, without depending on the output length m . Furthermore, the new reduction can still work even for a seed-extending PRG, $G(x) = (x, E(x))$, where $E(x)$ is longer than x .

Based on this new reduction, we significantly improve extractors for two important types of recognizable sources as follows.

2.2.1 Circuit-recognizable sources

Kinne et al. proved that the well-known Nisan-Wigderson pseudorandom generator construction [20] can be made seed-extending. Therefore, assuming hardness against small circuits, we can construct an extractor for sources recognizable by small circuits.

► **Proposition 9.** *For any $\Delta = \Delta(n) > 0$ and positive integers $l < n$, if there is a function H that is ϵ -hard at input length $\sqrt{l}/2$ for circuits of size $s + (n - l)2^{O(\log(n-l)/\log l)}$ and depth $d + 1$, then we can get an $(n - \Delta, (n - l)2^{\Delta\epsilon})$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-l}$ for any sources recognizable by circuits of size s and depth d .*

Using the hardness of the parity function against AC^0 [13], we significantly improve Shaltiel's extractor [25] for AC^0 -recognizable sources.

► **Theorem 10.** *For any $\Delta = \Delta(n) > 0$ and positive integers $l < n$, there exists a polynomial time computable $(n - \Delta, (n - l)2^{\Delta - \Omega(l^{1/(2d+2)})})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-l}$ for any sources recognizable by circuits of size $2^{n^{1/d}}$ and depth d .*

In particular, for min-entropy $n - n^{1/(\alpha d)}$, our extractor outputs $n - n^{2/\alpha + O(1/d)}$ bits, whereas Shaltiel's extractor outputs only $n^{1/(\alpha d)}$ bits. When $\alpha > 2d/(d - 1)$ is a large enough constant, our extractor outputs $n - o(n)$ bits whereas Shaltiel's extractor outputs only $n^{1/(\alpha d)}$ bits. For min-entropy $n - \text{polylog}(n)$ bits, our extractor outputs $n - \text{polylog}(n)$, whereas Shaltiel's extractor outputs only $\text{polylog}(n)$ bits.

Our methods also apply to formulas. Komargodski, Raz and Tal [17] constructed an explicit function $h : \{0, 1\}^n \rightarrow \{0, 1\}$ that is $2^{-\Omega(r)}$ -hard for any deMorgan formula of size $n^{3-o(1)}/r^2$. Based on this hardness result, we can construct an efficient extractor for sources recognizable by deMorgan formulas of size close to $n^{3/2}$.

► **Theorem 11.** *For any $\Delta, r, \alpha > 0$ and $m \leq (1 - \alpha)n$, there exists a polynomial time computable $(n - \Delta, m2^{\Delta - \Omega(r)})$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ for any sources recognizable by deMorgan formulas of size $n^{3/2 - o(1)}/r^2$.*

2.2.2 Sources recognizable by efficient randomized algorithms

Note that there are no efficient seed-extending cryptographic PRGs. Otherwise, with revealed seeds, it is easy to efficiently distinguish the output of an efficient seed-extending PRG, $G(x) = (x, E(x))$, from a random string (x, y) , by checking whether y equals $E(x)$.

We show that there is an inefficient seed-extending cryptographic PRG implied by the existence of one-way permutations. By our reduction, we show that a one-way permutation with exponentially small error yields an $(n - n^{\Omega(1)}, 2^{-n^{\Omega(1)}})$ extractor extracting $n - n^{O(1)}$ bits from sources recognizable by BPP algorithms. Formally, this follows by taking $\epsilon = 2^{-cn^\alpha}$ and $q(n) = n^{w(1)}$ in the following theorem.

► **Theorem 12.** *For any polynomial-time computable functions $t(\cdot)$ and $\epsilon(\cdot)$, assume that $f : \{0, 1\}^* \rightarrow \{0, 1\}^*$ is a one-way permutation with error $\epsilon(\cdot)$ against $t(\cdot)$ -bounded inverters. Then for any $\Delta = \Delta(n) > 0$ and a positive constant $\delta < 1$, we can construct an $(n - \Delta, O(2^{\Delta} \epsilon(n^\delta)^{c_\delta}))$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-n^\delta}$ for sources recognizable by randomized algorithms running in time $(t(n^\delta))^{c_\delta}$, where c_δ is a constant depending on δ . The running time of the extractor is a polynomial times the time to compute the inverse function f^{-1} of the one-way permutation f with input length n^δ . Due to the space limitation, we prove the following theorem in the full version of this paper.*

Furthermore, the running time of such an extractors will be quasi-polynomial if there exists a sufficiently strong one-way permutations. In particular, by scaling down, we have the following corollary.

► **Corollary 13.** *For any constants $a, b, c, \delta > 0$, assume that there exists a one-way permutation invertible in time $O(2^{n^a})$ with error 2^{-n^c} against $2^{\delta n^b}$ -bounded inverters. Then, for any positive constants α and $\beta < 1$, we can get an $(n - c_\beta \log^{c_\alpha}(n), O(2^{-c_\beta \log^{c_\alpha}(n)}))$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-n^\beta}$ for sources recognizable by randomized algorithms running in time $2^{c_\beta \delta \log^{b_\alpha}(n)}$, where c_β is a constant depending on β . The running time of the extractor is $O(2^{\log^{a_\alpha}(n^\beta)})$.*

3 Overview of our main constructions and proofs

3.1 From XOR amplification to Extractors

In this subsection, we describe how to construct a seedless extractor for \mathcal{C} -recognizable sources if there exists a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$ such that for any $g \in \mathcal{C}$ and $k \leq n/t$, $\text{Cor}(h^{\oplus k}, g) \leq 2^{-\Omega(k)}$. Think of $t = O(1)$.

We start with the statistical XOR lemma³, usually attributed to Vazirani. We say a random variable Z over $\{0, 1\}$ is ϵ -biased if $\text{bias}(Z) = \text{Cor}(Z, 0) = |\Pr[Z = 0] - \Pr[Z = 1]| \leq \epsilon$.

► **Lemma 14** (Statistical XOR Lemma). *Let X_1, \dots, X_m be 0-1 random variables such that for any nonempty $S \subseteq \{1, \dots, m\}$, the random variable $\bigoplus_{i \in S} X_i$ is ϵ -biased. Then, the distribution of (X_1, \dots, X_m) is $\epsilon 2^{m/2}$ -close to uniform.*

Let $g_i(x)$ be the i -th bit of $\text{Ext}(x)$ for each $i \in [m]$. Thus, to show that the output of Ext is close to uniform, it suffices to show that for any non-empty set $S \subseteq [m]$, $g_S = \sum_{i \in S} g_i$ is low-biased conditioned on $f(x) = 1$ for each $f \in \mathcal{C}$. By XOR amplification, it is enough to guarantee that each g_S is the sum of $\Omega(n)$ independent copies of h , and hence g_S has $2^{-\Omega(n)}$ correlation with any function in \mathcal{C} .

A linear code is a natural candidate to guarantee that each g_S is the sum of $\Omega(n)$ independent copies. Let $h^{(l)} : \{0, 1\}^{tl} \rightarrow \{0, 1\}$ denote the concatenation of l copies of h and M be the generating matrix of an asymptotically good $[l, m, r]_2$ code. Our construction is simply

$$\text{Ext}(x) = (g_1(x), \dots, g_m(x)) = h^{(l)}(x)M.$$

Finally, we observe that the bias of g_S conditioned on $f(x) = 1$ can be bounded by the correlation between g_S and f plus the bias of g_S .

³ The statistical XOR lemma is unrelated to the XOR amplification used in our proof.

► **Lemma 15.** $|\Pr[g_S(X) = 1|f(X) = 1] - \Pr[g_S(X) = 0|f(X) = 1]| \leq \frac{\text{Cor}(g_S, f) + \text{bias}(g_S)}{2\Pr[f(X)=1]}.$

That is, if we choose a good linear code, then $\text{Ext}(x) = h^{(l)}(x)M$ is an extractor for \mathcal{C} -recognizable sources with exponentially small error.

For details, see Section 5.

3.2 Algebraic extractors over GF(2)

In this subsection, we describe our algebraic extractor construction.

Notice that to construct a degree- d algebraic extractor that outputs only one bit, it is enough to let the extractor have small correlation bounds with degree- d polynomials. This fact is implicitly proved by Dvir [9] and observed by others, e.g., Eshan Chattopadhyay and Avishay Tal (personal communication). Based on this fact, we combine XOR amplification and linear codes to extend the output length from one bit to more.

First we observe that an algebraic source over n bits defined by n -variate polynomials p_1, \dots, p_k is also a source recognizable by the product $\prod_{i \in [k]} (p_i + 1)$. Let \mathcal{V}_d denote the set of all products of polynomials of degree at most d . Thus, for any positive integer n , to get an extractor for n -bit algebraic sources of degree d , it suffices to construct an extractor for \mathcal{V}_d -recognizable sources over n bits. In particular, by the previous discussion, it suffices to show that XOR amplification holds for \mathcal{V}_d .

Second we observe that to show that a function f has low correlations with \mathcal{V}_d , it suffices to show that f has low correlation with any d -degree polynomials. This is because the L1 norm of the Fourier transform of the AND function is at most 2.

Viola and Wigderson [30] proved XOR amplification for low-degree polynomials over GF(2). Specifically, if a Boolean function h over $\{0, 1\}^{O(d)}$ has correlation at most $1 - 1/2^d$ with degree- d polynomials, then the correlation between $h^{\oplus l}$ (see Section 1.2) and degree- d polynomials drops exponentially with l . Such h are known.

For details, see Section A.1.

3.3 From seed-extending PRGs to Extractors

We start with a new reduction from pseudorandom generators to seedless extractors. Observe that a seedless extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ partitions $\{0, 1\}^n$ as $\bigcup_{z \in \{0, 1\}^m} \text{Ext}^{-1}(z)$. If Ext is a (k, ϵ) -extractor for \mathcal{C} -recognizable sources, then for every $f \in \mathcal{C}$ with $|f^{-1}(1)| \geq 2^k$, most intersections $\text{Ext}^{-1}(z) \cap f^{-1}(1)$ should have almost the same size. That is, for most m -bit strings z , the preimage $\text{Ext}^{-1}(z)$ is an ϵ -pseudorandom set against any $f \in \mathcal{C}$ with $|f^{-1}(1)| \geq 2^k$.

Now, given PRGs, how do we construct extractors? From the above observation, converting an ϵ -pseudorandom set into a partition of ϵ -pseudorandom sets is a possible way. If each preimage $\text{Ext}^{-1}(z)$ of Ext is an ϵ -pseudorandom set for \mathcal{C} , Ext should be an extractor for \mathcal{C} -recognizable sources with a bit worse parameters.

To make $\text{Ext}^{-1}(z)$ an ϵ -pseudorandom set for each z , we need a seed-extending PRG $G(x)$, i.e., $G(x) = x \circ E(x)$ for some function $E : \{0, 1\}^d \rightarrow \{0, 1\}^{n-d}$. By linearly shifting the set $\{(x, E(x))\}$, we can partition $\{0, 1\}^n$ as $\bigcup_{z \in \{0, 1\}^{n-d}} \{(x, (E(x) \oplus z)) : x \in \{0, 1\}^d\}$. We therefore define $\text{Ext}(x, z) = E(x) \oplus z$. Since \mathcal{C} is a flip-invariant function family, we have that the set $\text{Ext}^{-1}(z) = \{(x, (E(x) \oplus z)) : x \in \{0, 1\}^d\}$ fools any function f in \mathcal{C} .

For details, see Section 6.

3.4 Algebraic extractors over prime fields

We remark that the main results used in building our algebraic extractor over $\text{GF}(2)$ – the XOR amplification, the statistical XOR lemma and the asymptotically linear code – all have been extended to prime fields. Thus, to generalize our algebraic extractor, the remaining technical parts are not hard.

Bogdanov, Kawachi and Tanaka [4] proved XOR amplification for low-degree polynomials over prime fields, i.e., the sum of k independent copies of h was $q^{-\Omega(k)}$ -hard for P_d if h was mildly hard. However, besides the sum of copies, we require the same hardness result for linear combinations of k copies of h . We prove this hardness result by using the original proof of Bogdanov, Kawachi and Tanaka with some slight modifications. The main revision of our proof uses the fact that the Gowers norm is multiplicative for functions over disjoint sets of input variables.

Furthermore, over a prime field \mathbb{F}_q , an algebraic source over n bits defined by n -variate polynomials p_1, \dots, p_k is a source recognizable by the product $\prod_{i \in [k]} (1 - p_i^{q-1})$. We need to analyze the product of the special form $\prod_{i \in [k]} (1 - x_i^{q-1})$, as an analog of the AND function over $\text{GF}(2)$.

The reason we assume prime fields in our results is that XOR amplification for polynomials is known only over prime fields.

For details, please check the full version of this paper.

4 Preliminaries

In the following, for any two binary strings x, y , let $x \circ y$ denote their concatenation, and let $x \oplus y$ denote their bitwise XOR when x and y have the same length.

► **Definition 16** (Statistical distance). *Let D_1 and D_2 be two distributions over a set S . Define the statistical distance between D_1 and D_2 as $|D_1 - D_2| = \frac{1}{2} \sum_{s \in S} |\Pr[D_1 = s] - \Pr[D_2 = s]|$. We say D_1 is ϵ -close to D_2 , denoted by $D_1 \approx_\epsilon D_2$, if $|D_1 - D_2| \leq \epsilon$.*

► **Definition 17** (Recognizable source). *For any boolean function $f : \{0, 1\}^n \rightarrow \{0, 1\}$, define the source recognizable by f , denoted by U_f , as the uniform distribution over $f^{-1}(1)$. For short, we call this distribution the f -recognizable source.*

For any boolean function family \mathcal{C} , the set of \mathcal{C} -recognizable sources is the set of f -recognizable sources for $f \in \mathcal{C}$.

For $l \in \mathbb{N}$, let U_l denote the uniform distribution on l bits.

► **Definition 18** (Extractor for recognizable sources [25]). *Let \mathcal{C} be a class of functions $C : \{0, 1\}^n \rightarrow \{0, 1\}$. We say that $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ is a (k, ϵ) -extractor for \mathcal{C} -recognizable sources if for every $f \in \mathcal{C}$ such that $|f^{-1}(1)| \geq 2^k$, $\text{Ext}(U_f) \approx_\epsilon U_m$.*

Note that when the output length $m = 1$, the extractor is simply a boolean function which has low correlation with any function in \mathcal{C} .

4.1 Algebraic sources

An algebraic set is a set of common zeros of one or more multivariate polynomials defined over a finite field \mathbb{F} .

► **Definition 19** (Algebraic set). *For any s polynomials $f_1, \dots, f_s \in \mathbb{F}[x_1, \dots, x_n]$, the set $V(f_1, \dots, f_s) = \{x \in \mathbb{F}^n \mid f_i(x) = 0, \forall i \in [s]\}$ is an algebraic set. We say V is an algebraic set of degree d , if each polynomial f_i has degree at most d .*

An *algebraic source* is a random variable distributed uniformly over an algebraic set as initially defined by Dvir [9].

► **Definition 20** (Algebraic source). *An algebraic source is the uniform distribution U_V over an algebraic set V . If V is a degree- d algebraic set, then we say U_V is an algebraic source of degree d .*

► **Definition 21** (Algebraic extractor). *We say that $\text{Ext} : \mathbb{F}^n \rightarrow \mathbb{F}^m$ is a (k, d, ϵ) -algebraic extractor if for any degree- d algebraic source U_V with $|V| \geq |\mathbb{F}|^k$, $\text{Ext}(U_V) \approx_\epsilon U_m$.*

► **Definition 22** (Linear codes over prime fields). *For a prime q , a linear code of length n and dimension k is a k -dimensional linear subspace C of the vector space \mathbb{F}_q^n . If the distance of the code C is d , i.e., the minimum number of two codewords in which they differ, we say that C is an $[n, k, d]_q$ code. A family of codes $\{C_n\}$ is asymptotically good if there exist constants $0 < \delta_1, \delta_2 < 1$ s.t. $k \geq \delta_1 n$ and $d \geq \delta_2 n$.*

Note that every linear code has an associated generating matrix $M \in \mathbb{F}_q^{k \times n}$, and every codeword can be expressed as vM , for some vector $v \in \mathbb{F}_q^k$. There are explicit constructions of asymptotically good linear codes, such as the Justesen codes over $\text{GF}(2)$ constructed in [14] and the expander codes over $\text{GF}(q)$ in [1] for any prime q .

► **Definition 23** (Correlation over prime fields). *Let $f, g : \mathbb{F}_q^n \rightarrow \mathbb{F}_q$ be two functions over n inputs. The correlation between f and g with respect to the uniform distribution is defined as*

$$\text{Cor}(f, g) := |\mathbb{E} e_q[f(x) + g(x)]| \in [0, 1],$$

where $e_q[x] := w^x$ for $x \in \{0, 1, \dots, q-1\}$, where w denotes the q -th root of unity.

For a class \mathcal{C} of functions, we denote by $\text{Cor}(f, \mathcal{C})$ the maximum of $\text{Cor}(f, C)$ over all $C \in \mathcal{C}$ whose domain is the same as f .

Furthermore, when $q = 2$, we have $e_2[x] = (-1)^x$, and $\text{Cor}(f, g) = |\Pr[f(x) = g(x)] - \Pr[f(x) \neq g(x)]|$. We often write $e_2[x]$ as $e[x]$ for convenience.

► **Definition 24** ($f^{(m)}, f^v$). *For any function $f : \mathbb{F}_q^n \rightarrow \mathbb{F}_q$, let $f^{(m)}$ denote the concatenation of m copies of f , i.e., $f^{(m)}(x_1, x_2, \dots, x_m) := (f(x_1), \dots, f(x_m))$, where $x_1, \dots, x_m \in \mathbb{F}_q^n$. For each $v = (v_1, \dots, v_m) \in \mathbb{F}_q^m$, let f^v denote the linear combination of m copies of f according to v , i.e., $f^v(x_1, x_2, \dots, x_m) := \sum_{i \in [m]} v_i f(x_i)$.*

Let $\mathbb{F}_q^* = \mathbb{F}_q \setminus \{0\}$ denotes the set of non-zero elements in \mathbb{F}_q . We remark that the statistical XOR lemma has been generalized to prime fields by e.g., Goldreich [11].

► **Lemma 25** (Statistical XOR Lemma over \mathbb{F}_q). *Let $X = (X_1, \dots, X_m)$ be random vector over \mathbb{F}_q^m such that for any nonzero vector $v = (v_1, \dots, v_m) \in \mathbb{F}_q^m \setminus \{0^m\}$, the random variable $v \cdot X = \sum_{i \in [m]} v_i X_i$ is ϵ -biased. Then, the distribution of (X_1, \dots, X_m) is $\epsilon q^{m/2}$ -close to the uniform distribution over \mathbb{F}_q^m .*

For example, when $m = 1$, for a random variable X over \mathbb{F}_q , to show that $X \approx_\epsilon U_{\mathbb{F}_q}$, we need to show that $\text{bias}(\alpha X) \leq \epsilon/\sqrt{q}$ for each $\alpha \in \mathbb{F}_q^*$.

4.2 Seed-extending PRGs

► **Definition 26** (Flip-invariant family). *We say a boolean function family \mathcal{C} over n bits is flip-invariant if for any string $s \in \{0, 1\}^n$, $f \in \mathcal{C}$ implies $f(x \oplus s) \in \mathcal{C}$.*

72:12 Improved Extractors for Recognizable and Algebraic Sources

► **Definition 27** (Seed-extending pseudorandom generator). *A seed-extending pseudorandom generator is a generator G that outputs the seed as part of the pseudorandom string.*

Formally, a seed-extending (d, ϵ) -pseudorandom generator $G : \{0, 1\}^d \rightarrow \{0, 1\}^n$ for a class of functions over n bits, is a seed-extending function, i.e., $G(s) = (s, E(s))$ for some function E , such that

$$|\Pr[f(G(U_d)) = 1] - \Pr[f(U_n) = 1]| \leq \epsilon.$$

5 From XOR Amplification to Extractors for Recognizable Sources

First we define XOR amplification for a boolean function class that contains functions with various input lengths. Recall that $f^{\oplus m}(x_1, \dots, x_m) = \bigoplus_{i \in [m]} f(x_i)$.

► **Definition 28** (α -XOR amplification for a boolean function class). *Let $\mathcal{C} \subseteq \{\{0, 1\}^* \rightarrow \{0, 1\}\}$ be a class of boolean functions. For a positive constant α , we say \mathcal{C} has α -XOR amplification if there exists a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$ such that for any positive integer k , $\text{Cor}(h^{\oplus k}, g) \leq 2^{-\alpha k}$, for any $g \in \mathcal{C}$.*

However, for constructing extractors for n -bit recognizable sources, we need to focus on the specific subset $\mathcal{C}_n \subseteq \mathcal{C}$ that contains all n -variate functions in \mathcal{C} . We define XOR amplification for \mathcal{C}_n to also allow fixing some input bits.

► **Definition 29** ((α, w) -XOR amplification for functions with a fixed input length). *For a set \mathcal{C}_n of n -variate functions $C : \{0, 1\}^n \rightarrow \{0, 1\}$ and a positive constant α , we say \mathcal{C}_n has (α, w) -XOR amplification for a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$ if for any vector $v \in \{0, 1\}^{\lfloor n/t \rfloor}$ with at least w ones, $\text{Cor}(h^v, \mathcal{C}_n) \leq 2^{-\alpha w}$, where we add dummy variables to the input of h^v if h^v has less than n input variables.*

Moreover, we say \mathcal{C}_n has α -XOR amplification for h , if \mathcal{C}_n has (α, w) -XOR amplification for h for each positive integer $w \leq \lfloor n/t \rfloor$.

Note that if \mathcal{C} is closed under restrictions, the fact that \mathcal{C} has α -XOR amplification implies that \mathcal{C}_n has also α -XOR amplification for every positive integer n . Formally,

► **Lemma 30.** *Let $\mathcal{C} \subseteq \{\{0, 1\}^* \rightarrow \{0, 1\}\}$ be a class of boolean functions closed under restrictions. Let $\mathcal{C}_n \subseteq \mathcal{C}$ denote the set of all n -variate functions in \mathcal{C} . If \mathcal{C} has α -XOR amplification for a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$, then \mathcal{C}_n has also α -XOR amplification for h for every positive integer n .*

Proof. Assume that \mathcal{C} has α -XOR amplification for a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$, i.e., $\text{Cor}(h^{\oplus k}, \mathcal{C}) \leq 2^{-\alpha k}$ for each positive integer k . Then, we need to prove that for every positive integer n , \mathcal{C}_n has also α -XOR amplification for h . In particular, fix n and let $l = \lfloor n/t \rfloor$. It suffices to prove that for any vector $v \in \{0, 1\}^l$ with k ones, $\text{Cor}(h^v, \mathcal{C}_n) \leq \text{Cor}(h^{\oplus k}, \mathcal{C})$, as $\text{Cor}(h^{\oplus k}, \mathcal{C}) \leq 2^{-\alpha k}$.

To prove this, without loss of generality, assume that the first k coordinates of v are all 1's, and the remaining coordinates are all 0's. Thus, h^v depends only on the first kt variables. For any n -variate function $C(x_1, \dots, x_n) \in \mathcal{C}_n$,

$$\begin{aligned} \text{Cor}(h^v, C) &= E_{X \sim U_{kt}, Y \sim U_{n-kt}} e[h^v(X, Y) + C(X, Y)] \\ &= E_{Y \sim U_{n-kt}} [E_{X \sim U_{kt}} e[h^v(X, Y) + C(X, Y)]] \\ &\leq \frac{1}{2^{n-kt}} \sum_{Y_0 \in \{0,1\}^{n-kt}} \text{Cor}(h^{\oplus k}(X), C(X, Y_0)) \\ &\leq \frac{1}{2^{n-kt}} \sum_{Y_0 \in \{0,1\}^{n-kt}} \text{Cor}(h^{\oplus k}, C) \\ &= \text{Cor}(h^{\oplus k}, C). \end{aligned}$$

The last inequality follows since \mathcal{C} is closed under restrictions, i.e., $C(X, Y_0) \in \mathcal{C}$ for any $Y_0 \in \{0, 1\}^{n-kt}$. \blacktriangleleft

► **Theorem 31.** *Let \mathcal{C}_n be a family of boolean functions over n bits containing the constant function $f(x) = 0$. For any positive integers n, m, t , let M be the $l \times m$ generating matrix of an asymptotically good $[l, m, r_0]_2$ code, where $l = n/t$. Assume that \mathcal{C}_n has (α, r) -XOR amplification for $h : \{0, 1\}^t \rightarrow \{0, 1\}$, where $r \leq r_0$. Then, the function $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$,*

$$\text{Ext}(x) = h^{(l)}(x)M,$$

is an $(n - \Delta, 2^{m/2 + \Delta - \alpha r})$ extractor for \mathcal{C}_n -recognizable sources.

Proof. For convenience, let $(g_1(x), \dots, g_m(x)) = h^{(l)}(x)M$. To show that the output of Ext is $2^{m/2 + \Delta - \alpha r}$ -closed to the uniform, by the statistical XOR Lemma, it suffices to show that for any non-empty set $S \subseteq [m]$, $g_S = \sum_{i \in S} g_i$ is $2^{\Delta - \alpha r}$ -biased conditioned on $f(x) = 1$ for any $f \in \mathcal{C}_n$ with $|f^{-1}(1)| \geq 2^{n-\Delta}$.

First we observe that the bias of g_S conditioned on $f(x) = 1$ can be bounded by the correlation between g_S and f plus the bias of g_S .

► **Lemma 32** (Lemma 15, restated).

$$|\Pr[g_S(X) = 1 | f(X) = 1] - \Pr[g_S(X) = 0 | f(X) = 1]| \leq \frac{\text{Cor}(g_S, f) + \text{bias}(g_S)}{2 \Pr[f(X) = 1]}.$$

Proof. By multiplying $2 \Pr[f(X) = 1]$ on both sides, it is equivalent to prove that

$$2 |\Pr[g_S(X) = 1 \wedge f(X) = 1] - \Pr[g_S(X) = 0 \wedge f(X) = 1]| \leq \text{Cor}(g_S, f) + \text{bias}(g_S).$$

Notice that

$$\begin{aligned} \text{Cor}(g_S, f) &= |\Pr[g_S(X) = f(X)] - \Pr[g_S(X) \neq f(X)]| \\ &= |\Pr[g_S(X) = 1 \wedge f(X) = 1] + \Pr[g_S(X) = 0 \wedge f(X) = 0] \\ &\quad - \Pr[g_S(X) = 0 \wedge f(X) = 1] - \Pr[g_S(X) = 1 \wedge f(X) = 0]|, \end{aligned}$$

and

$$\begin{aligned} \text{bias}(g_S) &= |\Pr[g_S(X) = 1] - \Pr[g_S(X) = 0]| \\ &= |\Pr[g_S(X) = 1 \wedge f(X) = 1] + \Pr[g_S(X) = 1 \wedge f(X) = 0] \\ &\quad - \Pr[g_S(X) = 0 \wedge f(X) = 1] - \Pr[g_S(X) = 0 \wedge f(X) = 0]|. \end{aligned}$$

72:14 Improved Extractors for Recognizable and Algebraic Sources

Thus, by the triangle inequality,

$$\begin{aligned} \text{bias}(g_S) + \text{Cor}(g_S, f) &\geq |2 \Pr[g_S(X) = 1 \wedge f(X) = 1] - 2 \Pr[g_S(X) = 0 \wedge f(X) = 1]| \\ &= 2 |\Pr[g_S(X) = 1 \wedge f(X) = 1] - \Pr[g_S(X) = 0 \wedge f(X) = 1]|. \quad \blacktriangleleft \end{aligned}$$

Then, observe that not only is each g_i a sum of at least r independent copies, but also so is any non-empty sum of the g_i , and hence has exponentially small correlation with degree- d polynomials.

► **Lemma 33.** *For any nonempty set $S \subseteq [m]$, $\text{Cor}(g_S, \mathcal{C}_n) \leq 2^{-\alpha r}$.*

Proof. Note that

$$g_S(x) = \sum_{i \in S} h^{(l)}(x) M_i = h^{(l)}(x) \left(\sum_{i \in S} M_i \right),$$

where M_i denotes the i -th row of the matrix M . As M is the generating matrix of an $[l, m, r]_2$ code and S is non-empty, $\sum_{i \in S} M_i$ is a codeword and hence has at least r 1's. Thus, g_S is the XOR of at least r_0 independent copies of h . By the assumed (α, r) -XOR amplification, we know $\text{Cor}(g_S, \mathcal{C}_n) \leq 2^{-\alpha r}$. ◀

Since the constant function $0 \in \mathcal{C}_n$, we also have that $\text{bias}(g_S) = \text{Cor}(g_S, 0) \leq 2^{-\alpha r}$. Thus, by Lemma 32, the bias of g_S conditioned on $f(x) = 1$ is at most $2^{-\alpha r}/p$, where $p = \Pr[f(X) = 1]$.

At last, we have $p = \frac{|f^{-1}(1)|}{2^n} \geq 2^{-\Delta}$ by the min-entropy requirement that $|f^{-1}(1)| \geq 2^{n-\Delta}$. Therefore, $g_S(x)$ is $2^{\Delta-\alpha r}$ -biased conditioned on $f(x) = 1$. ◀

Combining with an explicit asymptotically good $[l, m, r]_2$ code, we prove the following theorem.

► **Theorem 34.** *Let $\mathcal{C} \subseteq \{\{0, 1\}^* \rightarrow \{0, 1\}\}$ be any boolean function class closed under restrictions and α be any positive constant. Let \mathcal{C}_n denote the set of all n -variate functions in \mathcal{C} . If \mathcal{C}_n has $(\alpha, \delta n)$ -XOR amplification for $h : \{0, 1\}^t \rightarrow \{0, 1\}$, where $\delta < 1/t$ is a positive constant, then there is an explicit $(n - c_1 \alpha l, 2^{-c_2 \alpha l})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{c_3 \alpha l}$ for \mathcal{C}_n -recognizable sources, where $l = n/t$ and c_1, c_2, c_3 are some positive constants.*

Moreover, if \mathcal{C} has α -XOR amplification for a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$, then for any positive integer n , there is an explicit seedless $(n - c_1 \alpha l, 2^{-c_2 \alpha l})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{c_3 \alpha l}$ for \mathcal{C}_n -recognizable sources, where $l = n/t$ and c_1, c_2, c_3 are some positive constants.

Proof. Note that if \mathcal{C} has α -XOR amplification for a function h , then by Lemma 30, \mathcal{C}_n also has α -XOR amplification for h for every positive integer n , i.e., \mathcal{C}_n also has $(\alpha, \delta l)$ -XOR amplification for h by definition. Now, we start with the assumption that \mathcal{C}_n has $(\alpha, \delta l)$ -XOR amplification for h . We use an explicit $[l, \delta_1 l, \delta_2 l]_2$ linear code for some constants $\delta_1 > 0$ and $\delta_2 > \delta$ by Justesen [14]. Therefore, Theorem 31 yields an $(n - \Delta, 2^{m/2 + \Delta - \alpha \delta_2 l})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ for \mathcal{C}_n -recognizable sources. That is, by setting $\Delta = c_1 \alpha l$ and $m = c_3 \alpha l$ for some small positive constants c_1, c_3 , we get the desired $(n - c_1 \alpha l, 2^{-c_2 \alpha l})$ extractor, where $c_2 = -(c_3/2 + c_1 - \delta_2) > 0$ is also a positive constant. ◀

6 From Seed-Extending PRGs to Extractors for Recognizable Sources

Note that Kinne et al. [16] already showed reductions between extractors for recognizable sources and seed-extending PRGs.

► **Lemma 35** ([16, Theorem 7]). *Let $C : \{0, 1\}^n \times \{0, 1\}^m \rightarrow \{0, 1\}$ be a function. Let $\Delta = m + \log(1/\epsilon)$ and let $E : \{0, 1\}^n \rightarrow \{0, 1\}^m$ be an $(n - \Delta, 2^{-\Delta})$ -extractor for \mathcal{C} -recognizable distributions, where each function in \mathcal{C} is of the form $f_r(x) = C(x, r)$ where $r \in \{0, 1\}^m$ is an arbitrary string. Then, $G(x) = (x, E(x))$ is ϵ -pseudorandom for \mathcal{C} .*

► **Lemma 36** ([16, Theorem 8]). *Let $f : \{0, 1\}^n \rightarrow \{0, 1\}$ be a function and let $E : \{0, 1\}^n \rightarrow \{0, 1\}^m$ be a function such that $G(x) = (x, E(x))$ is ϵ -pseudorandom for tests $T(x, r)$ of the form $T_z(x, r) = f(x) \wedge (r = z)$ where $z \in \{0, 1\}^m$ is an arbitrary string. For any $\Delta > 0$, if $\epsilon \leq 2^{-(m+2\Delta)}$ then E is an $(n - \Delta, 2^{-\Delta})$ -extractor for the distribution recognized by f .*

The Lemma 3.2 requires a tiny $\epsilon \leq 2^{-(m+2\Delta)}$ for the seed-extending PRG to get an $(n - \Delta, 2^{-\Delta})$ -extractor. In the following, we improve the reduction from seed-extending PRGs to extractors to require only $\epsilon \leq 2^{-2\Delta}$. Moreover, our extractor is even stronger – the output of our extractor is close to uniform with relative error, which will be defined as follows.

► **Definition 37** (Statistical distance with relative error). *We say that a distribution Z on $\{0, 1\}^m$ is ϵ -close to uniform with relative error if for every event $A \subseteq \{0, 1\}^m$,*

$$|\Pr[Z \in A] - \mu(A)| \leq \epsilon \cdot \mu(A), \text{ where } \mu(A) = |A|/2^m.$$

Note that if Z is ϵ -close to uniform with relative error, then it is also ϵ -close to uniform. Next we define extractors with relative error analogously.

► **Definition 38** (Seedless extractor with relative error, [2, Definition 1.19]). *Let \mathcal{C} be a class of distributions over $\{0, 1\}^n$. A function $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ is a (k, ϵ) -relative-error extractor for \mathcal{C} if for every distribution X in the class \mathcal{C} such that $H_\infty(X) \geq k$, $\text{Ext}(X)$ is ϵ -close to uniform with relative error.*

We remark that the notions of statistical distance and extractors with relative error were introduced by Applebaum, Artemenko, Shaltiel, and Yang [2]. They translate relative-error extractors for distributions recognizable by small circuits into incompressible functions. However, parameters of our relative-error extractors are not strong enough to get incompressible functions.

Now we prove the reduction lemma from seed-extending PRGs to seedless extractors with relative error, which directly implies the reduction from seed-extending PRGs to seedless extractors.

► **Lemma 39.** *Let \mathcal{C} be a flip-invariant family of boolean functions over n bits. If G is a seed-extending (d, ϵ) -pseudorandom generator $G : \{0, 1\}^d \rightarrow \{0, 1\}^n$, then we can construct an $(n - \Delta, 2^\Delta \epsilon)$ -relative-error extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-d}$ as follows. If $G(x) = (x, E(x))$ fools any function in \mathcal{C} , then $\text{Ext}(x \circ y) = y \oplus E(x)$ is an extractor for \mathcal{C} -recognizable sources, where $x \in \{0, 1\}^d, y \in \{0, 1\}^{n-d}$.*

For intuition, observe that a seedless extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$ partitions $\{0, 1\}^n$ as $\bigcup_{z \in \{0, 1\}^m} \text{Ext}^{-1}(z)$. If Ext is a (k, ϵ) -relative-error extractor for \mathcal{C} -recognizable sources, then for every $f \in \mathcal{C}$ with $|f^{-1}(1)| \geq 2^k$, all intersections $\text{Ext}^{-1}(z) \cap f^{-1}(1)$ should have almost the same size. That is, for most m -bit strings z , the preimage $\text{Ext}^{-1}(z)$ is an ϵ -pseudorandom set against any $f \in \mathcal{C}$ with $|f^{-1}(1)| \geq 2^k$.

Now, given PRGs, how to construct extractors? From the above observation, converting an ϵ -pseudorandom set into a partition of ϵ -pseudorandom sets is a possible way. If each preimage $\text{Ext}^{-1}(z)$ of Ext is an ϵ -pseudorandom set for \mathcal{C} , Ext should be a relative-error extractor for \mathcal{C} -recognizable sources with a bit worse parameters, which will be precisely calculated in the following formal proof.

To make $\text{Ext}^{-1}(z)$ an ϵ -pseudorandom set for each z , we need a PRG of the specific form: $G(x) = B(x) \circ E(x)$, for some bijection $B : \{0, 1\}^d \rightarrow \{0, 1\}^d$ and some function $E : \{0, 1\}^d \rightarrow \{0, 1\}^{n-d}$. By linearly shifting the set $\{(B(x), E(x))\}$, we can partition $\{0, 1\}^n$ as $\bigcup_{z \in \{0, 1\}^{n-d}} \{(B(x), (E(x) \oplus z)) : x \in \{0, 1\}^d\}$. Since \mathcal{C} is a flip-invariant function family, we have that the set $\text{Ext}^{-1}(z) = \{(B(x), (E(x) \oplus z)) : x \in \{0, 1\}^d\}$ fools any function f in \mathcal{C} .

Note that to convert the PRG of the form $(B(x), E(x))$ into an extractor, the above intuition gives $\text{Ext}(x) = E(B^{-1}(x))$. Thus, to get an efficient extractor, we have to assume that $E(B^{-1}(x))$ can be efficiently computed. That is, the PRG of the form $(B(x), E(x))$ also gives an efficient seed-extending PRG $(x, E(B^{-1}(x)))$. Therefore, for constructing extractors from the above intuition, we only need to focus on the seed-extending PRGs.

Proof. For convenience, let $m = n - d$ denote the output length of Ext .

First, we observe that, for any fixed z , $G_z(x) = (x, (E(x) \oplus z))$ fools any function $f(x, y)$ in \mathcal{C} . Notice that to prove $G_z(x)$ fools $f(x, y)$, it is equivalent to prove $(x, E(x))$ fools $f(x, y \oplus z)$. Because of the flip-invariant property of \mathcal{C} , we know if $f(x, y) \in \mathcal{C}$, then $f(x, y \oplus z) \in \mathcal{C}$. So $G(x) = x \circ E(x)$ fools $f(x, y \oplus z)$. That is, $G_z(x)$ fools the function $f(x, y)$.

Note that $\text{Ext}^{-1}(z)$ is the range of G_z . Then, we can get

$$\begin{aligned}
& \Pr[\text{Ext}(X \circ Y) = z | f(X \circ Y) = 1] \\
&= \frac{\Pr[\text{Ext}(X \circ Y) = z \wedge f(X \circ Y) = 1]}{\Pr[f(X \circ Y) = 1]} \\
&= \frac{\Pr[\text{Ext}(X \circ Y) = z]}{\Pr[f(X \circ Y) = 1]} \Pr[f(X \circ Y) = 1 | \text{Ext}(X \circ Y) = z] \\
&= \frac{\Pr[\text{Ext}(X \circ Y) = z]}{\Pr[f(X \circ Y) = 1]} \Pr[f(G_z(X)) = 1] \\
&= \frac{\Pr[\text{Ext}(X \circ Y) = z]}{\Pr[f(X \circ Y) = 1]} (\Pr[f(X \circ Y) = 1] \pm \epsilon) \\
&= \frac{p \pm \epsilon}{p} \Pr[\text{Ext}(X \circ Y) = z], \text{ where } p = \Pr[f(X \circ Y) = 1], \\
&= \frac{p \pm \epsilon}{p} \frac{1}{2^m}.
\end{aligned}$$

For any nonempty subset $S \subseteq \{0, 1\}^m$, summing over all $z \in S$, we deduce that the output of Ext is $\frac{\epsilon}{p} \mu(S)$ -close to the uniform distribution over S . Furthermore, we have $\frac{\epsilon}{p} \leq 2^\Delta \epsilon$, since $p = \frac{|f^{-1}(1)|}{2^n} \geq 2^{-\Delta}$ by the min-entropy requirement that $|f^{-1}(1)| \geq 2^{n-\Delta}$. Therefore, $\text{Ext}(x \circ y) = y \oplus E(x)$ is an $(n - \Delta, 2^\Delta \epsilon)$ -relative-error extractor for \mathcal{C} -recognizable sources. \blacktriangleleft

A Application of Theorem 2

A.1 Algebraic extractors over GF(2)

In this subsection, we will show that for any algebraic sources of constant degree over GF(2), there exists an efficient extractor that has linear output for linear min-entropy and exponentially small error. Formally, we will prove the following theorem:

► **Theorem 40.** *For any positive integer d , there is an efficient $((1 - 1/c_d)n, d, 2^{-\Omega(n/c_d)})$ -algebraic extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$, where $c_d = \Theta(d^2 4^d)$, $m = \Omega(n/c_d)$.*

Let P_d denote the set of all polynomials of degree at most d over GF(2). Let \mathcal{V}_d denote the set of all products of polynomials in P_d and $\mathcal{V}_{d,n}$ denote the set of all products of n -variate polynomials in P_d .

Notice that an algebraic source of degree d over n bits is also a $\mathcal{V}_{d,n}$ -recognizable source.

► **Lemma 41.** *An n -bit algebraic source of degree d iff it is a $\mathcal{V}_{d,n}$ -recognizable source.*

Proof. Let U_V denote an arbitrary algebraic source, where $V = \{x \in \{0, 1\}^n \mid p_i(x) = 0, p_i \in P_d, \forall i \in [k]\}$ is an algebraic set of degree d over n bits. Notice that V can be viewed as the set of 1-inputs of function $\prod_{i \in [k]} (p_i(x) + 1)$. That is, the uniform distribution over V is also the source recognizable by $\prod_{i \in [k]} (p_i(x) + 1) \in \mathcal{V}_{d,n}$. In other words, an algebraic source of degree d is a $\mathcal{V}_{d,n}$ -recognizable source.

For the other direction, let U_f denote an arbitrary $\mathcal{V}_{d,n}$ -recognizable source, where $f = \prod_{i \in [k]} p_i \in \mathcal{V}_{d,n}$ with $\deg(p_i) \leq d$ for each $i \in [k]$. Note that $f^{-1}(1) = \{x \in \{0, 1\}^n \mid p_i(x) = 1, \forall i \in [k]\} = \{x \in \{0, 1\}^n \mid p_i(x) + 1 = 0, \forall i \in [k]\}$. Hence, $f^{-1}(1)$ is the algebraic set of $p_1(x) + 1, \dots, p_k(x) + 1$. Since $\deg(p_i(x) + 1) = \deg(p_i) \leq d$ for each $i \in [k]$, $f^{-1}(1)$ is an algebraic set of degree d over n bits. Therefore, U_f is an n -bit algebraic source of degree d . ◀

Then, observe that \mathcal{V}_d is closed under restrictions. Thus, by Theorem 31, to get an extractor for $\mathcal{V}_{d,n}$ -recognizable sources, it is enough to show that \mathcal{V}_d has α -XOR amplification for some positive constant α .

Note that to show that a function f has low correlations with \mathcal{V}_d , it suffices to show that f has low correlation with any polynomial of degree at most d . Recall that the correlation between a function f and a class \mathcal{C} of functions is defined as the maximum of $Cor(f, C)$ over all $C \in \mathcal{C}$ whose input length is the same as f . In particular, to show that a function $f : \{0, 1\}^t \rightarrow \{0, 1\}$ has low correlations with \mathcal{V}_d , it suffices to show that f has low correlation with any t -variate polynomial of degree at most d .

► **Lemma 42.** *If a function $f : \{0, 1\}^t \rightarrow \{0, 1\}$ is ϵ -correlated with any polynomial of degree at most d in t variables, then f is at most 2ϵ -correlated with any product of polynomials of degree at most d in t variables.*

The lemma follows because the L1 norm of the Fourier transform of the AND function is at most 2.

Proof. We need to show that if for any t -variate $p \in P_d$ $Cor(f, p) = |Ee[f + p]| \leq \epsilon$, then for any product $\prod_{i \in [k]} (p_i + 1) \in \mathcal{V}_{d,t}$ where $p_1 + 1, \dots, p_k + 1 \in P_{d,t}$, we have

$$Cor\left(f, \prod_{i \in [k]} (p_i(X) + 1)\right) = \left| Ee\left[f + \prod_{i \in [k]} (p_i(X) + 1)\right] \right| \leq 2\epsilon.$$

Consider the Fourier expansion of the function

$$e\left[\prod_{i \in [k]} (y_i + 1)\right] = -\sum_{S \neq \emptyset} \frac{e\left[\sum_{i \in S} y_i\right]}{2^{k-1}} + (1 - 1/2^{k-1}).$$

Now, substituting each y_i by p_i , we have $e\left[\prod_{i \in [k]} (p_i + 1)\right] = -\sum_{S \neq \emptyset} \frac{e\left[\sum_{i \in S} p_i\right]}{2^{k-1}} + (1 - 1/2^{k-1})$.

That is,

$$\left| Ee\left[f + \prod_{i \in [k]} (p_i(X) + 1)\right] \right| \leq \sum_{S \neq \emptyset} \frac{|Ee[f + \sum_{i \in S} p_i(X)]|}{2^{k-1}}.$$

Notice that for each $S \neq \emptyset$, the sum $\sum_{j \in S} p_j$ is also a polynomial of degree at most d . For the polynomial of degree at most d , $\sum_{j \in S} p_j$, we have that $|Ee[f + \sum_{j \in S} p_j(X)]| \leq \epsilon$. In other words, $|Ee[f + \prod_{i \in [k]} (p_i(X) + 1)]| \leq 2^k \frac{2\epsilon}{2^{k-1}} = 4\epsilon$. ◀

Moreover, Viola and Wigderson [30] proved XOR amplification for GF(2) polynomials, which implies XOR amplification for \mathcal{V}_d by Lemma 42.

► **Theorem 43** ([30, Theorem 1.1]). *Let $h : \{0, 1\}^n \rightarrow \{0, 1\}$ be a function such that $Cor(h, P_{d,n}) \leq 1 - 1/2^d$. Then $Cor(h^{\oplus m}, P_d) \leq 2^{-\Omega(m/(4^d \cdot d))}$.*

Finally, by brute force search, it is easy to find a function h over $O(d)$ bits such that $Cor(h, P_d) \leq 1 - 1/2^d$ as d is a constant. That is, P_d has $\Omega(\frac{1}{4^d \cdot d})$ -XOR amplification for the function $h : \{0, 1\}^{O(d)} \rightarrow \{0, 1\}$. This implies that \mathcal{V}_d has $\Omega(\frac{1}{4^d \cdot d})$ -XOR amplification for the function $h : \{0, 1\}^{O(d)} \rightarrow \{0, 1\}$ by Lemma 42. Therefore, Theorem 34 yields our main theorem of this subsection, i.e., constructing an efficient $((1 - 1/c_d)n, d, 2^{-\Omega(n/c_d)})$ -algebraic extractor $Ext : \{0, 1\}^n \rightarrow \{0, 1\}^m$, where $c_d = \Theta(d^2 4^d)$, $m = \Omega(n/c_d)$.

We remark that an explicit example of h is the mod_3 function, which outputs 1 if and only if the number of input bits that are ‘1’ is congruent to 1 modulo 3. Smolensky [26] proved that the mod_3 function over $O(d^2)$ bits is $2/3$ -hard for P_d (see Viola [28] for a proof), that is, P_d has $\Omega(\frac{1}{4^d d})$ -XOR amplification for the function $\text{mod}_3 : \{0, 1\}^{O(d^2)} \rightarrow \{0, 1\}$. Using the mod_3 function, Theorem 34 yields an efficient $\left((1 - 1/c'_d)n, d, 2^{-\Omega(n/c'_d)}\right)$ -algebraic extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$, where $c'_d = \Theta(d^3 4^d)$, $m = \Omega(n/c'_d)$.

A.2 Sources recognizable by communication protocols

In this subsection, we construct an extractor for sources recognizable by randomized t -party protocols. Formally, we prove the following theorem.

► **Theorem 44.** *There exists an explicit seedless $((1 - 1/c_t)n, 2^{-c_1 n/c_t})$ extractor $\text{Ext} : (\{0, 1\}^{n/t})^t \rightarrow \{0, 1\}^{c_2 n/c_t}$ for sources recognizable by randomized t -party communication protocols of at most $c_3 n/c_t$ bits, where $c_t = \Theta(t 4^t)$ and c_1, c_2, c_3 are some positive constants.*

Let $\mathcal{RCC}_{n,t,w}$ denote the class of n -variate randomized t -party protocols using at most w communication bits. Now, to construct extractors for $\mathcal{RCC}_{n,t,w}$ -recognizable sources with exponentially small error, by Theorem 31, it suffices to show $\mathcal{RCC}_{n,t,w}$ has (α, r) -XOR amplification for some function h , where $r = \Omega(n)$ is the distance of some good linear code.

Notice that, Babai, Nisan, and Szegedy [3] proved a lower bound for randomized t -party protocols for the Generalized Inner Product (GIP) function, which is the XOR of AND functions. Formally, let $\wedge_t : \{0, 1\}^t \rightarrow \{0, 1\}$ denote the AND function on t variables. Then, the GIP function $\text{GIP}_{kt} : (\{0, 1\}^t)^k \rightarrow \{0, 1\}$ is defined as the function $\wedge_t^{\oplus k}$, i.e., $\text{GIP}_{kt}(x_1, \dots, x_k) := \bigoplus_{i=1}^k \wedge_t(x_i)$. Moreover, let $R_{t,\epsilon}(f)$ denote the complexity of the best randomized t -party protocol correlating f with at least ϵ .

► **Theorem 45** ([3, Theorem 2]).

$$R_{t,\epsilon}(\text{GIP}_n) = \Omega\left(\frac{n}{4^t} - \log(1/\epsilon)\right).$$

Now, for any constant $0 < \delta < 1/t$ and some constant $c_t = \Theta(t 4^t)$, we prove that $\mathcal{RCC}_{n,t,O(n/4^t)}$ has $(\Omega(1/c_t), \delta n)$ -XOR amplification for \wedge_t , which directly yields Theorem 44 by Theorem 34.

► **Proposition 46.** *For any constant $0 < \delta < 1/t$, $\mathcal{RCC}_{n,t,c'n/4^t}$ has $(c/c_t, \delta n)$ -XOR amplification for \wedge_t , where $c_t = \Theta(t 4^t)$, $c, c' > 0$ are constants.*

Proof. Assume by contradiction that $\mathcal{RCC}_{n,t,c'n/4^t}$ does not have $(c/c_t, \delta n)$ -XOR amplification for \wedge_t , where c, c' are some constants to be decided later. That is, there exists some vector $v \in \{0, 1\}^{n/t}$ with at least δn ones, $\text{Cor}(h^v, \mathcal{RCC}_{n,t,c'n/4^t}) \leq 2^{-\frac{c}{c_t} \delta n}$. That is, there exists a $(c'n/4^t)$ -bit randomized protocol that approximates h^v within $2^{-\frac{c}{c_t} \delta n}$ error. Furthermore, observe that h^v is the XOR of at least δn copies of \wedge_t , i.e, h^v depends on $\geq \delta n t$ variables. Therefore, by Theorem 45, we have

$$R_{t, 2^{-\frac{c}{c_t} \delta n}}(h^v) \geq R_{t, 2^{-\frac{c}{c_t} \delta n}}(\text{GIP}_{\delta n}) = \Omega\left(\delta \frac{n}{4^t} - \frac{c}{c_t} \delta n t\right).$$

That is, letting the constant c be small enough, we know there exists a positive constant c'' such that

$$R_{t, 2^{-\alpha \delta n}}(h^v) \geq c'' n / 4^t.$$

Now letting $c' < c''$ yields a contraction. Therefore, $\mathcal{RCC}_{n,t,c'n/4^t}$ has $(c/c_t, \delta n)$ -XOR amplification for \wedge_t . ◀

A.3 Halfspace sources

In this subsection, for halfspace sources, we construct an efficient extractor that has linear output for linear min-entropy and exponentially small error. Formally, we will prove the following theorem.

► **Theorem 47.** *There exists an explicit seedless $((1 - c_1)n, 2^{-c_2n})$ extractor $Ext : \{0, 1\}^n \rightarrow \{0, 1\}^{c_3n}$ for halfspace sources, where c_1, c_2, c_3 are some positive small enough constants.*

Note that Nisan already proved an exponentially small correlation bound for Inner Product function against LTFs. Formally, let $IP_n : (\{0, 1\}^2)^{n/2} \rightarrow \{0, 1\}$ denote the inner product function over n variables, i.e., $IP_n(x_1, \dots, x_{n/2}) = \bigoplus_{i \in [n/2]} \wedge_2(x_i)$. Then, we have the following lemma.

► **Lemma 48.** *For any LTF f on n variables, we have*

$$Cor(IP_n, f) \leq 2^{-\Omega(n)}.$$

Proof of sketch. Nisan proved that a LTF on n variables can be approximated within ϵ error by a randomized 2-party protocol of complexity $O(\log(n/\epsilon))$ by [19, Theorem 1]. Moreover, by Chor and Goldreich [7], we know at least $n/2 - \log(1/\epsilon)$ complexity needed for randomized 2-party protocol computing the function IP_n .

Therefore, for any LTF f over n variables, there is a protocol \mathcal{P} of complexity cn bits approximating f within $2^{-\Omega(n)}$ error and $Cor(IP_n, \mathcal{P}) \leq 2^{-\Omega(n)}$. That is, replacing f by IP_n in $Cor(IP_n, f)$, we can bound $Cor(IP_n, f) \leq 2^{-\Omega(n)} + Cor(IP_n, \mathcal{P}) = 2^{-\Omega(n)}$. ◀

Let \mathcal{LTF}_n denote the class of LTFs over n variables. Then, the above lemma directly yields that \mathcal{LTF}_n has $(\alpha, \delta n)$ -XOR amplification for \wedge_2 for any positive constant $\delta < 1/2$, where α is some positive constant. Hence Theorem 47 directly follows by Theorem 34.

B Application of Theorem 8

In this section, we construct extractors for sources recognized by several widely used function families. These constructions are all based on Lemma 39 proved in the previous section, which means we can convert seed-extending PRGs into extractors. In the following subsections, the main points are to construct seed-extending PRGs for some specific common function families.

B.1 Circuit-recognizable sources

Recall that we say a function $h : \{0, 1\}^t \rightarrow \{0, 1\}$ is ϵ -hard for \mathcal{C} if $Cor(h, \mathcal{C}) \leq \epsilon$.

For any circuit family, Nisan and Wigderson [20] already constructed a hardness-based PRG. Reviewing the NW generator, Kinne et al. [16] proved that it could be made seed-extending, and hence they gave a seed-extending PRG for circuits. In particular, they proved the following lemma.

► **Lemma 49** ([16, Lemma 2.9]). *Let l and m be positive integers and $H : \{0, 1\}^{\sqrt{l}/2} \rightarrow \{0, 1\}$ a function. If H is $\frac{\epsilon}{m}$ -hard at input length $\sqrt{l}/2$ for circuits of size $s + m \cdot 2^{O(\log m / \log l)}$ and depth $d + 1$, then there is a seed-extending (l, ϵ) -PRG $NW_{H;l,m} : \{0, 1\}^l \rightarrow \{0, 1\}^{l+m}$ for tests $T : \{0, 1\}^{l+m} \rightarrow \{0, 1\}$ computable by circuits of size s and depth d .*

Notice that the set of bounded-size circuits is flip-invariant since flipping the inputs of a circuit does not change its size. Thus, applying Lemma 39, we get an extractor.

► **Proposition 50.** *For any positive integer $l < n$, if there is a function H that is ϵ -hard at input length $\sqrt{l}/2$ for circuits of size $s + (n - l) \cdot 2^{O(\log(n-l)/\log l)}$ and depth $d + 1$, then for any $\Delta = \Delta(n) > 0$ we can get an $(n - \Delta, (n - l)2^{\Delta\epsilon})$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-l}$ for any sources recognizable by circuits of size s and depth d .*

We remark that, in the best case, the above lemma yields an $(n - \tilde{O}(\sqrt{l}), 2^{-\tilde{\Omega}(\sqrt{l})})$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-l}$, if we can get a function at input length $\sqrt{l}/2$ which is $2^{-\tilde{\Omega}(\sqrt{l})}$ -hard for circuits of polynomial size.

B.2 AC^0 -recognizable sources

Hastad [13] proved that the parity function is $2^{-n^{1/(d+1)}}$ -hard against any AC^0 circuit of size $2^{n^{1/(d+1)}}$ and depth d . Based on this hardness, Shaltiel [25] constructed extractors for AC^0 -recognizable sources.

► **Theorem 51** (Corollary 4.25, [25]). *For any $\Delta = \Delta(n) > 0$, there is a constant $\alpha > 0$ such that for every sufficiently large n , $m \leq n^{1/(\alpha d)}$, and sources recognizable by circuits of size $2^{n^{1/(\alpha d)}}$ and depth d , we can construct an $(n - n^{1/(\alpha d)}, 2^{-100m})$ -extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^m$.*

► **Theorem 52** (Theorem 4.21, [25]). *For any constants $c, d, e > 1$ there is a constant $d' > 1$ and a uniform family $E = \{E_n\}$ of circuits of polynomial-size and depth d' such that $E_n : \{0, 1\}^n \rightarrow \{0, 1\}^m$ for $m(n) = (\log n)^e$ and E_n is a $(n - 100m(n), 2^{-100m(n)})$ -extractor for sources recognizable by circuits of size n^c and depth d .*

However, directly using the Lemma 50 with the hardness of parity function, we can get the following lemma.

► **Theorem 53.** *For any $\Delta = \Delta(n) > 0$, there exists a polynomial time computable $(n - \Delta, (n - l)2^{\Delta - \Omega(l^{1/(2d+2)})})$ extractor $\text{Ext} : \{0, 1\}^n \rightarrow \{0, 1\}^{n-l}$ for any sources recognizable by circuits of size $2^{n^{1/d}}$ and depth d .*

► **Proposition 54.** *For any constants $c, d, e > 1$ there is a constant $e' < e$ and a polynomial-time computable uniform family $E = \{E_n\}$ such that $E_n : \{0, 1\}^n \rightarrow \{0, 1\}^m$ for $m(n) = n - (\log n)^e$ and E_n is a $(n - 100(\log n)^{e'}, 2^{-100(\log n)^{e'}})$ -extractor for sources recognizable by circuits of size n^c and depth d .*

In particular, for min-entropy $n - n^{1/(\alpha d)}$, our extractor outputs $n - n^{2/\alpha + O(1/d)}$ bits, whereas Shaltiel's extractor outputs only $n^{1/(\alpha d)}$ bits. When $\alpha > 2d/(d - 1)$ is a large enough constant, our extractor outputs $n - o(n)$ bits whereas Shaltiel's extractor outputs only $n^{1/(\alpha d)}$ bits. For min-entropy $n - \text{polylog}(n)$ bits, our extractor outputs $n - \text{polylog}(n)$, whereas Shaltiel's extractor outputs only $\text{polylog}(n)$ bits.

For circuit sources, Viola [29] also constructed extractors for AC^0 -samplable sources, extracting $k(k/n^{1+\gamma})^{O(1)}$ bits with super-polynomially small error from n -bit sources of min-entropy k , for any $\gamma > 0$. Nevertheless, AC^0 -samplable sources are different from AC^0 -recognizable sources.
